The substantial reduction in hypervector length achieved by our CiliaGraph is theoretically grounded in below. For two unit vectors x and y, they are ϵ-*quasi-orthogonal* if $(|x \cdot y| \leq \epsilon)$ and $\epsilon \in [0, 1)$, where ϵ is an angle relaxation easing the strict orthogonality [17]. Intuitively, when using ϵ-*quasi-orthogonal* to replace the traditional strict one in HDC, a larger ϵ can accommodate more mutually orthogonal hypervectors under a fixed vector length D. The theories in [12] and [17] have established that the magnitude of ϵ-*quasi-orthogonal* bipolar hypervectors, i.e., $dim_\epsilon(D)$, grows exponentially with D, i.e., $dim_\epsilon(D) = e^{D\epsilon^2/2}$. Since our *plastical orthogonal ring* (Sec. III-A) only requires the approximate orthogonality (Fig. 3) between the first and last hypervectors in each feature space ($\delta(l_1^i, l_m^i) \approx 0$), it can hold a large amount of features with significantly reduced D. The formal proof is shown in below.

Theorem 1. *For a graph with n node attributes and m quantization levels, using plastic random bit-flip encoding with quasi-orthogonality threshold $\epsilon = \frac{2}{(m-1)}$, the minimum dimension D required to ensure at least $2n$ quasi-orthogonal hypervectors satisfies $D \approx \frac{(m-1)^2}{2} \ln 2n$.*

Proof. The Hamming distance between l_1^i and l_m^i for the i-th space $\mathcal{L}^i$ is $\sum_{i=1}^{m-1} r_i \times D = \frac{D \times m}{2(m-1)}$, indicating the number of differing bits. Converting these into unit vectors, the value of ϵ is obtained as $\epsilon = |l_1^i \cdot l_m^i| = |1 - 2 \times \frac{m}{2(m-1)}| = \frac{1}{(m-1)}$. To ensure robust quasi-orthogonality while reducing computational overhead, $\epsilon = \frac{2}{(m-1)}$ is set. Since l_1^i and l_m^i from each $\mathcal{L}^i$ must maintain quasi-orthogonality, and this property must hold across all n attribute groups, we require $dim_\epsilon(D) = 2n$. Thus, we derive the minimum required dimensions $D \approx \frac{(m-1)^2}{2} \ln 2n$. □

According to above theory, the optimal D for the typical datasets tested in this work are between $[37, 122]$, reducing $1 - 2$ order of memory usage compared to traditional HDC-based GNNs (Sec. V-A).

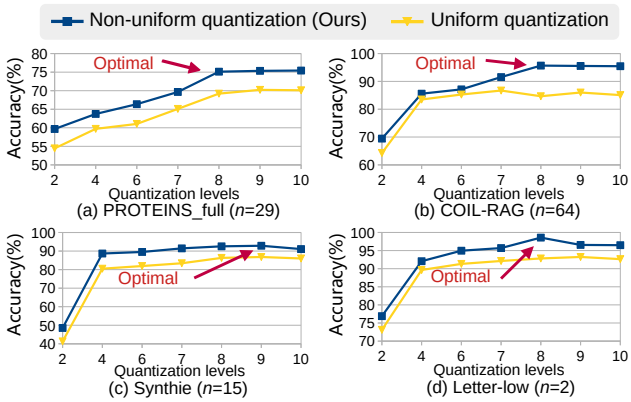

Fig. 8: Optimal quantization levels.

V. Experimental Results

To setup the experiments, seven real-world datasets selected from Tudataset testbed [10] to cover variant magnitudes of node features (n), including Letter-high (2), Letter-low (2), BZR (3), AIDS (4), Synthie (15), PROTEINS_full (29) and COIL-RAG (64).

For the baseline models, we tested: 1) HDC-GNN: GraphHD; 2) GNNs: GIN [18], GCN [19], GAT [20]; 3) SOTA k-hop GNNs: GIN-AK+, GIN-AK+-S [8], KPGIN [13] and MAG-GNN [21], where GIN-AK+-S serves as a sampling model for GIN-AK+ that reduces resource overhead. All GNNs are replicated on GPUs (duel NVIDIA GeForce RTX 4090), while HDCs are tested on both CPUs (AMD EPYC CPUs with 96 cores) and GPUs.

A. Memory reduction of CiliaGraph

As shown in Figure 7, the memory consumption of our proposed CiliaGraph is compared against eight baseline methods across four real-world graph datasets, with the vertical axis representing the logarithmic value of memory usage. By enjoying the ultra-short hypervectors ($D = 120$), CiliaGraph achieves an average memory saving of $292\times$, corresponding to a reduction of $1 - 2$ orders of magnitude in memory consumption. Notably, on the Synthie dataset, CiliaGraph exhibits only a 1.48% performance difference from the best-performing GNN model (Table I) while reducing memory usage by an impressive $2341\times$. This demonstrates that CiliaGraph is a memory-efficient graph classification model, making it well-suited for practical deployment and operation in resource-constrained environments such as on-edge graph processing.

B. Latency and Accuracy of Graph Classification Tasks

The ultra-shot hypervectors of CiliaGraph significantly reduce processing latency across both CPU and GPU platforms for the full graph classification tasks, while maintaining competitive accuracy (Table I). CiliaGraph achieves 85.09% higher accuracy than GraphHD on COIL-RAG, demonstrating its advantage via involving the intrinsic attributes of nodes. Particularly on the Synthie dataset [22], CiliaGraph's performance trails the best GNN model by only 1.48%, while offering a $2341\times$ reduction in memory usage and

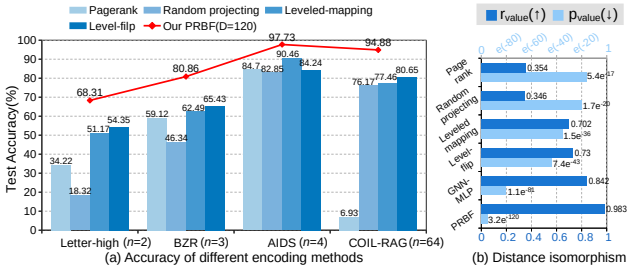

Fig. 9: The impact of different encoding methods.

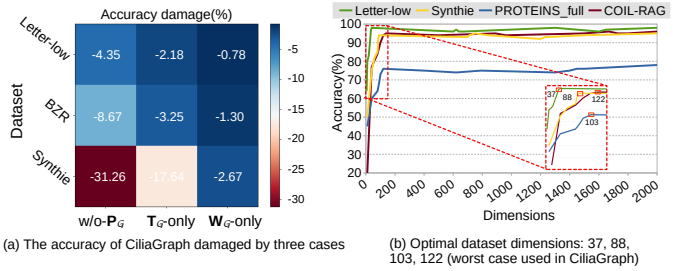

Fig. 10: Hyper-weights ablation and dataset-specified dimensions.

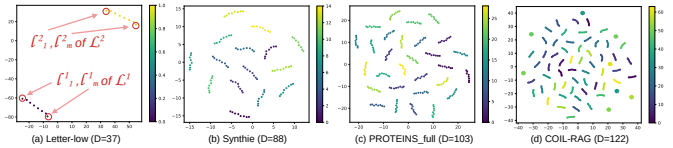

Fig. 11: t-SNE visualisation of initial $\mathcal{L}^i$. Both of coherence and orthogonality are stable across all optimal length of hypervectors (D).

a 313× speedup in training. On the GPU platforms, we didn't observe any acceleration of CiliaGraph on GPUs. The *nvprof* tool reports reveal that the computing reduction of CiliaGraph leads to the negligible *kernel* workloads that are even insufficient to hide the CPU-GPU transferring time for the hypervectors, which shows that CiliaGraph is such an energy-efficient model that general accelerators could be needlessly.

C. Picking Quantization Levels for the Worst Cases

To pick quantization levels can significantly affect data clustering and model accuracy. According to the formula provided in Theorem 1, the quantization level also determines the minimum required dimension. Thus, in all SOTA HDC solution, the dimension $D = 10,000$ is initially set to identify the optimal quantization levels. Fig. 8 illustrates the results for four datasets, with the yellow line indicating uniform quantization. Most datasets achieve the highest and most stable accuracy at $m = 8$. Subsequently, the formula changes to $D \approx \frac{(8-1)^2}{2} \ln 2n$. Therefore, even for the COIL-RAG dataset [10], [23], which has the largest number of node attributes at $n = 64$, the minimum required dimension is $D \approx \frac{(8-1)^2}{2} \ln (2 \times 64) \approx 118.87$ bits. For convenient in setting, D is uniformly approximated to 120, rather than 118.87, to standardize the effectiveness evaluation for all tests on CiliaGraph.

D. The Expression of Rich Features with PRBF Encoding

To assess the expressive power of the CiliaGraph node encoding method, we compare it against four alternative frameworks: 1) *PageRank*; 2) *Random projecting*; 3) *Leveled-mapping*; and 4) *Level-filp* with [15] flipping methods. All these four frameworks use the dimension $D = 10000$. As shown in Fig. 9(a), CiliaGraph achieves optimal performance across all tested datasets, with an average accuracy 15% higher than the *Leveled-mapping* and 39% higher than the *Pagerank*. These significant improvements evidence the effectiveness of our model and encoding methodology. Furthermore, the Pearson correlation coefficient [14] is employed to validate that CiliaGraph effectively maintains isomorphism (Fig. 9(b)) in feature distances between nodes before and after encoding, thereby preserving the original data features in $\mathcal{HD}$ space. In addition, the precise encoding is seen as a key reason to combat the Noise-1.

E. Ablation Experiment of Hyper-Weight Matrix

To validate the effectiveness of the more precise similarity weights and transition matrix introduced in Sec. III-B, CiliaGraph is compared to three ablating cases: 1) "w/o-$\mathbf{P}_\mathcal{G}$" is *without similarity weights matirx and transition matrix*; 2) "$\mathbf{T}_\mathcal{G}$-only" is *without similarity weights matrix*; and 3) "$\mathbf{W}_\mathcal{G}$-only" is *without transition matrix*. The accuracy differences of these frameworks are shown in Fig. 10(a). It is observed that the performance of all three frameworks progressively deteriorates, particularly for w/o-$\mathbf{P}_\mathcal{G}$ and $\mathbf{T}_\mathcal{G}$-only. This accentuates the inadequacies of basic edge encoding techniques which overlook the significance of connection strengths. The results of $\mathbf{W}_\mathcal{G}$-only demonstrate that integrating transition matrices with similarity weight matrices can enhance the model expressiveness, offering a refined depiction of inter-node connections. The results demonstrate that only the combined usage of $\mathbf{W}_\mathcal{G}$ and $\mathbf{T}_\mathcal{G}$ can prevent significant Noise-2.

F. The Optimal Dimensions for Individual Datasets

To further quantify the confidence of the minimal D proposed in Sec. IV-B, we first calculate the theoretical values of D via the Theorem 1 for each of datasets, including Letter-low (33.96), Synthie (83.33), PROTEINS_full (99.48), and COIL-RAG (118.87). Then, in measuring part, our experiments span D from the theoretical minimum 5 to 2000 and evaluate the CiliaGraph for the four datasets, as shown in Fig. 10(b). The accuracy curves indicate that they achieve their optimal performances at 37, 88, 103, and 122 respectively. The comparison between the theoretical and measured values hints that our theorem achieves predicting accuracy of 95.81% on average, which is a well predictor of hypervector length. In addition, a dimension reduction of features (t-SNE) in Fig. 11 shows that the generated initial hypervectors exhibit not only intra-cluster coherence (high k-means inertia) but also inter-group quasi-orthogonality among different features, which is the reliable short encoding exactly as expected in Sec. III-A.

VI. Conclusions

This paper presents a novel approach to address the memory challenges posed by long hypervectors in HDC-based graph processing. By introducing three new operators for feature-rich hypervectors, we improve the efficiency of feature representation and extraction, enabling HDC to operate more like traditional GNNs with significantly reduced memory requirements. The experiments indicate that the short vector length we predict is very close to the optimal in terms of minimizing memory usage.

ClusterKV: Manipulating LLM KV Cache in Semantic Space for Recallable Compression

Guangda Liu, Chengwei Li, Jieru Zhao†, Chenqi Zhang, Minyi Guo

***Abstract*—Large Language Models (LLMs) have been widely deployed in a variety of applications, and the context length is rapidly increasing to handle tasks such as long-document QA and complex logical reasoning. However, long context poses significant challenges for inference efficiency, including high memory costs of key-value (KV) cache and increased latency due to extensive memory accesses. Recent works have proposed compressing KV cache to approximate computation, but these methods either evict tokens permanently, never recalling them for later inference, or recall previous tokens at the granularity of pages divided by textual positions. Both approaches degrade the model accuracy and output quality. To achieve efficient and accurate recallable KV cache compression, we introduce ClusterKV, which recalls tokens at the granularity of semantic clusters. We design and implement efficient algorithms and systems for clustering, selection, indexing and caching. Experiment results show that ClusterKV attains negligible accuracy loss across various tasks with 32k context lengths, using only a 1k to 2k KV cache budget, and achieves up to a 2× speedup in latency and a 2.5× improvement in decoding throughput. Compared to SoTA recallable KV compression methods, ClusterKV demonstrates higher model accuracy and output quality, while maintaining or exceeding inference efficiency. Our code is available at https://github.com/sjtu-zhao-lab/ClusterKV.**

I. Introduction

Large Language Models (LLMs) have been widely deployed in a variety of applications, such as natural language understanding, coding copilots and chatbots. As LLMs are used for more complex tasks, the need for long context length is rapidly increasing to handle tasks such as long-document QA, repository-level code understanding, and complex logical reasoning [1–3]. This drives LLMs to support larger context windows, expanding from the original 4k to 32k [4, 5], 128k [6] and even up to 1M [7]. While models can support larger context window with continual training or extrapolation [5], inference with long contexts poses significant challenges on efficiency. As the size of key-value (KV) cache increases linearly with the context length, it can exceed the capacity of GPU memory, leading to inference failure or extremely high latency. Since the autoregressive decoding stage is typically the performance bottleneck of LLM inference and is memory-bound [8], accessing the KV cache of all previous tokens results in increased latency for long-context inference.

To mitigate the issues, recent works compress KV cache by selecting a subset of tokens and utilizing their keys/values to approximate attention computation. The tokens are typically selected with fixed patterns [9] or based on their attention weights [10–14], which represent each token's importance in attention computation. In most compression methods, unimportant tokens are evicted permanently; once evicted, they are never recalled in subsequent decoding steps, as shown in Fig. 1b. However, the token importance is dynamically changing during decoding: tokens initially considered unimportant and evicted may become important at later steps and vice versa. Non-recallable KV cache compression greedily evicts tokens based on positions or attention weights of tokens at the current decoding step, failing to capture the dynamic feature. This can degrade model accuracy and output quality.

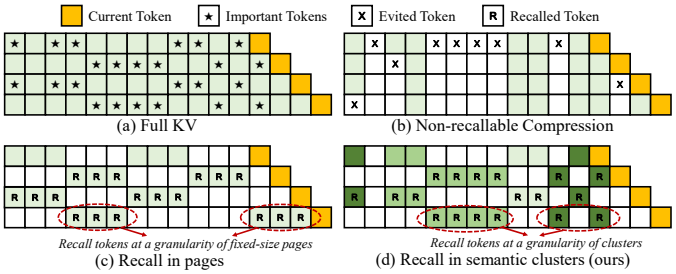

Fig. 1: Comparison of KV compression methods. Green boxes represent tokens selected for attention computation.

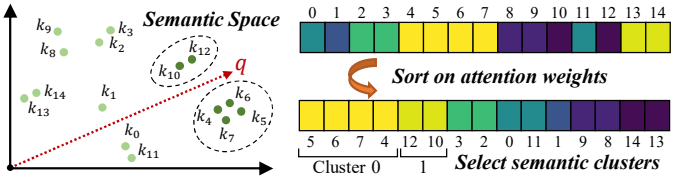

Fig. 2: Semantic space and attention weights of tokens in the last step of Fig. 1d. Lighter boxes indicate larger weights.

While making tokens recallable is promising, it incurs prohibitively high cost due to the computation of attention weights over all previous tokens. To reduce the cost, as illustrated in Fig. 1c, Quest proposed recalling at the granularity of pages [15]. A page consists of $page_size$ consecutive tokens, allowing Quest to reduce the selection overhead by a factor of $1/page_size$. However, since pages are divided simply by textual positions of tokens, internal fragmentation becomes an issue: a recalled page may contain unimportant tokens, wasting budget that could be allocated to truly important tokens.

To achieve efficient and accurate KV cache compression, we introduce ClusterKV, which recalls tokens at the granularity of token clusters in the semantic space, referred to as *semantic clusters*. As illustrated in Fig. 2, tokens that are close in their semantic space or key vector space exhibit similar attention weights. Therefore, as shown in Fig. 1d, ClusterKV

recalls tokens at the granularity of semantic clusters to ensure more precise token recall. Moreover, ClusterKV incorporates specialized system designs and optimized kernels to minimize recall overheads. Experimental results demonstrate that ClusterKV attains negligible accuracy loss across various tasks with context lengths up to 32k, using only a 1k to 2k KV cache budget. It also delivers up to a 2× speedup in latency and a 2.5× improvement in decoding throughput. Compared to state-of-the-art recallable KV compression methods, ClusterKV achieves significantly higher model accuracy and output quality, while maintaining or surpassing inference efficiency.

II. Background and Motivation

A. LLM Inference and KV Cache

LLMs encompass multiple Transformer layers, each containing a multi-head attention (MHA) module and a feed-forward network (FFN) with residual connections and normalization operations [16]. In MHA, the input tensor is linearly projected into query, key and value tensors ($Q, K, V \in \mathbb{R}^{N\times d}$) for each head, where N is the input length and d represents the number of channels or hidden dimensions per head. The MHA output is defined as $softmax(\frac{QK^T}{\sqrt{d}})V$, with outputs of all heads concatenated for subsequent FFN and normalization.

For generative inference, LLMs produce tokens in an autoregressive manner, appending each generated token to the input to generate the next token. To avoid the recomputation of K and V of previous tokens, these tensors are stored in memory for reuse, which is known as *KV cache*. The LLM inference includes two stages: prefill and decoding. The prefill stage processes the entire input sequence, computes KV cache and generates the first output token. During decoding, the query vector q of the latest generated token and K, V of previous tokens are used to compute attention for generating the next token, formulated as $softmax(\frac{qK^T}{\sqrt{d}})V$, where $q \in \mathbb{R}^{1\times d}$, $K, V \in \mathbb{R}^{L\times d}$ and L is the context length of previous tokens.

B. Long Context Inference and KV Cache Compression

Long context is an emerging trend of LLM inference, such as long-document QA [1, 17], repository-level code understanding [2] and complex logical reasoning [3]. Moreover, supported context windows of LLMs are extending rapidly, from 4k tokens of GPT3.5 and Llama-2 to 32k [5], 128k [6] and even 1M tokens [7]. However, long-context inference incurs significant memory and computation cost. The size of KV cache and complexity of attention computation during decoding increase linearly with context length, resulting in low inference efficiency or even inference failures.

Recent works reveal the sparsity of attention computation, i.e., only a small subset of tokens contributes to most of attention outputs [10, 13]. This observation enables KV cache compression by selecting a subset of tokens to approximate attention computation, which is formulated as $softmax(\frac{qK_S^T}{\sqrt{d}})V_S$, where $K_S, V_S \in \mathbb{R}^{B\times d}$ represents the keys and values of selected tokens, and B is the budget size of KV cache after compression. By setting a fixed budget, the KV cache size and decoding cost remain stable, regardless of the context length.

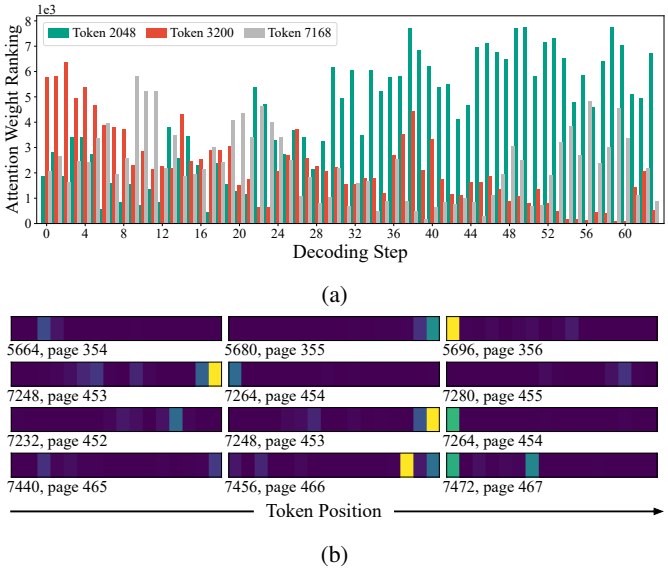

Fig. 3: (a) Variation in token importance across decoding steps with a context length of 8192. (b) Internal fragmentation of important tokens at the granularity of pages ($page_size = 16$).

Typically, K_S and V_S are selected based on attention weights (qK^T), as tokens with higher attention weights contributes more to the attention computation [10–12].

C. Related Work and Motivation

KV cache compression should be recallable. While selecting a subset of KV cache for computation ensures inference efficiency, computing all the attention weights for selection introduces substantial overhead. Therefore, most existing works only compute attention weights over tokens that have been selected, rather than for all previous tokens [10–12]. In this way, keys and values of tokens not selected at one decoding step are permanently evicted from the KV cache and never recalled in later inference steps, as shown in Fig. 1b.

However, we observe that the token importance changes dynamically during inference. Token that are unimportant with low attention weights at one decoding step can become important in later steps, and vice versa. Figure 3a shows changes in attention weight rankings during 64 decoding steps of Llama-3-8B. For instance, token 3200 is initially unimportant but becomes crucial after 20 steps, while the opposite occurs for token 2048. And importance of all tokens can fluctuate throughout inference, as seen with token 7168. Therefore, non-recallable compression inevitably overlooks some tokens with dynamically changing importance, leading to reduced model accuracy and a decline in output quality.

Defects of existing recallable KV compression methods. However, achieving recallable compression by computing attention weights with all previous tokens incurs an unacceptable cost of $O(Ld)$, which is comparable to attention computation with full KV cache and negates the benefits of compression. To reduce the cost, InfiniGen [18] reduces the dimensions of q and K by generating partial query and key weights offline using singular value decomposition, and projecting hidden states with these partial weights. However, it requires generating

and storing partial keys in addition to original keys, and the selection cost still scales linearly with the context length L.

Quest [15] selects tokens at the granularity of pages, which consist of several consecutive tokens, as depicted in Fig. 1c. To estimate importance of a page, it uses the per-channel maximal keys of all tokens within a page to compute attention weights. This approach reduces the selection cost to $O(Ld/page_size)$ as only one attention weight is needed for every $page_size$ tokens. However, recalling pages which are simply divided by token positions leads to internal fragmentation of important tokens. A selected page may contain only a few important tokens, while including unimportant ones for attention computation and wasting the KV cache budget. We illustrate this issue using attention heatmaps of Llama3-8B with an 8k context length in Fig. 3b, where lighter cells represent more important tokens with higher attention weights. As shown, each page of 16 tokens contains only one or two important tokens, and in some cases, two pages or 32 tokens are required to include two consecutive important tokens.

III. Algorithm Design

A. Problem Formulation and Design Rationale

Problem Formulation. For approximated attention computation with selected tokens formulated in Sec. II-B, let K_S to be $(k_{i_1}, k_{i_1}, ..., k_{i_B})^T$, where $I_T = \{i_1, i_2, ..., i_B\}$ denotes the indices of selected tokens. Our goal is to select tokens which contribute most to attention weights, thereby approximating the original computation as closely as possible. Specifically, I_T is supposed to be $\arg\max \sum_{i \in I_T} qk_i^T$, which corresponds to selecting tokens with top-B largest attention weights.

Design Rationale. Our observation is that *tokens which are close in semantic space tend to have similar attention weights for a given q*. Therefore, we propose KV selection at the granularity of semantic clusters. We first apply clustering to tokens in the semantic space. Then, we compute attention weights only with respect to the cluster representations, rather than individual tokens, and select clusters with the largest attention weights. Since the number of clusters is typically an order of magnitude smaller than the number of tokens, cluster-based selection significantly reduces recall overhead.

B. Clustering in the Semantic Space

Semantic Distance. As for a given q, attention weights are associated only with the key tensors, we measure the semantic distance between tokens by calculating the distance between corresponding key vectors. Furthermore, we find that *cosine similarity* is more suitable than L2 or inner product distances. This is due to the presence of outlier channels with large magnitudes in key vectors [19], which can cause drastic changes in L2 or inner product distances. Thus, we define distance between token i and token j in the semantic space as $\mathcal{D}(i,j) = 1 - \frac{\langle k_i, k_j \rangle}{|k_i| \cdot |k_j|}$, where distance is smaller for vectors with larger cosine similarity.

Clustering. We apply a simple K-means algorithm for clustering over key vectors as shown in Fig. 4 [20]. We first randomly sample key vectors as the initial centroids.

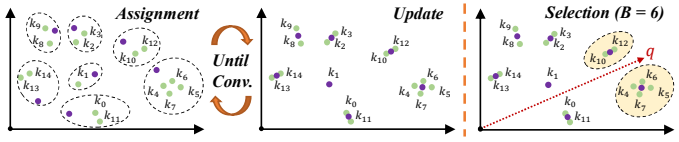

Fig. 4: Clustering and selection process. Green dots represent key vectors, and purple dots represent centroids of clusters.

Subsequently, we alternatively perform the assignment and update steps until convergence. In the assignment step, each key vector is assigned to the nearest centroid and given a corresponding *cluster label* based on the distance $\mathcal{D}$, i.e., assigned to the centroid with the maximum cosine similarity. Then in the update step, the mean of keys assigned to the same centroid are used as the new centroid. The algorithm converges when the assignment no longer changes, and keys assigned to the same centroid form a *semantic cluster*, with the centroid as the cluster representation.

During LLM inference, we first apply clustering to the key vectors of prompt tokens *after the prefill stage*. However, we note an exception for the initial tokens, referred to as attention sinks [9]. These tokens typically appear as outliers in the clustering process, as they are distant from other tokens in the semantic space. Therefore, we always retain the first 16 tokens and apply clustering to the subsequent tokens, generating C_0 centroids. We set $C_0 = \frac{L}{80}$, as our experiments indicate that for a 32k context, using 400 clusters achieves a balance between efficiency and accuracy. For tokens generated *in the decoding stage*, clustering is applied every m decoding steps to the key vectors of m generated tokens, creating C_+ new centroids. Since clustering keys of generated tokens together with those from the prefill stage can incur significant overhead, we instead apply clustering *within* the generated tokens only. To amortize the cost, we set C_+ and m to 4 and 320, respectively.

C. Selection at the Granularity of Semantic Clusters

Selection. We denote cluster centroids as $\mu_1, \mu_2, ..., \mu_C \in \mathbb{R}^d$. To select important tokens for a given query q, we sort those centroids based on their attention weights, i.e., $q\mu_i^T$, in descending order. While keys are clustered using cosine similarity distance, the distance between query vector and centroids is measured with inner product, as it better aligns with attention weight computation. Intuitively, keys assigned to clusters with centroids that have larger attention weights tend to have larger attention weights for the given q. Therefore, we retrieve the sorted centroids and collect KV of tokens from the corresponding clusters, until the top-B most important tokens are selected, as shown in Fig. 4.

D. Efficiency Concerns

Cluster-based selection avoids the internal fragmentation of important tokens and can achieve higher accuracy compared to page-based selection. However, it incurs efficiency concerns.

Concern 1. For clustering, the computational cost is $O(n_i CLd)$ where n_i is the number of iterations until convergence and C is the number of clusters, which is higher than the cost of obtaining page representations, such as per-channel maximal key vectors in Quest [15], which is $O(Ld)$.

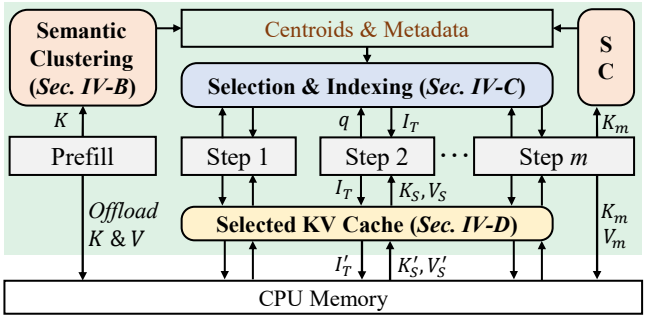

Fig. 5: System overview of ClusterKV. The green box represents components running on the GPU.

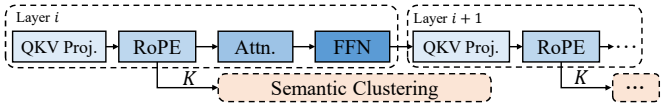

Fig. 6: Overlapping of clustering with other operations.

Concern 2. For selection in page-based methods (Fig. 1c), since page size is fixed and tokens within a page are consecutive, the number of needed pages can be easily computed as $\frac{B}{page_size}$, and the indices of selected tokens can be directly derived from the indices of selected pages. However, for semantic clusters, the sizes can vary, and the token positions within a cluster are dynamic and discontinuous. Therefore, the number of clusters needed and the indices of selected tokens cannot be easily determined in the same way as for pages.

Our system design addresses both concerns in Sec. IV.

IV. System Design & Implementation

A. System Overview

The system overview is shown in Fig. 5. During *the prefill stage*, the key tensors are processed with semantic clustering (SC) on GPU, producing centroids and corresponding metadata. The generated KV tensors are offloaded to CPU memory. During *the decoding stage*, as described in Section III-C, attention weights of the query vector q and cluster centroids are computed to determine the importance of each cluster. The results, along with clustering metadata, are used to generate indices (I_T) for selected tokens, which are then used to load selected KV (K_S, V_S) from CPU memory to GPU memory for attention computation. A cache for selected KV is maintained on GPU, so only KV not already cached (K'_S, V'_S) need to be loaded. For every m decoding steps, the clustering and KV offloading are performed for the m generated tokens.

B. Semantic Clustering

ClusterKV optimizes the efficiency of clustering at both system and kernel levels.

System-level Optimization. As shown in Fig. 6, ClusterKV applies clustering asynchronously, launching intermediately after the keys are computed from the QKV projection and RoPE modules. This allows clustering to be overlapped with other operations, including attention and FFN computation of the current layer, as well as the QKV projection and RoPE of the following layer. By overlapping these processes, ClusterKV minimizes the overhead associated with clustering.

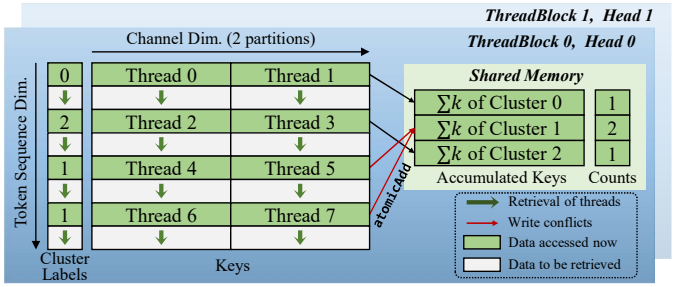

Fig. 7: Execution of the centroid update kernel. In this example, a *ThreadBlock* consists of 8 threads ($BlockSize = 8$), and the channel dimension is divided into two partitions.

Kernel-level Optimization. Since clustering needs to be applied individually for each head, a key optimization is to achieve batched clustering across heads. For the assignment step, which primarily involves `argmin` operations and matrix multiplications between keys and centroids, efficient batched Torch kernels are available [21]. Therefore, we focus on optimizing the centroid update step and implement a custom CUDA kernel where different heads are processed in parallel by individual *ThreadBlocks*, as shown in Fig. 7. The kernel retrieves keys, accumulates keys assigned to the same cluster, records corresponding accumulation counts in the shared memory, and computes the means as new centroids.

A potential issue is write conflict in shared memory, as accumulated keys and counts of the same cluster need to be computed using `atomicAdd`. To mitigate this, we apply several optimizations. As shown in Fig. 7, since distant tokens tend to be assigned to different clusters, we arrange threads in a strided manner along the sequence dimension to minimize the occurrence of concurrent processing of keys within the same cluster. Moreover, we partition the channel dimension into P partitions, with each partition processed by one thread. This results in $\frac{BlockSize}{P}$ keys being processed in parallel. There is a trade-off when choosing P: using a larger P reduces the number of keys processed in parallel and increases the number of iterations along the sequence dimension, while using a smaller P increases the number of iterations along the channel dimension within a thread, and potentially increases the occurrence of write conflicts. To determine the optimal value of P, we perform offline profiling of different P values. We find that for $BlockSize = 512$ using $P = 16$ or $P = 32$ for 128 channels yields optimal performance.

C. Selection and Indexing

The details are shown in Fig. 8. After clustering, ClusterKV stores cluster centroids and corresponding metadata, including cluster sizes, prefix sum, and sorted indices. In this example, k_0 and k_5 are assigned to cluster 2, k_1 is assigned to cluster 0, and k_2, k_3 and k_4 are assigned to cluster 1. The sizes of three clusters can then be obtained. Cluster labels and key indices are sorted by labels, and the sorted indices are stored.

During decoding, ClusterKV computes attention weights between the query vector q and cluster centroids μ, sorting the clusters in descending order of attention weights to determine

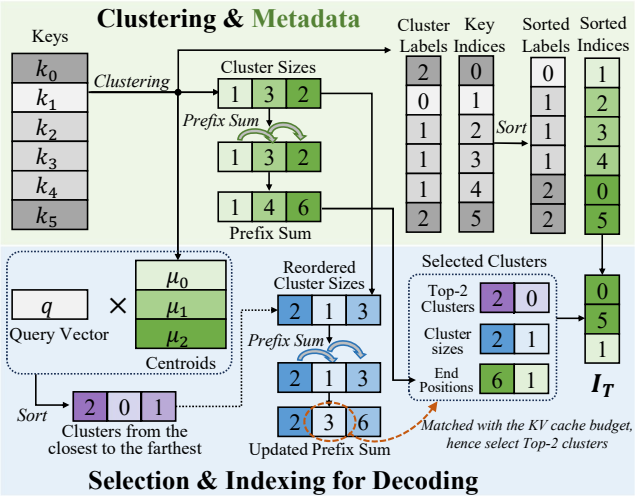

Fig. 8: Process of selection and indexing. Green boxes represent stored metadata from clustering. Here, KV budget is 3.

the closest clusters to q. Next, ClusterKV gathers and reorders their corresponding cluster sizes, and compute prefix sum. If we set the KV cache budget to three, which matches the second prefix sum, top-2 closest clusters will be selected. Then the labels, sizes, and end positions of selected clusters are gathered to determine the indices of selected tokens, I_T. Note that for cases where the summation of selected cluster sizes exceeds the budget, ClusterKV trims tokens from the last selected cluster to adhere to the budget limit.

Similarly to clustering, ClusterKV implements efficient CUDA kernels, processing the indexing of KV heads in parallel with individual *ThreadBlocks*. Metadata related to cluster sizes, which is accessed frequently, is stored in shared memory for improving performance.

D. Caching KV of Selected Tokens

ClusterKV maintains a cluster-granularity cache on GPU to store KV of selected tokens, reducing unnecessary data transfers from CPU memory to GPU memory and enhancing performance. During the decoding stage, the cache retains the KV of selected tokens from the last R decoding steps, along with the labels of corresponding selected clusters. At the current decoding step, the labels of selected clusters are compared with the cluster labels reserved by the cache. Only the KV of clusters not present in the cache are loaded from CPU memory. The cache introduces a trade-off between memory usage and caching effectiveness. In practice, we find that setting $R = 1$, i.e., retaining only the KV states from the last decoding step, strikes a good balance.

V. Evaluation

A. Experimental Setup

We evaluate ClusterKV on an NVIDIA Ada 6000 GPU. To assess model accuracy and output quality, we conduct experiments on eight datasets from LongBench [1], including 2WikiMQA, TriviaQA, HotpotQA, MultiFieldQA, MuSiQue, NarrativeQA, Qasper and GovReport. These datasets cover a variety of tasks, such as single-doc QA, multi-doc QA,

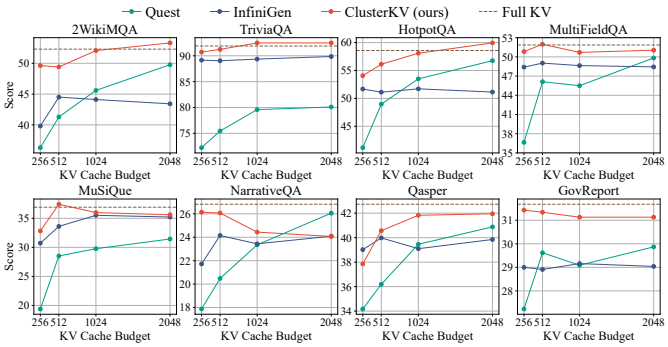

Fig. 9: Results on LongBench of different methods.

TABLE I: Average scores on eight LongBench datasets.

Method \ Budget	256	512	1024	2048
Quest	35.63	40.83	43.23	45.59
InfiniGen	43.69	45.04	45.13	45.14
ClusterKV (ours)	**46.69**	**48.02**	**48.34**	**48.7**
Full KV	49.01			

few shot learning and summarization, with context lengths reaching up to 32k. Additionally, we evaluate ClusterKV on the PG19 dataset for the language modeling task [22]. We use the state-of-the-art long-context GLM4-9B-Chat model for evaluation of model accuracy [7], which supports a context window of up to 128k tokens.

We compare ClusterKV with two state-of-the-art KV cache compression methods: Quest [15] and InfiniGen [18]. Most configurations of these methods remain as in their original settings, such as *page_size* for Quest and the partial weight ratio and selection threshold for InfiniGen. To align with settings of Quest which does not apply selection on the first two layers of the model, we also disable selection and use the full KV cache for the first two layers in ClusterKV and InfiniGen, in both model accuracy and inference performance evaluations. As both Quest and InfiniGen only support efficient inference for Llama-architecture models, we use Llama-3.1-8B for evaluation of inference performance.

B. Model Accuracy

Results on LongBench. Figure 9 presents the results on LongBench. ROUGE-L is used as the score metric for GovReport and F1 score is used for other tasks. We evaluate methods under the KV cache budgets of 256, 512, 1024 and 2048 tokens. ClusterKV outperforms Quest and InfiniGen in most settings, and achieves accuracy comparable to that of using the full KV cache with budgets as low as 1k to 2k tokens.

The average scores across the eight tasks under different budgets are summarized in Table I, where ClusterKV demonstrates significant improvement over Quest and InfiniGen.

Results on Language Modeling. We report the perplexity of the language modeling task in Fig. 10. The prompts are from the PG19 test set, with input lengths ranging from 1 to 32000 tokens. The KV cache budget is uniformly set to 1024 for ClusterKV, Quest, and InfiniGen. As shown, ClusterKV closely aligns with the full KV, with a perplexity deviation

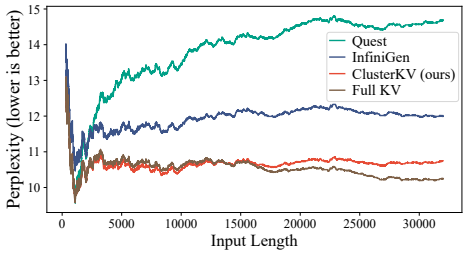

Fig. 10: Perplexity of language modeling with a KV cache budget of 1024 tokens.

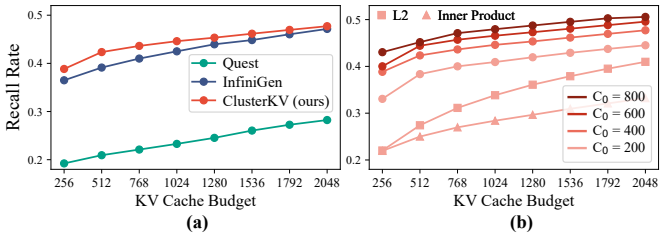

Fig. 11: Recall rate of important tokens: (a) comparison between different methods, and (b) comparison between different configurations of ClusterKV.

up to 0.5, while Quest and InfiniGen show deviations of approximately 4 and 2, respectively.

Recall Rate of important tokens. We extract a sample from the NarrativeQA dataset with a context length of 32k and compute the recall rates of important tokens during inference for different methods. The recall rate is defined as $\frac{|I_T \cap I_T^{true}|}{|I_T^{true}|}$, where $|I_T| = |I_T^{true}| = B$, I_T represents the indices of selected tokens, and I_T^{true} denotes the indices of tokens with the top-B largest attention weights. We report the recall rates averaged across layers, heads and decoding steps, and the budget B is varied from 256 to 2048 in increments of 256.

As shown in Fig. 11a, ClusterKV achieves higher recall rates across all budgets. We further explore the impact of different configurations for ClusterKV, including clustering distance metrics and the number of clusters C_0. In Fig. 11b, cosine similarity used by ClusterKV outperforms both L2 and inner product distance. In addition, increasing C_0 improves recall rates, while the improvements become less significant when $C_0 > 400$. Consequently, we use $C_0 = 400 = \frac{L}{80}$ as a balanced choice for accuracy and efficiency.

C. Inference Efficiency

Comparison with inference using full KV cache. We evaluate the inference latency of ClusterKV under various KV cache budgets and compare it against the full KV cache configuration. The experiments are conducted with prompt lengths (P) ranging from 8k to 32k and decoding lengths (D) ranging from 256 to 1024. As shown in Fig. 12, ClusterKV achieves significant efficiency improvements. For $P = 32k$ and $D = 1024$, the speedup in latency is 2× with a budget of 1024 tokens, respectively. Additionally, the decoding throughput increases by up to 2.5×. We also analyze the time spent during prefill. As shown, the clustering overhead of ClusterKV

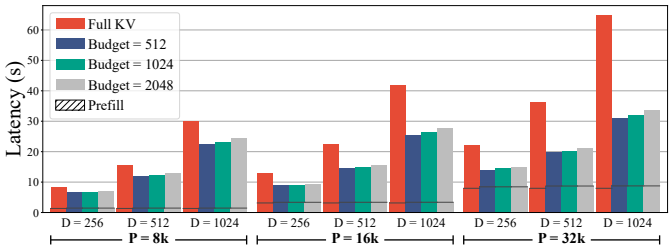

Fig. 12: Comparison of inference latency between ClusterKV and the full KV cache configuration.

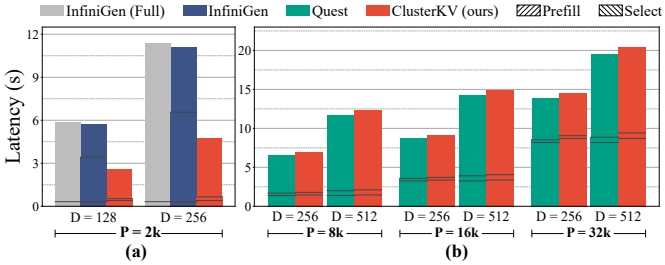

Fig. 13: Comparison of inference latency: (a) ClusterKV vs. InfiniGen with a budget of 256 tokens, and (b) ClusterKV vs. Quest with a budget of 1k tokens.

is minimal, accounting for only 6% to 8% of prefill and less than 2% of the total inference time.

Comparison with SoTA compression methods. InfiniGen is implemented based on FlexGen [23], which exclusively supports OPT [24] models with a 2k context window from scratch and is hard to adapt to other models, so we compare ClusterKV with InfiniGen using OPT-6.7B, as shown in Fig. 13a. ClusterKV achieves an average speedup of 2.3×. InfiniGen's latency is comparable to that of inference using the full KV cache, due to the high computational cost of its per-token selection, while ClusterKV's selection overhead accounts for only about 5% of the total decoding latency.

We present the comparison between ClusterKV and Quest in Fig. 13b, using Llama-3.1-8B model with a budget of 1k tokens. As shown, ClusterKV achieves performance very close to Quest, with latency deviations up to 5%, while ClusterKV delivers significantly higher model accuracy.

Effectiveness of caching. We analyze the hit rates of our cluster-granularity cache during inference, using a 32k-tokens sample from the NarrativeQA dataset. The average hit rates are 63% and 74% for $R = 1$ and $R = 2$, respectively. Compared to directly loading from CPU memory, the caching mechanism improves decoding throughput by 2.3× and 3×, respectively.

VI. Conclusion

This paper introduces ClusterKV, achieving efficient and accurate KV cache compression, recalling tokens at the granularity of semantic clusters. ClusterKV preserves model accuracy while significantly enhancing inference efficiency.

***Abstract*—Video Generation Models based on 3D full attention (3D-VGMs) have significantly enhanced video quality. However, their inference overhead remains substantial, primarily due to the high computational cost of the attention mechanism, which accounts for over 75% of computations. Inspired by the success of conventional video processing, where video compression exploits similarities among patches, we point out that *the attention mechanism can also harness the benefits from similarities among tokens*. Nonetheless, two critical problems arise: (1) How can similarities be efficiently acquired in real-time? (2) How can workload balance be maintained when similar tokens are randomly distributed?**

To address these problems and leverage similarities for 3D-VGMs, we propose SIMPICKER, a comprehensive attention-aware algorithm-hardware co-design for 3D-VGMs. Our core methodology is to fully utilize similarities in attention through both coarse-grained and fine-grained approaches while adopting dynamic adaptive strategies to leverage them. *From the algorithm perspective*, we propose a speculation-based similarity exploitation algorithm, allowing real-time importance speculation on the frame level, which is coarse-grained, and the token level, which is fine-grained. *From the micro-architecture perspective*, we propose a buffered lookup table-based (LUT-based) multiplication architecture for FP-INT multiplication and further eliminate potential bank conflicts to accelerate unimportant attention computation. *From the mapping perspective*, SIMPICKER proposes an adaptive grouping strategy in speculation to tame workload imbalance caused by randomly distributed similar tokens and allow seamless integration of our algorithms. Extensive experiments show that SIMPICKER achieves an average of 5.21×, 1.45× speedup and 17.92×, 1.63× energy efficiency compared to the NVIDIA A100 GPU and the state-of-the-art accelerators.

I. INTRODUCTION

Video Generation Models (VGMs) [1]–[3] have successfully created photorealistic videos using diffusion models. These models show a strong understanding of physical laws [4], marking a milestone towards advanced world models [5]. Diffusion transformer-based models [6]–[8] have shown superior performance in video generation tasks, tackling efficiency and scalability problems that challenge traditional UNet-based structures [9], [10]. The original 2D+1D attention VGMs (2D+1D VGMs) [7], [8], [11] handle spatial and temporal dimensions separately while resulting in temporal inconsistency of videos [12]. 3D-VGMs [12]–[15] are more powerful alternatives which integrate spatial and temporal information, producing higher-quality videos with better consistency.

Despite their superior performance, 3D-VGMs demand significantly more computational resources. Fig. 1 (a) illustrates the computation gap between 2D+1D VGMs and 3D-VGMs, showing that 3D-VGMs have 2×, 4× computation compared to their 2D+1D counterparts in medium-length videos and long videos. Additionally, the primary computational bottleneck shifts to the attention, which consumes over 75% of aggregate computations. The data is evaluated on CogVideoX [12] and Latte1 [8], aligning all the parameters.

Video processing technologies [16]–[18] have achieved remarkable effects due to their ability to leverage spatial and temporal similarities between patches. For instance, Discrete Cosine Transform (DCT) [19] exploits similarities between patches by converting spatial data into the frequency domain with the most energy concentrated in low-frequency components, significantly reducing high-frequency details and minimizing data redundancy. Guided by this, **we can harness the benefits from similarities among tokens for 3D-VGMs**.

However, two challenges hinder their potential for accelerating the inference of 3D-VGMs. First, **how can similarity be efficiently acquired in real time?** Existing works acquire approximate maps of attention importance via low-bit matrix multiplication [20], [21], but this approach results in significant accuracy loss of over 5% while offering nearly no acceleration in 3D-VGMs. Second, **how can workload balance be maintained when similar tokens are randomly distributed?** Although many works [22]–[24] have reused one token's results for other similar tokens based on similarities, they incur heavy workload imbalance due to randomly distributed similar tokens (computing utilization $<$37%).

To tackle the above challenges, we propose SIMPICKER, a comprehensive attention-aware algorithm-hardware co-design. Our core methodology is to fully utilize similarities in attention by both fine-grained and coarse-grained approaches and adopt dynamic and adaptive strategies to tap their full potential. The contributions can be summarized as follows:

- We introduce a **speculation-based similarity exploitation** algorithm to exploit similarities on the frame/token level. We identify the important parts in attention by pre-

*Equal Contribution.

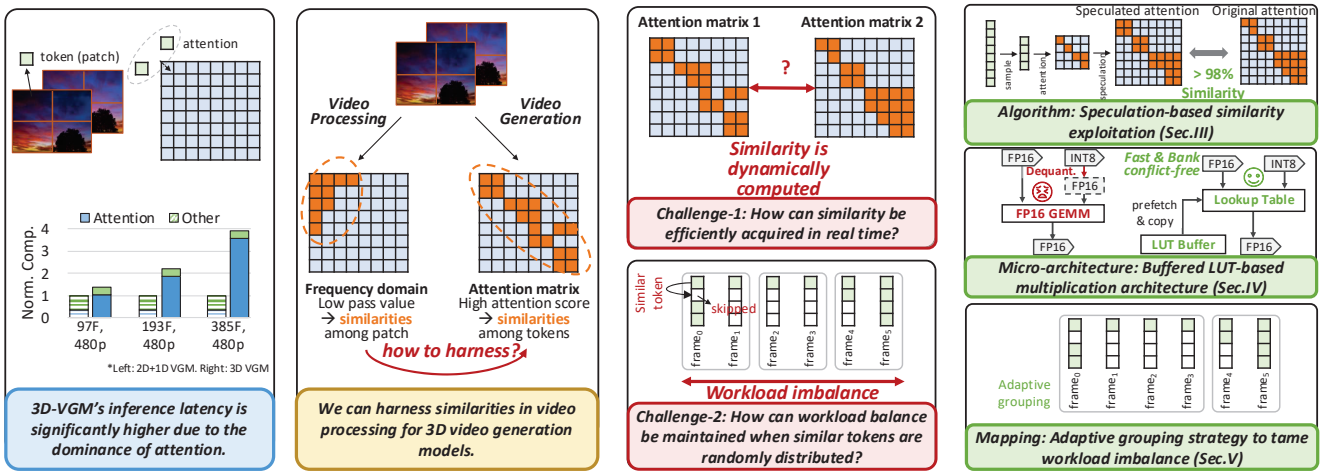

Fig. 1: Overview of SIMPICKER, a comprehensive attention-aware algorithm-hardware co-design in 3D-VGMs.

computing a small frame-level importance map so we can perform mixed-precision multiplication for unimportant parts. Also, we speculate on the input tokens and leverage their similarities to reuse results. By our speculation-based similarity exploitation algorithm, SIMPICKER can reduce over 65% FP-FP multiplications to FP-INT multiplications in attention computation, thus achieving 2.01× speedup compared with the original VGM.

- We propose a **buffered lookup table-based(LUT-based) multiplication architecture**, SIMCORE, to provide support for our algorithm. SIMCORE supports FP-INT multiplication and eliminates the bank conflicts during parallel accesses by a prefetching strategy of LUT Buffer. Our architecture achieves 1.45× speedup compared to naive design without buffered LUT.
- We propose an **adaptive grouping strategy** to tame workload imbalance introduced by randomly distributed similar tokens, allowing seamless integration between our frame-level and token-level speculations, accelerating the model by 1.10× on average.

Extensive experiments on various models and datasets demonstrate that SIMPICKER achieves an average of 5.21×, 1.45× speedup and 17.92×, 1.63× energy efficiency compared to the NVIDIA A100 GPU, and the SOTA accelerators.

II. BACKGROUND AND MOTIVATION

A. Diffusion Transformer and 3D Full Attention

3D-VGMs commonly utilize DiT as their backbone for its scalability and performance. Fig. 2 illustrates 3D-VGMs' structure and the noise prediction process, which takes CogVideoX [12] as an example. At a specific diffusion timestep [25], the input comprises a partially denoised video and prompt, both of which undergo tokenization and embedding to form a continuous token sequence $X^{2\times TN\times C}$. Here, 2 corresponds to the batch size, T denotes the number of video frames, N represents the number of tokens per frame, and C

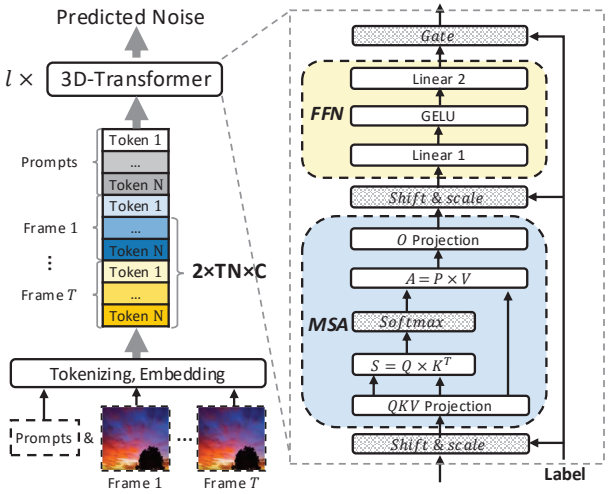

Fig. 2: 3D-VGM's structure and the noise prediction process.

indicates the hidden dimension. The token sequence is then processed through l layers of DiTs, which compute attention across all tokens from different frames.

A DiT includes a multi-head self-attention (MSA), a feed-forward network (FFN), and label embedding operators. The computing flow of MSA can be expressed by $QKV = XW_{QKV}$, $S = QK^T$, $P = Softmax(\frac{S}{\sqrt{d}})$, and $A = PV$.

B. Motivation

As illustrated in Fig. 1 (a), the primary bottleneck lies within the attention computation, which constitutes over 75% of the total computational amount. This finding prompts us to mitigate the overhead associated with the attention mechanism. Drawing inspiration from successful video processing techniques, our approach exploits the similarities and speculates importance at the frame and token levels. Also, we need dynamic and adaptive strategies to tackle the workload imbalance problems caused by similarity exploitation and fully utilize our integrated framework.

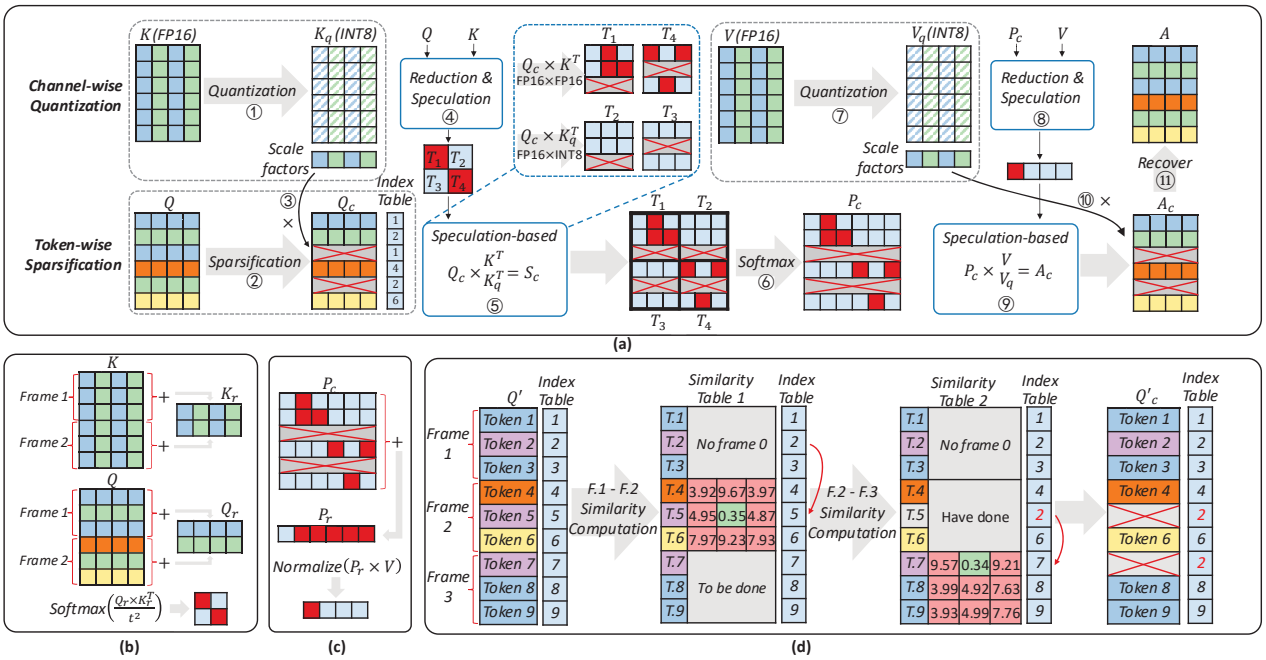

Fig. 3: (a) Overview of the algorithm. We speculate token-level similarities in Q by computing similarities and employ a speculation-based matrix multiplication algorithm for attention. (b) Speculation method for computing QK^T. (c) Speculation method for computing PV. (d) A simple example of temporal token-level similarity exploitation.

III. Speculation-based Similarity Exploitation

A. Algorithm Overview

Fig. 3 demonstrates the overview of our speculation-based similarity exploitation approach. We exploit similarities and speculate important attention parts by pre-computing a small frame-level importance map. Besides, we exploit similarities in the input tokens of the query matrix Q, thereby sparsifying it to accelerate the following computations.

B. Speculation-based Tile-level Similarity Exploitation

Importance Speculation in Attention. Guided by the observation that a small fraction of tiles holds most attention scores, we can perform importance speculation to accelerate attention computation. We aim to speculate $Z = XY$ at the tile granularity of $h \times w$, where Z can be P or A matrix in attention. We first reduce X by computing the sum over every h consecutive rows and Y over every w consecutive columns, generating the reduced matrices X_r and Y_r. We then compute the reduced product $Z_r = X_r Y_r$ and process Z_r row by row, greedily selecting the largest values until their sum exceeds a pre-defined proportion of the aggregated sum. This provides an importance map Z_{pred}, an indicator of importance for the actual computation of $Z = XY$. Fig. 3 (b) and Fig. 3 (c) illustrate the reduction and speculation process for $P = Softmax(\frac{QK^T}{\sqrt{d}})$ and $A = PV$. The ideal granularity for P's computation is $N \times N$. For A, the optimal tile size is $M \times 1$, where M is the total number of tokens.

The overhead of speculation relative to original matrix multiplication is approximately $\frac{M+N^2}{NM}$ for P and $\frac{M+d}{Md}$ for A. For the normal settings of 480p, 96-frame videos for CogVideoX, they are 3.92% and 1.57%, respectively, which are negligible. Despite some slight differences between our speculated importance map for P and P's actual importance map introduced by the $Softmax$ operator, they incur nearly no accuracy loss as most parts of them are the same.

Speculation-based Attention Computation. We quantize the K, V matrices channel-wise with symmetric 8-bit quantization for their channel-wise distribution pattern, obtaining scale factors and the quantized forms K_q and V_q. We do not quantize Q, as our token-level similarity exploitation sparsifies its structure. During the computation of QK^T and PV, we choose to perform FP-INT multiplication for unimportant parts and FP-FP multiplication for the rest, based on the frame-level importance map acquired during the aforementioned speculation. Thus, we significantly reduce over 65% FP-FP multiplications to FP-INT multiplications.

C. Speculation-based Token-level Similarity Exploitation

We exploit Q's token-level similarity to reduce computations in row dimension by speculating that tokens with similar values also have similar outputs after attention. We adopt such speculation in temporal and spatial dimensions in every layer, allowing full utilization of token-level similarity.

At the temporal dimension, the token-level similarity exploitation is performed frame by frame. We set t as a pre-defined window length, and for every token we process, we choose a $t \times t$ window in the previous frame and perform a similarity check with every token inside. We use the L2 norm to represent the similarity between two tokens. Among the $t \times t$ similarity values, we compare the minimum value with a pre-defined threshold τ. The computation of this token is reduced

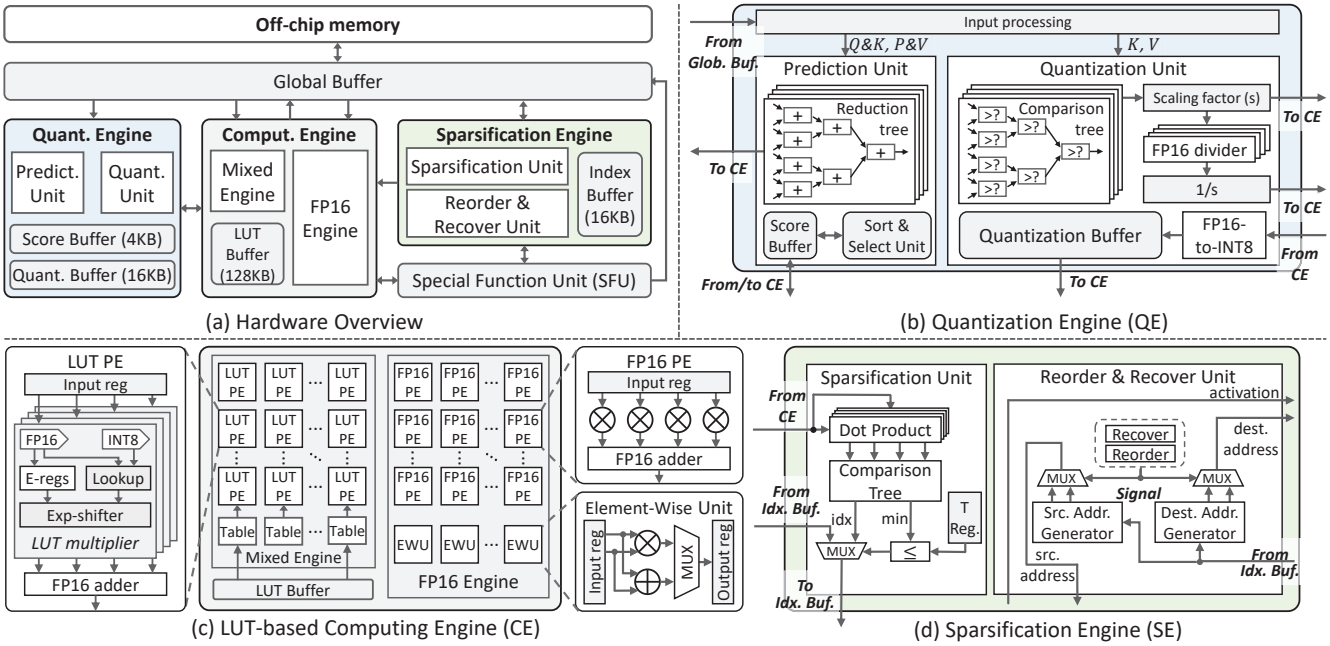

Fig. 4: (a) Our hardware architecture, SIMCORE, features (c) a LUT-based Computing Engine, and units that support our algorithm: (b) Quantization Engine, (d) Sparsification Engine

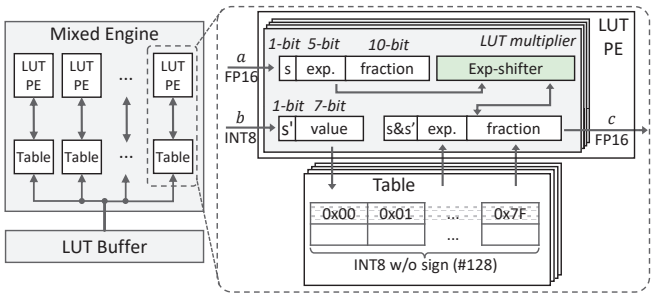

Fig. 5: The LUT-based multiplier. Each LUT multiplier is paired with a local table that prefetches and copies the intermediate results for multiplication, eliminating bank conflicts.

if the minimum value is less than τ. Fig. 3 (d) illustrates our temporal similarity exploitation.

In the spatial domain, we exploit token-level similarity by grouping tokens in each frame. We choose a reference token within each group and compute the similarity between every other token and the reference token in this group. For every non-reference token, we similarly check the threshold and adopt the result of the reference token if it is met.

IV. BUFFERED LUT-BASED MULTIPLICATION ARCHITECTURE

A. Overview of SIMCORE

We present SIMCORE, an end-to-end 3D-VGM accelerator featuring a buffered LUT-based Computing Engine that accelerates the computation of unimportant attention. SIMCORE also includes additional architectural supports for the importance speculation in attention and the token-level similarity exploitation. Fig. 4 shows our hardware overview.

B. LUT-based Computing Engine

The LUT-based Computing Engine (LUT-based CE), as illustrated in Fig. 4 (c), includes an FP16 Engine that manages FP-FP computations and a Mixed Engine that handles FP-INT multiplication with a LUT Buffer. The FP16 Engine deploys Element-Wise Units (EWU) to perform element-wise computations for quantization and sparsification. It also contains FP16 PEs that handle FP-FP matrix multiplication.

The Mixed Engine contains an array of LUT PEs, as depicted in Fig. 5. We employ the observation that the products between the 7-bit INT8 magnitudes and the 10-bit FP16 fractions can be precomputed, and they only occupy 128KB on-chip buffer size. By storing these precomputed products in the LUT Buffer, the FP-INT multiplication can be simplified into one lookup in LUT and one shift in the exponent, thus significantly reducing computations.

However, bank conflicts must be solved since different LUT PEs may require the same intermediate results, which stalls our LUT-based CE and deteriorates efficiency. Our solution utilizes a group of local tables for each PE, whose multipliers share the same FP16 operands. Before each FP-INT MAC, we prefetch intermediate results by copying the table from the LUT Buffer to each PE's local tables. We leverage double-buffer trick so that the cost of our prefetch strategy can be hidden by the computation time of the multiplier.

C. Additional Architectural Support

Shown in Fig. 4 (b), the Quantization Engine is mainly composed of a Prediction Unit (PU) and a Quantization Unit (QU). The PU aggregates input matrices via a Reduction Tree and multiplies the reduced matrices. It sorts the matrix, greedily selects the highest values with its Sort&Select Unit(S&SU), and stores the importance map in the Score Buffer. The

QU quantizes K and V into the 8-bit one's complement representation, where the last 7 bits represent magnitude.

Fig. 4 (d) shows the Sparsification Engine, which is composed of a Sparsification Unit (SU), a Reorder & Recover Unit (R&RU), and an Index Buffer. After the query matrix Q is generated, the SU exploits token-level similarity by computing the similarities and letting the Comparison Tree find the highest similarity, which is compared to the threshold in the T register. If the condition is satisfied, the Index Buffer will be updated. The R&RU reorders Q to sparsified Q_c and recover A from sparsified A_c. For both reordering and recovering, We traverse the index table, generating each index's source and destination addresses. Then, the data will be transferred according to the index and the addresses.

V. Adaptive Grouping Strategy

A. Algorithm-Hardware Mapping Overview

We describe the MSA dataflow on SimCore. Other phases in 3D-VGMs primarily involve FP-FP operations and element-wise operations and do not use the devised engines.

Initially, Q and K are reduced, and the importance map for P is generated in the Prediction Unit with the assistance of the Special Function Unit (SFU) and S&SU. Concurrently, the SU and QU produce sparsified Q_c and quantized K_q, respectively. The CE then computes S and P row-by-row, leveraging both the FP16 Engine and Mixed Engine, guided by the importance map of P. This row-by-row computation maximizes parallelism and enables the fusion of $P = Softmax\left(\frac{S}{\sqrt{d}}\right)$ and $A = PV$. As every t rows of S are computed in parallel, they are forwarded to the SFU to generate P. This row slice of P is sent to the QE to obtain the importance map for A. Here, we employ an adaptive grouping strategy for P (Sec. V-B). Subsequently, V columns are reordered and grouped based on the importance map for optimized resource utilization. Upon completing the full attention process, the Recovery Unit in the SE restores the A_c matrix to its original form.

B. Adaptive Grouping Strategy to Tame Workload Imbalance

Randomly distributed similar tokens lead to workload imbalances in the sparsified Q_c matrix. For instance, during the attention computation phase, the workload of each PE is imbalanced, necessitating the compression of Q_c to utilize computational resources fully. Such imbalance also occurs in the importance map speculation for A, where we need to recover P_c into P for speculation fully, and the distribution of P_c's indices is random and uneven. Moreover, the recovery incurs significant memory overhead due to the separation of similar token pairs in different frames.

We propose an adaptive grouping strategy to tame workload imbalance and integrate our frame-level and token-level speculations seamlessly. Instead of recovering P from P_c, we directly reduce P_c for subsequent speculation, as our observations show that the value distribution in each column of A in even, allowing such a strategy with no accuracy loss.

TABLE I: Accuracy of SimPicker in 3D-VGMs.

Component	Method	CLIPSIM ↑	VBench ↑
Open-Sora-Plan v1.2	Baseline	0.196	0.305
	SimPicker (Ours)	0.196	0.305
CogVideoX-5B	Baseline	0.304	0.311
	SimPicker (Ours)	0.307	0.312

VI. Evaluation

A. Experimental Setup

Hardware Setup. We implement SimCore using Verilog. We set CE comprising 16×8 LUT PEs with 8 LUT multipliers in each, 8×8 FP16 PEs with 8 multipliers in each, and 4×8 EWUs. The configurations of the QE and SE are aligned with CE's parallelism, enabling pipelined operator processing. The on-chip buffer includes a 208KB Global Buffer, 256KB Lookup Table, 128KB Lookup Table buffer, 16KB Index buffer, 16KB Quantization buffer, and 4KB Score buffer.

The area and power of logic units are evaluated at 1 GHz frequency using Synopsys Design Compiler under a 32nm process. Cacti 7 [26] are used for on-chip buffer evaluations.

Models and Datasets. We evaluate SimPicker on two SOTA 3D-VGMs, CogVideoX-5B [12] and Open-Sora-Plan v1.2 [14]. CogVideoX-5B concatenates text prompt tokens and video tokens together without MCA, while Open-Sora-Plan v1.2 still uses cross-attention to capture the correlation between prompt and video. We evaluate the impact of SimPicker on model accuracy on the VBench dataset [27], a carefully designed benchmark containing comprehensive prompts that describe the scene in detail.

Tasks and Metrics. We evaluate the quality of videos generated by SimPicker with two metrics, CLIPSIM [28] and the evaluation model in VBench [27]. CLIPSIM employs CLIP [28] to evaluate the similarity between the text prompt and the generated video. The evaluation metric of VBench gives a comprehensive analysis from multiple perspectives.

Baselines. To compare the performance and energy efficiency of SimPicker with SOTA works, we run open-sourced 3D-VGMs on the NVIDIA A100 GPU [29]. The inference latency and power of A100 are measured by python time library [30] and CUDA event API [31]. We also compare several SOTA ASIC accelerators, including two DiT-based works (InterArch [22] and CMC [32]) and two attention-based works (Sanger [20] and FACT [21])uu. For a fair comparison, we unify the number of FP16 MACs, on-chip buffer capacity, and frequency with those of SimCore. The off-chip bandwidth is set to 128GB/s. We design and implement a cycle-level behavioral simulator to model the operational execution of different accelerators. The CODEC auxiliary module in CMC is excluded from the evaluation.

B. Evaluation of Model Accuracy

We choose the original models with FP16 precision as the baseline. For SimPicker, the token-level similarity threshold is set to 2.5, while the proportion of the aggregated sum of important tiles in speculation is 0.65. Table. I shows that SimPicker has no accuracy loss on both metrics.

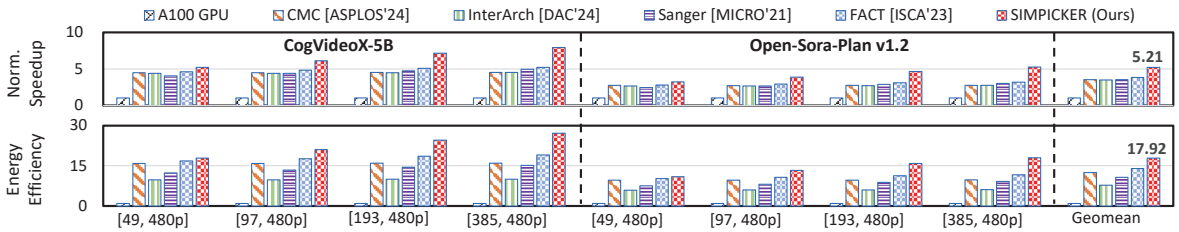

Fig. 6: Overall Performace of SIMPICKER. The horizontal axis represents [frames, resolution] of the generated video.

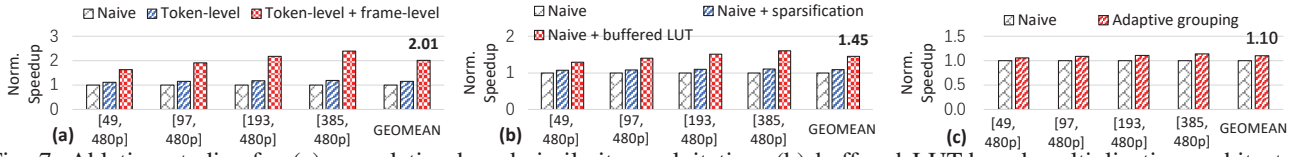

Fig. 7: Ablation studies for (a) speculation-based similarity exploitation, (b) buffered LUT-based multiplication architecture, and (c) adaptive grouping strategy. The horizontal axis represents [frames, resolution].

TABLE II: The area and power of SIMCORE.

Component		Area (mm^2)	Power (mW)
Computing Engine	16×8 LUT PEs	1.23	47.10
	8×8 FP16 PEs	2.71	323.07
	4×8 EWUs	0.04	3.58
Quantization Engine	Prediction Unit	0.02	1.40
	Quantization Unit	0.03	1.89
Spasification Engine	Sparsification Unit	0.14	16.36
	Reorder and Recovery Unit	0.06	2.69
Special Function Unit		0.23	11.02
628KB On-chip buffer		1.47	61.67
Total (32nm)		5.93	468.79

C. Hardware Analysis

The area and power of SIMCORE are shown in Table. II. The total area of SIMCORE is 5.93 mm^2, and the power is 468.79 mW. The Computing Engine is the main module, accounting for the largest proportion of 67%. The additional Quantization Engine and Sparsification Engine are only 0.25 mm^2, accounting for 4.21% of the total area.

D. Overall Performance

For both models, we evaluate the end-to-end latency and the power consumption among NVIDIA A100 GPU [29] and the ASIC accelerators under the same prompt and workload.

Performance with GPUs. For NVIDIA A100 GPU, SIMPICKER achieves 5.21× speedup on average due to our-buffered LUT-based FP-INT multiplication architecture that efficiently supports mixed-precision multiplication. Besides, SIMPICKER also achieves an average of 17.92× energy efficiency since our adaptive grouping strategy fully utilizes the hardware computing resources. The gap between SIMPICKER and GPU further expands when the video length increases, showing that SIMPICKER is also suitable for scalable settings.

Performance with ASIC accelerators For the SOTA ASIC accelerators, our SIMPICKER achieves an average 1.49× speedup and 1.87× energy efficiency compared to DiT-based accelerators CMC and InterArch. For attention-based accelerators, we get an average 1.41× speedup and 1.33× energy efficiency for Sanger and FACT.

E. Ablation Study

Speculation-based similarity exploitation algorithm. We test SIMPICKER's end-to-end latency with a naive algorithm and the algorithm that only exploits token-level similarity in our architecture under the setting of no accuracy loss. As shown in Fig. 7 (a), SIMPICKER increases the speedup by an average of 2.01×, which shows that our algorithm can effectively exploit the similarity in both frame-level and token-level. To be mentioned here, GPU cannot fully support our algorithm since there's an FP-INT multiplication.

Buffered LUT-based multiplication architecture. Experiments are taken to evaluate the end-to-end latency of our model compared to the naive one and a naive one equipped with a sparsification engine. The naive architecture only has an FP16 Engine and a Quantization Engine. As shown in Fig. 7 (b), such design significantly impacts the end-to-end latency of 1.45× on average, which indicates that our architecture can effectively support our algorithm.

Adaptive grouping strategy. As illustrated in Fig. 7 (c), we evaluate SIMPICKER's latency and breakdown with and without the adaptive reduction strategy. Results show the adaptive grouping strategy achieves a 1.10× speedup compared to a workload-imbalanced one. That's because token-level similarities are harder to exploit in 3D-VGMs due to their capabilities of generating more continuous video than their 2D+1D counterparts, leading to a low ratio of similar tokens.

VII. CONCLUSION

In this paper, we propose SIMPICKER, a comprehensive attention-aware algorithm-hardware co-design for 3D-VGMs inspired by video processing methods. SIMPICKER achieves 5.21×, 1.45× speedup and 17.92×, 1.63× energy efficiency compared to NVIDIA A100 GPU and SOTA accelerators. We hope that more works can be inspired and existing methods in video processing can be harnessed to boost video generation.

***Abstract*—To address the growing security issues faced by ARM-based mobile devices today, TrustZone was adopted to provide a trusted execution environment (TEE) to protect sensitive data. Such TrustZone-based models have been proven to be effective, but they target CPU architectures and do not work for the security of widely used heterogeneous computing platforms such as FPGAs. To solve this issue, we propose a comprehensive SoC-FPGA security framework, FPGA-TrustZone, to support FPGA TEE by extending the security of ARM TrustZone. Experiments on real SoC-FPGA hardware development boards show that FPGA-TrustZone provides high security with low performance overhead.**

***Index Terms*—Trusted execution environment (TEE), SoC-FPGA, ARM TrustZone, security extension**

I. Introduction

In the era of big data, emerging applications like deep learning, intelligent traffic control, and large-scale database management demand information processing capabilities beyond what traditional CPUs can provide. Consequently, new high-performance computing platforms like GPUs, FPGAs, and processing-in-memory chips have emerged [1], [2]. Specifically, FPGAs offer high parallelism, low energy consumption, and programmability [3], making them increasingly popular in the commercial sector. To integrate FPGAs' computing capabilities into traditional CPU-based systems, heterogeneous SoC-FPGA architectures (e.g., Xilinx ZCU102, Xilinx ZCU104, Xilinx Zynq-7010) have been widely deployed in recent years.

Ongoing confidential data leaks have caused significant economic losses and psychological harm, raising widespread concern. At present, data security has become the main concern in the digital age besides performance and energy consumption. Trusted execution environment (TEE) is a trending topic in modern hardware-assisted security architectures for solving data security problems, and it has gained significant attention from both industry and academia. TEEs provide an isolated, protected environment for sensitive data and code, using hardware isolation and encryption to prevent unauthorized access or tampering. A large number of TEE designs implemented on various instruction set architectures including Intel SGX [4], Keystone [5] and ARM TrustZone [6]. ARM TrustZone offers hardware-level protection and isolation, and it is widely used in embedded systems and mobile devices [7], [8].

However, mainstream TEEs protect only CPUs, leaving heterogeneous computing platforms vulnerable. As FPGA-based heterogeneous platforms become more common, they face increasing attacks. Researchs [9]–[11] have explored extending TEE security features to FPGAs, including hardware isolation and secure environments for third-party applications. Therefore, existing solutions face challenges like insufficient security protection and high overhead. This paper proposes FPGA-TrustZone, extending ARM TrustZone's security features to SoC-FPGA heterogeneous architectures, ensuring FPGA resources are protected. The main contributions of this paper are summarized below:

- We propose a TEE for SoC-FPGA, in which it protects sensitive data and code from external attacks with the TrustZone extension.
- To support security isolation between FPGA programs, a comprehensive FPGA security framework, including the FPGA Secure Monitor, Secure Monitor-Extension and BRAM Protector, is designed.
- We implement a system prototype using an SoC-FPGA board for functional verification and performance analysis. The experimental results demonstrate that the proposed framework can guarantee security while the additional cost is acceptable.

The rest of the paper is organized as follows. Section II introduces the background and the related work for TEEs in FPGA. Section III presents the threat models. Section IV describes the proposed system and design details. Section V shows the experimental setup and evaluations. Section VI concludes this paper.

II. Background and Related Work

ARM TrustZone is an ARM architecture technology designed to enhance security by dividing the system into secure and non-secure execution environments (i.e., TEE and REE), widely used in embedded systems and mobile devices. It enhances system security by isolating external and memory resources at the hardware level. TrustZone virtualizes the CPU

core into secure and non-secure states to manage transactions in the Secure and Normal Worlds separately. A high-permission controller, called the secure monitor, controls the operation of these cores. By integrating software and hardware, ARM TrustZone offers a robust security solution for mobile devices and embedded systems, safeguarding sensitive data and critical tasks from attacks, and enhancing user privacy.

To meet diverse application requirements and evolving market demands, SoC-FPGA heterogeneous platforms have emerged. The SoC-FPGA platform integrates FPGA and CPU on a single chip. The integration of FPGAs with CPUs has unlocked new avenues for innovation in fields like data analytics, machine learning, and embedded systems [12], [13]. This integration offers greater flexibility, configurability, and performance across various applications. However, SoC-FPGA also brings additional security risks. Thus, protecting the security of the SoC-FPGA heterogeneous architecture is crucial.

Yanling Wang et al. [14] propose a scheme called RCTEE, offering remote users a runtime-customizable TEE on a cloud SoC-FPGA. This scheme supports secure and dynamic IP deployment and invocation. SGX-FPGA [11] proposes a framework that connects SGX enclaves and FPGA, creating a secure hardware isolation path between the CPU and FPGA to ensure the confidentiality and integrity of heterogeneous CPU-FPGA systems. In SoC-FPGA architecture, Ambassy [9] uses an FPGA terminal to build a secondary TEE for third-party Trusted Applications, extending TrustZone's use. This not only shields trusted applications in the secondary TEE from the Normal World but also protects both secure and normal operating systems from malicious third-party applications. However, the secondary TEE does not address the trusted boot of the FPGA. TEEOD [10] proposes isolation tools to create secure environments for common applications and creates a secure processor for each isolated environment. However, there are different problems such as high overhead, high communication cost, insufficient external storage security and so on when the existing schemes are really applied to the actual applications. This is the challenge we strive to address in this paper.

III. Threat Model

In this work, we target an emerging new system architecture, the SoC-FPGA heterogeneous architecture, which does not have a commonly adopted threat model definition in the community. The integration of FPGAs in SoCs introduces new attack surfaces that need to be considered in TEE systems. These attack surfaces can be categorized into four aspects:

1) *Internal attacks on the FPGA.* Modern FPGAs support concurrent execution for multiple tasks. The concurrent execution introduces a risk of stealing confidential models or data by leveraging internal FPGA resources. And attackers embed malicious logic into FPGA designs, such as through third-party IP or unverified code modules, to disrupt system functionality, steal or leak sensitive data [14].

2) *Using a compromised FPGA to attack CPU-side resources.* FPGAs in mobile devices typically have access permissions to the CPU-side memory, which contains sensitive data. Then attackers can inject malicious logic into the FPGA-side, directly accessing the memory or registers of the CPU-side, thereby stealing or tampering with sensitive data, which is more likely to cause system crashes.

3) *Invaded CPU attacks the FPGA.* Attackers can control the Normal World on the CPU-side through malicious code injection, thereby achieving deep penetration into the entire system, directly affecting the security of the system [10]. Then the invaded CPU can exploit its control over resources to attack the FPGA through malicious code, communication protocol vulnerabilities, etc., illegally accessing FPGA-side resources, changing logic functions, stealing sensitive user data, and disrupting system integrity and user data confidentiality.

4) *External attacks between CPUs and FPGAs.* In the SoC-FPGA system architecture, the AXI bus serves as a critical communication channel between CPUs and FPGAs. This interface plays an important role in coordinating complex operations, but it introduces new vulnerabilities in data security such as corrupting communication signals and response signals [15]. And attackers can use various means to monitor, interfere with, and steal user data transmitted on the AXI bus.

IV. System Design

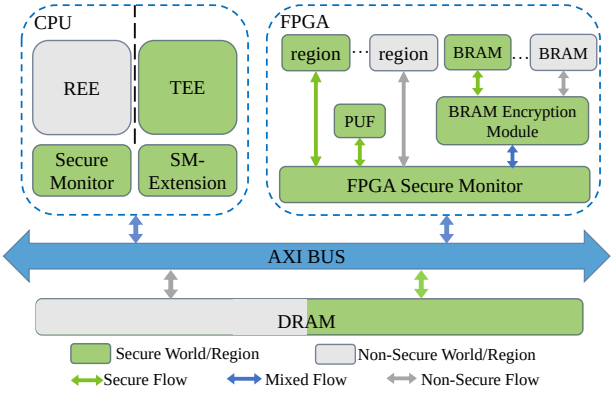

Fig. 1. Overall Framework of FPGA-TrustZone.

We propose FPGA-TrustZone, which builds FPGA TEE by extending the security features of ARM TrustZone to the SoC-FPGA platform. As shown in Fig. 1, FPGA-TrustZone consists of three essential components: *FPGA Secure Monitor* (*FPGA-SM*), *Secure Monitor-Extension* (*SM-Extension*), and *BRAM protector*. We design the *FPGA-SM* to provide a lightweight inner resource isolation mechanism for the FPGA by extending the security features of ARM TrustZone. The *SM-Extension* working on the CPU-side is designed to cooperate with the work of the *FPGA-SM*. *BRAM protector* utilizes the constructed physical unclonable function (*PUF*) to support the *BRAM Encryption Module* to encrypt the BRAM to protect sensitive information from unauthorized access and tampering.

A. Challenges of Protecting Soc-FPGA

To develop the FPGA-TrustZone for the secure SoC-FPGA heterogeneous architecture, we have three challenges to overcome:

- First, to protect the data and code of the FPGA program at runtime, FPGA-TrustZone needs to ensure that the data and code are secure when they exist on the FPGA.
- Second, as FPGA resources are shared by multiple applications, we need to ensure proper security isolation. Specifically, we need to not only enforce security isolation between CPU and FPGA applications, but also the isolation among FPGA applications.
- Third, FPGA resources are limited; therefore, FPGA-TrustZone should be lightweight and not significantly affect the performance of FPGA applications.

In the following sections, we will discuss how we address these challenges in detail.

B. FPGA Secure Monitor

FPGA-SM is the core component of the FPGA-TrustZone in FPGA. In order to ensure the security of the data code of the FPGA program during the lifecycle on the FPGA, FPGA-SM implements three functions: trusted boot, security isolation and secure transmission.

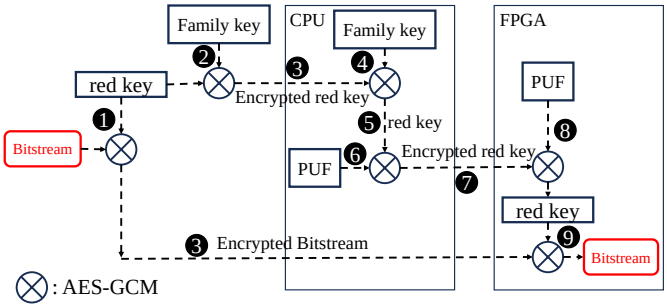

Fig. 2. Trusted Boot of the FPGA.

Trusted Boot. FPGA-TrustZone implements a trusted boot for the FPGA, protecting the system's lifecycle security, including both the startup and runtime. The trusted boot of the FPGA revolves around how to securely transfer Bitstream stored in external memory to the FPGA-side, while also ensuring that adversaries cannot obtain hardware designs or other sensitive information in the Bitstream. Therefore, it is necessary to encrypt the data during the boot process. At the same time, Bitstream also holds sensitive data such as the FPGA-TrustZone encryption keys and other firmware code. So, the data stored in the external memory also needs to be encrypted. Therefore, we designed a trusted boot process as shown in Fig. 2. FPGA-TrustZone uses AES-128bit encryption with Galois/Counter Mode (GCM) for the entire trusted boot process, which defends against replay attacks. First, ❶FPGA-TrustZone encrypts Bitstream and other mirror partitions belonging to CPU using a standards-compliant AES key (called red key). After that, ❷FPGA-TrustZone uses the Family Key interface offered by the Vitis design tools to encrypt the red key. The Family Key is only saved in the on-chip memory in the ARM core. It is a constant AES key value hard-coded into the devices.

The encrypted red key and other ciphertexts are packaged into a boot image and placed in external memory. When CPU boots, ❸the Configuration Security Unit(CSU) in CPU loads the image from external memory and decrypts the red key❹, which is then used to decrypt any other image partitions belonging to CPU except Bitstream❺. After that, ❻FPGA-TrustZone uses the Key-Encryption Key generated by the PUF in the CSU to encrypt the red key and ❼ sends it along with the encrypted Bitstream to the FPGA, where the PUF on the FPGA decrypts the red key❽, and then decrypts the Bitstream with the red key❾, and the FPGA is trusted to run. All Zynq UltraScale+ devices have a built-in physically unclonable function, which can generate a cryptographically strong, device-unique encryption key. This key cannot be read by a user, allowing for a heightened level of key security.

Security Isolation. To enforce security isolation among FPGA applications, FPGA-SM implements security isolation for the shared FPGA resources. Then, FPGA-TrustZone uses FPGA-SM to isolate memory, IP, and other FPGA components, enforcing access restrictions to prevent interference or malicious tampering during runtime, thereby enhancing data security.

After receiving a transaction from CPU requesting the creation of an isolation zone, *FPGA-SM* first determines whether the transaction is secure or non-secure through the AxPROT bit in the transaction, and then creates a secure or non-secure zone (called region). The AxPROT bit can also indicate whether the transaction is privileged and whether the transaction is a data transaction or an instruction transaction. The hardware basis for isolation between the area is the regional identifier (called AxRegion) of the AXI bus protocol. With the identifier, the *FPGA-SM* can manage up to 16 regions, and it can control each region independently. Each region does not affect each other. Using AxPROT to divide FPGA resources into secure and non-secure parts does not achieve isolation between regions. In order to refine isolation to each region, FPGA-TrustZone divides the hardware resources on the SoC-FPGA platform, assigning a DeviceID to each hardware, and transactions issued from that hardware will come with a DeviceID. When creating a region, the *FPGA-SM* creates a device access list belonging to the region. The device list maintains the devices that can access the region. In this way, the FPGA-TrustZone applies isolation to each region.

Secure Transmission. It can be used to perform secure communication with the CPU. In this component, *FPGA-SM* can decrypt the encrypted transactions transmitted from the CPU-side and transmits them to the corresponding region for processing. The transactions on FPGA-side are encrypted and transmitted to CPU-side through AXI bus. And it can provide a dynamic configuration interface to support dynamic configuration of *SM-Extension* at runtime.

In order to check whether a transaction has permission to access the target region, we implement a *Transaction monitor* in *FPGA-SM*. *Transaction monitor* acts as a checkpoint for passing transactions. FPGA-TrustZone specifies that a secure transaction can access its own secure region and all non-secure regions. When performing a security check, *Transaction monitor* first checks whether the security level of a transaction

is the same as that of the target region. If the security level is acceptable and the target region is secure, *Transaction monitor* continues to check whether the DeviceID carried by the transaction is in the device access list of the target region. If all the checks pass, the transaction is forwarded to the target region, else the *Transaction monitor* poisons the transaction and sends an interrupt request (IRQ) to the platform management unit (PMU). Specifically, *Transaction monitor* has two poison methods: 1) Return an error code (default). 2) Modify the destination address of the transaction so that it redirects to an empty area.

C. Secure Monitor-Extension

The implementation of the FPGA-SM is inseparable from the help of the CPU-side, i.e., the *SM-Extension*, which provides the security features of ARM TrustZone, the dynamic configuration of application security requirements, and the handling of secure transmission. *SM-Extension* is the extension of Secure Monitor, the core component of ARM TrustZone, to implement the secure communication between CPU and FPGA. It can ensure the security and credibility of the system.

Dynamically configure. *SM-Extension* proposes multiple interfaces for applications. An application can use these interfaces to create, configure, use, and destroy a FPGA region and it can control the entire life cycle of the region.

Secure Transmission. *SM-Extension* is able to handle secure and non-secure transactions from FPGA to prevent potential security threats and attacks. It is used for encrypting and decrypting transactions transmitted between CPU and FPGA, to ensure the security of data transmission, and minimize the additional overhead of performance. It uses the symmetric key algorithm AES-128bit with Electronic CodeBook mode. The key is stored in the *SM-Extension* and *FPGA-SM* through hardcoding. It can also handle transactions from FPGA. After the FPGA sends the transaction to CPU, SM-Extension first checks its security level, then decrypts the data with the corresponding key and forwards the data to the corresponding applications.

D. BRAM Protector

In order to prevent the leakage of BRAM by malicious means, FPGA-TrustZone proposes *BRAM Protector* to protect sensitive information. BRAM Protector implements the *PUF* to generate the Initialization Vector (IV) values of the AES-CBC algorithm to ensure the uniqueness and randomness of the IV. Then BRAM Protector can encrypt BRAM to protect sensitive information in the system from unauthorized access and tampering.

The PUF is a security feature based on physical properties that generate unique identifiers using small differences in chip manufacturing processes. The PUF can be used for various security applications, including device authentication and key generation, as well as other security fields, providing reliable solutions for various security applications. Here, PUF is used to generate IV values in the AES-CBC algorithm. The IV generated by the PUF can satisfy uniqueness and randomness well. Our design combines Arbiter PUF and RO PUF, including ring oscillators, latches, and arbitrators. The arbiter is responsible for controlling the operational status of the ring oscillator and latch, while the ring oscillator and latch are responsible for generating the output data of the PUF.

BRAM Encryption Module is used to encrypt BRAM. The structure is shown in the Fig. 3. In order to reduce the clock overhead of BRAM storage and ensure the security of sensitive data, *BRAM Encryption Module* provides optional data encryption services. Regions can use the IS_ENCRY register to indicate whether the data transaction needs to be encrypted. Each transaction has an additional IS-ENCRY bit to indicate whether the transaction needs to be encrypted. If IS-ENCRY=1, encryption or decryption is required. If IS_ENCRY = 1, it needs to be encrypted. We add a *BRAM Encryption Module* between the BRAM and regions. When the region does not enable memory encryption, data from the region to BRAM will not have any additional delays.

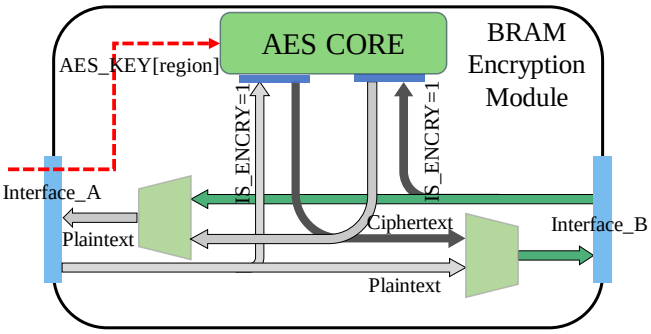

Fig. 3. BRAM Encryption Module.

BRAM Encryption Module uses the AES encryption core with a cipher block chaining (CBC) mode for encryption. Additionally, we consider the security of AES keys. FPGA-TrustZone stores AES keys in FPGA-SM, keeping them transparent to regions. Regions cannot see ciphertext and can only access plaintext decrypted by the *BRAM Encryption Module*, making it difficult to derive the key from plaintext alone. Encrypting BRAM data enhances confidentiality and security, protecting against physical and logical attacks. This ensures the storage security of the FPGA.

E. Data Flow Analysis

The FPGA-TrustZone security architecture encompasses both boot-time and runtime security. Boot-time security is ensured by ARM TrustZone and the FPGA trusted boot process. Runtime security relies on system components to protect programs and data from leakage or tampering. Fig. 4 provides a detailed overview of the data flow in the FPGA-TrustZone architecture. The PMU continuously monitors the system for abnormal behavior and illegal operations during data transmission.

During interaction between CPU applications and FPGA regions, secure-sensitive data is first encrypted by *SM-Extension*, ensuring it remains in ciphertext form during transmission, thereby enhancing resistance to side-channel attacks. Upon

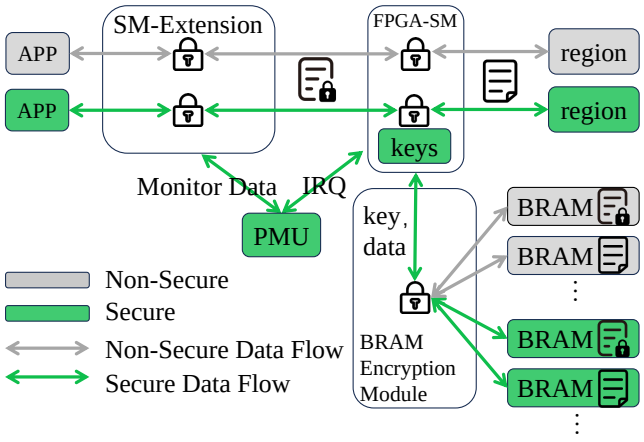

Fig. 4. Secure Data Flow.

TABLE I
ANALYSIS OF SECURITY ABILITIES OF THREE ARCHITECTURES

Ability	FPGA-TrustZone	SGX-FPGA	TPM-TrustZone	PUF-TrustZone
CPU Secure Boot	✓	✓	✓	✓
FPGA Secure Boot	✓	✓	✓	✗
BRAM Encryption	✓	✓	✓	✗
Monitoring Access	✓	✓	✗	✗
PMU IRQ Analysis	✓	✗	✗	✗
Poison Illegal Access	✓	✗	✗	✗
Cold-boot Attack Resistant	✓	✗	✓	✓

data arrival, *FPGA-SM* performs a legitimacy check on the transmission transaction. If the transaction is illegal, *FPGA-SM* sends an IRQ to the PMU and poisons the transaction. If the transaction is legal, *FPGA-SM* decrypts the data and transfers it to the corresponding region for processing. After processing, *FPGA-SM* encrypts the results and sends them to the CPU's *SM-Extension* for decryption and return to the application. Additionally, the region can use the *BRAM Encryption Module* to encrypt its BRAM. This allows sensitive data to be stored in encrypted form in BRAM, further enhancing system security.

V. EXPERIMENTAL EVALUATION

We implement a prototype system for the FPGA-TrustZone security framework on the Zynq UltraScale+XCZU9EG-2FFVB1156E MPSoC (ZCU102). Based on the prototype system, this section conducts two types of experiments to comprehensively evaluate the effectiveness and performance of FPGA-TrustZone: 1) security evaluation, in which we specifically analyzed how the security function implemented by FPGA-TrustZone is to resist the threat model proposed in Section III; 2) performance analysis, in which we analyze the cost of resources and time of FPGA-TrustZone.

A. Security Evaluation

The security of FPGA-TrustZone is verified through various situations, various applications and various illegal means to access the secure and non-secure regions. And we compare the security of FPGA-TrustZone with other secure FPGA architectures including SGX-FPGA ,TPM-TrustZone [16] and PUF-TrustZone [17] in Table I. FPGA-TrustZone demonstrates prominent advantages.

Moreover, FPGA-TrustZone can effectively prevent the threat model proposed in Section III: 1) *Internal attacks on the FPGA:* FPGA-TrustZone divides the FPGA-side into secure and non-secure areas, providing logical resource isolation and preventing malicious IPs from unauthorized access. And, FPGA-TrustZone implements a trusted boot process, ensuring system integrity and security. Data stored in external memory is encrypted, ensuring it exists as ciphertext. Even if attackers obtain the ciphertext, recovering the plaintext is difficult, so as to protect firmware code and key data from leakage or theft. Encrypting the Bitstream ensures data confidentiality during transmission and storage, thereby preventing tampering during transmission.

2) *Using a compromised FPGA to attack CPU-side resources:* FPGA-TrustZone resists attacks on the CPU-side by using ARM TrustZone to secure sensitive data and critical operations within a protected environment. Additionally, *SM-Extension* and *FPGA-SM* control FPGA access to the CPU, preventing threats by monitoring and verifying access transactions.

3) *Invaded CPU attacks the FPGA:* The *FPGA-SM* strictly controls CPU access, preventing unauthorized users from tampering with the FPGA security area and protecting the system from potential harm.

4) *External attacks between CPUs and FPGAs:* The encrypted data transmission can effectively prevent attacks such as eavesdropping and tampering, thereby ensuring data confidentiality.

TABLE II
RESOURCE USAGE OF THE INITIAL HARDWARE DESIGN, PUF, BRAM ENCRYPTION MODULE AND FPGA-SM.

Component	LUT	FF	LUTRAM	BUFG	BRAM
PUF	96 0.04%	292 0.05%	0 0%	0 0%	0 0%
BRAM Encryption Module	6765 2.47%	4939 0.90%	0 0%	4 0.99%	0 0%
FPGA-SM	3435 1.25%	2046 0.37%	0 0%	0 0%	0 0%
The Initial Hardware Design	24321 8.87%	25595 4.67%	3098 2.15%	6 1.49%	4 0.44%

B. Performance Evaluation

Then we measure the performance overhead of FPGA-TrustZone on the ZCU102 development board. The main hardware resources used on devices are as follows:

1) LookUp Table (LUT) and Flip-Flop (FF), used to implement logical functions.

2) LookUp Table RAM (LUTRAM) and BRAM, used to store data.

3) Global clock buffer (BUFG), used for clock signal management, allocation, and processing.

TABLE III
TIME OVERHEAD OF CRITICAL OPERATIONS.

Operation	Time Overhead
IV_generation	0.5 clock cycles
AES_CBC Algorithm	14.5 clock cycles
Memories access	2 ms
Poisoning illegal access	202 ms

TABLE IV
PERFORMANCE EVALUATION.

Benchmarks	Baseline	FPGA-TrustZone	Additional Overhead
Vadd	92439ns	113037ns	22.28%
Matmul	11665ns	13834ns	18.59%
Matmul: partition	1706ns	2042ns	19.70%

Firstly, we evaluate the resource overhead of FPGA-TrustZone. PUF, BRAM Encryption Module and FPGA secure monitor as the three major components. Here, *Used* represents the hardware resources used in the designed solution, while *Available* means the total number of configurable resources for ZCU102 development board. Then *Utilization Ratio=Used / Available*.

We evaluate the resource usage of three main components and the initial hardware design on the ZCU102 development board. Table II presents the hardware resource utilization. Results indicate that the resource cost brought by each component no more than 3% and the overall resource consumption does not exceed 9%. Users can customize hardware designs as needed, provided resource usage stays within available limits. Since the FPGA-TrustZone framework maintains a constant footprint across different SoC-FPGAs, its relative resource usage decreases on platforms with larger capacities.

In addition, we evaluate the time cost of part key operations related to the FPGA-side, including the BRAM encryption module's time consumption, illegal access poisoning time, and memory access operation time. Table III shows the results.

We test runtime performance using three Xilinx benchmark programs: vector addition, matrix multiplication, and matrix multiplication (partition). Table IV presents a comparison between our solution and an unsecured SoC-FPGA. Results show that FPGA-TrustZone introduces a 22.28% overhead for basic operations, which is acceptable given its protection of data storage, computation, and transmission security. Additionally, FPGA-TrustZone incurs an 18.59% overhead for parallel computation, indicating its suitability for parallel execution. The overhead introduced while protecting the overall security of the SoC-FPGA architecture is acceptable.

In summary, FPGA-TrustZone is feasible in terms of overhead on the ZCU102 development board.

VI. CONCLUSION

This paper proposes FPGA-TrustZone, a solution that extends Arm TrustZone's security features to the FPGA, achieving hardware resource isolation and protecting sensitive data in Soc-FPFA architecture. FPGA-TrustZone introduces three important components: FPGA Secure Monitor, Secure Monitor-Extension, and BRAM Protector. FPGA-TrustZone monitors transactions in real-time using Secure Monitor-Extension and FPGA Secure Monitor, verifying the legitimacy of access transactions and poisoning unauthorized access. This approach effectively enhances the overall security of the system. In addition, to further ensure the security of data, FPGA-TrustZone introduces BRAM Protector for encrypting data stored in BRAM. Our implementation and evaluation of actual hardware indicate that FPGA-TrustZone provides relatively low resource and performance overhead while ensuring security, providing a solid guarantee for system security and performance.

***Abstract*—Resistive random-access memory (ReRAM) based Physical Unclonable Functions (PUFs) have emerged as an attractive hardware security primitive due to their low energy consumption and compact footprint. However, the reliability of existing ReRAM-based PUFs is challenged by read noise and temperature variations, as well as their resistance to Deep Neural Network (DNN) modeling attacks and Side Channel Attacks (SCAs). In this paper, we propose a novel 3T2R ReRAM-based reconfigurable PUF to address these challenges. By adopting the digital 3T2R voltage division cell design, we improve its reliability against ReRAM read noise and temperature variations, while the adjustable analog supply voltage of inverters enables quick, low-cost reconfigurability without reprogramming ReRAMs, effectively mitigating DNN modeling and SCA vulnerabilities. Our Re^{4}PUF chip has been experimentally validated, achieving a low Bit Error Rate (BER) of 1% at 85°C, a 7.59-fold reduction compared to existing ReRAM-based PUFs. It also demonstrates robust resistance to both DNN modeling attacks (MLP and Transformer) and SCAs, with success rates of approximately 50% and less than 70%, respectively.**

***Index Terms*—ReRAM; PUF; SCA; DNN modeling attack; Reconfigurable.**

I. Introduction

The rapid progress of smart IoT necessitates enhanced security features, such as unique, device-specific fingerprints for key generation [1]. ReRAM-based PUFs uses inevitable variation in fabrication and redox reaction as the entropy source, which is promising for the high integration density, low operating energy consumption, reduced fabrication costs. However, these attributes also pose significant challenges to reliability, particularly in harsh environments. For instance, elevated temperatures of 85°C can result in a substantial BER of up to 11.5% [2]. Moreover, adversaries may model PUFs by collecting Challenge-Response Pairs (CRPs) and employing DNNs to replicate the functionality of the PUF, thereby impersonating the associated identity. This vulnerability is further intensified by SCAs, where attackers can probe ReRAM conductance [3].

ReRAM-based PUFs. In the early stages, ReRAM-based PUFs mimicked CMOS PUFs (e.g., arbiter PUFs [4], [5]). For instance, Ref. [4] leverages the random conductance of memristors to form two paths with different conduction latencies, generating a final 1-bit response through a D Flip-Flop. Subsequent advancements saw researchers organizing

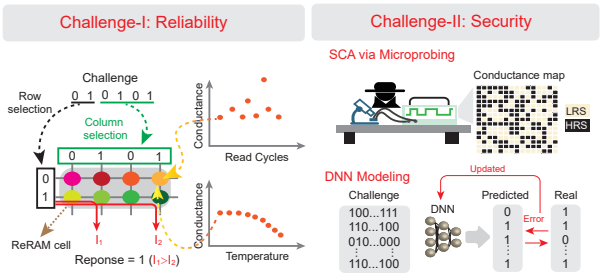

Fig. 1. Challenges faced by ReRAM-based PUFs: (I) Reliability issues arising from read noise and temperature variations. (II) Security vulnerabilities due to DNN modeling attacks and SCAs via microprobe techniques.

ReRAM into 2D and later 3D crossbar structures to serve as memory-based PUFs [2], [6]–[9]. These efforts primarily focused on exploiting the inherent randomness of ReRAM as an entropy source. For instance, Ref. [8] proposes using metal-oxide memristive crossbars to implement PUFs. In their design, the challenge signal serves as both the row and column selection signal, applying voltage to the ReRAM device at the intersection of these signals. The current of the two (even-numbered) columns is then compared to output the corresponding 1-bit 0/1 response.

Challenges. Both arbiter and memory-type ReRAM-based PUFs encounter significant challenges related to reliability and security, as illustrated in Fig. 1.

Regarding reliability, an ideal PUF should produce identical responses upon the same challenge, or a zero BER. However, the reliability of these PUFs is compromised by cycle-to-cycle (i.e., read) variations and sensitivity to temperature changes.

In terms of security, these ReRAM-based PUFs have been validated against various machine learning (ML) and DNN models, including logistic regression, support vector machines, and simple RNNs [2], [6]–[8]. However, their theoretical resistance to ML or DNN modeling attacks is limited due to the strong fitting capabilities of these models [10], which have seen significant advancements in recent years [11].

Current Solutions. To address reliability issues, existing solutions often incorporate additional peripheral circuitry or reprogramming strategies to enhance stability. For instance, Ref. [12] employs post-processing techniques such as Temporal Majority Voting (TMV) and Masking [13], which reduce the BER from 6% to zero. Similarly, Ref. [6] utilizes con-

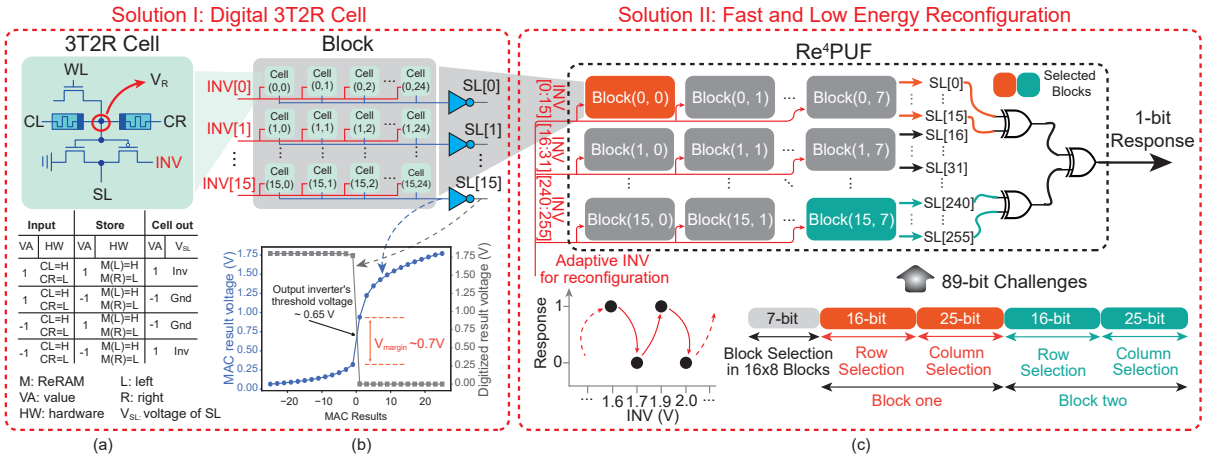

Fig. 2. Re^{4}PUF architecture. (a-b) A novel digital 3T2R cell in a 16×25 block. ReRAM cells form a voltage divider, with output binarized by an inventor. This mitigates reliability issues caused by read noise and temperature variation. (c) Fast and low energy reconfiguration to resist DNN modeling and SCA, by adapting inverter voltage INV in the option set (1.6V, 1.7V, 1.9V, 2.0V)

tinuous programming of each cell for calibration, lowering the BER from 8.4% to approximately 0.014%. However, the inclusion of additional peripheral circuitry undoubtedly introduces extra energy and area overhead, and reprogramming often requires iterative write-verification resulting in significant latency overhead.

To address the security issue, a promising Concealed ReRAM-based PUF [3], [12] has been proposed. This approach restores private conductance information during use and erases it when not in use, thereby mitigating SCAs. However, the repeated erasing and rewriting (i.e., SET and RESET programming of ReRAM) introduces additional latency and energy overhead. Furthermore, ReRAM devices have finite programming endurance [14]. The process of reprogramming also introduces write noise, resulting in inconsistencies with the original PUF. Additionally, the Concealed ReRAM-based PUF does not offer improvements in reliability.

Our Solution. To address these concerns, we propose a ReRAM-based strong PUF that employs an innovative 3T2R cell design. This 3T2R cell uses a voltage division circuit, significantly improves reliability and achieves a 1% BER at 85°C. Our design includes a lightweight reconfiguration mechanism, achieved by adjusting the supply voltage of inverters in the 3T2R cells. This effectively counters powerful DNN modeling attacks and SCAs. Specifically, our innovations are as follows,

- We identify two primary challenges for ReRAM-based PUFs: reliability and security. Additionally, we introduce two novel criteria for comprehensively evaluating the performance of ReRAM-based PUFs: resistance and reconfiguration.
- To address the reliability issue, we propose a new 3T2R cell design utilizing a voltage division circuit (refer to Solution I in Fig. 2 (a-b)). This design significantly reduces the BER, achieving a remarkable 1% BER at extreme temperatures of 85°C, compared to the traditional weighted-current summation (WCS) designs.
- To tackle the security challenge, we propose a reconfiguration method that eliminates hardware programming by adjusting the inverter supply voltage INV (refer to Solution II in Fig. 2 (c)). This lightweight approach effectively counters DNN modeling attacks (MLP and Transformer) and SCAs, with success rates of around 50% and less than 70%, respectively.

The remainder of the paper is organized as follows: Sections II and III present the proposed PUF design and its workflow. Section IV showcases the experimental results. Finally, Section V provides the conclusion.

II. Re^{4}PUF Design

A. Architecture design

Digital 3T2R cell. Existing ReRAM-based PUFs rely on analog memristor circuits to produce responses [2], [3], [6]–[8]. Typically, these systems utilize WCS to compare bitline (BL) currents with either the current generated from another BL or a reference current, thereby generating a response bit. However, the reliability of these systems is compromised by factors such as read noise and operating temperature fluctuations, which lead to undesirable conductance drift and variation.

Inspired by the voltage division cell design in [15], [16], which substantially enhances reliability in the face of memristor variations, we propose an innovative 3T2R cell (Fig. 2 (a)). This cell integrates two ReRAMs in complementary states, an inverter, and a programming transistor. The output of the ReRAM voltage divider (refer to V_R in Fig. 2 (a)) is binarized by the inverter, effectively performing a multiplication operation between the input (refer to CL/CR in Fig. 2 (a)) and the stored conductance. The binary inverter within the 3T2R cell further mitigates fluctuations in ReRAM resistance, such as read noise and temperature variations. The output voltages from all cells are aggregated on a source line (SL), which, after passing through a binary inverter, yields an output of either "0" or "1" (Fig. 2 (b)).

Fast and low energy reconfiguration. Our designed Re^{4}PUF consists of 16×8 blocks. Cells on the same SL share

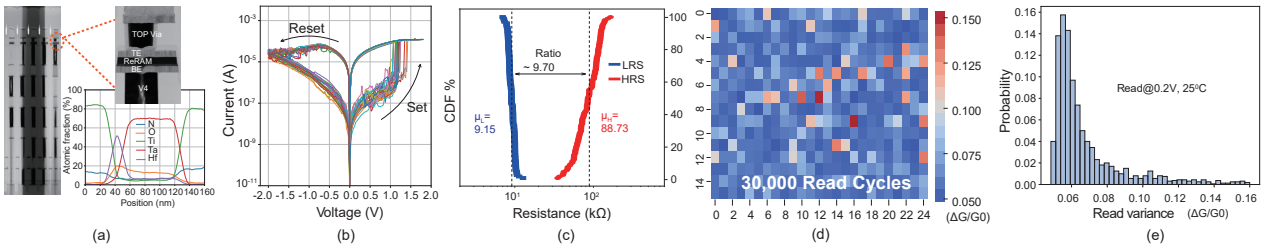

Fig. 3. (a) Cross-sectional Transmission Electron Micrograph (TEM) of a TaOx/HfOx-based ReRAM cell and the Energy-dispersive X-ray Spectroscopy (EDS) compositional profile. (b) DC I-V sweeps over 50 switching cycles. (c) LRS/HRS cumulative resistance distribution for 50 switching cycles. (d-e) The conductance variation heatmap and histogram of all cells within a block after being read 30,000 times at a voltage of 0.2V. ΔG stands for the variance conductance, and G0 is initial conductance.

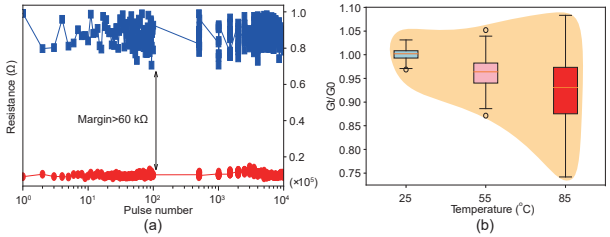

Fig. 4. (a) The endurance of LRS/HRS ReRAM cells. (b) Changes in conductance after baking for 24 hours at 25°C, 55°C and 85°C, Gt represents the measured conductance after baking, G0 is initial conductance.

the same inverter supply voltage INV. Different SLs have different INV voltages. Each combination of INV voltages of all SLs yields a unique PUF. Therefore, adjusting the INV vector reconfigures the PUF (Fig. 2 (c)). Here, each SL opts for one of four INV biasing voltages (1.6V, 1.7V, 1.9V, 2.0V), resulting in a vast selection space of 4^{256} for 256 SLs. An 89-bit challenge is partitioned into three segments: block selection (7-bit, choosing 2 blocks), row selection (32 bits, 16 bits per block), and column selection (50 bits, 25 bits per block). The output signals from the two blocks are individually subjected to two XOR operations, which are combined with an additional XOR operation to generate a 1-bit response (Fig. 2 (c)).

B. Device characteristics

Fabrication. ReRAM cells are integrated via back-end-of line (BEOL) process between Via4 and Metal5 of 180nm technology. They comprise top and bottom TiN electrodes (TE and BE) and a TaO_x/HfO_x switching layer (Fig. 3 (a)).

Entropy source. The operational principle of ReRAM hinges on the reversible switching between a low resistance state (LRS) and a high resistance state (HRS). The transition from HRS to LRS, termed the SET process, and the reverse transition, known as the RESET process, are both driven by the application of voltages exceeding specific thresholds. These processes involve stochastic formation and dissolution of conductive filaments within the memory material. Our experimental 50 cycles I-V sweeps, affirming the reproducibility of this bipolar switching behavior. The threshold voltages for SET and RESET are approximately 1.3V and -1.7V, respectively. Notably, the I-V characteristics for each cycle exhibit variations due to stochastic filament formation/rupture, leading to cycle-to-cycle (i.e., read variance) and device-to-device variation (i.e., write variance) (Fig. 3 (b)).

Write & Read variance. For write variance, HRS and LRS follow Gaussian distributions, with mean values of 9.15 kΩ and 88.73 kΩ respectively. This results in an on/off ratio of 9.7 (Fig. 3 (c)). This discrepancy between the expected and the actual programmed conductance values in both LRS and HRS underscores the intrinsic variability of ReRAM, providing the entropy source.

The read variance of ReRAM cells over 30,000 cycles is illustrated in Fig. 3 (d). The histogram indicates a maximum read variance of 0.16 (Fig. 3 (e)). This read variance can induce instability in PUF responses, presenting substantial challenges to the reliability.

Endurance & Temperature. To investigate the endurance of ReRAM cell, cyclic SET and RESET operations were conducted using a voltage pulse with an amplitude of +1.3/-1.6V and a width of 300/400ns. Simultaneously, a reading voltage pulse with an amplitude of 0.3V and a width of 5ns was applied to the ReRAM cell to measure its resistance. The results (Fig. 4 (a)) demonstrate that ten thousand SET and RESET cycles do not affect the performance of the ReRAM cell.

The conductance variance after baking at 25°C, 55°C, and 85°C for 24 hours exhibits significantly increased variation and a reduced mean value (Fig. 4 (b)). This observation suggests that higher temperatures have a pronounced impact on ReRAM-based PUFs, potentially leading to inconsistent responses and increased BERs.

III. Re^{4}PUF Workflow

The Re^{4}PUF workflow consists of three stages: initialization, reconfiguration, and CRPs generation, as illustrated in Fig. 5 (a).

Initialization. During the initialization phase, the conductance of the 3T2R ReRAM cells are programmed to random binary bits using the intrinsic programming stochasticity of ReRAM. The initialized system is ready for reconfiguration or CRPs generation.

Reconfiguration. Following initialization, the system enters the reconfiguration phase. During reconfiguration, the ReRAMs are not reset; instead, the inverter's voltage INV for each SL is set to specific values (1.6V, 1.7V, 1.9V, and 2.0V), which leads to a unique mapping between challenges and responses.

CRPs Generation. In the CRPs generation stage, the system processes the 89-bit challenge signal. The selection signals

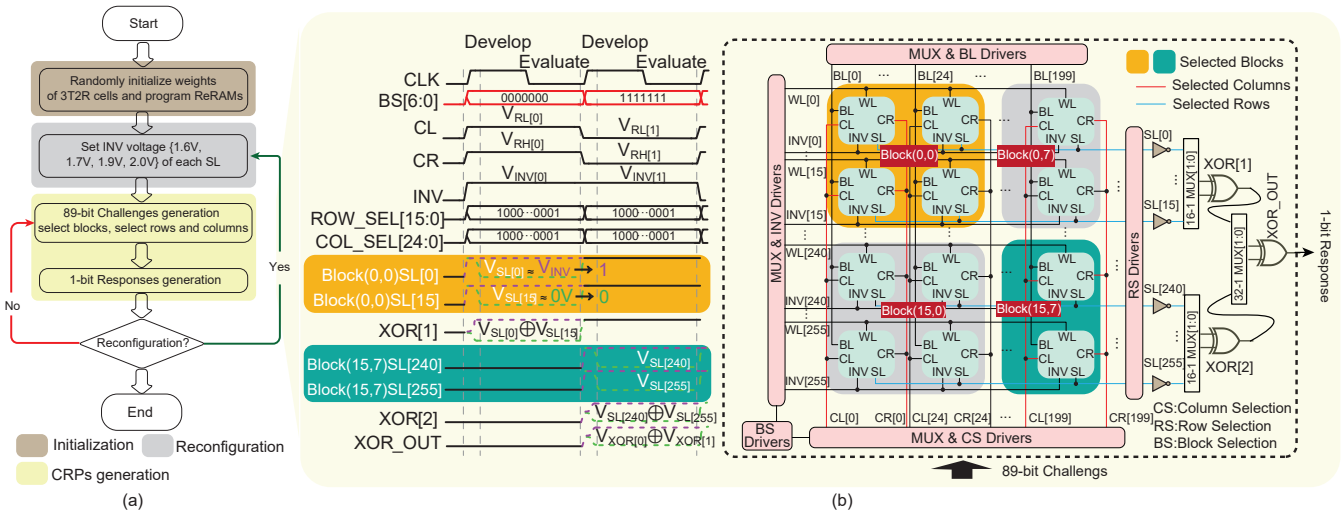

Fig. 5. (a) The workflow includes initialization, reconfiguration and CRPs generation. (b) During the CRPs generation, two blocks are activated by the BS[6:0] signal from the challenge signal. COL_SEL[24:0] signals from the challenge signal is applied to the CL and CR. The chosen block's outputs are selected by ROW_SEL[15:0] signals from the challenge and then undergo XOR operations, which produces the final 1-bit PUF response.

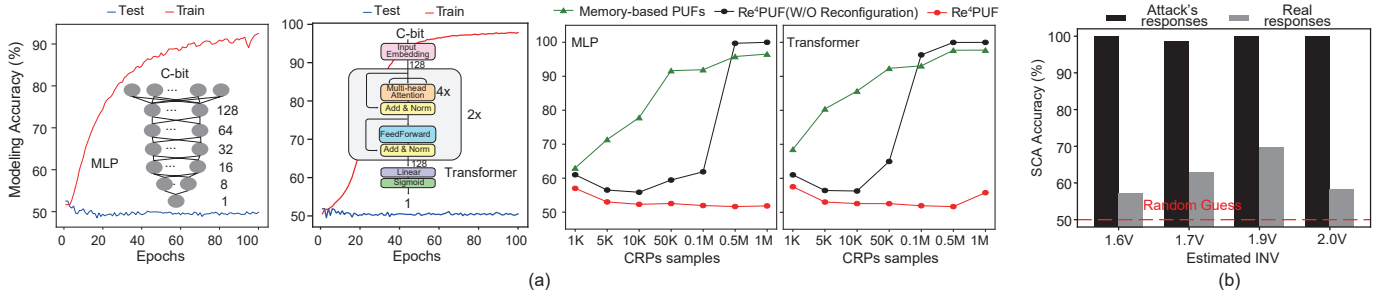

Fig. 6. (a) Re^{4}PUF successfully defends against DNN modeling, including MLP and Transformer. (b) In SCA, attackers fail to predict real responses due to the absence of true INV.

and their interactions during this phase can be further visualized by the waveform shown in Fig. 5 (b), which illustrates how the challenge signals propagate and interact within the ReRAM array. The BS[6:0] of the challenge activates specific blocks within the 16×8 ReRAM block array. The BS[6:3] signals select one of the 16 rows within the block array, while the BS[2:0] signals indicate one of the 8 columns. Following this, the COL_SEL[24:0] signal from the challenge determines which two columns, CL (left column) and CR (right column), within the selected block will be activated. Additionally, the ROW_SEL[15:0] signal from the challenge input refines the selection of row outputs from the activated blocks, further determining which rows will contribute to the response. Once the challenge signals are applied to the selected columns and rows, the activated ReRAM blocks produce two output bits via the two SLs, they undergo XOR operations to produce a unique 1-bit response specific to the applied challenge.

After generating the 1-bit response, the system assesses whether the reconfiguration is required or not.

IV. Experimental Results

The ReRAM of the Re^{4}PUF, featuring a cell size of 0.08μm × 0.08μm and composed of TiN/TaO_x/HfO_x/TiN layers, was fabricated using standard 0.18μm technology through the following steps: First, the TiN layer was deposited via physical vapor deposition to serve as the bottom electrode. Next, the TaO_x and HfO_x layers were sequentially deposited on top of the TiN layer using atomic layer deposition. Finally, a second TiN layer was deposited as the top electrode, using the same method as for the bottom layer. The electrical characteristics of the ReRAM cell and the performance of the PUF were evaluated using a Keysight B1500A Semiconductor Device Analyzer and a SUMMIT 12000 Probe Station.

A. Resistance

Resistance measures the effectiveness against modeling attacks and SCAs. For modeling attacks, this includes ML models like SVM, as well as powerful DNN models such as MLP and Transformer models [11]. Modeling accuracy ranges from 50% (indicating strong resistance) to 100% (indicating weak resistance). For SCAs, attackers can read ReRAM array conductance using probes [3].

Re^{4}PUF effectively defends against DNN modeling, including MLP and Transformer (refer to Fig. 6 (a) for model details). Increasing training epochs or the number of training samples does not improve the accuracy on test CRPs, which remains around 50%, akin to random guessing. Compared to traditional memory-based PUF in [8] (simulated here for comparison) and non-reconfigurable Re^{4}PUF, the reconfigurable Re^{4}PUF maintains strong resistance (Fig. 6 (a)).

Furthermore, even if attackers read ReRAM array conductance using probes [3] and train DNNs for a given INV

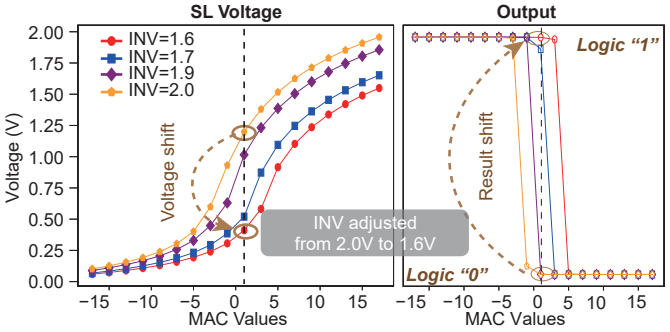

Fig. 7. INV voltage changes SL output, allow fast and low energy reconfigurability. When INV is adjusted from 2.0V to 1.6V, the output voltage of SL shifts from logic "0" to "1".

voltage vector, the real responses remain random guesses due to Re^{4}PUF's reconfigurable nature (Fig. 6 (b)).

B. Reconfiguration

Reconfiguration alters the mapping between challenges and responses, enabling the same input challenge to yield different output responses under different configuration. An optimal reconfiguration strategy should be both energy-efficient and low latency. Concealed ReRAM-based PUF necessitates the erasure of conductances to counter DNN modeling attacks and SCAs, a process that incurs significant costs due to erasing and reprogramming ReRAM cells [3]. To mitigate these drawbacks, our Re^{4}PUF leverages adjustments of inverter supply voltage INV for reconfiguration, avoiding the need to alter cell conductance values.

As illustrated in Fig. 7, modifying the INV voltage directly influences the SL output voltage, thereby changing MAC results. For instance, when the INV voltage is decreased from 2.0V to 1.6V, the SL voltage correspondingly drops from approximately 1.2V to 0.4V. This shift causes the SL inverter's output to transition from logic "0" to logic "1". This reconfiguration method is not only rapid but also get rid of ReRAM programming energy compared to Concealed ReRAM-based PUF [3].

C. Reliability

Reliability is assessed by evaluating the reproducibility of the PUF response under varying environmental conditions, such as temperature fluctuations. This reliability is quantified by the BER. An ideal PUF should produce the same response upon a given challenge across all conditions, or a BER of zero. However, the reliability of ReRAM-based PUFs is often compromised by read noise and conductance drift due to temperature changes.

Traditional memory-type PUFs in [8] (simulated here for comparison) can exhibit a peak BER of 2.5% in repeated CRP generation (Fig. 8 (a)) and up to 30% when more devices are selected for response generation (Fig. 8 (b)). In stark contrast, our Re^{4}PUF, utilizing a voltage divider in each cell, achieves a 0% BER, representing a significant enhancement. As temperature rises, the single ReRAM cell design used in memory-type PUF can lead to conductance changes and current variations, resulting in accumulated errors and higher BER. Our 3T2R

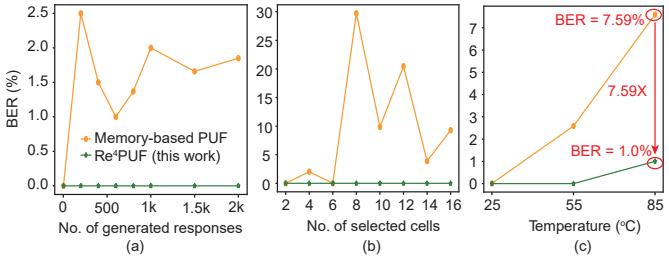

Fig. 8. The BER of Re^{4}PUF under 2k generation cycles (a), the population of selected cells (b), and temperature variations (c).

voltage division design integrates two ReRAMs in complementary states, an inverter, and a programming transistor. This configuration ensures that fluctuations in individual cell conductance do not impact the overall resistance ratio, thereby significantly enhancing reliability. Specifically, while the BER of traditional memory-type PUF in [8] escalates to 7.59% at 85°C, our Re^{4}PUF maintains a low BER of 1% under the same conditions (Fig. 8 (c)).

D. Security Metric

Uniformity (UF) measures the ratio between "0"s to "1"s in PUF's responses. The uniformity of a K-bit-long binary response is defined as the normalized hamming weight [8],

$$UF(B_i) \equiv \frac{1}{K}\sum_{k=1}^{K} b_{ki}, \tag{1}$$

where b_{ki} denotes the k-th bit of the i-th response B_i. The average uniformity is given by,

$$\langle UF \rangle = \frac{1}{C}\sum_{i=1}^{C} UF(B_i), \tag{2}$$

where C is the total number of CRPs. An ideal PUF should yield responses with 50% "0"s and "1"s, as any deviation from this balance could compromise security.

Uniqueness (UQ) measures the dissimilarity between response vectors from different PUF instances under the same input challenge. The uniqueness between two response vectors to the same i-th challenge, from the l-th and p-th PUF instances, is defined as the inter-PUF normalized hamming distance [8], where d measures the hamming distance between two binary vectors,

$$UQ(B_i^p, B_i^l) \equiv \frac{1}{K} d(B_i^p, B_i^l). \tag{3}$$

The uniqueness for the i-th challenge, averaged across all possible pairwise combination of PUF instances, is,

$$\langle UQ(B_i) \rangle \equiv \frac{2}{P(P-1)}\sum_{p=1}^{P}\sum_{l=p+1}^{P} UQ(B_i^p, B_i^l), \tag{4}$$

where P is the total number of PUF instances. Then the final averaged uniqueness is,

$$\langle UQ \rangle \equiv \frac{1}{C}\sum_{i=1}^{C} \langle UQ(B_i) \rangle. \tag{5}$$

The ideal value for uniqueness is 50%, indicating maximum dissimilarity.

# The number of CRPs in each $M \times N$ ReRAM array (block), where m and n represent the selected rows and columns, respectively

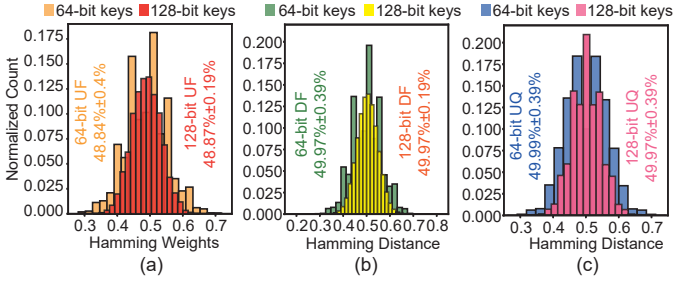

Fig. 9. The UF (a), DF (b) and UQ (c) distributions are computed based on 10k randomly generated 64-bit and 128-bit keys at 0.2V and 25°C.

Diffuseness (DF) quantifies the unique information in a PUF instance. It is defined as the intra-PUF normalized hamming distance d between the i-th and j-th responses [8],

$$DF(B_i, B_j) = \frac{1}{K} d(B_i, B_j). \tag{6}$$

The average diffuseness for all pairwise combination of challenges is,

$$\langle DF \rangle \equiv \frac{2}{C(C-1)} \sum_{i=1}^{C} \sum_{j=i+1}^{C} d(B_i, B_j), \tag{7}$$

with an ideal value of 50%.

The average uniformity, diffuseness, and uniqueness (across 10 dies) of the 64-bit and 128-bit keys generated by Re^{4}PUF, which are composed of 64-bit and 128-bit responses respectively, are close to the ideal value of 50%, as shown in Fig. 9.

E. Comparisons

Table I provides a comparative analysis of the proposed Re^{4}RAM PUF against other state-of-the-art ReRAM-based PUFs. The PUFs discussed in Refs. [2], [3], [6]–[8] utilize challenges to select different ReRAM cells within a 2D or 3D array, performing WCS and current comparison, featuring a large space of CRPs. In contrast, Ref. [12] employs a voltage division scheme with two adjacent device cells, yielding fewer CRPs. To increase the CRP space, we develop 2D ReRAM array using a 3T2R cell design that inherently supports voltage division. The CRP space is calculated as $\binom{M}{m}\binom{N}{n}$ per block.

At 85°C, existing ReRAM PUFs [6], [12] require reprogramming or techniques like TMV and Masking [13] to reduce the BER. In contrast, our 3T2R cell achieves a 1% BER without TMV or Masking.

Current ReRAM-based PUFs typically rely on SET/RESET operations for reconfigurability, whereas we achieve this with simple voltage adjustments. For modeling attacks and SCAs, previous ReRAM-based PUFs are tested against SVM and shallow MLP. We verify our design on DNNs including deep MLP and Transformer models, showing approximately 50% DNN modeling accuracy and and less than 70% SCAs accuracy, which confirms the strong resistance.

V. CONCLUSION

ReRAM-based PUFs have historically faced significant challenges in both reliability and security. Current ReRAM-based PUFs typically operate in a weighted-current summation mode, but due to the inherent noise of the devices, their stability is relatively poor. Furthermore, post-tapeout chips are essentially fixed black boxes, unable to theoretically or practically resist DNN modeling attacks. Existing reconfigurable PUFs based on conductance programming methods require extensive programming operations in practice, which not only incurs significant overhead but also may fail to restore the original PUF functionality. Re^{4}PUF with a 3T2R cell design significantly enhances reliability, while the adjustment of the INV voltage streamlines the reconfiguration process and enhances security. We believe that Re^{4}PUF will provide the hardware security community with a lightweight, secure, and reliable PUF solution.

***Abstract*—The demand for efficient large language model (LLM) inference has propelled the development of dedicated accelerators. As accelerators are vulnerable to hardware faults due to aging, variation, etc, existing accelerator designs often reserve a large voltage margin or leverage algorithm-based fault tolerance (ABFT) techniques to ensure LLM inference correctness. However, previous methods often overlook the inherent fault tolerance of LLMs, leading to high computation and energy overhead. To enable reliable yet efficient LLM inference, in this paper, we propose a novel algorithm/circuit co-design framework, dubbed ReaLM. For the first time, we systematically characterize the fault tolerance of LLMs by performing a large-scale error injection study of representative LLMs and natural language understanding tasks. Then, we propose a statistical ABFT algorithm that fully leverages the error robustness to minimize error recovery as much as possible. We also customize the error detection circuits to enable a low-cost online collection of error statistics. Extensive experiments show that with only 1.42% circuit area and 1.79% power overhead, our ReaLM can reduce perplexity degradation from 18.54 to 0.29. Compared to existing methods, ReaLM consistently reduces recovery costs across different operating voltages and improves energy efficiency by up to 35.83% without compromising LLM performance. Our error injection code is available at https://github.com/PKU-SEC-Lab/ReaLM_DAC25/.**

***Index Terms*—Large language model, algorithm-based fault tolerance, algorithm/circuit co-design**

I. Introduction

Large language models (LLMs) have demonstrated remarkable performance across various tasks such as natural language processing [1], text generation [2], etc. With trillions of operations, LLMs are widely deployed on customized accelerators such as TPU-like systolic arrays (SAs) [3], [4] to meet their enormous computational demands. However, due to aging, process variation, noise, etc [5]–[8], reliability issues, e.g., timing violations, may emerge and make it challenging to ensure the computational correctness on these accelerators. Therefore, how to enable reliable yet efficient LLM acceleration becomes an important question and attracts increasing attention.

Although a large voltage margin can be reserved to prevent timing errors, it is usually not preferred due to the drastic increase in hardware costs. Meanwhile, directly reducing the voltage margin may raise the computation bit error rate (BER) and result in severe performance degradation, as shown in Fig. 1(a). To enable reliable yet efficient computation, various fault mitigation techniques from the circuit to the algorithm level have been proposed but often remain costly in the context of LLM inference. At the circuit level, techniques such as redundancy [9], [10], and Razor flip-flops (FFs) [11]–[14] are developed for traditional logic circuits but usually lack scalability for deep learning accelerators. At the algorithm level, fault-aware fine-tuning has been suggested for conventional convolutional neural networks (CNNs) [15]–[17]. However, the associated costs for LLM fine-tuning are prohibitive. Algorithm-based fault tolerance (ABFT) [18], an algorithm and circuit co-design technique designed for general matrix-matrix multiplication (GEMM), emerges as a cost-effective solution for error detection. ABFT detects errors in the computation results and triggers error recovery mechanisms, e.g., overvolting in dynamic voltage frequency scaling (DVFS) [19]–[21], recomputation, leading to much better efficiency.

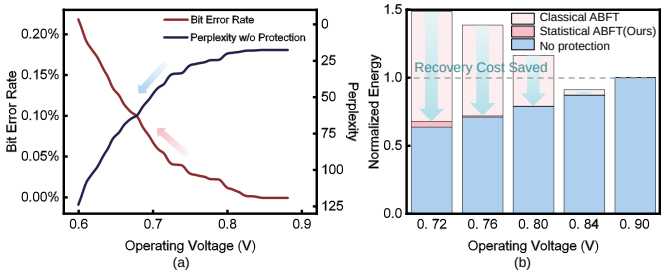

Fig. 1. (a) Lower operating voltages increase BER, leading to significant perplexity degradation without protection. (b) Leveraging model resilience can reduce recovery costs. BERs are synthesized on an SA with commercial 14nm PDK (nominal voltage: 0.9V), aligning with prior studies [11], [22], [23]. Perplexity is evaluated using `OPT-1.3B` on WikiText-2 dataset.

However, as shown in Fig. 1(b), we observe that ABFT still faces efficiency challenges due to the high recovery costs. This is because classical ABFT triggers recovery for each detected computation error, which may not be necessary. As in Fig. 1(a), LLM performance does not degrade immediately at low BER, indicating inherited error resilience. By leveraging the error resilience, unnecessary recovery can be minimized to boost the system's energy efficiency. Nevertheless, the error resilience of LLMs is still not yet well understood. While past works have studied CNNs extensively [24]–[27], the complex architecture, diversified computation patterns, and unique quantization strategies of LLMs can make it significantly different.

Therefore, to fully exploit this inherent error resilience, we propose ReaLM, an algorithm-circuit co-design framework that features reliable and efficient LLM inference. To the best of our knowledge, this is the first work that systematically and comprehensively characterizes the error resilience of LLMs. Our investigation reveals significant variations in error resilience across LLM network components due to the normalization operations. We also identify a trade-off between error magnitude and frequency in their impact on model performance. Building on these characterization insights, ReaLM further proposes a statistical ABFT approach to enable reliable and efficient LLM inference. ReaLM leverages the inherent resilience variations in LLMs to adaptively protect LLM network components in a cost-effective manner. We summarize our contributions as follows:

- We perform a large-scale error injection study on representative LLMs and systematically characterize how various hardware faults affect LLM performance. Our characterization reveals significant inherent resilience variations across LLM network components and identifies a trade-off between error magnitude

and frequency.

- Based on the characterization insights, we propose a statistical ABFT strategy featuring an adaptive error correction *algorithm* and a customized low-cost error detection *circuit*. The proposed strategy integrates seamlessly with SA, minimizing recovery costs while maintaining performance. It further enables energy savings by leveraging LLM's inherent resilience characteristics.
- Experimental results demonstrate that the proposed ReaLM significantly enhances error tolerance. ReaLM reduces perplexity degradation from 18.54 to 0.29 with only 1.42% circuit area and 1.79% power overhead, preserving LLM performance while significantly reducing recovery costs and delivering up to 35.83% energy savings compared to state-of-the-art methods.

II. Background

A. Quantized Inference of Generative LLMs

A typical LLM architecture primarily consists of stacked Transformer blocks, each containing several GEMM operations and various nonlinear functions. Fig. 2(a) and (b) illustrate the architectures of two popular Transformer variants, namely the `OPT` block [28] and the `LLaMA` block [29], respectively. Both variants consist of various **network components**, as labeled in Fig. 2, which will be referred to as `Q`, `Down`, and so on throughout this paper. Existing works [30]–[32] have enabled low bit-width integer quantization of these GEMM operations, while nonlinear functions are retained in floating-point (FP) for accuracy. The generative inference process of an LLM is divided into two stages: the prefill stage takes a prompt sequence as input, and the decode stage produce a single output token each time.

B. Fault-Tolerant Deep Learning

Error sources. Hardware accelerators are susceptible to various permanent and transient faults. Permanent faults often result from fabrication defects, while transient faults primarily arise from timing errors [7], [35]. As CMOS technology scales down to the nanoscale, effects such as aging, variation, and noise become increasingly pronounced [5]–[8]. while voltage underscaling further reduces the design margin intended to mitigate these issues. Together, these factors lead to unintended timing delays, ultimately causing timing errors, as shown in Fig. 1(a).

Model resilience. To effectively characterize the inherent resilience of neural networks, many works [22], [36]–[39] have employed a single-bit flip error model. [25] analyzed fault propagation in networks, and [26] assessed how quantization improves fault tolerance. [27] identified vulnerability differences of certain feature maps and suggested selective protection. [23], [40] further extended resilience studies to reinforcement learning applications. While [41] explored error resilience in LLMs, they did not quantify the relationship between errors and model performance. Considering the intricate model architecture, diversified network components, and unique quantization strategies, the error resilience of LLMs can be significantly different from traditional CNN models.

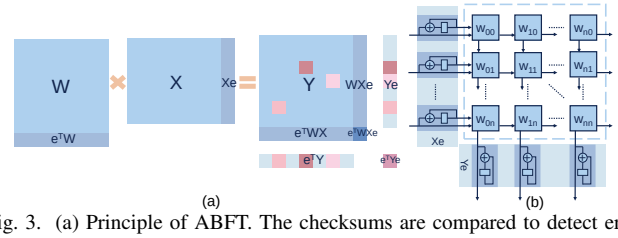

Fig. 3. (a) Principle of ABFT. The checksums are compared to detect errors and capture error statistics. (b) Implementation of ABFT on SA [44].

Error mitigation techniques. Error correction code (ECC) [42] can effectively address hardware faults in memory or on-chip buffers. Mitigating transient faults in computational datapaths is more challenging [38]–[40], [43], where various levels of protection can be leveraged, as summarized in Tab. I. However, these methods incur significant hardware or runtime overhead, particularly for LLMs. For example, redundancy methods [9], [10] such as double-modular redundancy (DMR), require multiple copies of computations to be performed concurrently. Circuit-level techniques [11]–[14] integrate shadow FFs to detect timing errors but lack scalability in modern accelerators. Algorithmic-level approaches [15]–[17] incorporate faults in fine-tuning to enhance error resilience. However, retraining LLMs is prohibitively computation-intensive.

C. Algorithm-Based Fault Tolerance (ABFT)

ABFT leverages checksums to enhance reliability in GEMM [18], as depicted in Fig. 3(a). In classical ABFT, matrices W and X are augmented with a checksum row $e^{\mathrm{T}}W$ and column Xe for error detection, where e is a unit column vector. Recent studies [33], [34], [44]–[46] also propose various lightweight detection algorithms which only compute one-side checksums, i.e., $e^{\mathrm{T}}WX$ or WXe, or matrix sum deviation (MSD), i.e., $e^{\mathrm{T}}WXe$, to lower ABFT hardware cost, as shown in Fig. 3(a). We also show an example of integrating ABFT with the SA following [44] in Fig. 3(b). While ABFT is suitable for LLMs that depend extensively on GEMM operations, it relies on precise checksum-based comparisons and overlooks the inherent resilience of neural networks. Recent work ApproxABFT [45] uses MSD to assess the error significance and allow small computational errors. However, this method ignores the impact of error frequency on the model accuracy and can lead to unnecessary recomputations.

Therefore, to address these challenges, we introduce ReaLM, a circuit-algorithm co-design framework designed to enhance the reliability and efficiency of LLM inference. We first inject computational errors into LLMs to study their resilience characteristics. Based on this characterization, we determine an adaptive error detection strategy to avoid unnecessary error recovery. Guided by this strategy, we customize a low-cost circuit to capture the computational error statistics.

III. Error Injection Framework

To study the resilience of LLMs, we performed statistical error injection experiments, the most widely used approach for assessing the effects of hardware faults on various models.

A. Error Model

Given that (i) permanent errors are relatively straightforward to detect [47] and do not require mitigation during runtime, and (ii) hardware faults in memory can be effectively addressed using ECC [27], [38]–[40], [43], in this work, we focus on transient computational errors occurring during inference and assume that data is correctly fetched from memory elements. To model hardware faults, we adopt the commonly used random bit-flip model [22], [36]–[39] as an abstraction. Specifically, timing errors are modeled by injecting

TABLE I
COMPARISON OF REPRESENTATIVE FAULT MITIGATION TECHNIQUES.

Method	Level	Detection Capability	Hardware Efficiency	Recovery Efficiency	Recovery Capability	Scalability	Compatibility w/ Accelerators
Redundancy [9], [10]	circuit	high	low	low	high	medium	medium
Razor FFs [11]–[14]	circuit	high	low	medium	low	low	low
Fault-aware Fine-tuning [15]–[17]	algorithm	-	-	prohibited	-	low	-
Classical ABFT [18], [33], [34]	circuit-algorithm	high	medium	low	high	high	high
Ours	circuit-algorithm	high	high	high	high	high	high

errors to higher bits, since they often affect more significant bits [7], [22], [46]. The severity of transient faults can be controlled by varying bit error rates.

B. Error Injection Method

We conduct our error injection study on two representative LLMs: `OPT-1.3B` [28] and `LLaMA-2-7B` [29]. To simulate computational errors, we developed a dynamic error injection simulation framework using PyTorch, wherein bit flips are emulated as tensor operations during runtime. Following [30], the inputs of GEMM are quantized to INT8, while the results are in INT32 format. Errors are then injected into the INT32 results of GEMM to realistically emulate compute errors in accelerators, which aligns with previous works [36]–[39].

Furthermore, to discern the different impacts of individual large errors versus multiple smaller errors that yield the identical MSD, we inject identical errors with defined error magnitude (mag) and error frequency ($freq$), adhering to the relationship $MSD = freq \times mag$. It is important to note that while this method diverges from the error models discussed in Sec. III-A, its effectiveness in assessing the resilience of LLMs is preserved.

C. Performance Benchmarks

To assess the effects of error injection, we also construct a comprehensive benchmark framework. Consistent with previous studies [30]–[32], we evaluate model performance using the LAMBADA commonsense QA benchmark [48] and the WikiText-2 language modeling task [49]. Performance on LAMBADA is measured by accuracy (↑), while WikiText-2 is evaluated using perplexity (↓) [50]. We further capture the autoregressive generation capabilities of LLMs using the X-Sum [51] text summarization task, measured by ROUGE-1 [52] scores (↑), and the GSM8K [53] arithmetic reasoning task, evaluated by accuracy (↑). Our framework can be extensible to other benchmarks, like Hellaswag [54] (measured by accuracy (↑)), which we examine in the evaluation section.

IV. LLM RESILIENCE CHARACTERIZATION

In this section, we present our LLM resilience characterization in detail, setting out to answer the following research questions:

- **Q1.1**: How does resilience vary across different layers of LLMs? (Sec. IV-A1)
- **Q1.2**: What is the bit-wise resilience of LLMs? (Sec. IV-A2)
- **Q1.3**: How does resilience vary among different components within LLMs during the prefill stage? (Sec. IV-A3)
- **Q1.4**: What is the correlation between error magnitude and frequency in impacting LLM performance? (Sec. IV-A4)
- **Q2.1**: How does the resilience of LLMs compare between the prefill stage and the decode stage? (Sec. IV-B1)
- **Q2.2**: How does resilience vary among different computational components within LLMs during the decode stage? (Sec. IV-B2)

To control for irrelevant variables, we implement the following protocols across research questions. (1) For Q1.4, we exclusively use `OPT-1.3B` model for fast assessment, whereas for Q2.1 and Q2.2, we employ only `LLaMA-2-7B` model to ensure reasonable performance. For all other questions, both models are utilized. (2) Error injections are applied to all layers for all questions, except for Q1.1. (3) In Q1.1, Q1.3, Q2.1 and Q2.2, we specifically target the 30th bit for flipping. (4) For Q1.1 and Q2.1, errors are injected across all network components within a single Transformer block simultaneously.

A. Resilience Study on Prefill Stage

In this subsection, we will directly give the conclusion of Q1.1 and Q1.2 since they are relatively straightforward, and we focus on discussing Q1.3 and Q1.4.

1) Layer-wise resilience: As shown in Fig. 4(a)(b), **while the layers exhibit comparable resilience behaviors, the earlier layers are more vulnerable to errors.**

2) Bit-wise resilience: By comparing error impacts in network components with FP outputs (`O`, Fig. 4(d)) and re-quantized INT8 outputs (`K`, Fig. 4(c)), we conclude that **while errors at lower bits have a negligible impact on model performance, errors at higher bits can reach a saturation point due to re-quantization.**

3) Resilience of different network components: As depicted in Fig. 4 (e)(f), our results reveal substantial differences in resilience behavior across the network components. Specifically, the `O` component in both models, `FC2` in `OPT-1.3B`, and `Down` in `LLaMA-2-7B` exhibit significantly higher sensitivity compared to other components. For ease of discussion, these components are referred to as ***sensitive components***, while the others are categorized as ***resilient components***.

Discussion: As demonstrated in Fig. 2, the sensitive components in both `OPT-1.3B` and `LLaMA-2-7B` are followed by normalization layers—LayerNorm and RMSNorm, respectively, unlike their resilient counterparts. We demonstrate in Fig. 5 that upon introducing a single error into the pre-normalization hidden states, a dramatic alteration in the subsequent elements is observed. This substantial variation is primarily due to the calculations of mean (μ) and standard deviation (σ) during normalization. In LLMs, hidden states inherently consist of a few outliers [30]–[32], while the majority of elements remain close to zero. These outliers predominantly influence the computation of μ and σ, shaping the overall statistics of the hidden states. Therefore, a larger error can manifest as an outlier and drastically skew these parameters, markedly altering the normalization outcome. In contrast, injecting a larger error into the resilient components affects only a localized set of elements. Thus, we conclude that **the network components followed by normalization exhibit much worse resilience than other components due to normalization.** Specifically, for $\mathtt{QK}^{\mathtt{T}}$ components followed by softmax, changes remain confined because softmax outputs between 0 and 1.

4) Tradeoff between error magnitude and frequency: While MSD can serve as a metric to depict the error severity, it cannot differentiate

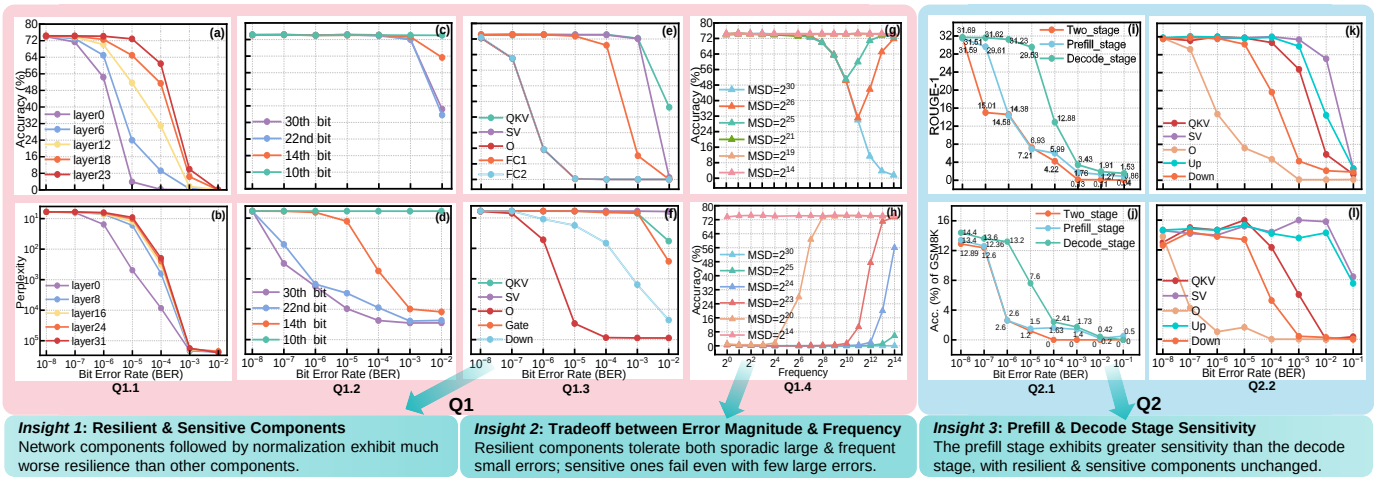

Fig. 4. **Q1.1**: (a)(b) Layer-wise resilience of different LLMs on different tasks. **Q1.2**: Bit-wise error resilience. (c) Error injection on `K`. (d) Error injection on `O`. **Q1.3**: (e)(f) Sensitivity to errors in different LLM components. **Q1.4**: Relationship between error frequency and magnitude. (g) Resilient components like `K`. (h) Sensitive components like `O`. Given MSD, the error magnitude decreases as the error frequency increases. **Q2.1**: (i)(j) Comparison between the prefill stage and decode stage. **Q2.2**: (k)(l) Impact of error injection across network components: `O`. and `Down` remain highly sensitive. (a)(c)(e)(g)(h) are evaluated with `OPT-1.3B` on LAMDABA; (b)(d)(f) with `LLaMA-2-7B` on WikiText-2; (i)(k) with `LLaMA-2-7B` on X-Sum; (j)(l) with `LLaMA-2-7B` on GSM8K.

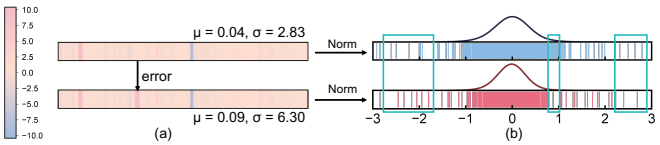

Fig. 5. (a) Data distribution of the pre-norm layer in LLMs, where outliers dominate μ and σ. Injecting larger errors can cause significant skew. (b) Data distribution after normalization is largely affected by the injected error.

between the impacts of a single large error and multiple smaller errors, despite them potentially yielding identical MSD values and having significantly different effects on model performance. Consequently, this section introduces additional metrics—error magnitude (mag) and error frequency ($freq$)—to more accurately represent error statistics. We define mag as $MSD/freq$ in Fig. 4(g)(h), indicating that an increase in $freq$ results in a decrease in mag. Our analysis reveals that resilient components exhibit non-monotonic resilience behavior: both sporadic large errors and frequent smaller errors minimally impact model performance. Conversely, a moderate frequency of medium-sized errors can severely impair performance. However, for sensitive components, acceptable performance is maintained only when numerous smaller errors are introduced.

Discussion. The non-monotonic resilience behavior observed in resilient components illustrates a trade-off between error magnitude and frequency. **Resilient components are tolerant to both sporadic large errors and frequent smaller ones, whereas sensitive components falter even with few large errors**. This finding aligns with earlier observations from Sec. IV-A3. Fig. 6 further delineates a critical region where significant performance degradation occurs.

B. Resilience Study on Decode Stage

LLMs are primarily different from CNNs due to their autoregressive decode stage. In this section, we explore the resilience characterization of the decode stage and differentiate it from the prefill stage.

1) Difference in prefill stage and decode stage: To differentiate resilience between the prefill and decode stages, we inject errors exclusively into the prefill stage, the decode stage, and both stages, respectively. As illustrated in Fig. 4(i)(j), our analysis indicates that performance degradation is consistently more severe during the prefill stage than during the decode stage across both tasks.

Discussion. **The prefill stage exhibits greater sensitivity to errors than the decode stage**. The reason lies in the KV-cache mechanism. During the decode stage, the newly generated query vector interacts with the KV-cache, which is primarily composed during the prefill stage. Consequently, errors during the prefill stage compromise most of the operations involved in generating the next token. In contrast, errors during the decode stage have a lesser impact, as the largely unaffected KV cache drives most of computations for the next token generation.

2) Resilience across compute units: Similar to the experiments described in Sec. IV-A3, we inject errors into various LLM network components and present the outcomes in Fig. 4(k)(l). Our findings confirm that **the sensitive components, specifically `O` and `Down`, continue to be highly vulnerable**, echoing observations from Sec. IV-A3.

V. Statistical Algorithm-Based Fault Tolerance

Building on the insights from Sec. IV, this section introduces our statistical ABFT framework. We integrate it with SAs, focusing on weight stationary (WS) and output stationary (OS) dataflows due to page limitations, though it is also compatible with input stationary (IS) dataflow.

A. Statistical-Based Error Detection Strategy

ReaLM utilizes MSD, error frequency ($freq$), and error magnitude (mag) as key statistics to characterize the error distributions. As shown in Fig. 6, an *acceptable* performance threshold can be empirically established to define the critical region where computational errors significantly impact LLM performance. ReaLM simply ignores errors outside the region.

In terms of the critical region, we find that for resilient components, the boundary of the critical error region is defined by a horizontal line and an inclined line with a slope greater than 1. The horizontal line suggests that resilient components are tolerable to errors below a frequency threshold θ_{freq}, i.e., the vertical coordinate of this line, regardless of their magnitude. For sensitive components, the critical region is bounded by the inclined line and horizontal axis. Note that the slope $a > 1$, the intercept $-b$ of the inclined line, and frequency threshold θ_{freq} are all fitted parameters.

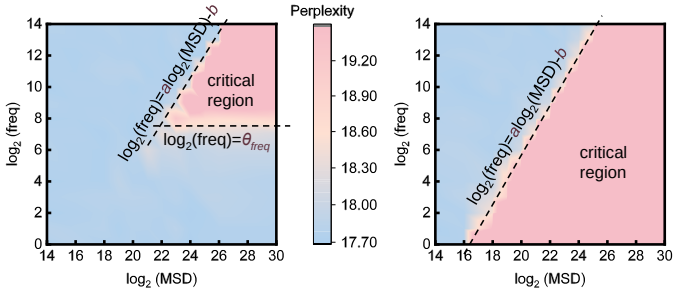

Fig. 6. Our statistical ABFT strategy only corrects errors falling inside the critical region.

We derive several key conclusions to guide our strategy: 1) the horizontal bound indicates that errors exceeding a certain MSD or magnitude all lead to unacceptable performance degradation at θ_{freq}. Therefore, errors larger than the threshold can be counted without distinction; 2) Errors positioned above the inclined line are deemed acceptable. This boundary delineates a clear threshold θ_{mag} beneath which errors, regardless of their frequency, do not significantly degrade the model performance; 3) Assuming that errors are equal, we can derive the upper bound of $\theta_{mag} = b-(a-1)\log_2 MSD$. Errors smaller than θ_{mag} have negligible impact on model performance.

Based on these insights, we assess the influence of errors with error statistics in real-time. Our methodology ignores errors smaller than θ_{mag} due to their minimal impact on performance. Instead, we only count significant errors to calculate the effective error frequency $freq_{eff} = \text{countif}(mag > \theta_{mag})$. We then compare $freq_{eff}$ to the threshold θ_{freq}; if $freq_{eff} > \theta_{freq}$, the recovery is triggered. Otherwise, the GEMM operation is considered safe.

B. Architecture Design of Statistical ABFT

We integrate our statistical ABFT into SA architecture and support both WS and OS dataflow (Fig. 7). We only need to add an extra "statistical unit", as shown in Fig. 7(c), to capture the error statistics and determine the need for recovery, which incurs a very small area overhead. For ease of explanation, we consider the example of computing a GEMM of matrices $W, X \in \mathbb{R}^{n\times n}$ on an $n \times n$ SA, resulting in $Y \in \mathbb{R}^{n\times n}$.

In the WS configuration of the SA (Fig. 7(a)), weights are stored within the processing elements (PEs), and inputs are streamed horizontally from left to right. The array computes partial sums that move vertically downward. A column of PEs is added on the right, storing $e^{\mathrm{T}}W$ for computing $e^{\mathrm{T}}WX$. Meanwhile, a row of adders at the bottom accumulates $e^{\mathrm{T}}Y$. This design minimizes the need for higher bit-width multipliers, as seen in [44], with only minimal area cost. The latency overhead of computing $e^{\mathrm{T}}WX$ and $e^{\mathrm{T}}Y$ is also negligible.

Similarly, for the OS dataflow (Fig. 7(b)), weights traverse horizontally from left to right, while inputs flow vertically from top to bottom. Outputs are generated directly at the intersection of weights and inputs within the PEs. We follow previous works [46] for our implementation. An additional column of adders is integrated on the left side of the array, dedicated to computing $e^{\mathrm{T}}W$. This checksum is then routed to an extra row of PEs positioned at the bottom and propagated rightward to calculate the product $e^{\mathrm{T}}WX$. The outputs y are vertically accumulated across the PEs to derive the output checksum $e^{\mathrm{T}}Y$. This configuration only requires the additional row of PEs to support higher-bit multiplications.

The proposed statistical unit comprises a subtractor, an accumulator, a Log2LinearFunction unit, and a sequence of n buffers

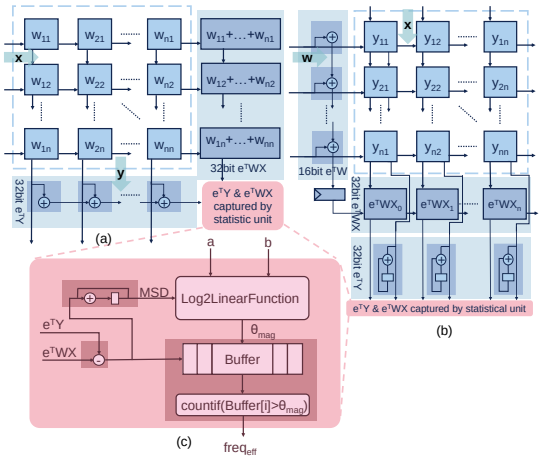

Fig. 7. Architecture design of statistical ABFT on SA: (a) ABFT implementation for WS dataflow; (b) ABFT implementation for OS dataflow; and (c) customized statistical units.

equipped with a comparator-based "countif" unit. The Log2LinearFunction unit is designed to calculate $\theta_{mag} = b-(a-1)\log_2 MSD$. Throughout the computation process, checksums are continuously fed into the statistical unit. They are first subtracted and the resultant differences are accumulated to compute MSD, which is then stored in the buffers. Once the accumulator completes the MSD computation, the data is forwarded to the Log2LinearFunction unit, where θ_{mag} is computed. Ultimately, the "countif" unit evaluates all buffer elements in parallel and counts the frequency of errors exceeding θ_{mag} to determine $freq_{eff}$.

In the decode stage, general matrix-vector multiplication (GEMV) dominates the computation. While batched GEMVs can also be treated as GEMMs, to which our method applies, GEMVs during non-batched inference are typically executed in specialized vector processing units, which fall outside the primary focus of SAs and ABFT techniques discussed in this paper.

Therefore, based on the insights in Fig. 4, the proposed statistical ABFT can enhance LLM resilience by adaptively leveraging captured error statistics. This, in turn, unlocks significant energy-saving opportunities, such as voltage underscaling, even in the presence of errors (Fig. 1), enabling both reliable and efficient LLM inference.

VI. Evaluation

A. Experiment Setup

We first use the lightweight `OPT-1.3B` measuring perplexity on WikiText-2 for rapid evaluation. To demonstrate generality, we also extend the evaluation to the recently released `LLaMA-3-8B` model and a different task, i.e., HellaSwag [54]. Timing errors are simulated by randomly flipping bits in the accumulation results (represented as 32-bit integers) following [7], [22]. The relation between the BER and the operating voltage follows Fig. 1. To determine the parameters for the proposed statistical ABFT, i.e., a, b, θ_{freq}, we inject errors into LLMs for performance evaluation. We empirically set the parameters to allow a 0.3 perplexity increase and a 0.5% accuracy decrease as the acceptable performance degradation.

The RTL for both our proposed and existing ABFT designs is implemented and integrated into SAs with 256 × 256 PEs supporting both WS and OS dataflows. These designs are synthesized using Synopsys Design Compiler with commercial 14nm PDK, where the nominal operating voltage is 0.9V. The clock cycle is set to 500 ps, with a critical path delay of 439 ps, and circuit area and power are obtained from synthesis results. We conduct timing

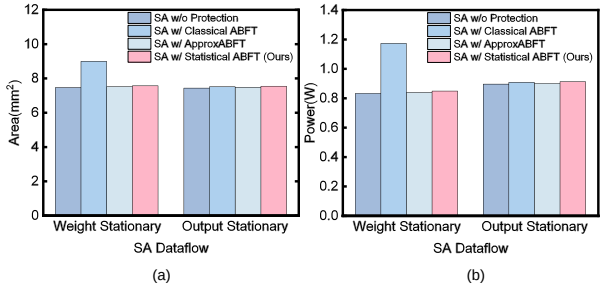

Fig. 8. (a) Area for WS and OS dataflow; (b) Power for WS and OS dataflow.

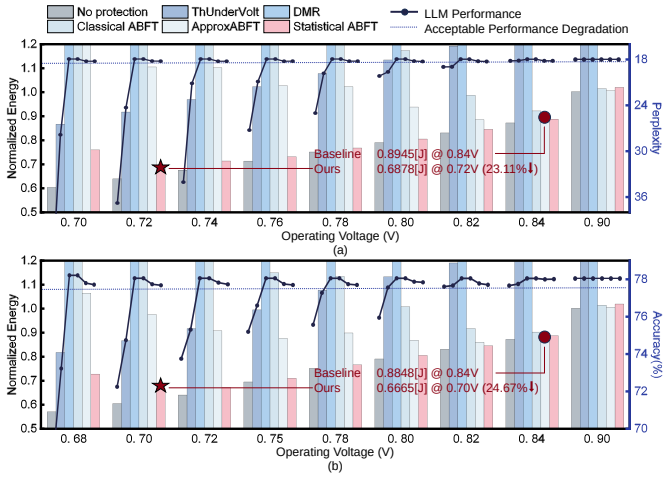

Fig. 9. LLM performance and total energy savings comparison. (a) `OPT-1.3B` on WikiText-2. (b) `LLaMA-3-8B` on HellaSwag. Our method preserves competitive performance with minimal protection overhead, achieving maximal energy savings at 0.72V and 0.70V, respectively.

analysis using Synopsys PrimeTime and HSPICE to capture BERs at reduced voltages, considering the toggle rate during real LLM inference, which is in line with previous chip measurement data [11], [22], [23]. Error recovery is assumed to be performed through recomputation at nominal voltage to ensure correctness, and the total energy consumption is evaluated accordingly.

B. Circuit Overhead Comparison

For both WS and OS dataflows, we analyze the circuit overhead in terms of area and power consumption across no protection, classical ABFT [46], ApproxABFT [45], and statistical ABFT, as depicted in Fig. 8. Compared to unprotected SAs, our design introduces minimal overhead, with only 1.43% area and 1.82% power overhead for WS dataflow, and 1.42% area and 1.79% power overhead for OS dataflow.

C. LLM Performance and Energy Savings

We apply our statistical ABFT to network component `K` in `OPT-1.3B` and `V` in `LLaMA-3-8B` as examples to demonstrate its effectiveness. Fig. 9 compares the total energy overhead and LLM performance for different methods: no protection, ThunderVolt [13], DMR, classical ABFT [46], ApproxABFT [45], and our statistical ABFT, across various operating voltages. Our statistical ABFT maintains comparable LLM performance while significantly reducing the recovery cost and therefore total energy. For `K` in `OPT-1.3B`, our approach achieves a sweet spot at 0.72V, reducing perplexity degradation from 18.54 to 0.29 and saving 23.11% energy compared to prior-art methods. Similarly, for `V` in `LLaMA-3-8B`, it finds a sweet spot at 0.70V, lowering accuracy degradation from 7.64% to 0.47% and saving 24.67% energy.

TABLE II
ENERGY SAVING ACROSS NETWORK COMPONENTS

`OPT-1.3B`			`LLaMA-3-8B`		
Network Component	Optimal Voltage (V)	Energy Saving	Network Component	Optimal Voltage (V)	Energy Saving
`Q`	0.70	28.68%	`Q`	0.71	24.26%
`K`	0.72	23.11%	`K`	0.72	24.17%
`V`	0.65	35.83%	`V`	0.70	24.67%
QK^T	0.67	33.54%	QK^T	0.73	19.46%
`SV`	0.75	17.44%	`SV`	0.66	34.46%
`O`	0.82	3.38%	`O`	0.83	2.40%
`FC1`	0.75	15.01%	`Gate`	0.78	10.21%
			`Up`	0.77	16.56%
`FC2`	0.83	3.14%	`Down`	0.83	3.12%

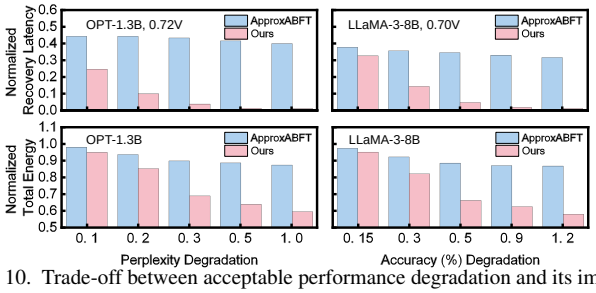

Fig. 10. Trade-off between acceptable performance degradation and its impact on recovery latency and total energy.

D. Energy Savings across LLM Components

We summarize the total energy savings for all network components in Tab. II. As shown, optimal operating voltages (i.e., sweet spots) and resulting benefits vary across components, reflecting the differences in resilience as discussed in Sec. IV. Our method achieves up to 35.83% energy savings on `V` in `OPT-1.3B` and 34.46% on `SV` in `LLaMA-3-8B`. While resilient components demonstrate benefits, sensitive components (`O`, `FC2`, and `Down`) show more limited savings due to their vulnerability to errors, which reduces the potential to exploit inherent resilience.

E. Tradeoff between Performance and Energy Savings

We explore the tradeoff between acceptable performance degradation and its impact on recovery latency and total energy over baseline [45] for `K` in `OPT-1.3B` and `V` in `LLaMA-3-8B`, as shown in Fig. 10. The recovery latency is evaluated at 0.72V and 0.70V, respectively, and the total energy is evaluated at the optimal voltages on each performance degradation constraint. This tradeoff demonstrates our design's flexibility in balancing computational efficiency with reliability requirements.

VII. Conclusion

In this paper, we introduce ReaLM, an algorithm/circuit co-design framework aimed at enhancing the reliability and efficiency of LLM inference. We conduct a systematic error injection experiment to characterize the resilience of LLMs, highlighting particular vulnerabilities in the normalization operation that significantly affect inference reliability. Building on these insights, we develop a statistical ABFT approach featuring a customized, low-cost error detection circuit and an adaptive error correction strategy, effectively reducing error recovery costs. Our evaluations reveal that ReaLM can significantly enhance LLM performance by reducing perplexity degradation from 18.54 to 0.29 with only 1.42% circuit area overhead and 1.79% power overhead. By fully leveraging the inherent resilience of LLMs, ReaLM can achieve up to 35.83% energy savings compared to existing methods while maintaining competitive model performance.

***Abstract*—Transformer-based video generation models have demonstrated significant potential in content creation. However, the current state-of-the-art model employing "3D full attention" encounters substantial computation and storage challenges. For instance, the attention map size for CogVideoX-5B requires 56.50 GB, and generating a video of 49 frames takes approximately 1 minute on an NVIDIA A100 GPU under FP16. Although model quantization has proven effective in reducing both memory and computational costs, applying it to video generation models still faces challenges in preserving algorithm performance while ensuring efficient hardware processing. To address these issues, we introduce PARO, a video generation accelerator with pattern-aware reorder-based attention quantization. PARO investigates the diverse attention patterns of 3D full attention and proposes a novel reorder technique to unify these patterns into a unified "block diagonal" structure. Block-wise mixed precision quantization is further applied to achieve lossless compression under an average bitwidth of 4.80 bits. In terms of hardware, to overcome the limitation of existing mixed-precision computing units could not fully utilize the attention map bitwidth to accelerate QK multiplication, PARO designs an output-bitwidth aware mixed-precision processing element (PE) array through hardware-software co-design. This approach ensures that the mixed-precision characteristics are fully utilized to enhance hardware efficiency in the bottleneck attention computation. Experiments demonstrate that PARO delivers up to 2.71× improvement in end-to-end performance compared to an NVIDIA A100 GPU and achieves up to 6.38∼7.05× speedup over state-of-the-art ASIC-based accelerators on the CogVideoX-2B and 5B models.**

***Index Terms*—Video Generation Model, Mixed-precision Quantization, Hardware Accelerator.**

I. Introduction

Diffusion Transformers (DiTs) [1] and video generation models [2] have garnered significant research interest after the impressive generation quality of OpenAI's SORA [3] in 2024. Previous researches, like OpenSORA [2], utilize "spatial-temporal" attention, which performs attention separately along the spatial and temporal dimensions. More recent models such as CogVideoX [4] adopt "3D full attention", which processes all the spatial tokens for all frames together. Such an attention scheme further enhances algorithm performance, thus achieving state-of-the-art video generation quality. However, such an attention scheme leads to an order of magnitude increase in the token length for attention computation, resulting in excessive storage and computation costs. For example, the token length is 17.8k for the CogVideoX model, and the attention map takes up 56.50 GB for each transformer block. The attention computation accounts for 67.93% of the overall latency on an NVIDIA A100 GPU, which becomes the major bottleneck.

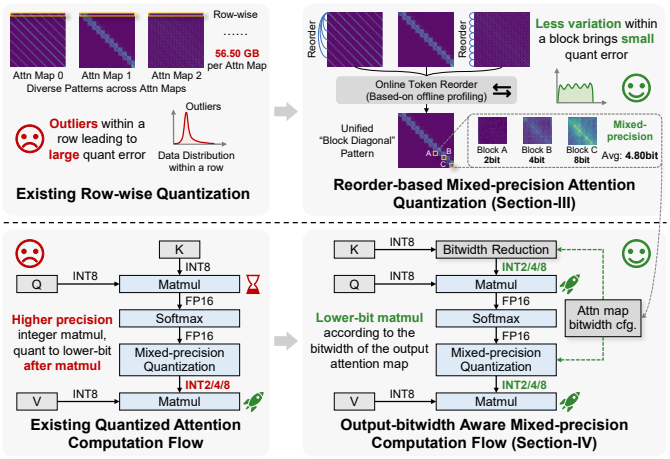

Fig. 1. Overview of the challenges and solutions in PARO.

To mitigate computation and memory consumption, model quantization is a highly effective technique that replaces high-precision floating-point weights and activations with low-bit integers. Low-bit integer multiplications are more hardware-efficient compared to high-precision floating-point operations. Although many existing researches have explored the quantization [5]–[10] of Vision Transformers (ViT) [11], directly applying existing methods to the models with 3D full attention causes notable degradation under INT8 and failure under INT4. Moreover, existing hardware accelerators can only benefit from the low-bit input tensors, failing to efficiently handle the scenario of computing the low-bit (e.g., 2bit) attention map from Q, K embeddings in higher-bits (e.g., 8bit), which is the bottleneck of 3D full attention video generation models.

To address these challenges, we delve into the data distribution characteristics of the attention maps. As illustrated in the upper left part of Fig. 1, we observe diverse "diagonal" patterns across different attention heads and transformer blocks. These patterns arise from the local information aggregation properties inherent in vision feature extraction. Traditional quantization methods assign the same set of quantization parameters to each row of the attention maps. However, the larger elements on the diagonal act as "outliers", leading to excessively large quantization scaling factors. In these cases, the majority of values are forcedly set to near-zero values,

*Both authors contributed equally to this work.

thus losing discriminative abilities, and resulting in large quantization errors. To mitigate this, we propose a reorder-based mixed-precision quantization method. By reordering the QK embeddings along the token dimension, we transform the diverse patterns into a unified "block diagonal" pattern and apply block-wise quantization. This reorder effectively clusters similar values into local blocks, reducing data variation within these blocks and thereby minimizing quantization errors. Moreover, different blocks show diverse attention values, contributing differently to the final attention outputs. Therefore, to compress for lower bits, we introduce mixed-precision quantization, which assigns higher bitwidths to blocks with larger attention values and quantization difficulty, thereby optimizing the overall quantization accuracy and efficiency.

In terms of hardware efficiency, existing mixed-precision computing units perform multiplication and accumulation (MAC) operations based on the bitwidths of the input tensors. These units are unable to leverage the mixed-precision of the output to reduce computational workload. Taking attention computation as a typical example, the attention map, as discussed earlier, can be quantized to mixed precision (e.g., 2/4 bits), while the QKV embeddings remain 8bit. For the $AttnV$ computation, the mixed-precision characteristics of the attention map can be effectively utilized by existing mixed-precision computing units. However, for $QK^\top$, despite the lower precision of the output attention map, existing computing units are constrained by the input bitwidths and must perform the matrix multiplication in 8bits. This limitation prevents them from exploiting the lower bitwidths of the output to further improve computational efficiency. To address this, with a pre-determined lower bitwidth configuration of the output tensor, the matrix multiplication can be performed in reduced bitwidths, aligned with the output precision. Unlike current methods that optimize only $AttnV$ [10], [12], this approach enables the acceleration of both $QK^\top$ and $AttnV$ computations, with negligible accuracy loss. By further exploiting the acceleration opportunities offered by mixed-precision attention maps, this method boosts the efficiency of attention processing, which is the performance bottleneck.

The contributions of PARO are as follows:

- We identify the key limitation of existing quantization methods by investigating the unique properties of "3D full attention" in video generation models, and design a reorder-based mixed-precision quantization method tailored for them.
- To fully harness the performance gain of mixed-precision quantization schemes, we design output-bitwidth aware mixed-precision processing elements (PEs). It fully exploits the capability of PEs to adapt to mixed-precision cases for both QK^T and $AttnV$ in attention computation.
- PARO achieves lossless quantization with an averaged 4.80bit and outperforms state-of-the-art ViT accelerator ViTCoD by 6.38∼7.05×. Evaluated under the same hardware resources, PARO achieves a 1.68∼2.71× speedup to an NVIDIA A100 GPU.

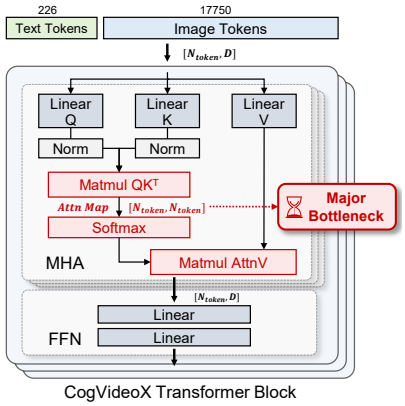

Fig. 2. Illustration of CogVideoX text-to-video generation model, in which the major bottleneck is the attention map related computations.

II. Background and Related Work

A. Video Generate DiTs

As discussed in Sec. I, our primary focus is to optimize the state-of-the-art video generation model, which utilizes a 3D full-attention mechanism, specifically the CogVideoX model. The model structure of CogVideoX is illustrated in Fig. 2, it comprises 42 transformer blocks. Each transformer block consists of two key components: multi-head self-attention (MHA) and feed-forward network (FFN). The computation of the MHA could be formulated as:

$$Q = XW_Q, K = XW_K, V = XW_V, O = \text{Softmax}(\frac{QK^T}{\sqrt{d}})V$$

Given an input token sequence with hidden dimension d, the attention projects it into query Q, key K, and value V matrices through linear layer with weights W_Q, W_K, W_V. Then, softmax is applied to the dot product of Q and K, divided by $\sqrt{d}$ to generate the attention map. Finally, the attention map is multiplied with V to generate the attention output. Subsequently, the FFN processes the attention output O with several full-connected linear layers. In CogVideoX, N_{token} is 17.8k, which is significantly larger than the hidden dimension (d), ranging from 1k to 4k. The computation of the attention map, which has a shape of $[N_{token}, N_{token}]$, becomes the major bottleneck (highlighted in red in Fig. 2).

B. DiT Quantization

Model quantization [13], [14] has been demonstrated as an effective method for model compression. By converting high bitwidth floating-point (FP) data into lower bitwidth integers, it significantly reduces both computational and memory costs. In this approach, weights and activations are quantized within each group G (e.g., tensor-wise or channel-wise). The quantization process approximates the FP value x using an integer representation x_{int} and quantization parameters (scaling factor s, zero point z):

$$x \approx \hat{x} = s(x_{\text{int}} - z)$$

For a group of size g, represented as the vector $x \in \mathbb{R}^g$, all elements share the same quantization parameters (s and z). The quantization operator Q with b-bit is described as:

$$x_{\text{int}} = Q(x; s, z, b) = \text{clamp}(\left\lfloor \frac{x}{s} \right\rceil + z, 0, 2^b - 1)$$

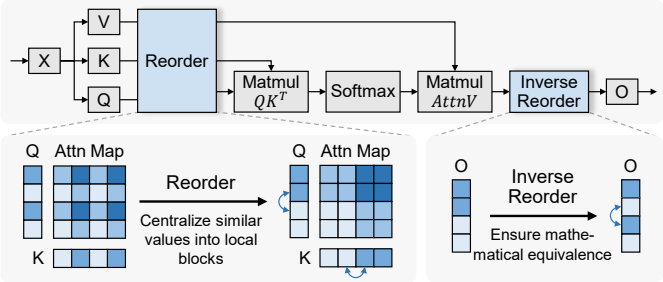

Fig. 3. Detailed description of the reorder process. Q, K, V are reordered along the token dimension to form a unified "block diagonal" pattern. The attention output O is inversely reordered to ensure mathematical equivalence.

In the quantization schemes used in recent work, weights are quantized offline, while activations are dynamically quantized online using a scaling factor $s = \frac{\max(x)-\min(x)}{2^b-1}$, where b is the bit width. The granularity for the quantization of weight and activation in linear layers is "per dimension" and "per token", respectively. For attention map quantization, the granularity is "per-row" for attention values and "per-dimension" for V.

C. Related Work

DiT Quantization. Existing methods [15] for DiT quantization focus on compressing the linear layers in video generation models with spatial-temporal attention. SageAttention and its follow-up work [16]–[18] further advance this by employing 8-bit quantization for QK in attention map computation to accelerate "3D full attention." In our method, we extend quantization to the linear layers, QKV, and attention maps, aiming to minimize expensive floating-point computations.

Hardware Accelerators. Extensive researches [19]–[24], have focused on designing customized accelerators for attention mechanisms. Sanger [25] introduces a locally structured sparse approach to reduce computational overhead. However, this method faces significant challenges when applied to video generation models. ViTCoD [26] addresses this issue with a threshold-based dynamic sparsification technique specifically designed for the attention mechanism in video generation models. It partitions the attention matrix into sparse and dense segments, processing them separately to improve efficiency. Other works [20], [24], [27] have explored strategies such as token pruning and joint video encoding to accelerate entire models. Despite these advancements, two major limitations persist for 3D attention mechanisms. First, existing methods fail to leverage the inherent similarities in 3D attention patterns, limiting opportunities for further optimization and compression. Second, their coarse-grained compression techniques struggle to achieve a balance between maintaining high accuracy and delivering significant acceleration, particularly without requiring additional model retraining.

III. Reorder-based Attention Quantization

A. Reorder-based Block-wise Quantization

In the popular 3D full attention models (e.g., CogVideoX), the token length (N_{token}) is significantly larger than the hidden dimension (d), leading to attention computation dominating the overall computational cost due to its quadratic complexity with respect to token length. As such, quantizing the attention map is critical for resource efficiency. However, attention quantization presents unique challenges. SageAttention, for instance, only quantizes the Q and K tensors, which accelerates only half of the attention computation.

In this paper, we extend this approach by quantizing Q, K, V, and the attention map. We begin by adopting a naive quantization scheme, adopting dynamic min-max quantization, using row-wise grouping for the attention map and dimension-wise grouping for V. However, we observe severe quality degradation under INT8 when solely quantizing the attention map. Additionally, the INT4 results in unreadable noise outputs. To investigate the causes of these issues, we visualize the attention map. As shown in the upper left part Fig. 1, the data within each quantization group (a row in the attention map) exhibits significant variation. A small subset of values, or "outliers", are significantly larger than the rest. The scaling factor (s) is determined based on these outliers, resulting in an excessively large scaling factor for most elements and introducing significant quantization errors. Based on these findings, we aim to reduce quantization errors by minimizing data variation within each quantization group.

We further visualize and analyze the structure of attention maps and observe distinct patterns across different blocks and heads, as illustrated in the upper left part of Fig. 1. An intuitive approach is to leverage these patterns to design specialized quantization groupings that reduce data variation within groups. However, the diversity of these patterns introduces challenges in designing distinct groupings for each case. To address this, we propose transforming these diverse patterns into a unified, hardware-friendly format to enhance hardware efficiency. Through detailed analysis, we find that all patterns essentially represent local aggregation across different dimensions (e.g., the same token across frames or neighboring spatial tokens). By reordering tokens, we can reorganize these patterns into local blocks, as shown in the upper right part of Fig. 1(b). Using block-wise grouping for quantization minimizes variation within each block, thereby reducing quantization error and improving overall performance.

Given an input token of size $N_{\text{frame}} \times N_{\text{width}} \times N_{\text{height}}$, we achieve local block-wise patterns by permuting these dimensions for the QK embeddings through token-level reorder. There are a total of 6 possible reorder plans for each attention head. Notably, the observed patterns remain consistent across different timesteps and input noise or prompts. We select the reorder plan that minimizes quantization error for each head and block offline. The reorder itself is performed online. Due to the compute-bound nature of the model, the overhead introduced by reorder is negligible.

B. Importance-guided Mixed Precision

As shown in the upper right part of Fig. 1, after reordering, similar values are grouped into localized blocks, however, different blocks still exhibit varying value distributions and contribute differently to the final results. These blocks have diverse "quantization sensitivities". Consequently, applying the

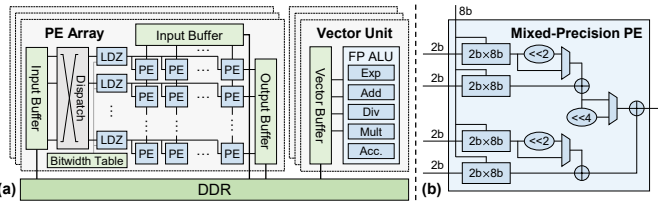

Fig. 4. (a) Overall architecture of PARO. (b) Each PE supports three multiplication mode: 2bit×8bit, 4bit×8bit, 8bit×8bit.

same bitwidth to all blocks results in a suboptimal trade-off between algorithm quality and hardware efficiency. A natural solution is to adopt mixed-precision quantization, allocating higher bitwidths to blocks with higher sensitivity.

Accurately estimating the "quantization sensitivity" is crucial for effective mixed-precision bitwidth allocation. We identify two key characteristics of data distribution that influence quantization sensitivity: (1) **"Block Importance"**: The average absolute values of each block vary, reflecting their relative significance for attention values. (2) **"Quantization Difficulty"**: Within each block, the degree of data variation differs, representing the block's "quantization difficulty". Both highly important blocks and those with larger quantization difficulty should be assigned higher bitwidths. Considering these factors, we propose the following sensitivity metric:

$$\mathcal{S} = (\sum_{i}^{G} x_i)^{\alpha} * (||x_i - x_q||)^{(1-\alpha)}, x \in R^G$$

For each block containing G values, we employ the average attention value as the "importance" and the quantization error to represent the "quantization difficulty". The hyper-parameter α serves to balance the relative emphasis between these two factors. Then, we formulate mixed precision bitwidth allocation as an integer programming problem as follows:

$$\begin{aligned} &\underset{c_{i,b}}{\text{argmin}} \quad \sum_{i=1}^{N} \sum_{b=0,2,4,8} c_{i,b} \cdot \mathcal{S}_{i,b} \\ &\text{s.t.} \quad \sum_{b=0,2,4,8} c_{i,b} = 1, \quad \sum_{i=1}^{N} \sum_{b=0,2,4,8} c_{i,b} \cdot b \leq \mathcal{B} \cdot N, \\ &\quad c_{i,b} \in \{0,1\}, \quad \forall i \in \{1, \cdots, N\}, \forall b \in \{0,2,4,8\} \end{aligned} \tag{1}$$

where N is the number of blocks in the model; $c_{i,b} = 1$ indicates that the i-th block will be quantized to b-bit, and $\mathcal{S}_{i,b}$ is the corresponding sensitivity score, $\mathcal{B}$ indicates the average bitwidth budget.

IV. PARO Architecture

A. Architecture Overview

The overall architecture of PARO is shown in Fig. 4(a), comprising multiple PE arrays, vector units, DDR, and a controller (not shown in the figure). Among these components, the fixed-point PE arrays serve as the primary fixed-point computation unit of the architecture, executing all matrix multiplications since PARO applies quantization to all linear and attention layers. The vector unit features a floating-point arithmetic and logic unit (ALU) and handles floating-point computations outside matrix multiplications (e.g., softmax).

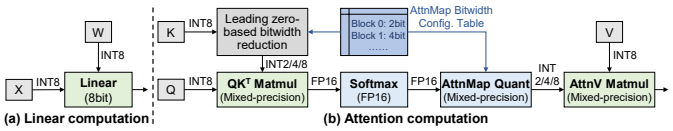

Fig. 5. (a) For linear computations, matrix multiplication operates in 8bit precision. (b) For attention computations, the bitwidth is dynamically reduced based on the attention map's bitwidth configuration.

As the quantization scales for linear and attention layers are in FP16 format, fixed-point accumulation results computed by the fixed-point PE arrays are forwarded to the vector unit. The vector unit converts these results to FP16 format and performs floating-point accumulation, yielding the final FP16 output for matrix multiplication.

B. Mixed-precision PE Array

The structure of each PE in the mixed-precision PE array is shown in Fig. 4(b). Each PE consists of four 2bit×8bit fixed-point multipliers. By adjusting the control signals of the multiplexers, each PE can execute one 8bit×8bit, two 4bit×8bit, or four 2bit×8bit multiplications per cycle.

For linear layers with W8A8 quantization, the PE array operates in 8bit×8bit mode, as shown in Fig. 5(a). In contrast, for attention layers, the bitwidth varies across different blocks in the attention map, while the QKV matrices remain 8bit. Since $QK^\top$ and $AttnV$ each account for half of the computations in attention, the PE array must efficiently handle two scenarios:

- $AttnV$: One input matrix (attention map) is mixed-precision while the other (V) is 8bit.
- $QK^\top$: Both input matrices (Q, K) are 8bits, but the output matrix after softmax is quantized to mixed-precision.

For $AttnV$, computations can be directly mapped to the PE array by dynamically configuring the PE mode based on the bitwidth table of each block in the attention map. For $QK^\top$, performing matrix multiplication at the bitwidth of the inputs is often computationally expensive because the output may be quantized to extremely low bitwidths (e.g., 2bit) after softmax. In extreme cases, such as when the attention map block has a bitwidth of 0, the computation for that block can be skipped entirely. To reduce computational costs, the matrix multiplication can be performed at a lower precision that approximates the same result after softmax quantization.

Inspired by this, PARO adopts an output-bitwidth-aware mixed-precision computation flow to leverage the mixed-precision characteristics of the output attention map. As illustrated in Fig. 5(b), this approach dynamically reduces the bitwidth of K to match the bitwidth of the corresponding output attention map block with little error. Experiments show that this optimization produced no perceptible differences in the quality of the generated video. By performing matrix multiplication at lower precision, the mixed-precision PE Array effectively accelerates $QK^\top$ computation.

Bitwidth reduction of K is implemented using a leading zero (LDZ) unit, integrated beside each PE row, as shown in Fig. 4(a). The LDZ unit identifies the most significant valid bit (MSVB) of the data and outputs the MSVB along with the following $K-1$ bits. The MSVB is the first 1 for positive

TABLE I
ALGORITHM PERFORMANCE OF TEXT-TO-VIDEO GENERATION ON COGVIDEOX PROMPT SET. THE DESCRIPTION OF METRICS IS PROVIDED IN SEC. V-A. WE COMPARE PARO QUANTIZATION METHOD WITH BASELINE METHODS, AND ABLATES EACH TECHNIQUE.

Method	Block-wise	Reorder	Mixed Precision	Bitwidth	FVD-FP16 (↓)	CLIPSIM (↑)	CLIP-Temp (↑)	VQA (↑)	Flicker. (↑)

PARO MP	✓	✓	✓	4.80	0.15	0.205	0.998	52.61	96.9

values and the first 0 for negative values. For example, if the LDZ unit is configured as 2bit, the 8bit value `8b00011010` is compressed to `2b11`. After multiplication, the result is restored by left-shifting based on the bit index of MSVB.

The varying bitwidths (0/2/4/8) across different blocks result in differing throughputs for processing these blocks. Therefore, a dispatcher is integrated into each PE array to balance the workloads across blocks. Notably, PARO supports 0bit quantization blocks. The dispatcher bypasses computation for 0bit blocks and maps the next block to the appropriate PE row.

V. EVALUATIONS

A. Evaluation Setup

Software Implementation. We apply the PARO quantization method, referred to as "PARO MP," to the CogVideoX-5B model. In PARO MP, the weights and activations of all linear layers are quantized to INT8. For attention computation, $QKVO$ are quantized to INT8, while the attention map after softmax is quantized using mixed precision (0, 2, 4, 8 bits). Notably, "0 bit" signifies skipping the computation for the corresponding block. Following the official implementation, we generate the 640×480, 49 frames videos, using CogVideoX example prompt set, DDIM [28] 50 steps. We evaluate the generation quality from various aspects following prior literature [15]. The "FVD-FP16" [29] estimate the fidelity of generated videos through measuring the feature space difference between quantized and FP16 outputs. The "CLIPSIM" [30] and "CLIP-Temp" [31] measures the text-video alignment and consistency of clip features across frames. The "VQA" [32] assesses the video quality from the aesthetic and technical perspective. The "Flicker." measures the temporal flickering. higher value denotes less flickering. We present both the statistical and qualitative results in Tab. I and Fig. 7.

Platforms for Comparison. We evaluate our architecture against two state-of-the-art ASIC-based accelerators, Sanger [25] and ViTCoD [26]. The attention map is pruned following the methods described in their papers, ensuring that the generation quality and accuracy remain consistent with PARO. Additionally, we measure the performance of the NVIDIA A100 using CUDA Events for execution time and `nvidia-smi` for power consumption.

TABLE II
AREA AND POWER BREAKDOWN OF PARO.

Component	Config	Area (mm^2)	Power (W)
PE Array	32×32×32 PEs	2.52 (30.8%)	3.60 (32.2%)
	Leading Zero Unit	0.65 (8.0%)	0.78 (7.0%)
	Others	0.39 (4.8%)	0.54 (4.8%)
Vector Unit	Exp/Div/Add/Mult/Acc.	2.79 (34.1%)	4.55 (40.6%)
Buffer	1.5 MB SRAM	1.82 (22.3%)	1.73 (15.4%)
Total	TSMC 12nm	8.17 (100%)	11.20 (100%)

Hardware Implementation. PARO is implemented using RTL for its hardware components and synthesized under TSMC 12nm process at 1 GHz using Synopsys Design Compiler to evaluate area and power. The hardware components are detailed in Tab. II. The DDR bandwidth of PARO is 51.2 GB/s. We use CACTI 7 [33] to assess the on-chip buffer in PARO. To ensure a fair comparison, we develop a cycle-accurate simulator to model the behavior and performance of both PARO and the baseline accelerators under the same hardware resource constraints. Furthermore, we align PARO's hardware resources (e.g., peak computing performance, memory bandwidth, frequency, on-chip buffer size, etc.) with those of the NVIDIA A100 GPU to evaluate our performance gains over modern GPUs, denoted as "PARO-align-A100".

B. Evaluation Results

Algorithm Performance. We evaluate the algorithm performance (generated video quality) against baseline methods, as detailed in Tab. I and Fig. 7. From both statistical and qualitative perspectives. "PARO-MP 4.80bit" demonstrates comparable or superior algorithm performance to baseline model compression techniques like "SageAttention" and "N:M sparse". It notably outperforms "PARO INT4" in all aspects and achieves similar algorithm performance to "PARO INT8". Compared to the FP16 baseline, "PARO-MP 4.80bit" incurs only a 0.25 VQA decrease and a 0.2 flickering score loss, which is hardly noticeable, as presented in Fig. 7.

Ablation Studies for Algorithm. We perform ablation studies for each component of the PARO quantization method, as shown in Tab. I. The "Naive" represents the naive round-to-nearest quantization scheme, and both "Naive INT8" and "Naive INT4" exhibit significant algorithm performance degra-

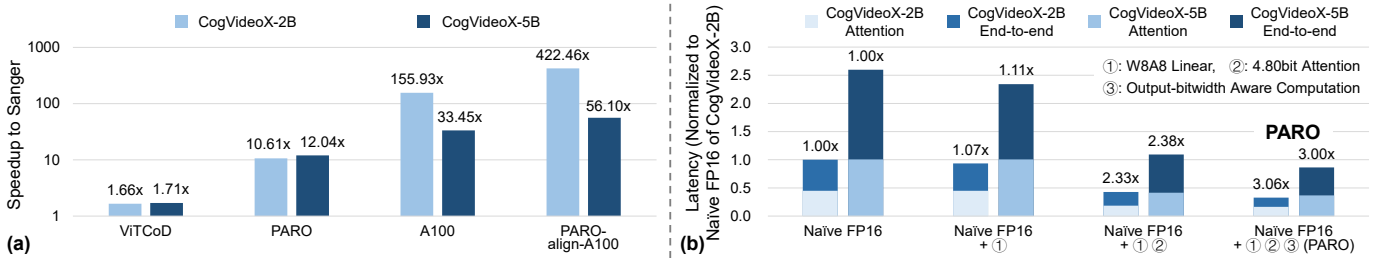

Fig. 6. (a) End-to-end speedup on CogVideoX-2B/5B, normalized to Sanger [25]. (b) The ablation study on different optimizations in PARO.

dation across multiple metrics. Incorporating block-wise quantization notably enhances visual quality under INT4, improving from 16.79 to 46.53. Further integrating reorder to balance the data distribution within blocks further elevates the generation quality. Ultimately, by adopting mixed precision quantization, "PARO-MP" achieves algorithm performance on par with INT8 and FP16, averaging 4.80bit.

Analysis of Attention Patterns. We visualize the attention maps before and after reorder in Fig. 8. The reorder effectively unifies diverse patterns into quantization- and hardware-friendly "block diagonal" pattern. It highlights that different attention heads conduct local aggregation along various dimensions, such as "frame" and "height" in the examples shown.

End-to-end Speedup. As shown in Fig. 6(a), we normalize the performance of PARO, other accelerators and GPUs to Sanger. Compared with Sanger and ViTCoD, PARO obtains performance improvements of 10.61/12.04× and 6.38/7.05× on CogVideoX-2B/5B, respectively. Although the A100 achieves higher end-to-end performance than PARO, this is mainly due to the higher peak performance and memory bandwidth of A100. When PARO uses the same hardware parameters as the A100, it achieves a performance improvement of 1.68/2.71× compared to the A100. This is primarily due to the mixed-precision attention quantization and our output-bitwidth aware mixed-precision computation flow.

Ablation Study for Performance. The breakdown of PARO's performance gains are illustrated in Fig. 6(b). The naive FP16 version includes no optimizations in PARO. Building on this baseline, we introduced W8A8 linear layer quantization, 4.80bit attention layer quantization, and output-bitwidth aware mixed-precision computing unit. For the 2B/5B models, linear layer quantization achieved a 1.07/1.11× speedup. Adding attention mixed-precision quantization further improved the speedup to 2.33/2.38×. Finally, incorporating the output-bitwidth aware mixed-precision optimization increased the speedup to 3.06/3.00×. Among these optimizations, 4.80bit attention quantization contributed the most significant improvement, as 3D full attention is the performance bottleneck.

Reorder Overhead. We evaluate the overhead of introducing the reorder for $QKVO$ during inference in PARO. Experimental results show that for the CogVideoX-2B/5B models, the reorder operation accounts for only 1.26% and 1.07% of the end-to-end latency, respectively. This is because the data size of the $QKVO$ matrices is only 0.36% of the attention map, making the overhead negligible in the highly compute-bound attention computations.

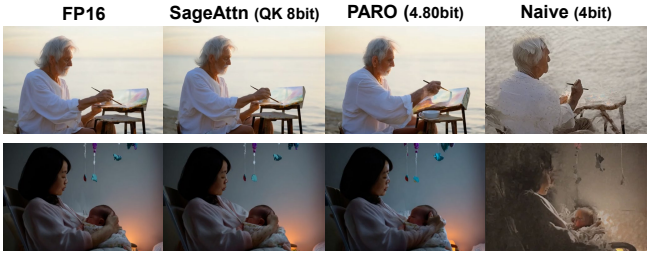

Fig. 7. Comparison of generated videos for different quantization methods. The PARO quantization method could generate videos without visual difference with FP16 generated videos with an averaged of 4.80bit.

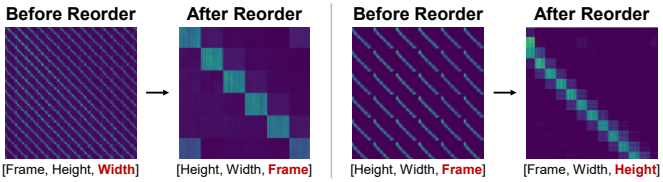

Fig. 8. Visualization of attention pattern before and after reorder. The reorder unifies different patterns into "block diagonal" pattern.

Energy Efficiency. Thanks to our hardware-friendly attention quantization and efficiently mixed-precision PE array, PARO achieves energy efficiency of 3.46/3.61 TOPS/W on the CogVideoX-2B/5B models, respectively, which are 4.86/6.43× higher compared to NVIDIA A100 GPU.

VI. Conclusions

We present PARO, a video generation accelerator that leverages hardware-software co-design with pattern-aware reorder-based attention quantization. PARO examines 3D full attention patterns and introduces a reorder technique to consolidate them into a block diagonal structure. Block-wise mixed precision quantization achieves lossless compression with an average bitwidth of 4.80. The hardware integrates a dynamically reconfigurable mixed-precision PE array, ensuring full utilization of mixed-precision characteristics. Experimental results demonstrate PARO delivers up to 2.71× improvement in end-to-end performance compared to an NVIDIA A100 GPU and achieves up to 6.38∼7.05× speedup over state-of-the-art ASIC-based accelerators on the CogVideoX-2B and 5B models.

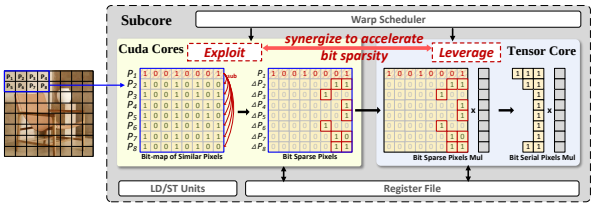
Abstract*—Vision Transformers (ViTs) have demonstrated remarkable performance in computer vision tasks by effectively extracting global features. However, their self-attention mechanism suffers from quadratic time and memory complexity as image resolution or video duration increases, leading to inefficiency on GPUs. To accelerate ViTs, existing works mainly focus on pruning tokens based on value-level sparsity. However, they miss the chance to achieve peak performance as they overlook the bit-level sparsity. Instead, we propose Inter-token Bit-sparsity Awareness (IBA) algorithm to accelerate ViTs by exploring bit-sparsity from similar tokens. Next, we implement IBA on GPUs that synergize CUDA and Tensor Cores by addressing two issues: firstly, the bandwidth congestion of the Register File hinders the parallel ability of CUDA and Tensor Cores. Secondly, due to the varying exponent of floating-point vectors, it is hard to accelerate bit-sparse matrix multiplication and accumulation (MMA) in Tensor Core through fixed-point-based bit-level circuits. Therefore, we present SynGPU, an algorithm-hardware co-design framework, to accelerate ViTs. SynGPU enhances data reuse by a novel data mapping to enable full parallelism of CUDA and Tensor Cores. Moreover, it introduces Bit-Serial Tensor Core (BSTC) that supports fixed- and floating-point MMA by combining the fixed-point Bit-Serial Dot Product (BSDP) and exponent alignment techniques. Extensive experiments show that SynGPU achieves an average of 2.15× ∼ 3.95× speedup and 2.49× ∼ 3.81× compute density over A100 GPU.

I. Introduction

Recently, attention-based models in the form of Vision Transformers (ViTs) [1] have achieved exceptional performance in the field of computer vision (CV) tasks such as image classification [2], object detection [3], and video recognition [4]. Compared to traditional convolutional neural network (CNN) models, ViTs leverage their ability to extract global features effectively, offering both enhanced performance and greater flexibility in diverse applications.

However, the achievements of ViTs are at the cost of inefficiency. As is well known, the self-attention mechanism in ViTs exhibits quadratic time and memory complexity with respect to the number of input tokens. Consequently, as image resolution or video duration increases, the computational performance of ViTs on GPUs deteriorates significantly. To address this limitation, various approaches have been proposed [5]–[8], focusing on reducing value-level redundancy by exploiting token similarity across image patches or video frames. Beyond value sparsity, our analysis reveals that bit-level redundancy offers an opportunity to further enhance the computational efficiency of ViTs.

As illustrated in Fig. 1, adjacent image pixels often manifest similar values, leading to many 0-bits in their differences. Building on this observation, we propose an Inter-token Bit-sparsity Awareness (IBA) algorithm that calculates the distances between input tokens and computes token differences by subtracting similar pairs. These token differences demonstrate increased bit-level sparsity, which can be effectively leveraged to accelerate computations. To implement this strategy on GPUs, we utilize the two inherently separate computing cores within the GPU: CUDA Cores and Tensor Cores, ***utilizing their complementary functions to enhance the efficiency of ViTs by harnessing bit-level sparsity***.



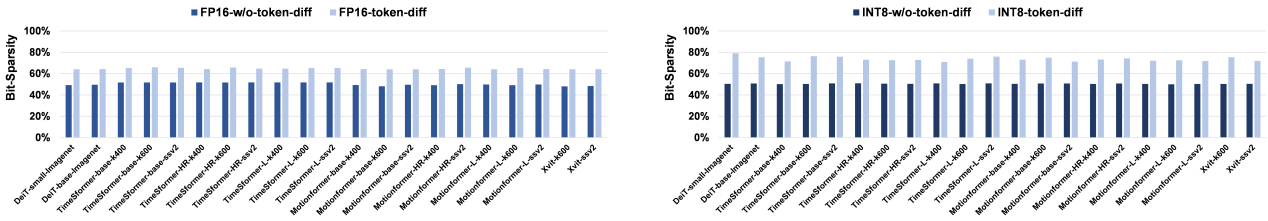


Fig. 1. Synergy mechanism of SynGPU.

The key insights of this scheme lie in two points: *first, leveraging the high-precision capabilities of CUDA Cores to exploit bit-level sparsity among similar tokens without compromising accuracy; second, utilizing Tensor Cores, optimized for high-throughput matrix multiplication and accumulation (MMA) operations, to enable bit-sparse acceleration.* However, achieving efficient synergy between CUDA Cores and Tensor Cores presents two critical challenges. Firstly, CUDA Cores and Tensor Cores compete for Register File (RF), which can result in RF bandwidth congestion, hindering their ability to operate in full parallelism. Secondly, Tensor cores implement the floating-point MMA by executing dot product (DP) operations in parallel. It is non-trivial to design bit-level circuits to support both fixed-point and floating-point DP due to the variability in the exponents of floating-point values within the vectors.

(a) Bit-level sparsity in FP16

(b) Bit-level sparsity in INT8

Fig. 2. Bit-level sparsity in FP16/INT8 between token differences and token without differences

In this paper, we propose SynGPU, an algorithm-hardware collaborative framework, that synergizes CUDA Cores and Tensor Cores for accelerating ViTs on the GPU. Specifically, to address the first challenge, SynGPU includes a novel data mapping scheme that enhances data reuse in Tensor Cores. This approach significantly reduces the frequency of RF accesses by Tensor Cores, thereby freeing up RF resources for CUDA Cores. Moreover, to tackle the second challenge, we develop a Bit-Serial Dot Product (BSDP) algorithm along with the Bit-Serial Tensor Core (BSTC), which aligns the exponents of floating-point values within each vector and repackages the results of DP operations. This design enables SynGPU to support both floating-point and fixed-point bit-sparse operations effectively.

In summary, our contributions are as follows:

- We propose SynGPU, an algorithm-hardware co-design framework that leverages the synergy between CUDA Cores and Tensor Cores on GPUs to accelerate bit-sparse ViTs. By utilizing CUDA Cores to exploit bit-level sparsity derived from token similarity and coordinating with Tensor Cores to perform bit-sparse MMA, SynGPU achieves substantial performance improvements for ViTs. To the best of our knowledge, SynGPU is the first framework specifically designed for bit-level ViTs acceleration on GPUs.
- At the algorithmic level, we propose two algorithms: IBA and BSDP. IBA is designed to extract bit-level sparsity among similar tokens, and BSDP focuses on combining both fixed-point and floating-point MMA by aligning the exponents of floating-point vectors to enable efficient bit-level sparse floating-point MMA.
- At the hardware level, we make two contributions. Firstly, we design a new data mapping that resolves the issue of bandwidth congestion, enabling full parallelism between CUDA cores and tensor cores. Secondly, we develop BSTC that is capable of accelerating bit-sparse MMA operations in fixed- and floating-point formats.

II. Background and Motivation

A. Vision Transformer

Inspired by the remarkable performance of Transformer [9] on NLP tasks, numerous efforts have been made to adapt Transformers for visual applications. Among them, ViTs stands out with its concise design and powerful capabilities in image and video tasks. ViTs divide images or video frames into patches, which are then converted into tokens through a Patch-Embedding Layer, enabling them to be directly fed into the Transformer.

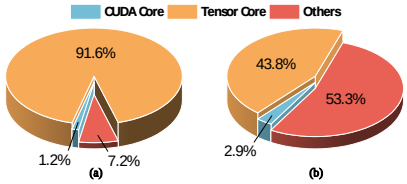

Fig. 3. The occupancy of RF bandwidth (a) and activation time (b) of CUDA Cores and Tensor Cores on A100 when executing ViTs.

Several accelerator architectures [5]–[7] have been proposed to optimize ViTs. For instance, DynamicViT [6] designs a dedicated dynamic prediction module to predict and prune redundant tokens. ViTCoD [5] employs an autoencoder module to reorder attention maps, creating denser or sparser fixed patterns to balance ViTs' workload. However, these advancements primarily focus on optimizing value-level sparsity and neglect the potential bit-level sparsity among similar tokens.

B. Ampere GPU

In recent years, the rapid advancement of neural networks and their substantial computational requirements have driven significant evolution in GPU structure and performance. The Nvidia A100 [10] serves as a prime example, featuring multiple Streaming Multiprocessors (SMs). Each Subcore of SM comprises several CUDA cores and a Tensor Core, sharing a common RF. Specifically, CUDA cores are utilized for high-precision general-purpose computations, whereas Tensor Cores are designed for high-throughput MMA operations, incorporating numerous DP units that support various fixed- and floating-point formats.

C. Motivation

While current research on ViT accelerators mainly focuses on value-level sparsity, our experimental results display a more promising form of bit-level sparsity among similar tokens. As demonstrated in Fig. 2, we run the implementation of various representative ViT models and subtract similar tokens within the attention map. As a result, we observe a significantly higher number of 0-bits for both FP16 and INT8, with bit sparsity increasing from 50.19% to 65.98% and from 50.48% to 75.82%, respectively.

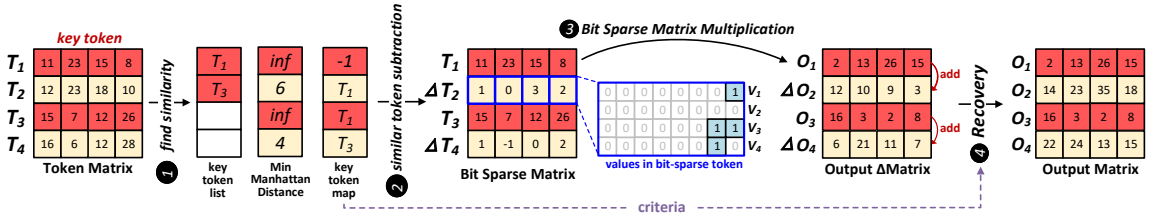

Fig. 4. Overview of the Inter-token Bit-sparsity Awareness algorithm.

Based on such observations, we intend to extract and leverage the bit-level sparsity to accelerate ViTs by collaborating with CUDA Cores and Tensor Cores. However, as shown in Fig. 3, when Tensor Core operates at full capacity with the RF bandwidth occupancy of 91.6%, CUDA Cores are mostly idle due to the competitive access to RF. Furthermore, different exponents of floating-point vectors impede accelerating MMA in Tensor Cores with fixed-point bit-level designs [11], [12]. Despite the effort made by Bitlet [13] to support bit-level floating-point formats, it leads to insufficient hardware utilization in lower-bit fixed-point computations. To address such inefficiencies, we propose SynGPU, an algorithm-hardware co-design framework that facilitates concurrent utilization of CUDA Cores and Tensor Cores to accelerate ViTs.

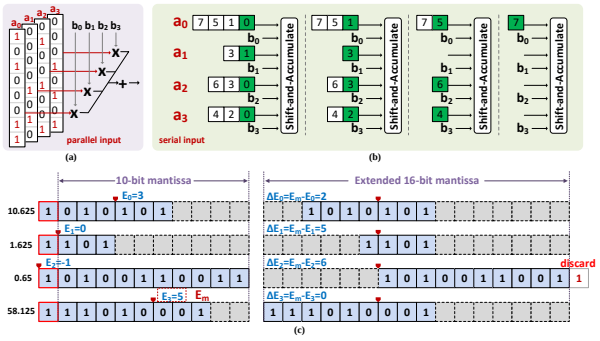

Fig. 5. Details of: (a) Parallel Dot Product. (b)Bit-Serial Dot Product. (c) Exponent alignment algorithm

III. Algorithm

A. Inter-token Bit-sparsity Awareness

In this section, we introduce Inter-token Bit-sparsity Awareness (IBA), an algorithm aimed at exploiting bit-level sparsity within ViTs. As illustrated in Fig. 4, in **step ❶**, we select a subset of key tokens at a regular interval, while the remaining tokens are non-key ones. Next, we compute the minimum Manhattan Distance as the criteria to locate the most similar key token to each of the non-key tokens and record them in a key token map. In the given example, we select key tokens at an interval of 2 and find that the most similar tokens to T_2 and T_4 are T_1 and T_3. **Step ❷** then subtracts the similar token pairs to acquire the Bit Sparse Matrix composed of numerous bit-sparse difference tokens. The blue-highlighted part displays the binary expressions of the values in the difference token $\Delta T_2 = T_2 - T_1$, exhibiting that the similarity between tokens leads to more redundant 0-bits. Subsequently, **step ❸** executes bit-sparse MMA operations to obtain the Output ΔMatrix efficiently. Finally, based on the linearity of MMA operations, **step ❹** utilizes the information in the key token map to add the outputs of O_1, O_3 to ΔO_2 and ΔO_4, respectively, thereby recovering the Output Matrix losslessly.

B. Bit-Serial Dot Product

The main challenge of performing bit-sparse MMA is to support both floating-point and fixed-point formats, particularly given the varying exponents of floating-point vectors. Since floating-point multiplication consists of two main operations: exponent addition and mantissa multiplication, with the latter following the same mechanism as fixed-point multiplication, we propose Bit-Serial Dot Product (BSDP), an algorithm that combines fixed-point bit-serial multiplication with floating-point exponent alignment to address the challenge.

Fixed-point BSDP. The conventional DP operation depicted in Fig. 5(a) computes all bits in parallel. To avoid unnecessary 0-bits, as illustrated in Fig. 5(b), we need to transform the multiplication process into a bit-serial input mode by encoding the matrix elements into bit index format. This approach converts multiplication into a series of shift-and-accumulate operations, effectively skipping the 0-bits.

Floating-point BSDP. A floating-point operand is expressed as $X = 2^E \times M$, where M is the mantissa, and E is the exponent (we omit the sign bit for simplicity). The floating-point BSDP consists of three steps: exponent alignment, mantissa multiplication, and repackage. As illustrated in Fig. 5(c), we first align the exponents of all elements in the vector to the largest E_m by right-shifting the mantissa. Additionally, since the right-shifting may cause overflow and subsequent loss of precision, we extend the 10-bit mantissa to 16 bits:

$$X_i = 2^{E_i} \times M_i = 2^{E_m} \times (M_i \gg \Delta E_i) \tag{1}$$

where $\Delta E_i = E_m - E_i$ are the right-shifting bits for mantissa. As for floating-point BSDP $\vec{a} \times \vec{b}$, we separately align both exponents and then multiply the mantissa following the same way as fixed-point BSDP. Subsequently, we repackage the result into the standard floating-point format by adding the unified exponents by Eqn. (2):

$$\begin{aligned} dp &= \sum_{i=0}^{m} [2^{E_i^a} \times M_i^a] \times [2^{E_i^b} \times M_i^b] \\ &= \sum_{i=0}^{k} 2^{E_m^a + E_m^b} \times (M_i^a \gg \Delta E^a) \times (M_i^b \gg \Delta E^b) \end{aligned} \tag{2}$$

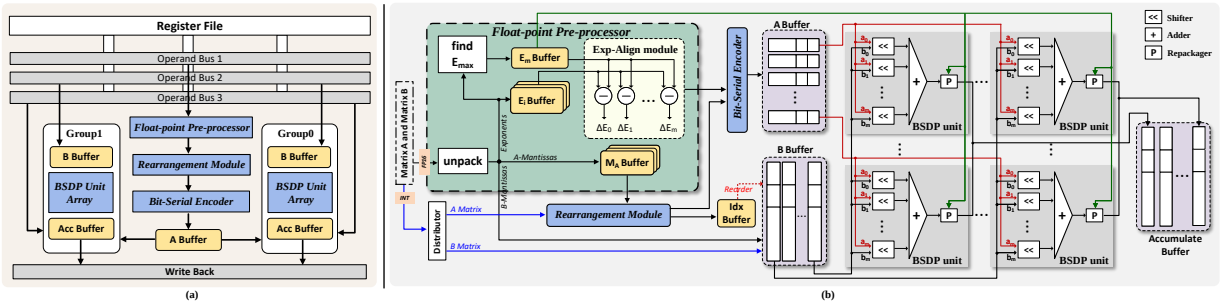

Fig. 6. Architecture of Bit-Serial Tensor Core: (a) Overview of BSTC. (b) Details of BSTC.

To reduce redundant computations, we further combine the two right shifts in alignment operations and the left shift in fixed-point BSDP to obtain the final result of floating-point BSDP operations, as shown in Eqn. (3):

$$dp = \sum_{i=0}^{k} \sum_{j=0}^{l} 2^{E_m^a + E_m^b} \times [M_i^b \ll (I_j - \Delta E^a - \Delta E^b)] \quad (3)$$

where I_j denotes the index of the 1-bit positions in the elements of $\vec{a}$.

IV. Architecture

A. Overview

The SynGPU architecture comprises two key designs. First, we introduce a data mapping scheme to solve the RF bandwidth congestion issue between CUDA Cores and Tensor Cores, enabling parallel processing capabilities for both cores. Second, we propose the Bit-Serial Tensor Core (BSTC), which is capable of computing both fixed- and floating-point MMA. Additionally, to maximize the efficiency of accelerating bit sparse MMA in BSTC, we design a rearrangement module to balance the matrix bit-sparsity.

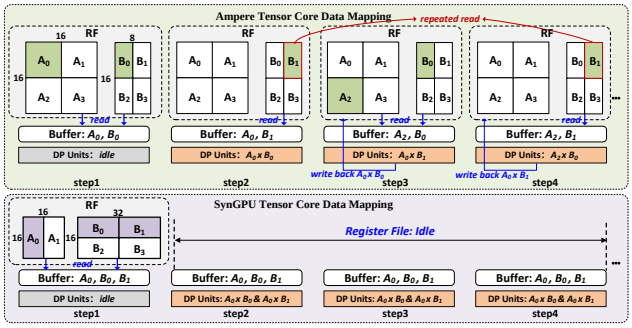

Fig. 7. Details of data mapping.

B. Data Mapping

When performing a 16 × 16 × 8 matrix operation in the original Tensor Core, it is separated into 8 steps of 8 × 8 × 4 MMA process (only 4 steps are given in Fig. 7), operating in a pipelined manner, with each process consisting of 3 parts: reading from RF, calculation, and writing back to RF. As depicted in the figure, in step 1, the Buffer reads A_0 and B_0, while the calculation and writing back correspond to step 2 and step 3. Unfortunately, the above execution consumes most of the RF's memory bandwidth, causing the CUDA cores to remain idle during Tensor Core operations. Additionally, this data flow of Tensor Core also leads to repeated data read-write operations, such as B_1 in steps 2 and 4, resulting in unnecessary overhead.

To address this issue, we propose to increase the capacity of the Tensor Core's data buffer, enabling it to read all required data for the current computation at once during step 1. By converting the bits of elements from parallel to serial processing in BSDP operations, the RF becomes idle during subsequent DP computation steps, allowing it to be utilized by CUDA cores.

Moreover, as the serial process decreases parallelism in the Tensor Core, we expand the dimension of the B matrix to ensure that the throughput does not decrease. Specifically, due to the 16-bit extended mantissa detailed in III-B, the worst-case scenario requires up to 16× cycles to compute MMA than Ampere Tensor Core. Thus, the expansion of the B matrix is set as 16 × 32. Additionally, to handle the repeated read-write operations, we split the A matrix into two groups, each with a size of 16 × 8, to compute $A_0 \times B_0$ and $A_0 \times B_1$ simultaneously.

C. Bit-Serial Tensor Core Design

As mentioned in III-B, to achieve bit-sparse MMA, floating-point numbers are required to be pre-processed for exponent alignment, while fixed-point numbers are able to directly perform BSDP operations. Therefore, as illustrated in Fig. 6 the architecture of BSTC mainly consists of two modules: the BSDP Array and the Floating-point Pre-processor.

BSDP Array. To implement bit-sparse matrix A × matrix B, we replace the DP Units within the Tensor Core with BSDP Units and arrange them in a grid array to concurrently work on performing a number of BSDP operations, where the (x, y)-th Unit executes BSDP between the x-th row of A and the y-th column of B. Each BSDP Unit consists of several shifters, an adder, and a repackage module to accomplish the fixed-point BSDP described in III-B. Within each cycle, a vector from the B Buffer and a serial of bit index code of matrix A from the A Buffer are fetched to perform shift-and-accumulate operations, which are repeated until the entire vector DP is finished.

Floating-point Pre-processor. The primary function of the Floating-point Pre-processor is to unpack floating-point elements in matrices and align the exponents in terms of

vectors. Initially, the unpacking process splits and extracts the exponents and mantissa from the floating-point data, and then finds the largest exponents as E_m, respectively storing all the segments into E_i Buffer, M_A Buffer, and E_m Buffer. Notably, since the B-Mantissas do not necessitate bit-serial encoding, they can be directly deposited in the B Buffer for subsequent DP computations. Next, the Exp-Align module works on subtractions $\Delta E_i = E_m - E_i$ as mentioned in Eqn. (3). Subsequently, based on the principles discussed in III-B, the Bit-Serial Encoder combines ΔE_i and M_A for encoding into bit-serial forms and stores them in the A Buffer for BSDP operation with B-mantissas. Finally, the repackage module that interfaces with the E_m Buffer is added at the end of each Unit to normalize the DP results to standard floating-point format, merge $E_m^a + E_m^b$ into the final exponent, and store them into the Accumulate Buffer before writing back.

D. Rearrangement Module Design

Despite the capability of BSTC in IV-C to facilitate the acceleration of fixed- and floating-point bit-sparse MMA operations, we discover that a primary bottleneck limiting the compute performance is the bit imbalance in the elements of matrix A. Apparently, the speed of BSDP operation executed in a BSDP Unit shown in Fig. 5(b) is constrained by the element a_0 including the most 1-bits in the vector. Likewise, in the BSDP Array, there is the same barrier over the entire matrix A. Moreover, due to the random matrix distribution, there is usually at least one bit-dense element in the matrix, significantly decreasing the speed of the BSDP Array.

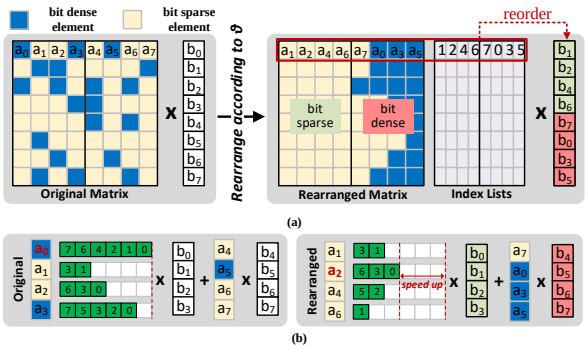

Fig. 8. Details of: (a) The Rearrangement scheme. (b) Speedup.

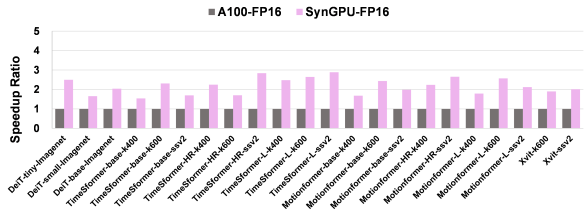
To settle the imbalance problem, as described in Fig. 8, we take twice the length of the BSDP Unit's vector as a unit to organize the rows of the matrix into bit-sparse and bit-dense sections, which respectively correspond to the mapping size stated in IV-B. Specifically, we sample a few elements from matrix A to roughly predict the sparsity of the matrix, which serves as a threshold θ for data rearrangement. Next, we compare the sparsity of each value against θ, thus creating a bit-sparse balanced matrix. In the given example, we rearrange the elements from a_0, a_1, a_2, a_3 into a_1, a_2, a_4, a_6. As a result, the rearrangement module reduces the cycle from 6 to 3. Moreover, to correctly realize MMA based on the rearranged A matrix, we maintain an index list, stored in Idx Buffer, as the reference to reorder the B matrix.

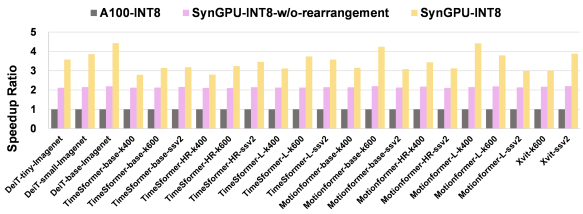
V. Evaluation

A. Methodology



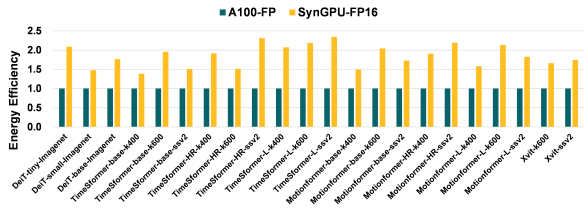
Software implementation. To verify the effectiveness of the SynGPU framework, we select DeiT [2] with ImageNet2021 [14] dataset as the representative of ViTs in image tasks and select TimeSformer [4], Motionformer [15], and Xvit [16] with Kinetics-400 (K400), Kinetics-600 (K600) [17], and SSv2 [18] datasets as the representative of ViTs in video tasks. All models are implemented using the official source code and pre-trained models without fine-tuning. Moreover, the interval used in the IBA algorithm is 80 and the batch size is set as 8 in the following experiments.

Hardware implementation. For kernel-level evaluation, we set the NVIDIA A100 GPU as the baseline. We employ Accel-Sim [19], an open-source cycle-accurate simulator, with integrating SynGPU model to simulate the computing performance in FP16 and INT8 format of A100 and SynGPU. We implement the proposed SynGPU architecture in Verilog and synthesize it by Synopsys Design Compiler to get the area and power consumption under 28nm technology. Given the absence of public data on the A100 Tensor Core area, and considering that the A100 utilizes a 7nm process while our study is based on a 28nm process, we follow work [20] to estimate A100's area and power under 28nm technology and 1.41GHz frequency. For SRAM-based on-chip buffers, we use CACTI 7 [21] to model their area and power consumption under 32nm technology and scale them to 28nm using DeepScaleTool [22].



B. Experiment

Speedup. We compare the performance between A100 Tensor Core and SynGPU BSTC on various models and datasets in FP16 and INT8 formats respectively, as shown in Fig. 9(a) and Fig. 9(b). Due to the fact that the A100 Tensor Core does not skip any 0-bits, it consumes the same number of cycles when processing tensors of the same data dimension. On the other hand, SynGPU BSTC, equipped with the capability to accelerate bit-sparse MMA, achieves varying speedup compared to A100 depending on the bit sparsity of the attention map for different input data. The average speedup achieved by SynGPU-FP16 and SynGPU-INT8-w/o-rearrangement is 2.2× and 2.15× respectively, with peak speedup ratios of 2.89× and 2.20×, which do not reach the ideal speedup according to the bit-sparsity ratio indicated in Fig 2. The reason is that BSTC cannot utilize bit-sparsity with maximum efficiency without rearrangement. Therefore, based on the INT8 format, we conduct ablation experiments to demonstrate that rearrangement effectively leverages the bit sparsity acceleration capability of BSTC, providing a 3.38× speedup on average.



Energy Efficiency. Fig. 9(c) and Fig. 9(d) illustrate the energy efficiency results. Compared to the A100 GPU, SynGPU delivers an average of 1.84×, 1.85×, and 2.68× energy efficiency improvements in FP16, INT8-w/o-rearrangement, and INT8 situations. The optimization in FP16 and INT8 without rearrangement (INT8-w/o-rearrangement) attributed to skipping unnecessary 0-bit calculations using SynGPU,

(b) Speedup in INT8

(c) Energy efficiency in FP16

(d) Energy efficiency in INT8

Fig. 9. Speedup and energy efficiency of SynGPU over A100 in FP16 and INT8 formats

thereby saving the dynamic on-chip energy. For INT8 with rearrangement, the enhancement is achieved by utilizing a rearrangement module to accelerate computation cycles, which in turn reduces the static on-chip energy.

TABLE I
AREA AND POWER OF SYNGPU ARCHITECTURE.

Parameter	Area(mm^2)	Area Ratio	Power(W)
16x16 Bit-Serial DP Units	0.9306		0.3000
1.25 KB A Buffer	0.0516		0.0358
1KB B Buffer	0.0233	**96.45%**	0.0269
2KB Acc Buffer	0.0857		0.1835
BSDP Array	**1.0913**		**0.5462**
FindExpMax	0.0006		0.0013
Exp-align	0.0003		0.0008
0.3KB Ma Buffer	0.0138	**1.91%**	0.1813
0.15KB Exp Buffer	0.0069		0.1813
Floating-point Pre-processor	**0.0216**		**0.3647**
Bit-Serial Encoder	**0.0019**	**0.16%**	**0.0430**
Comparators and selectors	0.0098		0.0225
0.15KB IdxList Buffer	0.0069	**1.48%**	0.1813
Rearrangement Module	**0.0167**		**0.2039**

Hardware Overhead and Area. Table I provides an overview of the hardware configurations and the area and power of the BSTC in each SM of SynGPU. The primary overhead of the BSTC is the BSDP Array, with an area of 1.0913mm^2. The other modules, the Floating-point Pre-processor, the Bit-Serial Encoder, and the Rearrangement Module with areas of 0.0216mm^2, 0.0019mm^2, and 0.0167mm^2, respectively, introduce about 1.91%, 0.16%, and 1.48% overhead of the entire Tensor Core, which are negligible compared to the area of the BSDP Array that occupies 96.45% of the chip area. Notably, the Rearrangement Module brings considerable speedup effects with little hardware overhead.

Compute Performance. Table II presents the compute performance of A100 Tensor Core and SynGPU BSTC in FP16 and INT8 formats. Despite the area of BSTC in SynGPU introduces a slight area overhead compared to the Tensor Core in A100 (1.13 mm^2 v.s. 0.98 mm^2), the peak computation performance of SynGPU has a significant advantage, reaching 901 TFLOPs in FP16 and 2761 TOPs in INT8, compared to 312 TFLOPs in FP16 and 624 TOPs in INT8 on A100. Thus, SynGPU achieves 2.49× and 3.81× improvements of compute density in FP16 and INT8 over A100, respectively under the same area budget. Moreover, according to the power simulation of computation modules given in Table I, we obtain the power efficiency of SynGPU for the FP16 and INT8 formats, which reaches 7.69 TFLOPs/W and 23.57 TOPs/W, respectively, delivering 2.58× and 3.95× increase over A100. Due to the acceleration and energy reduction arising from bit-level sparsity, SynGPU achieves substantial advancements in both compute density and compute power efficiency.

TABLE II
COMPUTE PERFORMANCE OF A100 AND SYNGPU.

Devices	Peak Perf.	Area Per SM	Compute Density	Power Efficiency
A100-FP	312 TFLOPs	0.98 mm^2	2.96 TFLOPs/mm^2	2.98 TFLOPs/W
A100-INT8	624 TOPs	0.98 mm^2	5.93 TOPs/mm^2	5.96 TOPs/W
SynGPU-FP	901 TFLOPs	1.13 mm^2	7.37 TFLOPs/mm^2	7.69 TFLOPs/W
SynGPU-INT8	2761 TOPs	1.13 mm^2	22.60 TOPs/mm^2	23.57 TOPs/W

VI. CONCLUSION

In this paper, we introduce SynGPU, an innovative algorithm-hardware co-design framework that synergizes CUDA Cores and Tensor Cores on GPUs to exploit and harness the bit-level sparsity among similar tokens, achieving significant performance enhancement of ViTs. SynGPU tackles two crucial challenges: firstly, the low parallelism caused by competitive access to the RF by CUDA Cores and Tensor Cores; secondly, the inability of tensor cores to accelerate bit-level sparse MMA due to differing exponents in floating-point vectors. Our innovative scheme fully exploits the bit sparsity of ViTs for acceleration, yielding remarkable outcomes without incurring accuracy loss.

***Abstract*—Spiking Neural Networks (SNNs) face increasing challenges for efficient deployment as architectures grow in complexity, necessitating network pruning to improve energy and computational efficiency. Existing pruning methods primarily focus on a single form of sparsity, overlooking the importance of joint pruning, which is critical for minimizing synaptic operations (SOPs) and enhancing energy efficiency. This paper presents a novel dynamic joint pruning framework that leverages both spatiotemporal spike sparsity and weight sparsity to minimize SOPs in SNN inference. Based on a comprehensive analysis of the SOPs model, we introduce an integrated solution that combines a multi-stage masking mechanism for fine-grained neuron firing threshold control, a temporal attention batch normalization (TABN) module with learnable time scaling factors, and a dynamic sparse strategy that adjusts importance coefficients based on real-time computational impact. Experimental results on CIFAR-10, CIFAR-100, and ImageNet validate the effectiveness of proposed framework. Our method achieves up to 126.38× compression ratio of SOPs on CIFAR-10 with minimal accuracy loss, establishing a new state-of-the-art in energy-efficient SNN pruning.**

***Index Terms*—spiking neural network, network pruning, low power computing**

I. Introduction

Spiking Neural Networks (SNNs), regarded as the third generation of neural networks [1], have attracted significant attention for their potential in energy-efficient machine intelligence [2], [3]. By leveraging sparse and event-driven spike signals, SNNs enable low-power and multiplication-free inference on neuromorphic hardware compared to Artificial Neural Networks (ANNs) [4]–[6]. However, to tackle increasingly complex tasks, modern SNN architectures have grown in depth and scale [7], [8], which requires greater computational resources and compromises their low power advantages.

Network pruning has emerged as a promising approach to eliminate redundancy and reduce model size in SNNs. Common techniques mainly focus on pruning synaptic connections, including magnitude-based pruning [9], [10], optimization-driven methods [11], [12], and bio-inspired algorithms [13], [14]. Although these methods achieve high weight sparsity and reduce computational resource requirements, they are less effective at directly reducing the number of synaptic operations (SOPs). SOPs reflect both the computational cost and energy consumption of SNN inference on neuromorphic hardware. Therefore, many works [4]–[6], [11] use SOP-related metrics (e.g., energy consumption per SOP) as indicators for assessing hardware energy efficiency. This indicates that minimizing SOPs is crucial for achieving low-power SNN computing.

To minimize SOPs in SNN inference, we develop a fine-grained SOPs model for SNNs and explore comprehensive pruning strategies. According to the SOPs model, weight sparsity and spatiotemporal spike sparsity are two fundamental factors determining SOP reduction. Additionally, the evolution of importance coefficients during pruning serves as another critical factor in the sparse training process. Previous works have achieved spike number reduction by different approaches [15]–[18]. In particular, sparse regularization as a pruning method directly eliminates model redundancy and achieves high spike sparsity [19]–[21].

However, studies that combine spike and weight sparsity to maximize SOP reduction remain limited. UPSNN [22] and ADMM [23] have preliminarily explored joint pruning with sparse regularization. The former introduces neuron sparsity but not the finer-grained spike sparsity, which directly determines SOP reduction. The latter simply performs weight pruning and activity regularization simultaneously without optimization, making it ineffective in achieving high sparsity during joint pruning. Consequently, neither method achieves the minimization of SOPs. Moreover, even after addressing these issues, joint pruning with sparse regularization still faces challenges: (1) spikes and weights being interdependent during pruning, as spikes are model outputs influenced by weights; (2) the need to balance the sparse strengths of different regularization terms during sparse training.

In this paper, we propose a dynamic joint pruning framework[1] that fully exploits available redundancy to minimize SOPs in SNN inference. Novel techniques are introduced to address the challenges in joint pruning. First, we use a multi-stage masking mechanism to decouple spike sparsity from weights. These masks partition neuron membrane potentials into multiple stages, enabling neurons to adopt different firing thresholds during inference and achieve spatial spike sparsity. Second, to address temporal redundancy, we introduce temporal attention batch normalization (TABN). TABN incorporates a trainable time scaling factor into standard batch normalization, thereby pruning redundant spike activity across time steps. Finally, we employ a dynamic regularization strategy for joint sparse training. Coefficients that reflect the importance of pruning candidates are dynamically updated based on the SOPs model to adjust sparse strengths. Experimental results demonstrate that the proposed framework significantly reduces SOPs, lowers energy consumption, and maintains high model accuracy.

In summary, our key contributions are as follows:

- We develop an SOPs model that incorporates the temporal dimension. This model identifies spatiotemporal spike sparsity, weight sparsity, and the evolution of importance coefficients as key factors influencing SOP reduction.
- We propose novel methods to achieve spatiotemporal spike sparsity: a multi-stage masking mechanism for spatial spike sparsity, which allows neurons to adopt variable firing thresholds, and temporal attention batch normalization (TABN), which prunes redundant spike activity across time steps to realize temporal spike sparsity.

[1]Our code: https://github.com/MmPple/SDJP

- We develop a dynamic joint pruning framework that comprehensively exploits the available redundancy for maximal SOP reduction. An dynamic strategy is introduced to adjust sparse regularization coefficients based on real-time computational impact.
- Experiments on CIFAR-10, CIFAR-100, and ImageNet demonstrate that our proposed framework significantly reduces SOPs and energy consumption while maintaining high model accuracy. On CIFAR-10, our method achieves an SOP compression ratio of up to 126.38× with only a 2.15% accuracy drop, significantly outperforming state-of-the-art methods.

II. Related Work and Background

A. Pruning for SNNs

Pruning induces sparsity in neural networks by removing certain elements, enhancing computational efficiency and reducing power consumption. In SNNs, the main forms of sparsity explored are weight sparsity and spike sparsity.

Weight Sparsity. Weight pruning in SNNs is widely studied because it enables low-power operation on neuromorphic hardware like Loihi [5], which supports unstructured sparsity. Inspired by pruning techniques in artificial neural networks (ANNs), magnitude-based pruning removes small weights during learning processes such as event-driven contrastive divergence [24], spike-timing-dependent plasticity [2], and ANN-to-SNN conversion [25]. Kim et al. [9] applied the lottery ticket hypothesis to SNN pruning using iterative magnitude pruning. ADMM combined spatio-temporal backpropagation with the alternating direction method of multipliers (ADMMs) [23]. Some incorporate biologically inspired strategies like synapse regeneration, such as Grad R [14] and ESLSNN [11].

Spike Sparsity. Sparse signals are inherently advantageous in SNNs, as sparse spiking patterns contribute to low-power computations in neuromorphic systems utilizing spike-triggered mechanisms. Pruning methods to achieve spike sparsity include regularization techniques and attention mechanisms. Regularization methods like L_p regularization [19] and low-activity regularization [20], [21], [23] promote high spike sparsity by eliminating redundancy without compromising performance. Attention mechanisms focus computational resources on critical information, reducing the number of spikes required for effective processing [18], [26], [27].

Hybrid Pruning. Some hybrid pruning methods have begun to combine sparsity at multiple levels. ADMM [23] performed weight pruning based on the ADMMs and activity regularization simultaneously. However, they simply combine the two without optimization, making it ineffective for joint pruning. UPSNN [22] combines unstructured weight and neuron pruning to maximize sparsity and enhance energy efficiency. However, UPSNN introduces neuron sparsity rather than finer-grained spike sparsity, and does not fully exploit redundancy to maximize energy efficiency.

B. Spiking Neural Network

Spiking neural networks apply the spiking neuron as the fundamental unit to collect signals from other neurons or inputs during a time step, and modulate the membrane potential by these signals. An output spike is generated and delivered to post-synaptic neurons when the membrane potential exceeds the threshold. The commonly used neuron model is Leaky Integrate and Fire (LIF) model [28]. It is defined as:

$$h[t] = u[t-1] + \frac{1}{\tau}(\sum_i w_i s_i[t] - u[t-1]), \tag{1}$$

$$u[t] = h[t] \cdot (1 - s[t]) + V_{reset} \cdot s[t], \tag{2}$$

where Eq.1 and Eq.2 describe the charging and resetting processes of a LIF neuron. t represents the current time step. s_i represents the spike train from the ith pre-synaptic neuron and w_i is the corresponding synaptic weight. $u[t]$ denotes the membrane potential at the end of the current time step t. V_{reset} represents the reset voltage, which we set to 0. $s[t] \in \{0, 1\}$ represents the output of the neuron in the current time step. The fire process is described as:

$$s[t] = \Theta(h[t] - V_{threshold}), \tag{3a}$$

$$\Theta(x) = 0, x < 0 \; otherwise \; 1, \tag{3b}$$

where $V_{threshold}$ is the threshold voltage.

For the learning process, we use the spatio-temporal backpropagation (STBP) [29] to train SNNs. To overcome the problem that Eq.3b is not differentiable at zero, we follow pervious works and use the arc tangent function as a surrogate function to replace Eq.3b in the backward phase [29].

III. Methodology

In this section, we present a framework for dynamic joint pruning in deep SNNs. Figure 1 shows an overview of the proposed framework. This framework performs sparse regularization with joint optimization to leverage spatiotemporal spike sparsity and weight sparsity. It integrates a sparse strategy that dynamically adjusts importance coefficients during sparse training. Our objective is to minimize SOPs in SNN inference while maintaining high model accuracy.

A. SOPs Model

The energy consumption in SNNs primarily arises from synaptic operations (SOPs). Specifically, the energy consumption for SNNs is given by:

$$E = C_E \cdot \#\text{SOPs} = C_E \cdot \sum_i s_i \cdot c_i, \tag{4}$$

where E represents the total energy consumption, C_E is the average energy required for each synaptic operation, s_i denotes the number of spikes fired by neuron i, and c_i is the number of synaptic connections from neuron i.

From Eq.4, reducing energy consumption depends on minimizing SOPs, which are determined by the number of spikes fired by each neuron (spike sparsity) and the number of synaptic connections (weight sparsity). To better describe spike sparsity, we incorporate the temporal dynamics of SNNs into the SOPs model:

$$\#\text{SOPs} = \sum_t \sum_i s_i[t] \cdot c_i, \tag{5}$$

where $s_i[t]$ denotes the number of spikes fired by neuron i at time step t. By considering time steps, we can further decompose spike sparsity across both time and space.

Based on Eq. 5, we define spatiotemporal spike sparsity, which describes the frequency and number of spikes fired by neurons across time and space. This provides a refined view of neuron activity, indicating the precise sparse pattern of spikes rather than simply whether a neuron is active. Furthermore, the SOPs model indicates that achieving high spatiotemporal spike sparsity and weight sparsity is critical for minimizing SOPs in SNN inference. This need to develop efficient joint pruning methods.

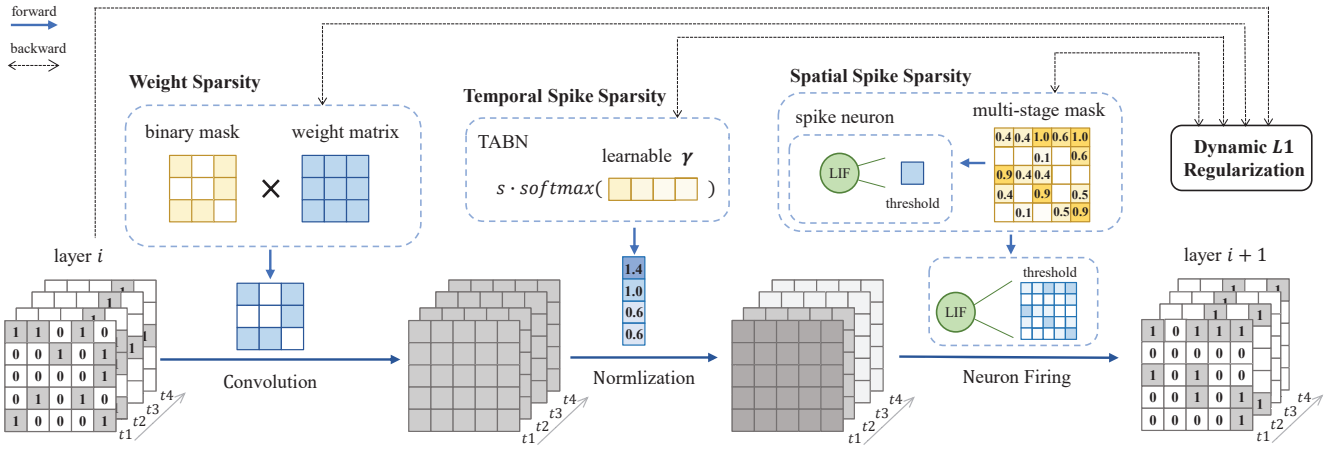

Fig. 1: The overview of proposed framework.

B. Spatial Spike Sparsity

To achieve high spike sparsity, L_1 regularization has proven effective [19]–[21]. However, this approach shows limited effectiveness when combined with weight pruning. Since L_1 regularization indirectly achieve spike sparsification through weight modification. This leads to a coupling between spike sparsity and weight sparsity.

To address this coupling issue, an intuitive solution is to independently reduce spikes through trainable gating parameters, such as neuron thresholds. However, the unbounded nature of threshold values, combined with the regularization constraint, poses significant challenges for training convergence. Thresholds may drift arbitrarily, destabilizing the optimization process. Moreover, completely pruning neurons would require manual threshold adjustments for each neuron, which is impractical and lacks scalability in large-scale networks.

We propose a novel multi-stage masking mechanism that equivalently substitutes variable thresholds in sparse training. Our approach applies a mask m_i^n to the neuron membrane potential $h_i[t]$:

$$h_i'[t] = m_i^n \cdot h_i[t] \tag{6}$$

where mask m_i^n is constrained to values from a set of K values uniformly distributed between 0 and 1. The multi-stage mask specifically addresses a key limitation of continuous masks, which typically converge toward a bimodal distribution of 0 and 1 during training, making it difficult to differentiate firing of neurons. This approach modulate membrane potentials through multiple stages, enabling fine-grained control over spike firing without complete neuron deactivation, thereby enhancing spatial spike sparsity.

To overcome the non-differentiability of step functions, we approximate the multi-stage mask by accumulating multiple sigmoid functions in practice:

$$m_i^n = \sum_{k=0}^{K-1} \frac{1}{K} \cdot \sigma\left(\beta_n \left(\theta_i - \frac{k}{K}\right)\right) \tag{7}$$

where $\sigma(x) = \frac{1}{1+e^{-x}}$ denotes the sigmoid function, β_n controls the function steepness, and θ_i represents the learnable parameter.

During the training process, θ_i are initialized to 0, and β_n is gradually increased, resulting in steeper sigmoid functions and increased difficulty for neurons to transition between stages. This gradual constraint allows neurons to naturally settle into different stages with corresponding firing thresholds.

During training, θ_i are initialized to 0 and trained with L_1 regularization, and β_n is gradually increased. This results in steeper sigmoid functions and makes it increasingly difficult for neurons to transition between stages. This gradual constraint allows neurons to naturally settle into different stages with corresponding firing thresholds.

C. Temporal Spike Sparsity

Recent studies have revealed significant redundancy in outputs across different time steps in SNN models—a phenomenon known as temporal information concentration [30] or spatio-temporal invariance [26]. This presents an opportunity for temporal spike sparsification. While existing temporal compression methods focus on directly reducing the number of time steps to decrease latency and computation, they are often ineffective for modern STBP-based SNNs that already operate with few time steps. Further reduction can lead to significant performance degradation.

To adaptively achieve temporal spike sparsity, we propose a novel data-independent temporal attention batch normalization (TABN) that incurs no additional computational cost during inference. TABN replaces the linear transformation in standard batch normalization layers with a temporal attention mechanism, enabling differentiated spike firing across time steps. The computation of TABN is formulated as:

$$v_i'[t] = s \cdot \left(\frac{v_i[t] - \mu}{\sqrt{\sigma^2 + \epsilon}}\right) \cdot \alpha_t + \beta, \tag{8}$$

where $v[t]$ represents the accumulated input of the i-th neuron at time step t, μ and σ denote the batch mean and standard deviation, and ϵ ensures numerical stability. The time step scaling factor α_t is normalized through a softmax function:

$$\alpha_t = \frac{e^{\gamma_t}}{\sum_{k=1}^{T} e^{\gamma_k}}, \tag{9}$$

where T represents the total number of time steps, and γ_t is a learnable parameter. The global learnable scaling factor s prevents spike and gradient vanishing during training, while β serves as a learnable bias term.

TABN learns temporal importance without introducing additional computational overhead. Specifically, we implement temporal spike sparsity at channel level, aligning with the observation that temporal output similarity manifests at the channel granularity [30]. Spike outputs of a channel represent a complete unit of feature expression and transmission. The channel-wise application of TABN enables

precise optimization of temporal redundancy while preserving feature integrity.

D. Dynamic Joint Pruning Framework

Combining proposed spatiotemporal spike sparsification mechanisms with L1 regularization, we develop a joint pruning framework comprising sparse training and fine-tuning phases.

In the sparse training phase, we jointly optimizes weight sparsity and spatiotemporal spike sparsity through the binary weight mask, multi-stage neuron mask, and TABN. We control the sparsity level using L1 regularization:

$$L_{\text{sparse}} = \lambda \left(\sum_i \|\boldsymbol{m}_i^w\|_1 + \sum_j \|m_j^n\|_1 + \sum_c \|\boldsymbol{\gamma}_c\|_1 \right) \tag{10}$$

where $\boldsymbol{m}_i^w$, m_j^n, and $\boldsymbol{\gamma}_c$ denote the weight mask vector for presynaptic neuron i, the multi-stage mask for neuron j, and the temporal weight vector for channel c, respectively. λ is a hyperparameter controlling the sparsity level. In practice, we use the approximation in Eq. 7 with $K = 1$ to overcome the non-differentiability of binary weight mask $\boldsymbol{m}_i^w$.

In the fine-tuning phase, we fix the sparse masks and convert multi-stage masks to neuron thresholds. The weights and neurons corresponding to zero masks with $\beta_n < 0$ are completely pruned. The learned temporal importance distribution of TABN is preserved. We retrain the pruned model without the sparsification loss L_{sparse} to recover performance loss induced by pruning during the sparse training phase.

To improve the joint pruning and minimize SOPs reduction, we introduce an strategy that dynamically adjusts sparse regularization terms based on real-time computational impact. According to the SOPs model Eq. 5, each sparsity form's contribution to computational efficiency is weighted by respective coefficients, leading to the dynamic sparse loss function:

$$L_{\text{sparse}} = \lambda \left(\sum_i s_i \|\boldsymbol{m}_i^w\|_1 + \sum_j w_j \|\boldsymbol{m}_j^n\|_1 + \sum_c w_c \|\boldsymbol{\gamma}_c\|_1 \right). \tag{11}$$

Here, the coefficients represent each sparsity form's computational impact:s_i measures spike count of presynaptic neuron i for weight sparsity, w_j reflects the preserved next-layer connection count of neuron j for spatial spike sparsity, and w_c indicates the remaining channel-level weights for temporal spike sparsity. These coefficients are dynamically updated during sparse training to ensure pruning decisions align with their actual computational efficiency impact.

For convolutional layers, we estimate coefficients at the channel level to simplify computation. Specifically, $\boldsymbol{m}_i^w$ represents weight masks associated with input channel i, encompassing all output channels and kernel spatial dimensions (height and width). The scaling factor s_i measures the spike count of input channel i. Similarly, the mask $\boldsymbol{m}_j^n$ corresponds to the multi-stage neuron mask vector for input channel j, and w_j reflects the number of preserved convolutional kernel weights associated with input channel j.

TABLE I: Hyperparameter settings for proposed method.

Dataset	Time Steps	Optimizer	Learning Rate	Batch Size
CIFAR10	8	Adam	0.0001	16
CIFAR100	4	SGD	0.025	64
ImageNet	4	Adam	0.001	256

IV. Experimental Results

A. Experimental Setup

In this section, we evaluate the proposed method for the image classification task on the CIFAR-10 [32], CIFAR-100 [32], and ImageNet [33] datasets. Following previous works, we employ spike frequency encoding and take the first convolutional layer of the model as a learnable encoder to transform static image inputs into spiking patterns. Our implementation is based on PyTorch and the SpikingJelly package. All experiments are executed on an RTX 3090 GPU.

We follow the hyperparameter setting from UPSNN [22]. For CIFAR-10, sparse training is performed over 800 epochs, followed by 200 fine-tuning epochs, while CIFAR-100 and ImageNet use 280 sparse training epochs and 40 fine-tuning epochs each. During the sparse training, β_n is linearly increased from 5 to 1000, with stage count K is fixed to 20. In the experiment of performance comparison, we use $\lambda = \{5, 10, 40\} \times 10^{-12}$ for CIFAR-10, $\{1, 2, 3\} \times 10^{-9}$ for CIFAR-100, and $\{1, 6, 10\} \times 10^{-11}$ for ImageNet. The details of other hyperparameters is shown in Table I.

B. Comparison with the State-of-the-Art Works

1) Performance Comparison: We compare our method with state-of-the-art SNN pruning algorithms including ADMM [23], Grad R [14], ESLSNN [11], STDS [31], and UPSNN [22], as summarized in Table II. In the table, "Avg. SOPs" indicates average SOPs per instance in inference. "Ratio" is the compression ratio, indicating the energy efficiency. "Sparsity Type" specifies the achieved sparsity: "W" for weight sparsity, "W+N" for weight and neuron sparsity, and "W+S" for weight and spike sparsity.

On CIFAR-10, our method achieves the highest accuracy of 92.65% while reducing energy consumption to 21.55M SOPs and achieving a compression ratio of 36.24. This outperforms UPSNN, which requires 38.32M SOPs with a ratio of 20.25 for similar accuracy. At higher sparsity levels, our method maintains superior accuracy and further reduces energy consumption, demonstrating up to 126.38× improvement in energy efficiency. For CIFAR-100, our method attains an accuracy of 72.51%, using only 17.11M SOPs, surpassing both STDS and UPSNN in accuracy and energy savings. On the more challenging ImageNet dataset, our method achieves 61.96% accuracy, using only 227.45M SOPs, outperforming previous methods that either have lower accuracy or require more SOPs. These results demonstrate that by jointly pruning weights and spikes, our method effectively balances high accuracy with significant energy reduction across various datasets.

2) Sparsity Comparison: Table III presents the effect of joint pruning in achieving spike sparsity and weight sparsity at different accuracy levels. We compare proposed method with UPSNN [22] and ADMM [23] on SEW ResNet18 for CIFAR-100. In Table III, "#Spike" and "Avg. FR" denote the average number of spikes and the average spike firing rate per neuron across instances in test set. "Param." indicates the total number of remaining weights after pruning. Our method achieves the best performance among the compared methods. Compared to UPSNN, our method significantly reduces both the total number of spikes and the average firing rate. This reduction is attributed to our fine-grained control over neuron spike firing. These results demonstrate the efficiency of our method in joint pruning for spike and weight sparsity.

C. Ablation Study Results

1) Performance with different SOPs: We evaluate the robustness of proposed method across various average SOPs. As depicted in Fig-

TABLE II: Performance comparison between proposed method and the state-of-the-art works. We mark the best results in bold.

ure 2a, our method consistently maintains high test accuracy on the CIFAR-100 dataset even as the average SOPs decrease significantly. When reducing the average SOPs from 38.23M to 3.82M, which is a reduction of over 10 times, the test accuracy only declines from 73.72% to 69.12%. These results highlight that our method remains effective across a wide range of SOP levels, especially at lower SOPs corresponding to lower energy costs.

2) Effect of Different Mechanisms: To understand the impact of each mechanism in our method, we perform an ablation study by individually removing the multi-stage mask, temporal attention batch normalization (TABN), and the dynamic coefficient strategy. As shown in Figure 2a, the absence of the multi-stage mask results in a sharper accuracy loss as SOPs decrease, indicating that spatial spike sparsity plays a crucial role in reducing SOPs. Removing TABN and the dynamic coefficient strategy also affects accuracy, especially at higher SOPs levels. This is because, at this point, there is more redundant spike activity across time steps and greater variance in the importance among different sparsity terms, offering more opportunity for effective sparsity.

(a) (b)

Fig. 2: (a) Results of pruned models with different mechanisms for CIFAR-100. (b) Results of pruned models fro CIFAR-100 with different stage count K in the multi-stage mask.

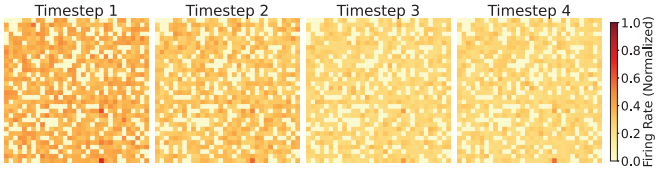

Fig. 3: Visualization of spatiotemporal spike sparsity in feature maps of the penultimate layer of pruned model on CIFAR-100.

3) Effect of Stage Count K: We evaluate the impact of different stage count settings K in the multi-stage mask on the performance of our method. As shown in Figure 2b, when $K = 1$, the multi-stage mask reduces to a binary mask, leading to suboptimal performance. As K increases, the performance improves, demonstrating the benefit of using a multi-stage mask with finer granularity. In particular, our method exhibits stable performance across a wide range of K values (from 5 to 50), indicating that it is robust to the choice of stage count.

4) Visualization of Spatiotemporal Spike Sparsity: To further illustrate the effect of proposed method, we visualize the spatiotemporal spike sparsity in the feature map outputs of the penultimate layer of pruned model on CIFAR-100, As shown in Figure 3, the color intensity indicates the average neuron firing rate. The visualization reveals both spatial and temporal spike sparsity achieved by our method. Spatially, at a single time step, neurons exhibit significant variations in firing rates, demonstrating that the multi-stage mask effectively promotes sparsity by selectively suppressing less important neurons. Temporally, we observe that spikes are mainly concentrated in the first two time steps. This is attributed to the TABN, which reduces redundant spike activity over time.

V. Conclusion

In this paper, we propose a dynamic joint pruning framework for SNNs that fully exploits weight sparsity and spatiotemporal spike sparsity to maximizing SOPs reduction and energy efficiency in inference. Our multi-stage masking mechanism and temporal attention batch normalization enable fine-grained control over spatiotemporal neuron activity without compromising model accuracy. Experimental results demonstrate that our framework significantly reduces SOPs and energy consumption, achieving superior performance compared to state-of-the-art methods. This work highlights the importance of jointly optimizing multiple forms of sparsity and provides a foundation for future research in low-power SNN computing.

SAGA: A Memory-Efficient Accelerator for GANN Construction via Harnessing Vertex Similarity

Ruiyang Chen, Xueyuan Liu, Chunyu Qi, Yuanzheng Yao, Yanan Sun, Xiaoyao Liang, and Zhuoran Song*
Shanghai Jiao Tong University, Shanghai, China
{chenruiyang, songzhuoran}@sjtu.edu.cn

***Abstract*—Graph-traversal-based Approximate Nearest Neighbor (GANN) search and construction have become key retrieval techniques in various domains, such as recommendation systems and social networks. However, deploying GANN in real-world scenarios faces significant challenges, as high-dimensional vertices within the graph can lead to intensive memory demands. Although architectures like NDSearch have been proposed to accelerate GANN search, they are hard to deploy for GANN construction, as their pre-processing methods introduce massive overhead in dynamic graphs. In this paper, given the observation that neighboring vertices in a dynamic graph exhibit feature similarity, we propose SAGA, the first accelerator that alleviates memory bound in GANN construction. To capture this similarity, we directly leverage the first step of construction to gather vertices with the same starting point into a cluster to minimize the similarity detection overhead. Next, we decompose vertices into key and non-key ones, where their deltas fall in a narrow range, which is suitable to be quantized to lower bit widths. Building upon this approach, we design a specialized architecture, which efficiently implements the GANN construction by two-level scheduling and a mixed-precision supported bit-serial unit. Through comprehensive evaluation, we demonstrate that SAGA can achieve an average speedup of 9.30×, 4.87×, 4.15× and 35.46×, 7.60×, 5.15× energy savings over CPU, GPU and NDSearch, respectively, while retaining task accuracy.**

I. Introduction

Graph-traversal-based Approximate Nearest Neighbor (GANN) construction and search have become critical techniques in various domains, including recommendation systems [1], [2], computer vision [3], [4], and social networks [5], [6]. In these applications, GANN first performs construction to generate a graph that can guide searches, after which it searches the constructed graph to find the top-K nearest vertices to a given query. Unfortunately, considering that high-dimensional vertices consume substantial memory, the deployment of GANN in real-world scenarios is significantly constrained by memory bottlenecks [7]–[13]. Moreover, since the graph is **dynamically** updated during construction but remains **static** during searching, the construction stage is more complex. *Therefore, the goal of this work is to alleviate the memory bottleneck in GANN construction.*

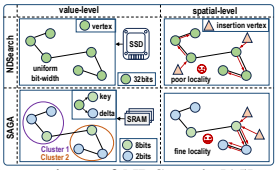

Fig. 1. Comparison of NDSearch [15] and SAGA.

To address the memory-bound problem of GANN, many existing works [14], [15] focus on accelerating GANN search. Taking NDSearch [15] as an example, it involves pre-processing the static graph by remapping the neighboring vertices on the same page of SSD to improve the search locality. However, since the graph is dynamically updated during GANN construction, deploying NDSearch in construction requires iteratively executing its pre-processing method at runtime, incurring significant latency and making GANN search accelerators ill-suited for construction. In contrast, our approach leverages the unique characteristics of GANN to accelerate the construction process. **Inspired by the *homophily theory* [16] in social networks, where users within the same community tend to share similar characteristics such as ages or interests, we discovered that neighboring vertices exhibit feature similarity. This similarity allows us to reduce precision in representing the differences between similar features, thus alleviating the memory bandwidth stress.** For example, given two vertices (20, 18, 10, 9) and (20, 17, 9, 8) and their difference (0, 1, 1, 1), naively storing each vertex takes 4 Bytes, while storing their difference only takes 1 Byte, saving 75% of memory storage.

In this paper, we propose **the first accelerator for GANN construction**, named SAGA. We observe that the first step in construction can naturally indicate vertices' similarity, so we carefully leveraged the intermediate results from this step to gather vertices into clusters and decompose vertices into one key vertex and multiple non-key vertices. To take advantage of value-level similarity within each cluster, we differentiate non-key vertices from key ones to construct deltas, which fall in a narrower range compared to the original vertices, making them more suitable for low-precision representation. Moreover, given that similar vertices are more likely to access the same vertex during graph traversal, we propose to exploit such a spatial-level similarity by rearranging the access order of vertices. To further illustrate the superiority of SAGA, Fig. 1 provides a comparison between NDSearch and our

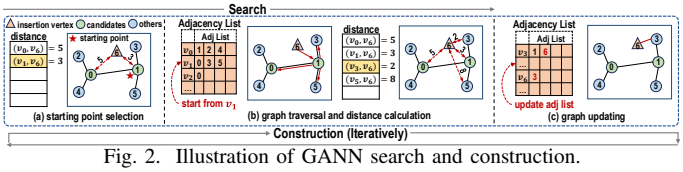

Fig. 2. Illustration of GANN search and construction.

approach. At the value level, NDSearch stores vertices in SSD with full precision, whereas we use a reduced bit width for delta storage, making GANN fit within on-chip SRAM. At the spatial level, NDSearch constructs vertices in a random order, while we reorder the execution sequence of similar vertices, thus achieving better locality.

Our contributions can be summarized as follows:

- From the algorithm perspective, we propose a similarity detection algorithm that gathers similar vertices into clusters. Then we introduce a quantization algorithm that leverages vertex similarity to reduce storage bit width.
- From the hardware perspective, we present an architecture design and develop a two-level scheduling that optimizes both the insertion and access order of vertices.

II. Background

A. GANN Construction and Search

GANN construction consists of three steps: starting point selection, distance calculation, and graph updating. First, starting point selection is used to reduce redundant calculations during construction. To simplify the search space, GANN samples certain vertices from the vertex set as candidates for the starting point, corresponding to vertices v_0 and v_1 in Fig. 2(a). Then, it calculates the distance from insertion vertex v_6 to these candidates and selects the closest candidate as the starting point. Typically, the distance is measured using either Inner Product (IP) or Euclidean (L2) distance, where the mathematical forms are $v_i \cdot v_j$ and $(v_i - v_j)^2$, respectively, with v_i and v_j being the vertices in the calculation. Second, distance calculation computes the distance between the insertion vertex and all neighbors of the starting point. In Fig. 2(b), v_6 sequentially computes distances to v_0, v_3, and v_5, which are 5, 2, and 8. Thus, the closest vertex to v_6 is identified as v_3. Notably, distance computation is iterative; if the neighbors of the starting point also have neighbors, they will also be calculated until the algorithm's pre-defined conditions are met. Finally, graph updating establishes a bi-directional link between the insertion vertex and its top-K closest neighbor. In Fig. 2(c), a bi-directional link is added between v_6 and v_3, and the adjacency list is then updated.

Given a constructed graph, GANN search uses the starting point selection and distance calculation steps to find the top-K nearest vertices to a given query, as shown in Fig. 2. Note that during the search process, the graph is completely static, while during construction, the graph is dynamic.

B. Related Works

There is a series of works on accelerating GANN [14], [15], but they all focus on searching rather than construction. SmartSSD [14] is the first architecture to accelerate GANN search. To make graph search algorithms more efficient on their hardware, SmartSSD pre-partitions the original static graph offline and performs searching separately on each sub-graph, narrowing the search scope. NDSearch [15] is the state-of-the-art accelerator for GANN search. NDSearch proposes remapping vertices on the SSD so that the neighboring vertices of each vertex are physically adjacent. To determine such remapping order, NDSearch conducts an expensive breath-first search (BFS) traversal of the entire graph during pre-processing. Unfortunately, both of their pre-processing approaches need to be iteratively executed whenever the graph is changed, which frequently happens during construction. As a result, their methods will introduce significant latency and may not be the proper option for GANN construction.

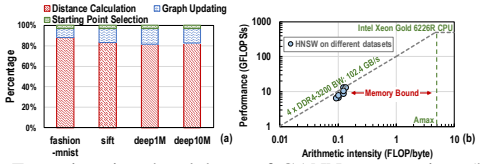

Fig. 3. (a) Execution time breakdown of GANN construction; (b) Roofline model in distance calculation.

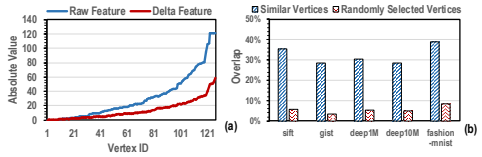

Fig. 4. (a) Value distribution in ascending order; (b) Graph traversal overlap.

III. Motivation

To find the performance bottlenecks in GANN construction, we conducted a breakdown analysis of the construction process on a CPU, which reveals that the majority of the execution time originates from distance computations, as shown in Fig. 3(a). Following this, we present our roofline model experiment for the distance calculation step in Fig. 3(b), demonstrating that all results fall into the left side of the roofline, which is in the DRAM bandwidth-constrained region. This sub-optimal performance is mainly due to the high dimension of vertices and their irregular memory accesses. This motivates us to find a solution that optimizes both storage and locality problems during distance calculations.

Observation 1: Vertex features contain redundancy at the value level. Fig. 4(a) visualizes the differences between neighboring vertices on sift [17] dataset. Compared to vertices' raw features, deltas have a narrower distribution, making them better suited for low-precision representation. Based on this observation, we propose quantizing deltas to a lower bit width, thus improving bandwidth utilization.

Observation2: Graph traversal exhibit reuse at the spatial level. As shown in Fig. 4(b), we compare the proportion of graph traversal overlap for similar vertices, and the proportion of graph traversal overlap for randomly selected vertices. The comparison between them shows that similar vertices are more likely to access the same vertex. This motivates us to bundle similar vertices together to enhance data locality.

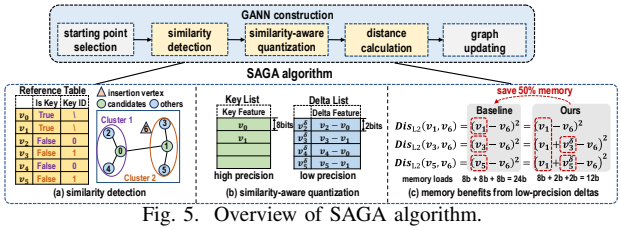

Fig. 5. Overview of SAGA algorithm.

IV. SAGA Algorithm

In this section, we introduce our SAGA algorithm, which comprises three essential operators: similarity detection, similarity-aware quantization and distance calculation.

A. Similarity Detection

To capture the similarity between vertices, we propose leveraging the intermediate results from the starting point selection step. This proposal builds on a well-known theory that users owning similar features in the community tend to connect through hubs [16]. Specifically, we find that candidates from construction's first step are naturally suited to serve as hubs, where vertices selecting the same candidate as a starting point are highly likely to be similar.

To implement similarity detection, we record the starting point of each insertion vertex and gather vertices with the same starting point into a single cluster. We designate this starting point as the **key** vertex, where other vertices are considered **non-key** vertices. To avoid duplicate storage of the same key vertex, each of the non-key vertices needs to record its key vertex's ID in a Reference Table. Fig. 5(a) shows an example of similarity detection: v_2 and v_4 both share v_0 as their starting point, so they are gathered into a cluster with v_0 as the key. In the Reference Table, we record whether each vertex is a key vertex (Is Key) and its corresponding key vertex's ID (Key ID). For instance, since v_2 is a non-key vertex, the Reference Table marks its Is Key identifier as False and records its Key ID as 0, allowing v_2 to directly reference its key vertex v_0.

B. Similarity-Aware Quantization

After identifying the similarities, we design a similarity-aware quantization algorithm to reduce storage bit width, which is a pre-processing step for distance calculations. Given the Reference Table and a non-key vertex v_i, we look up the key vertex v_j in the Reference Table and calculate the delta v_i^δ for v_i as follows: $v_i^\delta = v_i - v_j$. Next, we apply high-precision quantization to v_j with a wide range, while using low-precision quantization to v_i^δ with a narrow range. Fig. 5(b) illustrates our method: for key vertex v_0, we store its feature with 8-bit in the Key List; for non-key vertices, such as v_2, we compute its delta from v_0 and store it with 2-bit in the Delta List, recorded as v_2^δ. It is important to note that since there are numerous delta vertices but few key vertices, storing delta vertices with low precision effectively reduces the required bandwidth. Fig. 5(c) shows a specific example: with low-bit storage for deltas, the three distance calculations in our method require only 12 bits of memory loads, while the baseline approach requires 24 bits for the same calculations. Our method reduces memory overhead by 50%.

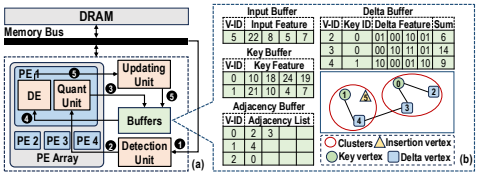

Fig. 6. Overview of (a) SAGA architecture; (b) Buffers (V-ID: Vertex ID).

C. Distance Calculation

Since we apply different bit widths for key and non-key vertices, the original distance calculation is no longer applicable, so we will discuss how to achieve distance calculation between insertion vertex v_{in} and both key and non-key vertices.

1. For key vertex v_j, we directly compute its distance to v_{in} by IP ($Dis_{IP}(v_{in}, v_j)$) or L2 ($Dis_{L2}(v_{in}, v_j)$). We store the distance in a partial sum table, indexed by v_j's ID, which will be used to avoid redundant computations for the same v_j.

2. For the non-key vertex v_i, the equations for the IP and L2 calculations are as follows:

$$Dis_{IP}(v_{in}, v_i) = Dis_{IP}(v_{in}, v_j) + Dis_{IP}(v_{in}, v_i^\delta) \quad (1)$$

$$\begin{aligned} Dis_{L2}(v_{in}, v_i) =& Dis_{L2}(v_{in}, v_j) - 2Dis_{IP}(v_{in} - v_j, v_i^\delta) \\ &+ Dis_{IP}(v_i^\delta, v_i^\delta) \end{aligned} \quad (2)$$

From the formulas, we see that the number of distance calculations increases from 1 to 2 (for the IP) and 3 (for the L2), which might seem to negate performance gains. Fortunately, we find that the distance calculations between v_{in} and v_i can be saved by reusing the distance between v_{in} and v_j ($Dis_{IP}(v_{in}, v_j)$ or $Dis_{L2}(v_{in}, v_j)$). Therefore, we retrieve $Dis_{IP}(v_{in}, v_j)$ or $Dis_{L2}(v_{in}, v_j)$ from the partial sum table and add it to the remaining terms in Eqn. 1 and Eqn. 2 to obtain the final result. Additionally, $Dis_{IP}(v_i^\delta, v_i^\delta)$ in the L2 distance calculation is also a constant value for each v_i^δ and can also be pre-computed during quantization.

D. Walk-Through Example

Fig. 5 also provides an example of how the SAGA algorithm integrates with the original construction process. Steps that remain unchanged are marked in grey, while steps improved by SAGA are highlighted in yellow. First, we perform the starting point selection, a step that remains unmodified. Next, SAGA leverages the results of the starting point selection for similarity detection, which in turn guides the similarity-aware quantization. Given the quantized vertices, SAGA calculates the distance based on whether a vertex is a key or a non-key vertex. Finally, the graph is updated based on the calculated distances. The above steps are repeated until all insertion vertices have been fully processed.

V. Proposed Hardware Design

A. Overview

To support our SAGA algorithm, we co-design a hardware architecture. Fig. 6(a) illustrates the overall architecture of SAGA, which includes several on-chip buffers, a Detection

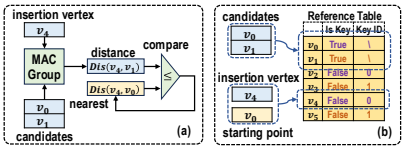

Fig. 7. Detection Unit for (a) starting point selection; (b) similarity detection.

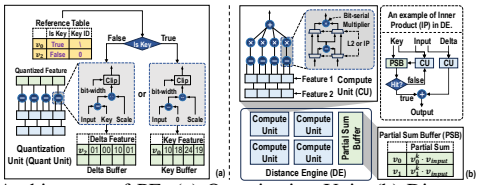

Fig. 8. Architecture of PE: (a) Quantization Unit; (b) Distance Engine.

Unit, an array of Processing Elements (PEs), and an Updating Unit. Each PE comprises a Quantization Unit (Quant Unit) and a Distance Engine (DE).

Dataflow. The dataflow in SAGA is also shown in Fig. 6(a), while the detailed buffer entries are illustrated in Fig. 6(b). ❶ To select the starting point, a batch of insertion vertices is transferred from DRAM to the Detection Unit via the memory bus. The Detection Unit then searches for the nearest starting point for each insertion vertex. ❷ In order to capture the similarity between vertices, the Detection Unit leverages the starting point information to generate a Reference Table, which stores whether each vertex is a key vertex and its Key ID. ❸ The Quant Unit performs quantization separately for key and non-key vertices and stores the features in Key Buffer and Delta Buffer, respectively. ❹ The DE retrieves the quantized features from Input Buffer, Key Buffer and Delta Buffer to compute distances. ❺ To update the constructed graph, the Updating Unit reads the distances computed by the DE, selects the top-K nearest vertices to the insertion vertex, and establishes bi-directional links in the Adjacency Buffer. The loop ❶ to ❺ repeats until the construction terminates.

B. Detection Unit

The Detection Unit is responsible for executing the starting point selection and similarity detection steps during the construction process. Fig. 7(a) illustrates how the Detection Unit selects starting points: given an insertion vertex, the Detection Unit uses a MAC group to compute its distance to all candidates and applies a comparator to select the nearest candidate as the insertion vertex's starting point. Fig. 7(b) depicts the similarity detection process. For candidates, the Detection Unit marks their Is Key identifiers as True. For insertion vertices, the Detection Unit sets their Is Key identifiers to False and records their starting point's ID as Key ID.

C. Processing Engine Array

The PE array of SAGA contains four PEs, each PE consists of a Quantization Unit and a Distance Engine.

Quantization Unit. The Quantization Unit (Quant Unit) is responsible for determining whether a vertex is a key vertex and performing its quantization. Fig. 8(a) depicts the architecture of the Quant Unit. The Quant Unit first determines whether a vertex is a non-key or key vertex based on the Is Key identifier recorded in the Reference Table. The Quant Unit then performs quantization and writes the quantized features into the corresponding buffer.

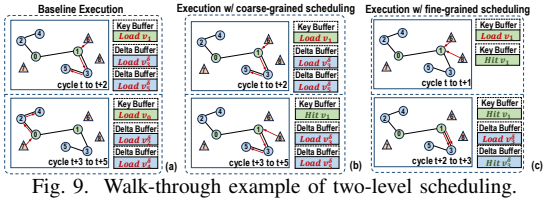

Fig. 9. Walk-through example of two-level scheduling.

Distance Engine. The Distance Engine (DE) is the most important component within the PE, responsible for computing the IP/L2 distances. As depicted in Fig. 8(b), each DE includes four Compute Units (CUs) dedicated to distance calculations and one Partial Sum Buffer (PSB). Each CU accepts two feature vectors as input and performs distance calculations based on the chosen metric (IP or L2); the PSB functions as a multi-way set-associative cache for storing reusable partial sums. Generally, a DE can simultaneously compute the distances for one insertion vertex and four neighboring vertices.

Based on the quantization algorithm outlined in Section IV-C, we will detail the distance calculations for both key and non-key vertices.

Key Vertex. When the insertion vertex requires a distance calculation with a key vertex, we retrieve v_{in} from the Input Buffer and v_j from the Key Buffer, then send them to the CU for the computation of the partial sum. Since vertices within the same cluster can reuse the partial sum, we store its value in the PSB and index it by the Key ID. If there is insufficient space in the PSB to accommodate the new partial sum, we identify an entry to evict according to the Least Recently Used (LRU) policy and replace it with the new partial sum.

Non-Key Vertex. According to Eqn. 1 and Eqn. 2, we trigger DE to compute $Dis_{IP}(v_{in}, v_i^\delta)$ or $Dis_{IP}(v_{in} - v_j, v_i^\delta)$. As for partial sum ($Dis_{IP}(v_{in}, v_j)$ or $Dis_{L2}(v_{in}, v_j)$), we first look it up in the PSB using the Key ID as an index. If it hits in PSB, we can retrieve the corresponding value; if it misses in PSB, we will compute the partial sum and store it in the PSB. At last, regarding the $Dis_{IP}(v_i^\delta, v_i^\delta)$ in Eqn. 2, we directly index it in the Sum column of Delta Buffer with V-ID.

Since key and delta features differ in bit width, we employ a bit-serial method in the CU to leverage the computational advantages of low bit width representation.

D. Updating Unit

The Updating Unit is used for sorting the distances and updating the graph accordingly. The Updating Unit receives the output from the DE and produces the top-K vertices with the smallest distances. To achieve this, Updating Unit employs a hardware implementation similar to that in [18], maintaining a minimum heap for up to one hundred input distances. After obtaining the top-K nearest vertices, the Updating Unit updates the corresponding entries in the Adjacency Buffer, completing the graph construction process.

E. Two-level Scheduling

In our previous design, we reduced storage and computational costs by lowering the bit width. However, due to the irregular memory access in construction, Key/Delta Buffers still encounter a high miss rate. Therefore, we propose a two-level scheduling that reorders vertex from both coarse-grained and fine-grained perspectives.

The coarse-grained scheduling rearranges the insertion order of the vertices, ensuring that vertices within the same cluster are executed sequentially. This is justified by the overlapping graph traversal paths of vertices in the same cluster. After coarse-grained scheduling, the fine-grained scheduling continues to reorder the access order of vertices. Considering that the reusable entries of insertion vertices in the Key/Delta Buffers may be evicted due to capacity constraints, we propose interleaving the distance computation for insertion vertices.

We then provide a walk-through example to illustrate the benefits of applying two-level scheduling. Fig. 9(a) shows the situation without scheduling, revealing poor locality in the Key/Delta Buffers. Fig. 9(b) illustrates the result of coarse-grained scheduling, where we reordered v_7 and v_8. This allows similar vertices v_6 and v_8 to be executed sequentially. It is evident that the coarse-grained scheduling strategy transforms v_8's access to v_1 from a miss to a hit, thereby improving the locality of the Key Buffer. However, due to the constrained capacity of the Delta Buffer, reusable entries (v_3^δ and v_5^δ) still get evicted, leading to a high miss rate in the Delta Buffer. Fig. 9(c) demonstrates the effect of applying both coarse-grained and fine-grained scheduling, where we interleave the distance calculations for v_6 and v_8, allowing for reuse of results in the Delta Buffer. With fine-grained scheduling, we make v_1 hit in Key Buffer and v_3^δ hit in Delta Buffer, demonstrating fine locality in both the Delta and Key Buffers.

VI. Evaluation

A. Experiment Methodology

Benchmark and datasets. We evaluated SAGA on HNSW [12], the most representative and widely cited GANN algorithm. The evaluation was conducted on five datasets from the ANN-benchmark [19]: sift [17], deep1M [20], deep10M [20], fashion-mnist [21], and gist [22]. For each dataset, we use the recommended parameter settings and distance metrics from the ANN-benchmark during construction.

Experiment Setup. To model the behavior of SAGA, we build a cycle-accurate simulator. We implement and synthesize the digital logic circuits at the 28nm technology node with 500MHz using Synopsys Design Compiler. The on-chip buffers are evaluated using CACTI 7.0 [23] with a 32nm technology node, and we use the DeepScaleTool [24] to scale the results down to 28nm. For CPU and GPU, we selected FAISS [25] and cuhnsw [26] libraries as implementations of HNSW. We use an Intel Xeon Gold 6226 CPU running at 2.0GHz as the baseline for the CPU, and an A100 GPU with 80GB VRAM as the baseline for the GPU. To compare SAGA with previous GANN accelerators, we selected the state-of-the-art NDSearch [15] as a baseline. As GANN iteratively updates the graph during construction, the BFS introduced by NDSearch must be re-executed after each update. Since NDSearch does not incorporate additional hardware to support BFS, we implemented BFS on the CPU using the high-performance kernel from GAP [27]. To ensure a fair comparison, we scaled NDSearch's compute units and buffers under the same area budget as SAGA.

TABLE I
Comparisons with NDSearch (FP32) and SAGA (CR: Compression Ratio).

Dataset	Config	Accuracy	Average Bits	CR
sift [17]	NDSearch	96.0±2.0%	32	1×
	SAGA	94.2±2.1%	2.19	14.63×
gist [22]	NDSearch	94.7±2.0%	32	1×
	SAGA	93.4±2.4%	2.07	15.48×
deep1M [20]	NDSearch	95.3±2.0%	32	1×
	SAGA	94.2±2.4%	2.36	13.52×
deep10M [20]	NDSearch	95.9±1.6%	32	1×
	SAGA	94.6±2.1%	2.43	13.18×

	SAGA	96.1±1.4%	2.29	13.97×

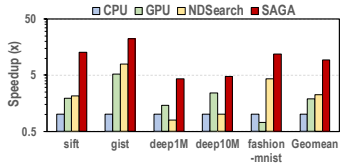

Fig. 10. The speedup of SAGA over CPU, GPU and NDsearch.

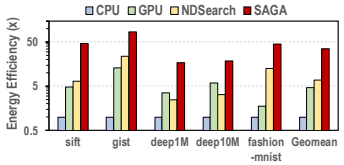

Fig. 11. The energy efficiency of SAGA over CPU, GPU and NDsearch.

B. Accuracy

In TABLE I, we present a comparison of accuracy and compression ratio between our method and NDSearch across various datasets. Extensive experiments demonstrate that our approach achieves a high compression ratio while maintaining accuracy. We leveraged the value-level similarity between vertices by using high-bitwidth representations for critical key vertices, while employing low-bitwidth representations for the majority of non-key vertices. This approach achieves a well-balanced trade-off between accuracy and compression ratio.

C. Overall Results

Speedup Fig. 10 illustrates the speedup of SAGA. Generally, SAGA achieves an average speedup of 9.30×, 4.87× and 4.14× over CPU, GPU and NDSearch. In comparison with CPU, SAGA manifests the benefits of customized architecture, which offers higher bandwidth utilization and better on-chip buffer locality. Compared to GPU, although they offer high throughput, GANN construction is not a compute-centric application, which leads to low utilization of the GPU cores. For example, in the fashion-mnist dataset, we observe that the GPU performance is even lower than the CPU. Additionally, SAGA outperforms the state-of-the-art GANN accelerator NDSearch because our quantization method achieves a higher

TABLE II
AREA AND POWER COMPARISON BETWEEN SAGA AND NDSEARCH.

-	SAGA		
	Config	Area (mm^2)	Power (mW)
Detection Unit	1×(32-bit)	0.19	5.51
Distance Engine	4×(bit-serial)	0.35	97.73
Quant Unit	4×(8-bit)	0.07	21.72
Updating Unit	1×(8-bit)	0.03	5.43
On-chip Buffers	320KB	0.62	197.34
Overall	-	**1.26**	**327.73**
-	NDSearch		
	Config	Area (mm^2)	Power (mW)
Detection Unit	1×(32-bit)	0.19	5.51
Distance Engine	512 MACs(32-bit)	0.58	173.75
Quant Unit	-	-	-
Updating Unit	1×(32-bit)	0.12	21.71
On-chip Buffers	320KB	0.64	202.40
Overall	-	**1.53**	**403.37**

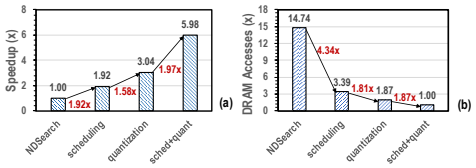

Fig. 12. The contribution of each method to (a) the improvement of performance and (b) the DRAM access reduction on the sift dataset.

compression ratio (see Table I). Moreover, we observe that the BFS operations performed by NDSearch introduce significant overhead. In the deep1M experiment, NDSearch even fails to outperform the CPU baseline, with BFS accounting for 77% of its execution time. Therefore, NDSearch is not well-suited for dynamic construction processes.

Energy Efficiency. Fig. 11 shows the energy efficiency of SAGA. For energy efficiency, SAGA offers an average energy efficiency of 35.48×, 7.60× and 5.15× over CPU, GPU and NDSearch. Thanks to SAGA's quantization algorithm, it achieves higher bandwidth utilization, significantly reducing the overall DRAM access time. Additionally, SAGA's scheduling algorithm enhances the locality of on-chip buffers and further reduces the volume of DRAM read and write, leading to substantial energy savings in memory access.

Area and Power. The area and power consumption of SAGA are summarized in Table II. SAGA utilizes only a small number of computational engines and units, as GANN construction is not a compute-intensive task. Compared to NDSearch, SAGA maintains the same buffer capacity but can store more data due to its lower bit width representations, significantly enhancing locality. Note that SAGA achieves a 17.65% reduction in area and an 18.75% reduction in power compared to NDSearch. This is attributed to SAGA's low-bitwidth hardware design, whereas NDSearch is designed for full precision.

D. Detailed Analysis

Ablation study. We conduct the ablation study on the proposed methods, including two-level scheduling (*scheduling*), similarity-aware quantization (*quantization*) and the combination of scheduling and quantization (*sched+quant*), which is the final version of SAGA. Fig. 12(a) illustrates the performance improvements achieved by SAGA's methods. As shown in the figure, SAGA achieves a 1.92× speedup due to enhanced buffer locality enabled by *scheduling*. SAGA also achieves a 3.04× speedup by leveraging lower bit width for storage using *quantization*. Finally, when combing *scheduling* and *quantization*, SAGA achieves a remarkable 5.98× speedup. Fig. 12(b) further demonstrates SAGA's improvement in DRAM accesses, our proposed methods achieve DRAM reductions of 4.34×, 7.88× and 14.74×, respectively.

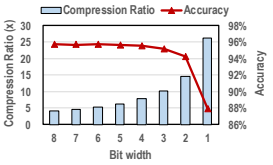

Fig. 13. Compression ratio (higher is better) and accuracy (higher is better) compared with NDSearch under different bit widths on the sift dataset.

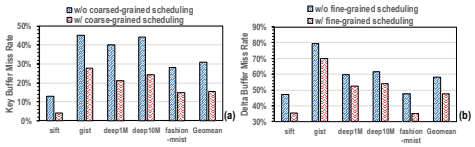

Fig. 14. The effect of scheduling in (a) Key Buffer miss rate (lower is better) and (b) Delta Buffer miss rate (lower is better).

Parameter Trade-off. In SAGA, we need to determine the bit width for deltas to balance the compression ratio and accuracy. Note that the key vertex is represented using 8-bit. As shown in Fig. 13, when the bit width decreases, SAGA achieves higher compression ratio, reaching up to 26.26× when the bit width is 1. However, the accuracy in this case drops significantly to 87.9%, which is unacceptable. Therefore, we select 2-bit for deltas, achieving a compression ratio of 14.63× while maintaining a high accuracy of 94.2%.

Scheduling. To evaluate the two-level scheduling, we explore the impact of coarse/fine-grained scheduling on the Key/Delta Buffers, respectively. Fig. 14 verifies that both coarse/fine-grained scheduling can effectively reduce miss rates of the two buffers. This improvement is due to the enhanced temporal locality of vertex accesses.

VII. CONCLUSION

In this paper, we propose SAGA, the first accelerator to leverage similarity to address the memory-bound challenges in GANN construction. To capture similarity, we first introduce a similarity detection algorithm that clusters vertices based on their starting points. Next, to reduce storage overhead, we propose a similarity-aware quantization algorithm that quantizes the deltas of similar vertices to lower bit width. We design a hardware architecture and develop a two-level scheduling algorithm to optimize locality in buffers. Experimental results demonstrate that SAGA achieves an average 4.15× speedup and 5.15× energy efficiency compared to the state-of-the-art NDSearch, with negligible accuracy loss.

***Abstract*—With low latency and collision-free communication, wavelength-routed optical networks-on-chip (WRONoC) become an effective solution to the growing demands for multi-core communications. Microring resonators (MRRs), the primary optical components in WRONoC, are susceptible to process variation. Under process variation, the MRR's transmission spectrum shifts, results reduced signal power and increased crosstalk. However, the impacts caused by process variation have not yet been considered in WRONoC designs. In this work, we propose a methodology to optimize the MRR radii and signal wavelengths to counter process variation. Specifically, we construct analytical models of expected signal power under MRR process variation and develop optimization methods to maximize the expected signal transmission power in WRONoC. Results show up to 7.51 dB improvement in worst-case expected signal transmission power compared to designs that do not consider process variation.**

***Index Terms*—Wavelength-routed optical networks-on-chip, design optimization, process-variation-aware**

I. Introduction

With the development of silicon photonics, optical networks-on-chip (ONoCs) become an effective solution to the growing demand for inter-core communications in multiprocessor systems-on-chip (MPSoCs) [1], [2]. With the wavelength-division multiplexing technology, a single waveguide can carry multiple optical signals on different wavelengths, providing high bandwidths [3], [4]. Wavelength-routed optical networks-on-chip (WRONoC) is a promising type of ONoC. On WRONoCs, all signal paths are fixed during the design phase, which eliminates the overhead for dynamic allocation paths and allows all initiators and targets to communicate simultaneously without data conflicts [5], [6].

The primary WRONoC components for signal routing are microring resonators (MRRs). An MRR consists of a looped waveguide and a coupling mechanism. Optical signals on different wavelengths can be coupled to different MRRs in the network and directed to different transmission paths. The coupling degree depends on the MRR radius and the signal wavelength [7], [8]. If the optical path circumference of an MRR is an integer multiple of the wavelength of a signal, the signal will be maximally coupled to the MRR, referred to as being *on-resonance* with the MRR. An MRR can resonate with multiple wavelengths, and these wavelengths are referred to as the *resonant wavelengths* of that MRR. On the other hand, signals on wavelengths other than the resonant wavelengths of an MRR will be hardly coupled to the MRR, referred to as being *off-resonance* with the MRR. Fig. 1(a) illustrates

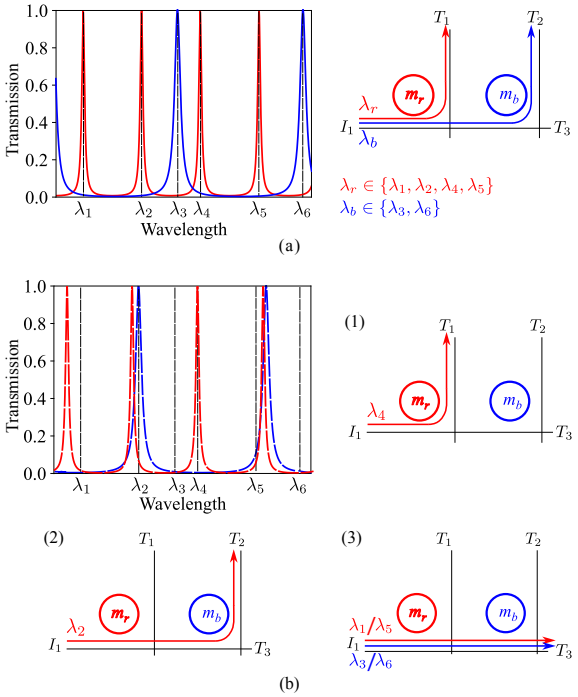

Fig. 1. (a) MRR coupling mechanism without process variation. Peaks of the red and blue spectra represent the resonant wavelengths of m_r and m_b, respectively. (b) MRR coupling mechanism considering process variation. (1) λ_4 is on-resonance with m_r despite the process variation. (2) λ_2 becomes on-resonance with m_b instead of m_r due to the process variation. (3) λ_1, λ_3, λ_5, and λ_6 become off-resonance with both m_r and m_b due to the process variation.

the coupling mechanism. The red and blue circles represent two MRRs of different radii, denoted as m_r and m_b, the transmission spectra of which are represented as red and blue curves. In particular, λ_1, λ_2, λ_4, λ_5 are on-resonance with m_r and off-resonance with m_b. λ_3, λ_6 are on-resonance with m_b and off-resonance with m_r. Thus, to send a signal from initiator I_1 to target T_1, we can modulate the signal on wavelength λ_1, λ_2, λ_4, or λ_5. To send a signal from I_1 to T_2, we can modulate the signal on wavelength λ_3 or λ_6.

However, MRRs are susceptible to process variation, which leads to changes in their radii and transmission spectra [9]. Fig. 1(b) illustrates an example of the shifts of the MRR transmission spectra due to the changes of the radii of m_r and m_b resulting from the process variation. Specifically, the influences of process variation on different wavelengths and

MRRs are different. For example, λ_4 remains on-resonance with m_r despite the process variation, as shown in Fig. 1(b)(1). However, λ_2, which was supposed to be on-resonance with m_r, becomes on-resonance with m_b instead, leading to the signal being misdirected to T_2 instead of T_1, resulting in crosstalk at this unintended destination, as shown in Fig. 1(b)(2). Also, λ_1, λ_3, λ_5, and λ_6, which were supposed to be on-resonance with m_r or m_b, are off-resonance with both m_r and m_b under process variation, and become crosstalk in the network, as shown in Fig. 1(b)(3). The example shows that different wavelengths and MRR radii react differently to process variation, and the wavelengths assigned to different signal paths and the radii assigned to different MRRs interact and thus need to be optimized to find robust radius and wavelength configurations under process variations.

Several approaches have been proposed to deal with the process variation in the MRR. [9] and [10] propose methods to adjust the physical design parameters of MRR to reduce the power loss as signals enter the MRR. Similarly, [11] introduces a sparse combined generalized polynomial chaos (gPC) model for analyzing the uncertainty and optimizing the design parameters of a five-ring coupled resonator filter under process variation, thereby enhancing the robustness. However, these studies are limited to adjusting the parameters of only one type of MRR for a specific signal wavelength range near 1550 nm. They cannot comprehensively optimize the parameters of all MRRs in a network. Besides, they do not consider common WRONoC communication scenarios in which an MRR may be passed by multiple signals, and a signal may pass through multiple MRRs along its path. Considering the process variation that may occur in WRONoC, [12] and [13] suggest adding backup MRRs to improve network reliability. However, this approach inevitably results in signals passing through additional MRRs, thereby increasing insertion loss.

In this work, we propose the first analytical model to characterize the expected signal transmission efficiency under process variation given different MRR radii and signal wavelengths. Based on the analytical model, we propose an integer linear programming (ILP) method to optimize the selection of MRR radii and signal wavelengths to maximize the worst-case transmission efficiency of all signals in the network. Since the complexity of the ILP problem is NP-hard, we further develop a WRONoC-tailored simulated annealing algorithm to efficiently approximate the global optimum. Experimental results show that our method can significantly improve the expected network performance and make WRONoCs more robust against process variation.

II. Background

There are two common optical switching elements: One is the parallel switching element (PSE), in which two waveguides are placed in parallel at the top and bottom of the ring. The other is the crossing switching element (CSE), where the waveguides are crossed orthogonally, and a ring is placed near the crossing waveguides. When a signal enters the switching element from the input port, a portion of its power will be coupled to the MRR and delivered to the drop port, while the remaining portion will exit the MRR via the through port. An MRR is designed to be a **drop MRR** if a signal is on-resonance and maximally transmitted to its drop port. Conversely, it is designed to be a **through MRR** if a signal is off-resonance and maximally transmitted to its through port. The portion of the signal power at the expected port is defined as the signal **transmission efficiency** at that MRR. For a given MRR radius r, and a given signal wavelength λ, the transmission efficiency of the signal at a drop or through MRR, denoted as $H_d(r,\lambda) \in [0,1]$ or $H_t(r,\lambda) \in [0,1]$, can be computed as follows [7]:

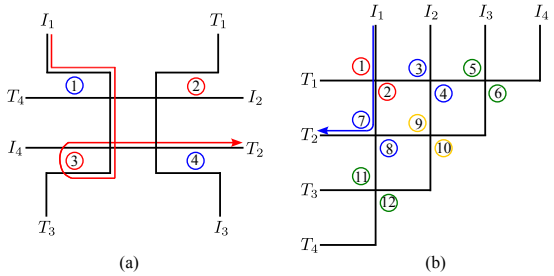

Fig. 2. WRONoC topologies with four ports. (a) Light Topology. The red line represents a signal path from initiator I_1 to T_2. (b) Snake Topology. The blue line highlights a signal path from initiator I_1 to T_2.

$$H_d(r,\lambda) = \frac{k^4}{1 - 2t^2 cos(\phi(r,\lambda)) + t^4} \tag{1}$$

$$H_t(r,\lambda) = 1 - H_d(r,\lambda) \tag{2}$$

where t and k denote the self-coupling and the cross-coupling coefficients with $t^2 + k^2 = 1$, and $\phi(r,\lambda)$ denotes the signal-pass phase shift [14], calculated as:

$$\phi(r,\lambda) = \beta(\lambda) 2\pi r \tag{3}$$

$$\beta(\lambda) = \frac{(2.57 - 0.85(\lambda \cdot 10^6 - 1.55))2\pi}{\lambda} \tag{4}$$

where $\beta(\lambda)$ is the propagation constant [14].

A WRONoC topology can be defined by a set $\mathcal{I}$ of initiators, a set $\mathcal{T}$ of targets, a set $\mathcal{P} \subseteq \mathcal{I} \times \mathcal{T}$ of signal paths, and a set $\mathcal{M}$ of MRRs. For a signal path $p \in \mathcal{P}$, we use $\mathcal{TM}_p \subseteq \mathcal{M}$, $\mathcal{DM}_p \subseteq \mathcal{M}$, and $\mathcal{M}_p = \mathcal{TM}_p \cup \mathcal{DM}_p$ to represent the set of through MRRs, drop MRRs and total MRRs along p, respectively. We also denote c_p as the number of waveguide crossings in p. Two representive topologies, Light [6] and Snake [15], are shown in Fig. 2.

Example 2.1: Fig. 2(a) shows a Light topology [6] with $\mathcal{I} = \{I_1, I_2, I_3, I_4\}$, $\mathcal{T} = \{T_1, T_2, T_3, T_4\}$, $\mathcal{P} = \{(I_1, T_2), (I_1, T_3), \cdots, (I_4, T_3)\}$, and $\mathcal{M} = \{m_1, m_2, m_3, m_4\}$. The signal path $(I_1, T_2) \in \mathcal{P}$ can be described with $\mathcal{TM}_{(I_1,T_2)} = \{m_1, m_4\}$, $\mathcal{DM}_{(I_1,T_2)} = \{m_3\}$, $\mathcal{M}_p = \{m_1, m_3, m_4\}$ and $c_{(I_1,T_2)} = 4$.

For each signal path, the portion of the signal power received by the target is defined as the signal **transmission efficiency of the path**, denoted as H_p. For a given signal on wavelength λ, H_p can be calculated based on the transmission

efficiency of the signal at the MRRs and the waveguide crossings along the path:

$$H_p = (1-cl)^{c_p} \prod_{m\in\mathcal{DM}_p} H_d(r_m,\lambda) \prod_{m\in\mathcal{TM}_p} H_t(r_m,\lambda) \quad (5)$$

where cl denotes the crossing loss parameter, r_m denotes the radius of MRR m and c_p denotes the waveguide crossing number in p.

III. Analytical Model of the Expected Signal Transmission Efficiency

MRRs are sensitive to process variations, under which the radii may change, leading to shifts in the transmission spectra. Consequently, the transmission efficiency of the signal path will also be varied.

Based on the fact that photonic circuit fabrication is non-uniform and that the fabrication data can be fit to a normal distribution [16]–[18], we model the radius of an MRR as a normally distributed random variable $R \sim N(r, (\eta\cdot r)^2)$, where $r \in \mathbb{R}^+$ is the mean value serving as the nominal radius of the MRR, η is the relative error resulting from the process variation, and $\eta \cdot r$ is the standard deviation. The **expected signal transmission efficiency**, which is the expected value of the signal transmission efficiencies at various possible radii of an MRR, weighted by their respective probabilities in the normal distribution, can be then modeled. The expected signal transmission efficiency at the drop or through port of the MRR can be denoted as $\mathbb{E}[H_d(R,\lambda)]$ or $\mathbb{E}[H_t(R,\lambda)] \in [0,1]$. To derive these, we need the following theorem [19]:

Theorem 3.1: The expected value of a non-negative continuous random variable X can be computed as $\mathbb{E}(X) = \int_0^\infty (1-F_X(x))\,dx$ with cumulative distribution function (CDF) $F_X(x) = P(X \le x)$, where $P(X \le x)$ is the probability of $X \le x$.

We denote $H_d(R,\lambda)$ as X, and the CDF of $H_d(R,\lambda)$ as $F_X(x)$, which can be calculated based on equation (2) as:

$$\begin{aligned} F_X(x) &= P\left(H_d(R,\lambda) \le x\right) \\ &\overset{(4)}{=} P(\cos(2\pi R\beta(\lambda)) \le (1-k^4/x+t^4)/(2t^2)). \end{aligned} \quad (6)$$

For convenience, we denote $\frac{1-\frac{k^4}{x}+t^4}{2t^2}$ as $g(x)$. Thus:

$$\begin{aligned} F_X(x) &= \sum_{n\in\mathbb{Z}} P\left(2n\pi + \arccos(g(x)) \le 2\pi R\beta(\lambda) \le \right. \\ &\qquad \left. 2(n+1)\pi - \arccos(g(x))\right) \\ &= \sum_{n\in\mathbb{Z}} (P(R \le (2\pi(n+1) - \arccos(g(x)))/(2\pi\beta(\lambda))) \\ &\qquad - P(R \le (2n\pi + \arccos(g(x)))/(2\pi\beta(\lambda)))). \end{aligned} \quad (7)$$

According to [19], the CDF of $R \sim N(r,(\eta\cdot r)^2)$ can be denoted as $P(R \le y) = \Phi\left(\frac{y-r}{\eta\cdot r}\right)$, where $y \in \mathbb{R}$ and Φ denotes the CDF of the standard normal distribution $Z \sim N(0,1)$. Therefore, we obtain

$$\begin{aligned} &P(R \le (2\pi(n+1) - \arccos(g(x)))/(2\pi\beta(\lambda))) \\ &= \Phi(((2\pi(n+1) - \arccos(g(x)))/(2\pi\beta(\lambda)) - r)/(\eta\cdot r)), \end{aligned}$$

$$P(R \le \frac{2n\pi + \arccos(g(x))}{2\pi\beta(\lambda)}) = \Phi(\frac{\frac{2n\pi+\arccos(g(x))}{2\pi\beta(\lambda)} - r}{\eta\cdot r})$$

which implies that

$$\begin{aligned} F_X(x) = \sum_{n\in\mathbb{Z}} [&\Phi((\frac{2\pi(n+1)-\arccos(g(x))}{2\pi\beta(\lambda)} - r)/(\eta\cdot r)) \\ &- \Phi((\frac{2n\pi+\arccos(g(x))}{2\pi\beta(\lambda)} - r)/(\eta\cdot r))]. \end{aligned} \quad (8)$$

We know that $x \in [k^4/(2-k^2)^2, 1]$ from equation (2). Thus, according to Theorem 3.1, we can calculate $\mathbb{E}[H_d(R,\lambda)]$ as:

$$\begin{aligned} \int_{\frac{k^4}{(2-k^2)^2}}^1 (1 - \sum_{n\in\mathbb{Z}} [&\Phi((\frac{2(n+1)\pi-\arccos(g(x))}{2\pi\beta(\lambda)} - r)/(\eta\cdot r)) \\ &- \Phi((\frac{2n\pi+\arccos(g(x))}{2\pi\beta(\lambda)} - r)/(\eta\cdot r))])\,\mathrm{d}x. \end{aligned} \quad (9)$$

To determine the range of n in the equations above, we first reference equation (7), which establishes $2n\pi + \arccos(g(x)) \le 2\pi R\beta(\lambda) \le 2(n+1)\pi - \arccos(g(x)))$. Given that the range of function $arccos$ within its domain is $[0,\pi]$, it follows that the maximum possible range of $2\pi R\beta(\lambda)$ is $2n\pi \le 2\pi R\beta(\lambda) \le 2(n+1)\pi$. From this, we derive the bounds for n as $R\beta(\lambda) - 1 \le n \le R\beta(\lambda)$. Considering R as a random variable requires the full range of its possible values to be considered. The three-sigma rule of a normal distribution states that 99.7% of the values for R fall within $[r-3\eta r, r+3\eta r]$ [20]. To include a broader range of possibilities, we extend this range to $[r-6\eta r, r+6\eta r]$, thus estimating the range of n as $[\lfloor(r-6\eta r)\beta(\lambda)-1\rfloor, \lfloor(r+6\eta r)\beta(\lambda)\rfloor]$. We divide the integration domain into 1000 equal subintervals and use the Left Riemann Sum to approximate the expected value.

Next, we need another theorem from [19] to calculate $\mathbb{E}[H_t(R,\lambda)]$:

Theorem 3.2: Let X and Y be two random variables, then $\mathbb{E}[X+Y] = \mathbb{E}[X] + \mathbb{E}[Y]$.

According to Theorem 3.2 and equation (2):

$$\begin{aligned} &\mathbb{E}[H_t(R,\lambda)] + \mathbb{E}[H_d(R,\lambda)] = \mathbb{E}[H_t(R,\lambda) + H_d(R,\lambda)] = 1. \\ &\mathbb{E}[H_t(R,\lambda)] = 1 - \mathbb{E}[H_d(R,\lambda)]. \end{aligned} \quad (10)$$

Subsequently, the expected transmission efficiency of a signal path, denoted by $\mathbb{E}[H_p]$, can be calculated as

$$(1-cl)^{c_p} \prod_{m\in\mathcal{DM}_p} \mathbb{E}[H_d(R_m,\lambda)] \prod_{m\in\mathcal{TM}_p} \mathbb{E}[H_t(R_m,\lambda)] \quad (11)$$

where $R_m \sim N(r_m, (\eta\cdot r_m)^2)$.

Finally, we define the **worst-case expected transmission efficiency**, denoted as $\mathbb{E}[H_w]$, as follows:

$$\mathbb{E}[H_w] = \min\{\mathbb{E}[H_p] | p \in \mathcal{P}\}. \quad (12)$$

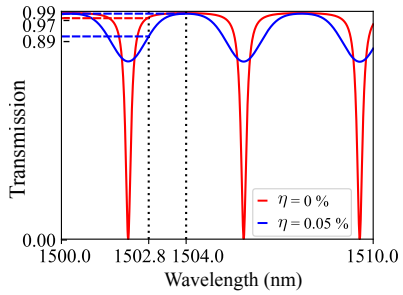

Fig. 3. Transmission efficiencies of signals on different wavelengths at the through port of an MRR.

IV. Problem Formulation

The expected signal transmission efficiency may differ given different combinations of MRR radii and signal wavelengths.

Example 4.1: As an example, Fig. 3 illustrates the transmission efficiency of signals in the wavelength range $\lambda \in [1500\,\text{nm},\ 1510\,\text{nm}]$ with a step size of $0.01\,\text{nm}$ at the through port of an MRR with a nominal radius of $25\,\mu\text{m}$, i.e. $r = 25 \cdot 10^{-6}$. The red curve represents the transmission efficiency calculated based on the nominal radius without considering process variation, i.e., $H_t(r, \lambda)$; and the blue curve represents the approximate expected transmission efficiency considering process variation, i.e., $\mathbb{E}[H_t(R, \lambda)]$, with $\eta = 0.05\%$, $R \sim N(r, (\eta r)^2)$ and $k = 0.4$ [10]. We highlight two signals on wavelengths $1502.8\,\text{nm}$ and $1504\,\text{nm}$. While both signals exhibit high transmission efficiency with $H_t(r, 1502.8 \cdot 10^{-9}) = 97\%$ and $H_t(r, 1504 \cdot 10^{-9}) = 99\%$ without considering process variation, the expected transmission efficiency $\mathbb{E}[H_t(R, 1502.8 \cdot 10^{-9})]$ drops to 89%, while $\mathbb{E}[H_t(R, 1504 \cdot 10^{-9})]$ remains at 99%. Thus, $1504\,\text{nm}$ is a more robust signal wavelength for a through MRR with $25\,\mu\text{m}$ nominal radius under process variation.

In this work, we propose to optimize the selections of MRR radii and signal wavelengths in a WRONoC topology to maximize the worst-case expected transmission efficiency, which determines the minimum laser power required to support the desired communications and is thus considered the most critical design factor. Therefore, we formulate the optimization problem as follows:

Input: (1) A WRONoC topology. (2) A range of MRR radii. (3) A range of signal wavelengths. (4) The relative error η. (5) The crossing loss coefficient cl. (6) The cross-coupling coefficient k.

Output: (1) The nominal radius of every MRR in the topology. (2) The wavelength used in every signal path.

Maximize: Worst-case expected transmission efficiency $\mathbb{E}[H_w]$.

V. Methods

To prepare for the optimization, we construct a set $\mathcal{R}$ of MRR nominal radii options and a set Λ of signal wavelengths options based on the input ranges and the step size between two options. Next, for each combination of the MRR nominal radius $r \in \mathcal{R}$ and for each signal wavelength $\lambda \in \Lambda$, we calculate the expected transmission efficiency of the signal at the drop or through port of the MRR in dB, denoted as $\mathbb{E}[H_d(R, \lambda)]_{\text{dB}}$ or $\mathbb{E}[H_t(R, \lambda)]_{\text{dB}}$, with $R \sim N(r, (\eta \cdot r)^2)$, based on our analytical model:

$$\mathbb{E}[H_d(R, \lambda)]_{\text{dB}} = 10 \log_{10} \mathbb{E}[H_d(R, \lambda)] \tag{13}$$

$$\mathbb{E}[H_t(R, \lambda)]_{\text{dB}} = 10 \log_{10} \mathbb{E}[H_t(R, \lambda)]. \tag{14}$$

A. Integer Linear Programming

We propose an integer linear programming method to formally model the optimization problem.

1) Radii and Wavelengths Assignment: We introduce a binary variable $b_{m,r}^{p,\lambda}$ for each signal path $p \in \mathcal{P}$ in the input topology, each MRR $m \in \mathcal{M}_p$ in path p, each nominal radius option $r \in \mathcal{R}$ and each wavelength option $\lambda \in \Lambda$ to represent whether the transmission efficiency of the signal in path p at MRR m should be calculated based on λ and r, with the following constraint:

$$\forall p \in \mathcal{P}\ \forall m \in \mathcal{M}_p : \sum_{r \in \mathcal{R}} \sum_{\lambda \in \Lambda} b_{m,r}^{p,\lambda} = 1. \tag{15}$$

2) Consistent Wavelength Selection: A signal path may involve multiple MRRs, and the transmission efficiency at different MRRs along the path should be calculated based on the same wavelength. In other words, if a wavelength is used for the calculation of the transmission efficiency at any MRR along the path, the same wavelength will also be used for the calculation of the transmission efficiency at other MRRs along the path. This can be modelled with the following constraint, where $m_p \in \mathcal{M}_p$ can be arbitrarily selected from $\mathcal{M}_p$:

$$\forall p \in \mathcal{P}\ \forall \lambda \in \Lambda\ \forall m \in \mathcal{M}_p \setminus \{m_p\} : \sum_{r \in \mathcal{R}} b_{m,r}^{p,\lambda} = \sum_{r' \in \mathcal{R}} b_{m_p,r'}^{p,\lambda}. \tag{16}$$

3) Consistent Radii Selection: An MRR m can appear in multiple signal paths, and the transmission efficiency at the same MRR in different signal paths should be calculated based on the same radius. Similar to Section V-A2, we introduce the following constraint, where $\mathcal{P}_m \subseteq \mathcal{P}$ denotes the set of signal paths that involve m, and p_m can be arbitrarily selected from $\mathcal{P}_m$:

$$\forall m \in \mathcal{M}\ \forall r \in \mathcal{R}\ \forall p \in \mathcal{P}_m \setminus \{p_m\} : \sum_{\lambda \in \Lambda} b_{m,r}^{p,\lambda} = \sum_{\lambda' \in \Lambda} b_{m,r}^{p_m,\lambda'}. \tag{17}$$

4) Expected Transmission Efficiency: For each $p \in \mathcal{P}$ and for each $m \in \mathcal{M}_p$, we introduce a continuous variables $v_{p,m} \in [-100, 0]$ to represent the expected transmission efficiency in dB at MRR m in path p with the following constraints:

$$\forall p \in \mathcal{P}\ \forall m \in \mathcal{DM}_p : v_{p,m} = \sum_{r \in \mathcal{R}} \sum_{\lambda \in \Lambda} (b_{m,r}^{p,\lambda} \mathbb{E}[H_d(R, \lambda)]_{\text{dB}}) \tag{18}$$

$$\forall p \in \mathcal{P}\ \forall m \in \mathcal{TM}_p : v_{p,m} = \sum_{r \in \mathcal{R}} \sum_{\lambda \in \Lambda} (b_{m,r}^{p,\lambda} \mathbb{E}[H_t(R, \lambda)]_{\text{dB}}). \tag{19}$$

We further introduce a continuous variable $v_w \in [-100, 0]$ to represent the worst-case expected transmission efficiency with the following constraints:

$$\forall p \in \mathcal{P} : v_w \leq c_p \cdot (1 - cl)_{\text{dB}} + \sum_{m \in \mathcal{M}_p} v_{p,m} \qquad (20)$$

where $(1 - cl)_{\text{dB}} = 10 \log_{10}(1 - cl)$ is the crossing loss in dB.

Thus, the optimization model can be formulated as follows:

$$\textbf{Maximize:} \quad v_w \ ; \ \textbf{Subject to:} \quad (15) - (20).$$

Notably, we use the existing topology, which defines all signal paths and the positions of drop and through MRRs. Our model automatically assigns optimal wavelengths to each path to maximize v_w, preventing signal paths from using the same wavelength when overlapping in waveguide sections.

B. WRONoC-Tailored Simulated Annealing

The NP-hard complexity of integer linear programming makes it difficult to find the optimal solution for large problems. Therefore, we develop a simulated annealing algorithm to approximate the optimal solution in an efficient manner. We denote the number of initial solutions as N_i, the initial temperature as T_i, the current temperature as T_c, and the cooling rate as α. Additionally, for each MRR, we define $\Lambda_{d,r}$ and $\Lambda_{t,r}$ as the sets of resonant and non-resonant wavelengths satisfying $H_d(r, \lambda) \geq \theta_1$ and $H_t(r, \lambda) \geq \theta_2$, where r is the nominal radius of the MRR, and θ_1 and θ_2 are the thresholds of the acceptable signal transmission efficiency at the drop or through port of the MRR. Optimization stops if either: (1) The maximum iteration number N_m is reached, or (2) $\mathbb{E}[H_w]$ does not change in N_s consecutive iterations. After the optimization, we calculate the $\mathbb{E}[H_w]$ in dB, denoted as $\mathbb{E}[H_w]_{\text{dB}}$, based on the following model: $\mathbb{E}[H_w]_{\text{dB}} = 10 \log_{10} \mathbb{E}[H_w]$.

Each initial solution is prepared as follows:

- $\forall m \in \mathcal{M}$, we assign a random radius, denoted as r_m.
- $\forall p \in \mathcal{P}$, we create a set Λ_p of candidate wavelengths with $\Lambda_p = (\bigcap_{m \in \mathcal{DM}_p} \Lambda_{d,r_m}) \cap (\bigcap_{m \in \mathcal{TM}_p} \Lambda_{t,r_m})$. If $\Lambda_p = \emptyset$, it implies that there is no available wavelength that can satisfy the efficiency threshold. In this case, we let $\Lambda_p = \bigcap_{m \in \mathcal{DM}_p} \Lambda_{d,r_m}$. We iterate Λ_p and calculate the expected transmission efficiency, i.e., $\mathbb{E}[H_p]$ on each $\lambda \in \Lambda_p$, and select the one that gives the highest transmission efficiency as the initial wavelength of p, denoted as λ_p.

In the k^{th} solution of our simulated annealing algorithm, we first identify the path with the worst expected transmission efficiency, denoted as p_w^k and $\mathbb{E}[H_{p_w}^k]$, respectively. Then, among $\mathcal{M}_{p_w^k}$, we identify the MRR with the worst expected transmission efficiency, denoted as m_w^k. Next:

- A new radius for m_w^k is chosen randomly from the radii options, denoted as $r'_{m_w^k}$.
- $\forall p^k \in \mathcal{P}_{m_w^k}$, we re-calculate their expected transmission efficiency and select a new wavelength with the same method for preparing the initial solution, denoted as λ'_{p^k}.
- Based on the new calculations, we identify the path with currently worst transmission efficiency, denoted as ${p_w^k}'$ and $\mathbb{E}[H_{p_w}^k]'$, respectively.
- If $\mathbb{E}[H_{p_w}^k]' > \mathbb{E}[H_{p_w}^k]$, we accept the new solution, i.e. we update the radius of m_w^k as $r'_{m_w^k}$, the wavelength of p_w^k as $\lambda'_{p_w^k}$, and the expected transmission efficiency $\mathbb{E}[H_{p_w}^k]$ as $\mathbb{E}[H_{p_w}^k]'$. If $\mathbb{E}[H_{p_w}^k]' \leq \mathbb{E}[H_{p_w}^k]$, the new solution is accepted with a probability $P_k = \mathbb{E}[H_{p_w}^k]' \cdot T_c$.
- After each iteration, the highest $\mathbb{E}[H_{p_w}^k]$ of all solutions is denoted as $\mathbb{E}[H_w]$. N_s is incremented by one if $\mathbb{E}[H_w]$ is unchanged compared to the previous iteration; otherwise, N_s is reset to zero. In the early stages, the algorithm searches all solutions to ensure that no potential optimization opportunities are missed. After several iterations, some solutions with low worst-case expected transmission efficiency are discarded.
- The current temperature T_c decreases based on the cooling schedule α.

VI. Optimization Results

A. Inputs and Parameter Settings

We implement our approach in C++ and run the optimization on an Apple M1 Pro 10-core CPU. We consider two well-known WRONoC full-connectivity topologies: Light [6], Snake [15] as input, where each node has a path for signal transmission with other nodes. Different than Light, a node in Snake also has a signal transmission path to itself. Additionally, we consider two application-specific topologies as input: CustomTopo [3] and FAST [21], where nodes without data transmission requirements are not interconnected. We consider the input MRR radii range as $[5\,\mu\text{m}, 30\,\mu\text{m}]$, and the wavelengths range as $[1500\,\text{nm}, 1600\,\text{nm}]$. We also tested different relative errors with $\eta = 0.01\%$, 0.05%, and 0.1%.

Since the simulated annealing (SA) algorithm is a stochastic optimization method, its solution quality is inherently uncertain. Therefore, we first solved the ILP model, which guarantees global optimal solutions, as a benchmark for evaluating the SA algorithm in small topologies. For the ILP model, we prepare 101 MRR radii options ($\mathcal{R}$) within the input range, with $0.25\,\mu\text{m}$ steps, and 126 wavelength options (Λ) within the input range, with $0.8\,\text{nm}$ steps. A wavelength $\lambda \in \Lambda$ is considered on-resonance with an MRR of radius $r \in \mathcal{R}$ if $H_d(r, \lambda) \geq 0.995$. We exclude MRR radii that cannot resonate with any wavelengths from $\mathcal{R}$ and signal wavelengths off-resonance with every MRR radius from Λ, resulting in 38 valid radii options and 33 valid wavelength options. Due to the high complexity of the ILP problem, we only consider 4-node topologies and solve the model with Gurobi [22]. For the SA algorithm, we prepare 1001 MRR radii options in the input radii range with a $0.025\,\mu\text{m}$ step between each option and 1001 wavelengths options in the input wavelength range with a $0.1\,\text{nm}$ step between each option. It took approximately 6 hours to prepare the expected values for the $1001 \cdot 1001 = 1002001$ radius-wavelength combinations under four relative errors. These are one-time calculations and are not repeated in subsequent steps. From the 50^{th} to the 140^{th} iteration in the SA experiment, five poor-quality solutions are discarded every ten iterations. Thus, after the

TABLE I
INPUT PARAMETERS

Parameter	Description	Value
k	Cross-coupling coefficient	0.4 [10]
t	Self-coupling coefficient	$\sqrt{0.84}$
cl	Crossing loss coefficient	0.009168 [6]
T_i	Initial temperature	1
N_i	Number of initial solutions	100
α	Cooling rate	0.99
θ_1	Selection criterion for $\Lambda_{\mathrm{d},r}$	0.85
θ_2	Selection criterion for $\Lambda_{\mathrm{t},r'}$	0.85
N_s	Consecutive number of no improvement	1000
N_m	Maximum number of iterations	3000

140^{th} iteration, only five high-quality solutions continue to be optimized until the algorithm reaches one of its stopping conditions. Other input parameters are shown in Table I.

Two experimental designs are set up for the comparative analysis. The first design, referred to as the **nominal design**, maximizes the worst-case signal transmission efficiency without considering process variation (i.e., $\eta = 0$). The second design, referred to as **variation-aware design**, maximizes the worst-case expected signal transmission efficiency considering process variation (i.e., $\eta \neq 0$). Then, using the optimally selected MRR radii and signal wavelengths of the nominal design, the expected transmission efficiencies of the signals through the MRRs affected by a given relative error are calculated, and their minimum value is determined and denoted as Nom. $\mathbb{E}$. This is then compared to the worst-case expected signal transmission efficiency under the variation-aware design with the same relative error, termed Var. $\mathbb{E}$. To ensure experimental fairness, both designs use the same initial solutions for the same topology scale under all relative errors in the SA algorithm. The results are shown in Table II and III.

B. Results Discussion

1) Designs: The worst-case expected transmission efficiencies under variation-aware designs are consistently greater than those under nominal designs with the same relative error. As shown in "Diff.", the optimization effect of the variation-aware design becomes more pronounced as the relative error increases. Even with a relative error of only 0.01%, the variation-aware design improves the worst-case expected transmission efficiencies in the range of $0.81\,\mathrm{dB}$ to $1.78\,\mathrm{dB}$. As the error increases, the variation-aware design improves the expected transmission efficiency by up to $7.51\,\mathrm{dB}$. This indicates that our strategy can effectively maximize the expected transmission efficiency.

2) Algorithms: The differences between the optimized expected transmission efficiencies of the SA algorithm and the ILP model are insignificant for the same topological scale and relative error. In all cases, the SA algorithm provides even superior optimized expected transmission efficiencies due to the wider range of optimization options available. Thus, we can consider the results of our WRONoC-tailored SA algorithm in larger-scale topologies under process variation to be reliable.

3) Optimization Time: The optimization time under nominal and variation-aware design is similar for the same network topology and scale. However, the ILP method generally takes much longer than the SA algorithm, except for the Light 4×3 topology with few MRRs. For 8-node and 16-node topologies, the ILP model fails to find the optimal solution within 10 hours. The SA algorithm can find high-quality solutions in 4-node topologies in two minutes, 8-node topologies in ten minutes, and 16-node topologies in only 36 minutes. This confirms that the SA algorithm can efficiently find a design resistant to process variation.

T.: the optimization time.

VII. CONCLUSION

In this work, we propose a stochastic optimization strategy to maximize the expected signal transmission efficiency of a given WRONoC topology under process variation. Distinct from existing solutions, we accurately evaluate the effects of variation using probability theory. We then construct an ILP model and validate it through a suite of small-scale topologies. To expand the scale of optimization and shorten the optimization time, we developed a WRONoC-tailored simulated annealing algorithm. Compared to the optimization results without considering process variation, our approach can improve the worst-case expected signal transmission efficiency by up to $7.51\,\mathrm{dB}$ and thus provide more robustness of WRONoC under process variation.

***Abstract*—Modern deep learning models, such as Relation Graph Convolutional Network (RGCN), Sparse Convolutional Networks (SpConv), and Mixture of Experts Networks (MoE), are significantly dependent on the (gather-matmul-scatter)$_s$ (abbreviated as (g-mm-s)$_s$) workload as their fundamental computational pattern. While existing works have made optimization attempts, several critical challenges remain unsolved, including domain-specific optimization migration, time-consuming exploration, and inefficient dataflow with dynamic inputs.**

To address these challenges, we introduce Efficient-GMS, a comprehensive framework that enhances (g-mm-s)$_s$ workload across diverse input scenarios. Our framework introduces (1) A Fusion-aware framework enabling cross-model optimization migration. We propose a comprehensive dataflow analysis that identifies shared computational patterns across models, enabling the development of four optimized dataflow patterns with vertical and horizontal fusion strategies. (2) Performance model-guided configuration space reduction. We develop a performance model to predict the relative execution efficiency across configurations, thereby reducing the search space and minimizing search time while ensuring optimal configuration selection. (3) Adaptive dataflow selection mechanism. We implement a lightweight heuristic model that dynamically selects optimal dataflow patterns based on the characteristics of the input and the hardware. Experimental results demonstrate that Efficient-GMS achieves significant performance gains, delivering an average end-to-end speedup of 1.46× in RGCN model, 1.32× in SpConv-based model, and 1.15× in MoE model compared to state-of-the-art methods.

***Index Terms*—gather, scatter, matmul**

I. Introduction

The advancement of deep learning models has enabled us to address complex relationships and patterns in irregular data. Examples include Relational Graph Convolutional Networks (RGCN [19], [29], [31]), Sparse Convolutional Networks (SpConv [12], [23]–[25]), and Mixture of Experts (MoE [7], [15]). These models, which support a wide range of applications from social network analysis [10], [13], [16], [26] to natural language processing [5], [14], [21], share a core computational pattern: (gather-matmul-scatter)$_s$ (abbreviated as (g-mm-s)$_s$), where the subscript "s" indicates the plural form.

The (g-mm-s)$_s$ workload represents a unified abstraction of core computations across these models. It consists of three key operations: (1) "gather", which collects features from relevant sources (e.g., neighboring nodes in RGCN, non-zero elements in SpConv, or expert components in MoE); (2)"matmul", which transforms these features through learnable weight matrices; and (3) "scatter", which distributes the updated results to appropriate destinations. This pattern, though conceptually straightforward, presents significant implementation challenges due to its varied forms across different models.

Although (g-mm-s)$_s$ captures the core computations of these models, traditional implementation methods often struggle to efficiently execute (g-mm-s)$_s$ in models with irregular structures, such as graphs with multiple relationships. For example, in RGCN, when PyG [8] executes the computation flow, it processes each set of gather, matmul, and scatter operations sequentially. This approach is inefficient due to indirect memory access and the challenges of fully utilizing parallel processing resources. Some studies [6], [22], [32], focus on optimizing multiple matmuls within the workload; however, they neglect the inter-operator relationships across the entire workload. Consequently, the performance improvements of the optimized models are limited.

Based on our analysis, we identify three fundamental challenges in optimizing (g-mm-s)$_s$:

- **Domain-specific optimization hindering cross-model migration**. Current optimization techniques are often designed for specific models, and applying these strategies to different models can result in significant performance differences. In some cases, directly using these techniques can cause severe performance drops—for example, applying the SpConv strategy to an RGCN model on the BGS dataset results in a 9.61× decrease in performance.
- **Time-consuming exploration within large configuration space**. The configuration space for operators within (g-mm-s)$_s$ workload is extensive, often encompassing thousands to even tens of thousands of possible configurations. Traditional approaches demand significant search time (up to 3000 seconds) to identify the optimal configuration. Furthermore, directly specifying configurations based on heuristic rule may result in suboptimal performance outcomes.
- **Inefficient static dataflow with dynamic inputs**. Traditional static optimization methods struggle with dynamic inputs, leading to inefficiencies with varying data characteristics. Performance varies widely across dataflow patterns, yet current systems lack the ability to dynamically select the most efficient pattern. Our experiments show that poor dataflow selection can cause up to a 14.77× performance degradation under varying workloads.

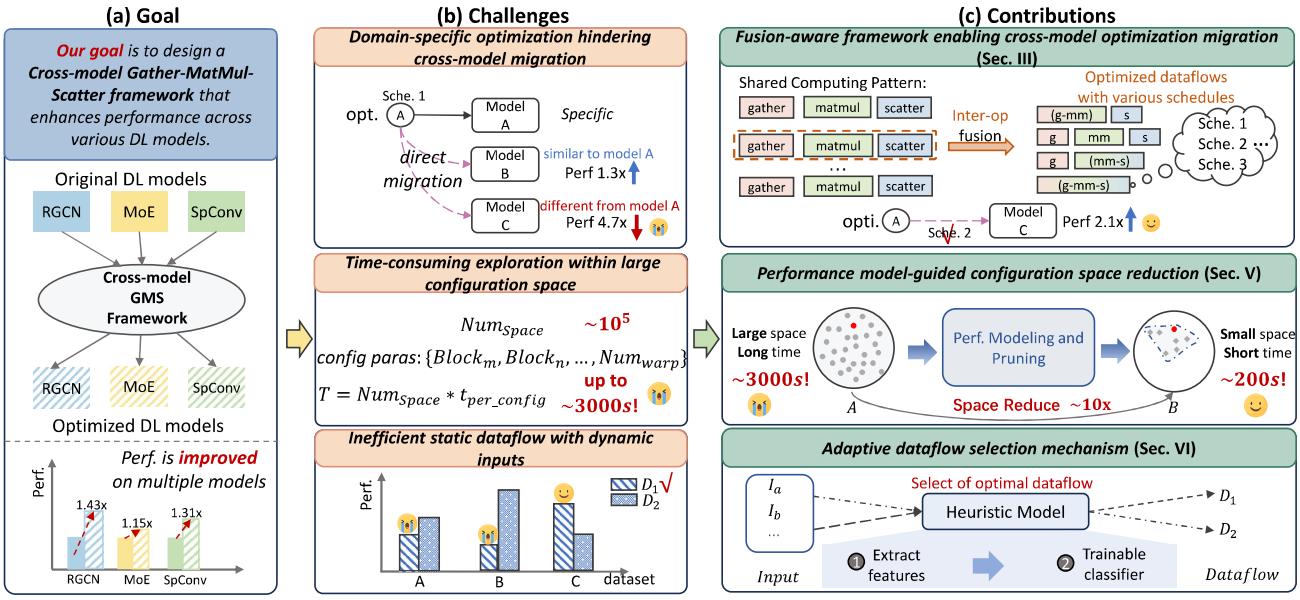

Fig. 1. Overview of Efficient-GMS, cross-model gather-matmul-scatter framework that enhances performance across various DL models.

To address these challenges, we present an efficient (g-mm-s)$_s$ framework with the following key contributions:

- **Fusion-aware framework enabling cross-model optimization migration**. We develop a comprehensive optimization framework that identifies fundamental computational workload shared by different models. By analyzing the commonalities of workloads, we present four optimized dataflow patterns that combine fusion strategies and implement optimal scheduling strategies for different inputs. This approach achieves stable performance improvements from 1.43× to 1.86× in different models.
- **Performance model-guided configuration space reduction**. We develop a performance model based on parallel efficiency and the compute-to-memory access ratio that predicts the relative execution efficiency for each configuration, significantly reduces the search space by 60% to 90% while ensuring optimal configuration selection, and achieves a 5.26× reduction in average search time.
- **Adaptive dataflow selection mechanism**. We propose a lightweight heuristic model that dynamically selects optimal dataflow patterns based on input and hardware characteristics. This approach delivers 1.67× to 6.03× performance improvement compared to static implementations, effectively addressing the dynamic input challenge.

In conclusion, we introduce Efficient-GMS, a comprehensive framework designed to enhances (g-mm-s)$_s$ workload across models and tasks. Experimental results demonstrate that our approach achieves an average speedup of **1.73**× and **1.52**× on the (g-mm-s)$_s$ kernel for RGCN and SpConv-based model, respectively. Furthermore, the end-to-end acceleration effects are significant, with average speedups of **1.43**×, **1.31**×, and **1.15**× on RGCN, SpConv-based model, and MoE tasks, respectively.

II. Background

Relational Graph Convolutional Networks (RGCN), Sparse Convolutional Networks (SpConv), and Mixture of Expert Models (MoE) have emerged as sophisticated computational frameworks for tackling complex tasks in diverse domains. RGCNs excel at capturing relationships in graph-structured data [17], [18], SpConvs efficiently process sparse data like 3D point clouds [1], [27], and MoEs leverage specialized subnetworks to handle different input patterns [14], [30]. While seemingly disparate, these models share an underlying computational theme: they all adaptively aggregate information from a selective subset of the input. In this section, we introduce these three models, focus on their dataflow and demonstrating their adherence to the (g-mm-s)$_s$ workload.

A. Relational Graph Convolutional Network (RGCN)

RGCN [19] extends the gather-matmul-scatter pattern to handle multi-relational graph data. During gathering, it collects information from neighboring nodes based on the graph's connectivity, considering different edge types as distinct relations. The matmul stage applies relation-specific weight matrices to transform the gathered information, enabling the network to learn relation-dependent feature representations. The scatter stage combines transformed information across all relations through summation, producing updated node representations that capture the graph's relational structure.

B. Sparse Convolutional Network

Sparse-based networks [12] implement an efficient gather-matmul-scatter pattern for sparse data like 3D point clouds. The gather stage collects features from neighboring points within a geometrically defined receptive field (e.g., sphere or cube). The matmul stage applies learned filters to gathered features, performing convolution in sparse space while computing only active points. The scatter stage aggregates these convolved features through summation, updating the

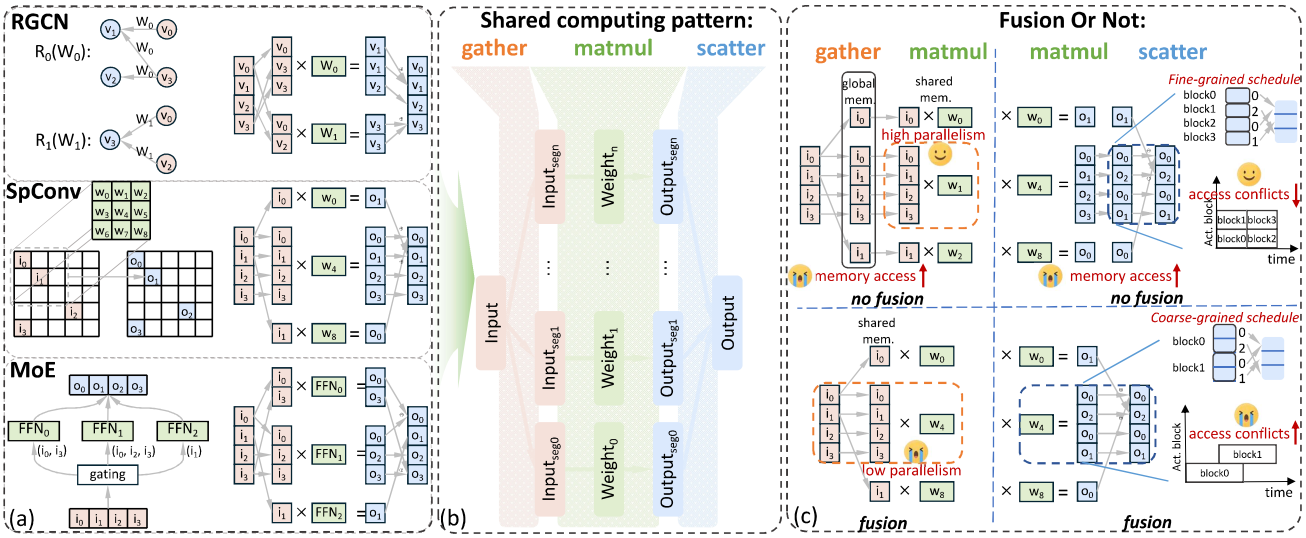

Fig. 2. (a). We demonstrate corresponding dataflows in RGCN, SpConv and MoE model. (b). gather-matmul-scatter is the shared computing pattern among three models. (c). Analyzing the advantages and disadvantages of fusion between operators.

central point's representation while maintaining computational efficiency through sparsity exploitation.

C. Mixture of Expert Model

MoE architectures [7], [15] adapt the gather-matmul-scatter pattern to ensemble learning. The gather stage employs a gating network that routes inputs to appropriate expert subsets. In the matmul stage, selected experts process inputs in parallel, each applying specialized computations. The scatter stage combines expert outputs through gating-weighted aggregation, producing final predictions that leverage multiple specialized networks. This architecture enables efficient scaling by activating only relevant experts for each input.

III. Fusion-aware framework enabling cross-model optimization migration

A. Motivation

The optimization techniques developed for various deep learning models demonstrate notable potential for cross-model applicability. For instance, the gather-matmul-scatter fusion used in SpConv can be adapted to RGCN's feature aggregation, while RGCN's segmentation-based computation strategy can benefit expert computation in Mixture of Experts (MoE). Experiments demonstrate notable performance gains from such migrations; for example, RGCN's feature aggregation on the IMDB dataset achieves a 4.64× speedup using SpConv's strategy.

B. Challenge

Despite the variety of optimization methods, most implementations remain domain-specific. Direct migration often leads to instability due to differences in model implementation details and data performance characteristics. For example, applying the operator fusion strategy to RGCN on the BGS dataset results in a 9.61× performance drop.

C. Insight

Our analysis reveals that seemingly diverse models share a fundamental (g-mm-s)$_s$ computational workload. This commonality enables the construction of a unified optimization framework, dynamically guiding strategy migration across models based on operator and data characteristics. Experiments validate the framework's efficacy, achieving stable performance improvements between 1.15× and 1.46× across various models.

D. Approach

We propose a **systematic optimization framework for (g-mm-s)$_s$ workload** and thoroughly analyze potential optimization methods in both vertical and horizontal dimensions. **Vertically**, parallel operator scheduling focuses on enhancing hardware utilization by combining small-scale gather, matmul, or scatter operations into larger ones. Inspired by segment-matmul methods [32], parallel scheduling of fused matmul operations significantly boosts performance. **Horizontally**, inter-operator fusion analyzes the interrelationships among gather, matmul, and scatter to refine four fundamental dataflows: $G-M_{seg}-S$, executing operators independently; $(GM)_{seg}-S$, combining gather and matmul; $G-(MS)_{seg}$, merging matmul and scatter; and $(GMS)_{seg}$, fully integrating all three operators. At the same time, the above four dataflows are executed based on guaranteeing parallel operator scheduling, and the subscript in the dataflow represents that the operator organizes operations in the way of the segment. These dataflows provide a versatile optimization framework adaptable to varying workloads and hardware architectures. Fusion can enhance data locality and reduce overhead, though it may increase memory access conflicts, affecting efficiency. By evaluating hardware characteristics, input data, and computational workload, the framework enables the dynamic selection of optimal dataflow, achieving significant performance gains across diverse computational scenarios.

E. Op Fusion Analysis

The fusion of gather and matmul operators involves a trade-off, especially for large-scale computations. Independent operators often outperform fused implementations by leveraging

enhanced parallelism. Separating gather operations enables concurrent processing across thread blocks, decoupling irregular memory access from structured matrix multiplication and maximizing GPU parallelism. This design also allows dynamic resource allocation and avoids bottlenecks seen in fused implementations.

For the fused $(MS)_{seg}$ kernel, performance suffers from atomic write conflicts during scatter operations. While fusion improves data reuse and reduces memory accesses, handling more rows per block increases conflicts, extending execution time. Separating matmul and scatter mitigates these conflicts, offering greater configurability and improved efficiency.

IV. Performance Model-guided Configuration Space Reduction

A. Motivation

The selection of configuration parameters in the dataflow directly determines computational efficiency, making configuration space optimization crucial for performance enhancement. In the (g-mm-s)$_s$ workload, gather operations involve non-contiguous memory access, matmul requires effective resource scheduling, and scatter entails complex data distribution. Parameters such as block size, affecting data locality, and thread allocation, influencing parallelism, are critical. Suboptimal configurations can degrade memory access efficiency and under-utilize computational resources.

B. Challenge

The optimization of configuration space is challenging due to its high dimensionality and interdependent parameters. In the (g-mm-s)$_s$ pattern, parameters like tile sizes ($Block_M$, $Block_N$, $Block_K$) influence data partitioning, while thread counts (Num_{warp}) control parallelism. These parameters are interrelated: larger tiles improve data reuse but limit parallelism, while more threads increase parallelism but risk resource contention. Input variations, such as sparsity and data scale, further complicate configuration needs, expanding the space to tens of thousands of possibilities. Exhaustive searches, taking thousands of seconds, are thus impractical.

C. Insight

Our key insight is that **configuration parameters and performance indicators can be quantitatively characterized,** forming a foundation for efficient optimization. Configuration parameters primarily impact performance through parallelism and memory access efficiency: tile size influences data locality and cache usage, while thread allocation affects resource utilization. These relationships are predictable and quantifiable, enabling theoretical modeling to evaluate configuration effects without execution. This facilitates the rapid identification of optimal configurations.

D. Approach

To address these challenges, we propose a novel approach for **optimization configuration through coarse-grained performance modeling**. As shown in Fig. 3(b), The proposed model evaluates the relative execution efficiency under various configurations while keeping the computational overhead

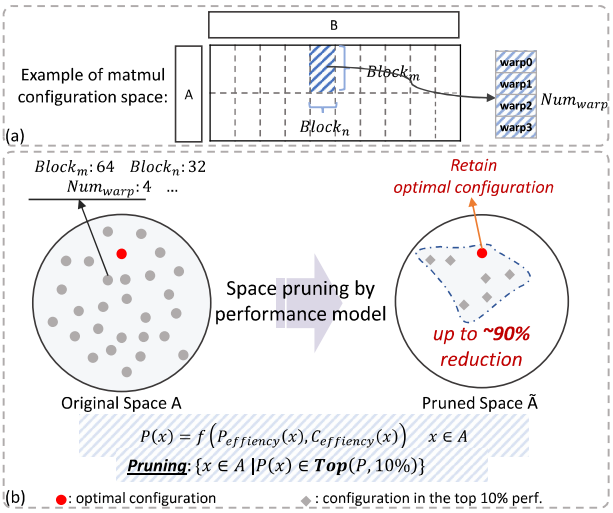

Fig. 3. (a).Example configuration space for matmul, which explains the meaning of the three configurable parameters (b). Performance-guided configuration space reduction.

minimal by analyzing the parallel efficiency and compute-to-memory efficiency of the operators under the current input. Subsequently, configurations within space $\mathcal{A}$ are ranked and pruned to generate a reduced configuration space $\mathcal{B}$, comprising approximately 10% to 40% of the original space. The system then executes configurations exclusively within space $\mathcal{B}$ on the kernel, selecting the configuration with optimal average execution time, thus substantially reducing the optimization process duration.

Taking the $(GM)_{seg}$ operator as an example, its performance can be modeled as follows:

$$P = (1 - \text{Pall}_{\text{efficiency}}) \cdot (1 - \text{Comp}_{\text{efficiency}})$$
$$\text{Comp}_{\text{efficiency}} = T_{\text{comp}} / (T_{\text{load}} + T_{\text{store}} + T_{\text{comp}})$$
$$\text{Pall}_{\text{efficiency}} = N_{\text{blk}} / \left(\lceil N_{\text{blk}} / N_{\text{max_act_blk}} \rceil \cdot N_{\text{max_act_blk}}\right)$$
$$N_{\text{blk/sm}} = \min\left(\text{shm}_{\text{max}} / \text{shm}_{\text{required}}, N_{\text{thread/sm}} / (\text{warp} \cdot 32)\right)$$
$$N_{\text{max_act_blk}} = N_{\text{blk/sm}} \cdot N_{\text{sm}}$$
$$T_{\text{comp}} = 2MNK / \text{PeakFLOPS}$$
$$T_{\text{store}} = (\text{st_bytes/sm} \cdot N_{\text{max_act_blk}} \cdot \lceil N_{\text{blk}} / N_{\text{max_act_blk}} \rceil) / \text{L2_bw}$$
$$T_{\text{load}} = T_{\text{load_A}} + T_{\text{load_B}}$$
$$T_{\text{load}_{A/B}} = \frac{\text{bytes}_{A/B}}{(1 - \text{L2_hit}_{A/B}) \cdot \text{dram_bw} + \text{L2_bw} \cdot \text{L2_hit}_{A/B}}$$

The modeling process for other operators is similar to that of $(GM)_{seg}$. Additionally, we utilize a caching mechanism to associate optimal configurations with their corresponding data characteristics. This enables direct retrieval of optimal configurations when encountering similar data characteristics, eliminating the need for redundant search processes.

V. Adaptive Dataflow Selection Mechanism

A. Motivation

Dynamically selecting the optimal dataflow pattern is essential to optimize the performance of the (g-mm-s)$_s$ framework. Experimental results demonstrate that no single dataflow pattern consistently achieves optimal performance across diverse input characteristics. This performance variance is primarily driven by the dynamic changes in input data attributes, such as data scale, sparsity, and access patterns,

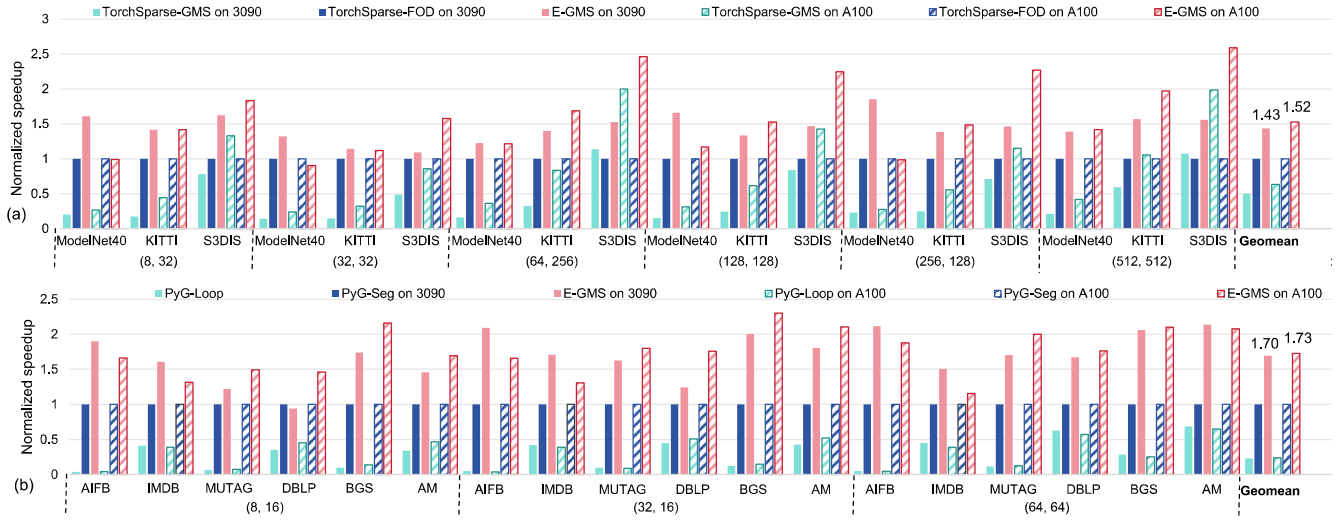

Fig. 4. Kernel performance. (a) kernel performance comparison between E-GMS and Torchsparse on the point cloud datasets. (b) kernel performance comparison between E-GMS and PyG on the heterogeneous graphs.

all of which significantly affect the execution efficiency of dataflow. Consequently, it is crucial to design a mechanism that dynamically selects the most suitable dataflow based on the specific input characteristics.

B. Challenge

Traditional static optimization strategies are not efficient in dynamic scenarios. Existing methods typically rely on predefined heuristic rules or fixed optimization approaches, which make it difficult to adjust the optimization strategy in time when facing input data features, leading to significant performance fluctuations. As shown in Fig. 8, selecting a static dataflow pattern can result in performance degradation of up to 14.77×.

C. Insight

A critical insight reveals **that dataflows exhibit different relative performances on different data**. Our analysis reveals two critical characteristics of dataflow performance: (1) the $(GM)_{seg} - S$ and $(GMS)_{seg}$ dataflows outperform other patterns in most cases, collectively accounting for 96.50% of optimal cases (52.50% and 44.00%, respectively); and (2) while $G - M_{seg} - S$ or $G - (MS)_{seg}$ may achieve optimal performance in rare scenarios (2.75% and 0.75% of cases, respectively), their advantages are marginal, with a maximum performance gap of 1.06×. These findings simplify dataflow selection by focusing on $(GM)_{seg} - S$ and $(GMS)_{seg}$, ensuring effective performance optimization while reducing selection complexity.

D. Approach

To address dynamic dataflow selection in the $(\text{g-mm-s})_s$ workload, we propose an **adaptive machine learning framework** leveraging **Singular Value Decomposition (SVD)** for dimensionality reduction and an XGBoost classifier for dataflow selection. Simple features, such as input-output dimensions, undergo standardization, while complex mapping features are processed using SVD to retain essential features. The framework merges these features into a unified vector, preserving interpretability and core mapping information. The best data flow is predicted by a trained XGBoost classifier. Supporting $(GM)_{seg} - S$ and $(GMS)_{seg}$ modes, the framework dynamically selects efficient dataflow, enabling real-time performance optimization.

VI. Evaluation

A. Experimental Setup

Our evaluation platform comprises NVIDIA GeForce RTX 3090 and A100 (80GB) GPUs, testing three key architectures: sparse point cloud models (SparseResNet [4]) with sparse convolution, heterogeneous graph neural networks (RGCN), and Mixture of Experts models (Misture-8x7B). Comparisons include Torchsparse implementations with gather-matmul-scatter and fetch-on-demand dataflows for point cloud models, PyG implementations using for-loop and segment-matmul for RGCN and HuggingFace implementation for MoE models. We utilize standard datasets: KITTI [11], ModelNet40 [28], and S3DIS [2] for point clouds, and AIFB, MUTAG, BGS, AM [20], IMDB [3], DBLP [9] for heterogeneous graphs.

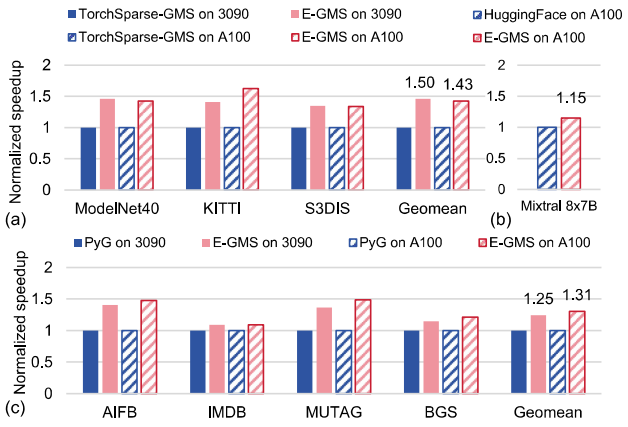

Fig. 5. End to end performance. (a)Performance comparison between E-GMS and Torchsparse on the point cloud datasets. (b)Performance comparison between E-GMS and PyG on the heterogeneous graphs.

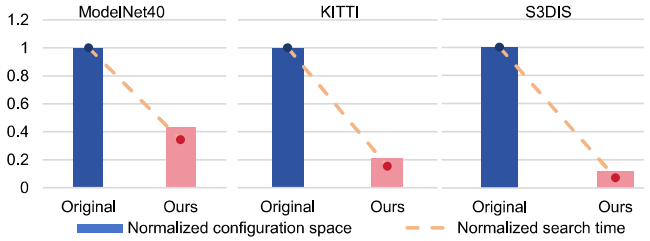

Fig. 7. Configuration space reduce and search time speedup

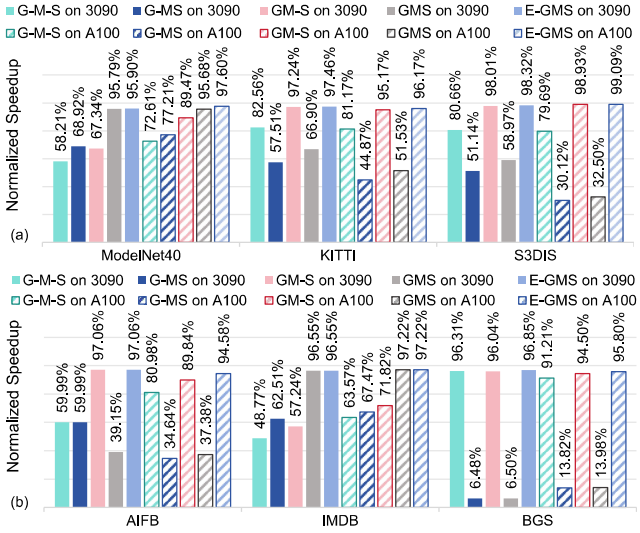

Fig. 8. Heuristic-model performance

B. Overall Performance

End-to-end Performance. We evaluated the end-to-end performance of our proposed Efficient-GMS (E-GMS) method and the state-of-the-art baseline engines across three different scenarios, as shown in Fig. 5. The results show that on the SpConv-based models, E-GMS achieves an average speedup of 1.43× and 1.46× with respect to TorchSparse-FOD on RTX 3090 and A100, respectively. On RGCN, E-GMS achieves an average speedup of 1.25× and 1.32× on RTX 3090 and A100 compared to PyG, respectively. On MoE, E-GMS achieves an average speedup of 1.15× compared to HuggingFace on A100. Notably, E-GMS achieves higher speedups over TorchSparse-FOD and PyG on A100 in two scenarios. This can be attributed to E-GMS's superior GPU utilization, which results in higher performance gains on more powerful GPUs.

Kernel Performance. We further evaluate the kernel performance of GMS operations, showcasing the effectiveness of E-GMS by varying input and output channel sizes for each dataset. We set six and three different channel sizes $(c_{\text{in}}, c_{\text{out}})$ for point cloud and RGCN model, respectively. The results are shown in Fig. 4. E-GMS achieves an average arithmetic speedup of 1.44× and 5.25× over TorchSparse-FOD and TorchSparse-GMS using the segment-matmul method on RTX 3090, respectively. On A100, these values are 1.60× and 2.58×, respectively. In particular, E-GMS achieves a peak speedup of 2.59× over TorchSparse-FOD on large channel size (i.e., (512, 512) on A100), with $(GM)_{seg} - S$ being the optimal dataflow configuration. For the RGCN model, E-GMS achieves an average arithmetic speedup of 14.05× and 1.7× compared to PyG-Loop and PyG-Seg on RTX 3090, respectively. Similarly, on A100, E-GMS provides speedups of 13.78× and 1.76×, showing its efficiency across different hardware platforms.

C. Ablation Study

Fusion-aware framework enabling cross-model optimization migration. As illustrated in Fig. 6, our approach outperforms the direct cross-model method, achieving an average performance improvement of 1.86× on point cloud and a 1.43× speedup on heterogeneous graphs on A100. These results demonstrate efficient scheduling of our method across diverse input types. **Performance model-guided configuration space reduction**. Fig. 7 highlights the efficiency of our performance model. For the GMS_{Seg} operator on the point cloud, the performance model reduces the configuration space by 60%–90% and achieves an average search time reduction of 5.26×, with a notable 13.89× reduction on large-scale datasets. **Heuristic Adaptive Dataflow**. Fig. 8 shows that the heuristic adaptive dataflow shows significant performance benefits, achieving 1.14× to 1.67× speedup on RTX 3090 and 1.03× to 2.23× on A100 for point cloud scenarios. RGCN scenarios show even more substantial improvements, with 1.23× to 6.03× speedup on RTX 3090 and 1.14× to 3.70× on A100, validating the effectiveness of our adaptive approach.

VII. Conclusion

In conclusion, this paper introduced Efficient-GMS, a comprehensive framework designed to enhances $(\text{g-mm-s})_{\text{s}}$ workload across models and tasks. By incorporating fusion-aware optimization, performance model-guided configuration selection, and an adaptive dataflow mechanism, Efficient-GMS successfully improves the workload under diverse input scenarios and hardware configurations. Our experimental results demonstrate that our approach achieves an average speedup of **1.73**× and **1.52**× on the $(\text{g-mm-s})_{\text{s}}$ kernel for RGCN and SpConv-based networks, respectively. Furthermore, the end-to-end acceleration effects are significant, with average speedups of **1.43**×, **1.31**×, and **1.15**× on RGCN, SpConv-based networks, and MoE tasks, respectively. We believe that the insights and techniques can benefit all tasks that fit in $(\text{g-mm-s})_{\text{s}}$ abstraction.

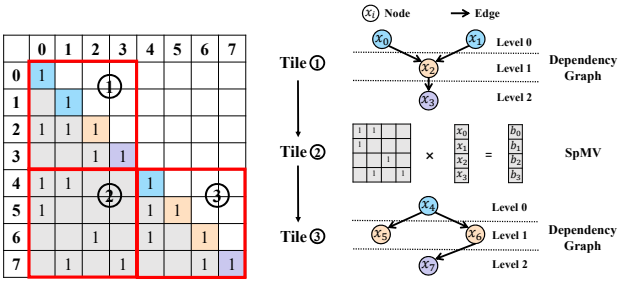
HiSpTRSV: Exploring Tile-Level Parallelism for SpTRSV Acceleration on FPGAs



Fan Sun, Fang Dong*, Dian Shen
School of Computer Science and Engineering
Southeast University
{fansun, fdong, dshen}@seu.edu.cn

***Abstract*—Sparse Triangular Solve (SpTRSV) is a critical level-2 kernel in sparse Basic Linear Algebra Subprograms (BLAS). While Field-Programmable Gate Array (FPGA) accelerators for SpTRSV focus on optimizing individual tiles, they overlook inter-tile parallelism. Designing an inter-tile parallelism accelerator poses challenges, including constructing fine-grained dependency graph, handling communication overhead, and balancing workloads. HiSpTRSV addresses these challenges through dependency graph parsing, tile-based highly parallel algorithm, filtering mechanisms, and bidirectional matching with modular indexing. Experiments show that HiSpTRSV outperforms the state-of-the-art SpTRSV accelerator in terms of a 34.3% performance improvement. HiSpTRSV achieves a 3.58× speedup and 9.59× higher energy efficiency compared to GPUs.**

***Index Terms*—Hardware accelerator, Computer systems organization, Reconfigurable computing.**

I. Introduction

SpTRSV is a fundamental computational operation for solving sparse triangular linear systems, expressed as $L\vec{x} = \vec{y}$, where L represents a sparse lower triangular matrix, $\vec{x}$ is the dense vector to be solved, and $\vec{y}$ is a known dense vector. SpTRSV is widely applied across various fields, including scientific computing [4], graph learning in machine learning [5], and dynamics analysis in physical simulations [6].

(a) 8×8 Sparse Matrix L (b) Sequential Computation for Three Tiles.

Fig. 1. Level-ST Algorithm Workflow.

In solving the SpTRSV problem, calculations have strict data dependencies: to compute an element $x[i]$, all the elements from $x[0]$ to $x[i-1]$ must first be computed. To address this challenge, researchers introduce the Level-Set algorithm to improve the parallelism of SpTRSV computations [15]. This algorithm represents matrix L as a dependency graph with **nodes** and **edges**. It achieves faster computation by processing these components in parallel. Furthermore, when handling large-scale matrices, the matrix is typically divided into tiles, and the Level-Set [7] algorithm applies to each tile sequentially. Fig. 1 shows an example to explain this computational process. Fig. 1(a) shows an 8×8 sparse triangular matrix L, divided into 3 tiles (indicated by red boxes). Fig. 1(b) illustrates the sequential process for solving tiles 1, 2, and 3, where dependency graphs are generated for tiles 1 and 3 based on the Level-Set algorithm.

Taking tile 1 from Fig. 1(b) as an example, nodes $x[0]$ and $x[1]$ in Level 0 are first solved in parallel, and the associated edges (arrows, indicating node dependencies) are computed. Next, node $x[2]$ in Level 1 is solved, along with its edges, followed by solving node $x[3]$ in Level 2. When tile 1 is solved, the values of $x[0]$ to $x[3]$ are determined. Next, tile 2 perform Sparse Matrix-Vector Multiplication (SpMV) computation based on $x[0]$ to $x[3]$. Finally, tile 3 is solved using results from tile 2 following similar steps.

Since the nodes and edges within tiles can be computed in parallel, researchers attempt to accelerate SpTRSV computation using FPGAs or GPUs [7]–[9]. However, these studies consider either inner-tile or inter-tile parallelism individually, failing to fully exploit SpTRSV's parallel potential. Therefore, a natural question arises: can both inner-tile and inter-tile parallelism be achieved simultaneously? In fact, this is feasible. Fig. 2 illustrates the computation flow for this concept, we overlapped computations between tile 1 and tile 2 using a fine-grained pipelined design, realizing inter-tile parallelism. Additionally, nodes and edges within each tile are computed in parallel, realizing inner-tile parallelism. It should be noted that for larger matrices, more tiles can be computed in parallel. We will discuss this in detail in Section II.

However, implementing an accelerator with the aforementioned characteristics on FPGAs presents several challenges. **Dependency Parsing (C1):** Inter-tile parallelism requires more complex dependency graphs to describe the relationships, and randomness in matrix sparsity and size further increases the challenge in constructing the dependency graph. **Routing and Resources (C2):** Fine-grained computation requires more submodules, which not only increases on-chip resource consumption but also introduces additional communication overhead. Meanwhile, the interconnection between submodules further complicates the routing stage. **Load Balanc-**

(a) 16×16 Sparse Matrix L (b) Parallel Computation Flow

Fig. 3. High Parallelism via Dependency Decomposition

ing (C3): Randomness in sparse matrices makes the element count for each Processing Element (PE) uncertain, leading to imbalanced computational loads across PEs.

In this paper, we propose HiSpTRSV to address these challenges, with the following innovation:

- **Flexible Data Dependency Parsing:** We design a fine-grained data dependency graph to describe the dependencies in the SpTRSV solution process. This enables highly parallel computation. Additionally, HiSpTRSV enables automated data dependency graph construction for matrices of any size. This addresses challenge **C1**.
- **Fully Streamed High-Parallelism SpTRSV:** We develop a novel Level-Set algorithm that achieves high parallelism through fine-grained tile partitioning, unlocking SpTRSV's parallel potential. Within the module, resource overhead reduces through resource reuse. Between modules, routing complexity and communication overhead are reduced through stream-based communication and data filtering. This addresses challenge **C2**.
- **Mod-Based Bidirectional Index Match:** We design bidirectional indexing strategy based on modular arithmetic, which allocating elements to each PE, ensuring correct matching between dependent elements across modules, and achieving load balancing among PEs. This addresses challenge **C3**.

II. Motivation and Tiled Highly Parallelized Level-Set Algorithm

In this section, we analyze the dependencies among different tiles in matrix L at a fine-grained level, demonstrating that these inter-tile dependencies are not strongly correlated. This observation creates opportunities for designing a highly parallel SpTRSV algorithm. For example, in Fig. 3(a), solving tile 2 depends on the SpMV result from tile 5, but it does not depend on tile 8. This means that the computations involving tile 2 and tile 8 can be carried out in parallel. Fig. 3 illustrates the analysis of inter-tile dependencies in the matrix, with the aim of implementing a highly parallel SpTRSV algorithm.

Fig. 3(a) presents a 16x16 lower triangular sparse matrix, which is divided into two types of tiles: tiles 1, 2, 3, and 4 represent the SpTRSV tiles, while tiles 5, 6, 7, 8, and 9 represent the SpMV tiles. When solving tile 1, tile 5 performs the SpMV computation in a pipelined parallel manner based on the results from tile 1, and stores the result on-chip. Once tile 1 is solved, tiles 2, 6, and 8 are computed in parallel. Similarly, tiles 3, 7, and 9 are computed in parallel, and once completed, the results of tiles 9 and 7 are accumulated. Finally, once tile 3 has completed its solution, tile 4 uses the stored result from tile 7 to proceed with its own computation. The computational flow is illustrated in Fig. 3(b), demonstrating that HiSpTRSV achieves higher parallelism.

Based on the above analysis, we design the Tiled High-Parallelism Level-Set Algorithm (THLS). This algorithm employs a tile-based strategy for computation, achieving high parallelism in SpTRSV while adhering to FPGA resource constraints. It enables full parallelism both inter-tile and inner-tile.

In the THLS algorithm, we organize the computation sequence for the SpTRSV and SpMV tiles as data dependency graphs G and M, with the computation step size at each stage managed by the $index$. The data dependency graph is allocated to P Processing Elements for parallel execution. Each PE executes SpTRSV computations (including node and edge computations) and SpMV computations in parallel, based on dependency graph indexing. When the tile completes, the PEs accumulate the results from the SpMV and SpTRSV tiles, storing the results on-chip in preparation for the next tile computation.

III. HiSpTRSV Design and Implementation

A. HiSpTRSV Architecture Overview

As shown in Fig. 4, HiSpTRSV is a dataflow-based architecture that consists of multiple Processing Element Groups (PEGs), several data load modules, a data merge module, and a data write module. Each PEG connects to a High Bandwidth Memory (HBM) channel. The data load module is responsible for reading the data dependency graph and the dense vector $\vec{y}$, streaming this data to the PEGs. The data merge module consolidates the computation results from the various PEGs,

while the data write module handles writing the dense vector $\vec{x}$ back to host memory.

Each PEG includes four core modules: computation module, filter module, cache module, and control module. The computation module includes the SpTRSV and SpMV modules, responsible for performing calculations in different tiles; the filter module filters out invalid elements during the synchronization process; the cache module manages the storage for intermediate computation results; and the control module serves as the core unit that oversees the operation of the PEG. We employ a fully streaming communication mechanism between the modules to optimize hardware resource utilization and simplify routing complexity.

In architecture-level communication, data synchronization between different PEGs is achieved through synchronous streams. We use a loopback data stream at the terminal PEG to return the synchronized data. This effectively implements a circular data synchronization stream among the PEGs, ensuring that each PEG receives the current solution $\vec{x}$, which

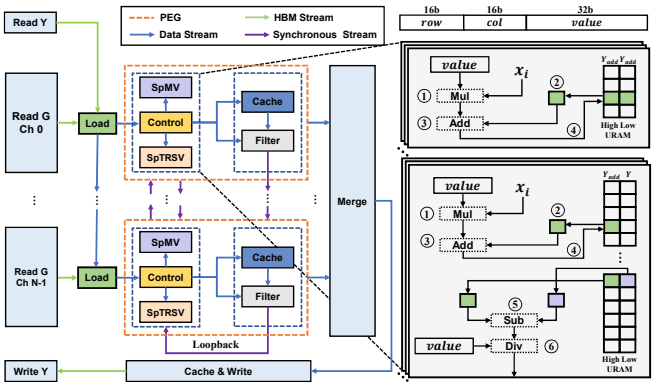

Fig. 4. HiSpTRSV Architecture and Computation Order for SpMV(Top) and SpTRSV(Bottom) Modules.

is required for the SpTRSV and SpMV computations in the next iteration. The dense vector $\vec{y}$ is loaded through a single HBM channel and then distributed to each loading module via a chained broadcast mechanism.

B. Processing Element Group (PEG) Design

To fully utilize HBM bandwidth, the PEG receives 512-bit wide data, containing 8 elements from the dependency graph. These 8 elements are distributed across 8 PEs, with each element using a 64-bit storage format that includes a 16-bit row index, a 16-bit column index, and a 32-bit value. The SpMV and SpTRSV serve as the core computational units in the PEG. The numerical labels in Fig. 4 indicate the execution sequence for the computation steps.

The SpMV module utilizes UltraRAM (URAM) units to store computation results, with the execution sequence comprising multiplication, read, addition, and write-back operations. Each URAM address is determined by the row index of the element. Once SpMV computations complete, data in URAM transfers in parallel to the SpTRSV module for accumulation. Given that the URAM unit is 72 bits wide, we divide the storage unit into two 36-bit regions (high and low) to store two accumulated values, optimizing the utilization of URAM resources. The design of Serpens and Sextans was referenced to accelerate the SpMV computation process [12], [18].

The SpTRSV module completes edge computations through steps similar to SpMV. The high region in URAM stores accumulation results from edge computations and SpMV computations, while the low region stores the $\vec{y}$ values. When the computation dependent on $x[i]$ is completed, the PEG first subtracts the Y_{add} value from the Y value. Then, it calculates $x[i]$ by performing a division operation.

C. Fine-Grained Data Dependency Graph

The dependency graph describes the SpTRSV computation process. We performed dependency analysis on matrix L at a fine-grained level and constructed a data dependency graph through tiling to support inter-tile parallel computation in SpTRSV. As shown in Fig. 5, we present an example data dependency graph for tiles 1, 5, and 8 from Fig. 3(a), with

row indices, column indices, and values labeled to correspond to elements in the sparse matrix.

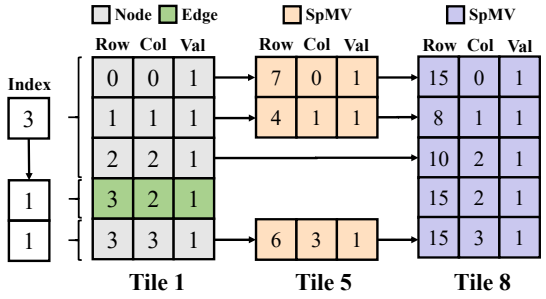

Fig. 5. Data Dependency Graph for Tiles 1, 5, and 8 in the 16x16 Matrix in Fig. 3(a).

The index list in Fig. 5 illustrates the solution process: First, three nodes are solved in parallel, followed by the computation of one edge, and finally, one node is solved. HiSpTRSV synchronously computes tile 1 and tile 5 based on dependency relationships. Once tile 1 is solved and the SpMV computation for tile 5 is complete, HiSpTRSV computes SpMV of tile 8 use dependency relationships and the values $x[0]$ to $x[3]$. The computation results from tile 8 are stored on-chip to enable subsequent computations for other tiles. Notably, HiSpTRSV can generate dependency graphs for matrices of any size, ensuring flexibility in its application.

D. Data Filtering Unit

HiSpTRSV assigns elements to PEs through modulo operations on row indices. Due to the randomness of sparse matrices and element dependencies, some PEs may be temporarily idle. Taking the sparse matrix in Fig. 3(a) as an example, Fig. 6 illustrates the solution sequence for tiles 1 and 2 by two PEGs (assuming each PEG contains two PEs). The number is the row index for the element. Since node 3 depends on node 2, nodes 0, 1, and 2 are solved in parallel during the first solution cycle while PE3 remains idle. In the second cycle, only PE3 solves node 3 while other PEs are idle. To align PE computation lengths, "bubble elements" (invalid elements) are added to the dependency graph. It should be noted that HiSpTRSV consists of 16 PEGs, each containing 8 SpTRSV PEs and 4 SpMV PEs, resulting in a total of 192 PEs to compute in parallel. Although increasing the PE count expands the scale for parallel computation, it also raises the likelihood for bubble elements. Therefore, we design a data filtering unit to handle bubble elements.

During the node solving process, the solution results stored in URAM need to be synchronized. For example, when PE3 solves node 7, it requires the values of $x[4]$ and $x[6]$, where $x[4]$ is stored in the URAM of PEG0. Therefore, data synchronization is required to ensure each PEG can access all $\vec{x}$ values within its own URAM. However, bubble elements introduce additional communication overhead to the synchronization process. We design a data filtering unit that identifies which elements should be written to URAM in parallel as PEGs perform write operations. When elements are

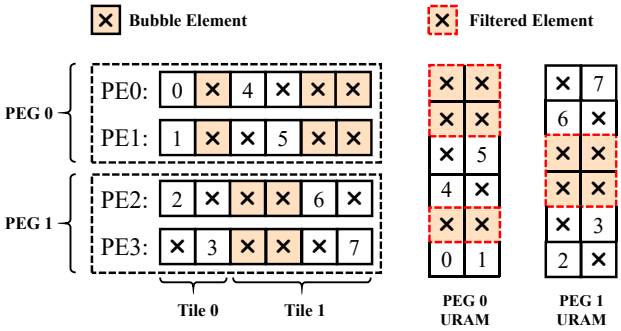

Fig. 6. Bubble Element Filtering Process.

bubble elements, URAM will reject storing them and record how many it successfully stores. This count represents the transmission length for data synchronization. Fig. 6 shows URAM-stored elements for PEG0 and PEG1, with red dashed lines indicating filtered elements that are neither stored in URAM nor participate in data synchronization.

E. Mod-Based Bidirectional Index Match

HiSpTRSV organizes the elements of SpMV and SpTRSV into a data dependency graph, assigns elements to PEs for computation, and ensures optimal load balancing. Fig. 7 shows the element allocation using modulo-based bidirectional matching.

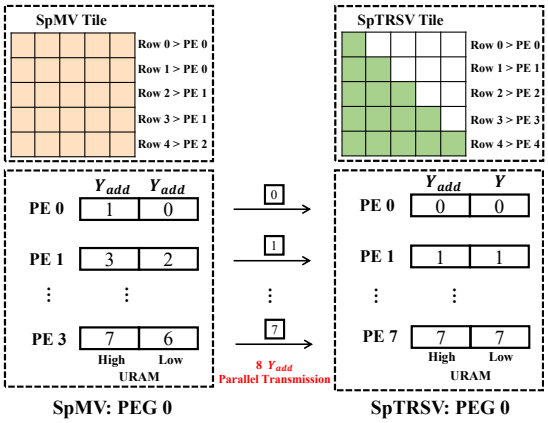

Fig. 7. Tiled SpMV and SpTRSV Element Mapping to PEs and URAM Layout.

For the elements in the SpMV tile, we assign two consecutive elements to the same PE because the URAM is divided into high and low regions to store accumulated values. The allocation method is: $row/2\%N_PEs$, where N_PEs represents the total number processing elements. For the elements in the SpTRSV region, only the high region of the URAM stores accumulated values. Meanwhile, one element is assigned to one PE at a time, and the allocation method is: $row\%N_PEs$. It is worth noting that SpTRSV relies on the results generated by SpMV. Therefore, the SpMV units transfer the accumulated values Y_{add} in parallel to the SpTRSV units, using row as a common index to ensure the accumulated values match correctly between SpMV and SpTRSV.

TABLE I
PERFORMANCE OF HISPTRSV ON ALVEO U55C AND CUSPARSE ON NVIDIAV100 AND RTX3060

IV. EVALUATION

A. Experiment Setup

We design the circuit using AMD Vitis HLS C++ and implement the prototype with Vitis 2023.1. The experiments are mainly conducted on the Xilinx Alveo U55C platform [1], Nvidia RTX 3060 [2], and Tesla V100 [3]. The HLS code is developed based on the RapidStream TAPA [11] streaming framework, with layout optimization achieved through Autobridge [10]. The performance and power consumption are measured on actual hardware: GPU power is recorded using the NVML tool, while FPGA power is collected with the xbutil tool during kernel execution. The measurement method for kernel execution time is kept consistent with LevelST [7] to ensure fair comparisons.

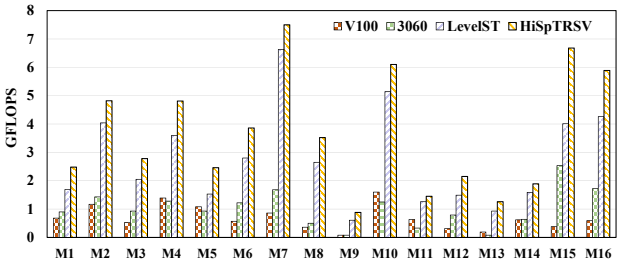

Fig. 8. FPGA and GPU Performance in GFLOPS.

We comprehensively compare our design against the state-of-the-art open-source SpTRSV accelerator LevelST [7] and the NVIDIA cuSparse library. The evaluation use 16 matrices from the SuiteSparse database [13], which are the same as those in the LevelST test set. Matrix sizes range from 16.3K to 1.97M rows, with non-zero elements between 440K and 5.58M. Tab. I lists detailed information for each matrix, including its size, the number of non-zero elements, and density. Matrix names with the suffix "trig" denote those derived through decomposition, while names without a suffix indicate directly extracted lower triangular matrices.

B. Overall Performance

The formula we use to compute GFLOPS is given by:

$$GFLOPS = \frac{2 \times NNZ}{10^9 \times \text{execution time}} \quad (1)$$

Here, NNZ represents the non-zero element count. We use GFLOPS as the primary performance metric, which directly reflects the computational efficiency and solving speed.

Tab. I provides a detailed list of the test results, with the last column showing the percentage improvement in performance compared to the LevelST. The 16 matrices exhibit throughput ranging from 0.88 to 7.50 GFLOPS. Compared to the state-of-the-art SpTRSV accelerator LevelST, HiSpTRSV achieves a 1.34× geometric mean speedup (up to 1.66×).

C. Communication

The random distribution in sparse matrix non-zero elements directly impacts the number of bubble elements within the dependency graph. The fewer the bubble elements, the lower the benefit of the filtering module. Fig. 9 shows the ratio of communication volume before and after using the filter module. Matrices M7, M15, and M16 display a relatively uniform pattern in non-zero element distribution, leading to balanced workloads across PEs and fewer bubble elements; consequently, communication volume does not decrease.

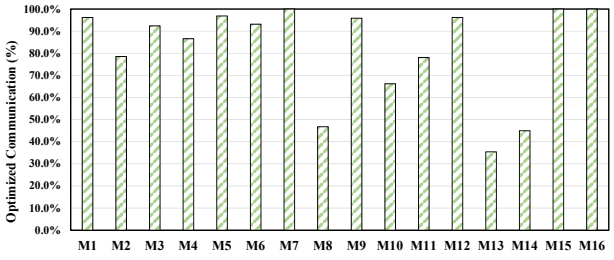

Fig. 9. Filter Module Optimization Ratio.

Conversely, matrices M8, M10, M11, M13, and M14 exhibit significant element clustering, with non-zero elements densely concentrated in specific rows. This distribution leads to severe load imbalance across PEs and generates numerous bubble elements, allowing the filter module to achieve significant optimization in these cases. The variation in optimization effectiveness not only confirms the design concept of the

filtering mechanism but also highlights the importance of matrix structure in parallel computation scheme design.

D. Resource Utilization and Design Frequency

Tab. II presents the resource utilization of HiSpTRSV on the U55C board. The SpTRSV module contains 8 PEs, while the SpMV module contains 4 PEs. We employ optimization directives to partition the Block RAM (BRAM) blocks within PEs to prevent BRAM conflicts between PEs, which implies that storing a single dense vector $\vec{x}$ consumes 8 BRAM blocks. Since BRAM features dual ports and can serve two PEs in a single cycle, the SpTRSV and SpMV modules utilize 32 and 16 BRAM blocks, respectively.

TABLE II
RESOURCE UTILIZATION OF HISPTRSV PROTOTYPE ON XILINX U55C FPGA BOARD

Resource	Available	Used	Utilization (%)
BRAM	2016	968	48.02
DSP	9024	1220	13.52
FF	2,607,360	821,979	31.53
LUT	1,303,680	547,430	41.99
URAM	960	640	66.67

URAMs are primarily utilized to cache intermediate results during computation in HiSpTRSV. The SpTRSV and SpMV modules each employ 8 URAM blocks, while the filter module, cache module, and write module collectively share 8 URAM blocks. Consequently, each PEG consumes a total of 40 URAM blocks. Given that the system incorporates 16 PEGs, the overall design occupies 640 URAM blocks. To fully utilize HBM's maximum bandwidth at 450 MHz with 512-bit ports, our kernels require only a frequency of 225 MHz [14]. HiSpTRSV operates at 246 MHz, successfully meeting this requirement.

E. Comparison to GPU

Fig. 8 compares the performance between Nvidia cuSparse running on 3060 and V100, and HiSpTRSV running on U55C. We select the better results between the 3060 and V100 for comparison with HiSpTRSV. For performance, HiSpTRSV achieve a geometric mean 3.58× speedup. For energy efficiency, HiSpTRSV achieve a geometric mean 9.59× improvement.

3060 GPU vs. HiSpTRSV. For performance, on average (geomean), HiSpTRSV is 4.10× faster than the 3060 GPU (up to 16.80×). On the other hand, Fig. 10 compares their energy efficiency. HiSpTRSV achieves better energy efficiency than the 3060 across all matrices, showing a geomean improvement by 9.82× (reaching up to 39.56×). When processing smaller sparse matrices, the RTX 3060 performs better due to its higher memory clock speed.

V100 GPU vs. HiSpTRSV. For performance, on average, HiSpTRSV is 5.44× faster than the V100 GPU (up to 16.29×). The geomean energy efficiency improvement is 25.08× (up to 59.94×). When processing larger sparse matrices, the V100 outperforms the RTX 3060 due to its larger on-chip memory and higher off-chip memory bandwidth.

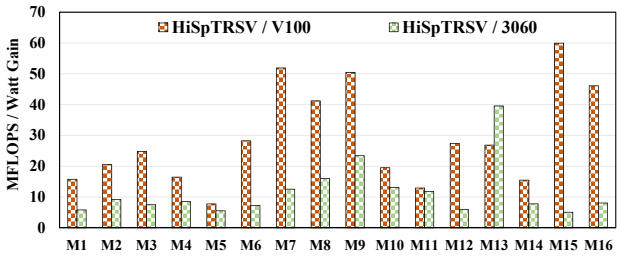

Fig. 10. Energy Efficiency Improvement of FPGA over GPU.

Due to the sparsity and dependencies in SpTRSV, some threads within the GPU remain idle during SpTRSV computations. However, these idle threads continue to consume power, leading to lower core utilization and higher energy consumption for the GPU. When handling sparse workloads, GPU peak utilization remains at only 0.6%, while average utilization reaches just 0.1% for workloads in [12], [16]. In addition, branch prediction and higher clock speeds significantly increase GPU kernel latency and power consumption [2], [17]. In contrast, we leverage FPGA reconfigurability to customize designs for specific applications, reducing additional latency and power consumption.

V. CONCLUSION

In this work, we develop the HiSpTRSV design to address the challenges faced in accelerating tile-based SpTRSV on HBM-based FPGAs. First, we implemented fine-grained dependency resolution at a granular level, enabling highly parallel computation in SpTRSV. Second, we develop a tile-based highly parallel SpTRSV algorithm and a stream-based filtering mechanism to achieve high parallel computation and low-overhead communication. Third, we design a modular bidirectional index matching mechanism to achieve balanced workload distribution. Moreover, HiSpTRSV can automatically construct and compute dependency graphs for matrices with any size. Experimental results demonstrate that our design significantly outperforms the state-of-the-art FPGA-based SpMV accelerator, LevelST, and Nvidia GPUs using cuSparse.

***Abstract*—Coarse-Grained Reconfigurable Arrays (CGRAs) balance the performance and power efficiency in computing systems. Effective compilers play a crucial role in fully realizing its potential. The compiler maps Data Flow Graphs (DFGs), which represent compute-intensive loop kernels, onto CGRAs. However, existing compilers often tackle DFG nodes individually, neglecting their intricate inter-dependencies. We introduce a novel mapping paradigm called Rewire that can place and route multiple nodes in one shot. Rewire first generates routing information that is shareable among multiple nodes via propagation. Then, Rewire intersects the routing information to generate individual placement candidates for each node. Finally, Rewire innovatively utilizes data dependencies as constraints to quickly find suitable placement for multiple nodes together. Our evaluation demonstrates that Rewire can generate more near-optimal mappings than prior works. Rewire achieves 2.1x and 1.3x performance improvement and 13.5x and 4.7x compilation time reduction, respectively, compared to two popular mappers.**

I. Introduction

Coarse-grained reconfigurable arrays (CGRAs) [1]–[20] have gained significant attention in recent years due to their excellent balance in terms of flexibility, performance, and energy efficiency. The domain-agnostic characteristic allows CGRAs to accelerate a broad spectrum of applications, such as machine learning, video processing, and graph processing. However, achieving superior performance and power efficiency for these applications heavily relies on efficient compilers to explore the enormous mapping space.

Mapping DFG, which represents the compute-intensive loop kernel, onto CGRAs is a well-known challenging problem [10], [14], [21]–[30]. Figure 1 shows a typical 4×4 CGRA architecture. The CGRA is programmable, consisting of processing elements (PE) executing the operations, on-chip memory to store the data, and a Network on Chip (NoC) to route the data among the PEs. The details of the architecture are exposed to the mapper to generate cycle-by-cycle configurations for the programmable units, including the PEs and the routers.

The mapping involves the placement of the DFG nodes onto the PEs of the CGRA, while routing the data dependencies among these nodes. The complex inter-dependencies among the nodes pose significant difficulty to the mapping algorithm. Complex data dependencies refer to rich but irregular connections among multiple nodes. These nodes subtly affect each other's mapping due to resource contention, which are aggravated by intricate dependencies. Conventional mapping approaches iterate over the DFG nodes individually. For each node, they first select the PE placement candidate and then evaluate the routability of the relevant edges. It is theoretically possible to choose the placement of multiple nodes in one shot and then find the routing of the relevant edges together. Unfortunately, such consolidated placement does not yield feasible routing due to complex

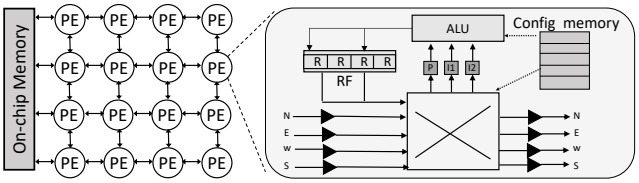

Fig. 1: A typical 4×4 CGRA.

data dependencies. Several works use a hierarchical approach [24]–[26], [31] of partitioning the DFG into several sub-DFGs. However, they still map the nodes individually within each sub-DFG.

There are two disadvantages to existing approaches. First, by mapping each node individually, they lack the ability to handle complex data dependencies collectively. As a result, these approaches need to backtrack whenever they cannot map the current node, causing numerous iterations to explore the multi-node mapping. Nevertheless, they still may fail to reach a feasible mapping within a reasonable compilation time. Second, they are unable to leverage the routing knowledge established for one edge when handling the next edge. Hence, they need to visit the same network repeatedly to evaluate the routability of the PE placement candidates.

To overcome these limitations, we propose *Rewire**, a novel CGRA mapping paradigm that can quickly generate feasible mapping for multiple nodes in one shot. As existing mappers usually create an initial mapping and improve step by step to achieve a valid mapping, Rewire focuses on amending the initial mapping and can take any initial mapping from other mappers, making Rewire orthogonal to these mappers. Rewire first leverages the inherent DFG structure characteristic to share the routing information among multiple DFG nodes and intersects the routing information to find placement candidates for each of the DFG nodes. Compared to previous path-finding-based routing, Rewire devises a propagation mechanism to generate the routing information for multiple nodes together. Finally, Rewire analyzes routing information and prunes the search space using inter-dependencies as constraints to generate multi-node placement. Therefore, Rewire can simultaneously coordinate the placement and routing of multiple nodes, advancing the current mapping paradigm.

We make the following key contributions:

- We identify a fundamental limitation of traditional CGRA mapping approaches that they can only map the DFG nodes individually, limiting the ability to coordinate multi-node mapping. In contrast, we propose a new mapping paradigm that can generate multi-node mapping in one shot.
- To the best of our knowledge, we are the first to propose sharing the routing information among multiple nodes. Through the sharing, we can reuse the routing information and further coordinate the mapping of multiple nodes.

*We name it Rewire due to the reuse of wire (routing) information and its ability to amend an invalid mapping through minimal alterations.

- Our evaluation demonstrates that Rewire can generate much more near-optimal mappings than prior works. Compared to the two popular works, Rewire can achieve 2.1x and 1.3x performance improvement and 13.5x and 4.7x compilation time reduction, respectively.

II. Related Work

Existing mappers can be classified into three main categories: (1) These approaches choose the placement that minimizes a predefined cost function to map a node [21], [23], [32]–[35]. For example, to map a DFG node, they need to evaluate the multiple placement candidates and select the candidate with the minimal cost. This process necessitates evaluating all potential candidates for the current node and often leads to local minima. If the current node cannot be mapped, a higher cost is assigned to the existing placement, and multiple rounds of partial remappings are performed to achieve a feasible solution. (2) These approaches find any placement that can route the edges connected to the current DFG node but may require many iterations to find a feasible mapping [10], [22], [29], [36]. To map a node, they can select any placement candidate if it can route the current data dependencies, and they do not need to evaluate any other candidates. (3) These approaches partition the DFG or the hardware to reduce the search space using a divide-and-conquer approach [24]–[26], [31], but may still rely on the aforementioned methods for each partitioned DFG. For example, if a partitioned sub-DFG is assigned to a sub-CGRA, they only need to evaluate candidates in the corresponding sub-CGRA. Despite substantial research, state-of-the-art CGRA compilers still only map one node at a time and cannot comprehensively manage multi-node data dependencies together. In contrast, Rewire can simultaneously map multiple DFG nodes together, greatly reducing the number of iterations needed to map multiple DFG nodes.

Furthermore, conventional approaches cannot reuse the routing knowledge, with the exception of EMS [28]. There are three levels in mapping: a mapper needs to map multiple DFG nodes, where mapping a DFG node needs to explore multiple placement candidates, and evaluating a candidate needs to route multiple edges. EMS can reuse the routing knowledge for a single edge when attempting different placement candidates. To map a node, EMS starts routing from its parent node and does not specify the PE candidate for the target node. Upon reaching a potential PE candidate, EMS employs a path search to route the other relevant edges. If unsuccessful, EMS still uses the routing information of the first edge and continues to find new potential PE candidates. EMS can only reuse the routing knowledge for a single edge and cannot extend to other edges. In contrast, Rewire can share the routing information among multiple edges, placement candidates, and DFG nodes, making it possible to coordinate the mapping of multiple DFG nodes.

III. Motivation and Intuition

In this section, we use a motivating example to demonstrate the fundamental limitations of the state-of-the-art CGRA compilation techniques and propose concrete strategies to overcome these limitations. Figure 2(a) shows a DFG example where three nodes A, B, and G have been placed onto PEs in the initial mapping. Figure 2(b) provides an example of initial mapping for the DFG depicted in Figure 2(a) onto a 4×4 CGRA. Figure 2(c) illustrates how typical conventional mappers [22], [26] attempt to map the nodes C, D, E, and F: map each node individually in multiple steps and can require checking multiple placement candidates for each DFG node.

The key problem is that such approaches cannot simultaneously coordinate the mapping of multiple nodes. For example, when it

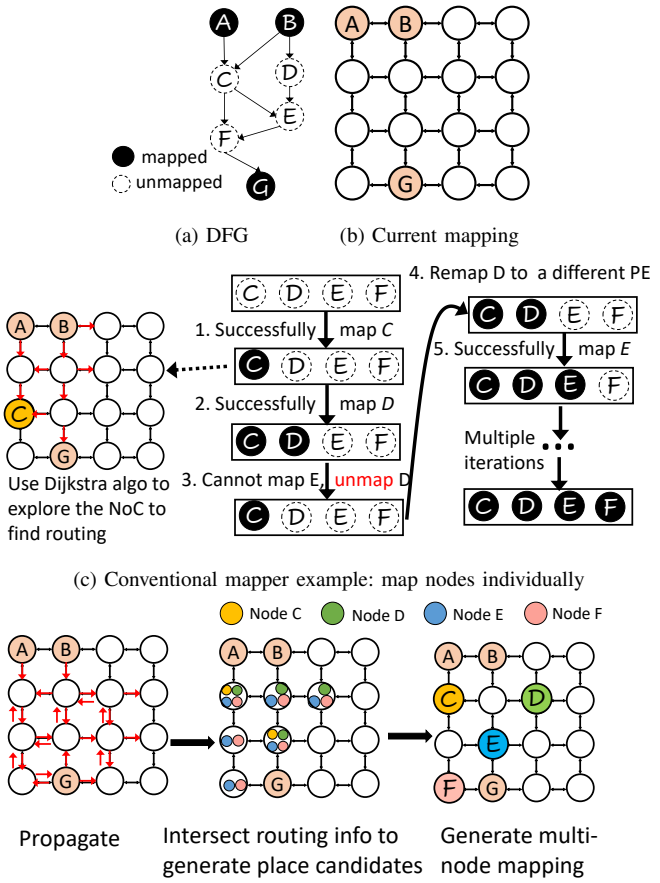

Fig. 2: Comparison between conventional mappers and proposed mapper

attempts to place node C onto a PE, it cannot guarantee that this placement leads to a successful mapping of the remaining nodes D, E, and F. Thus, when node E cannot be mapped (step 3), it usually performs partial remapping by removing a part of the current mapping and changing the placement of the affected nodes to different PEs. In this example, we unmap node D and move it to a different PE. Hence these conventional mappers need multiple backtracking iterations to find a feasible mapping. Another issue is that these conventional mappers cannot reuse routing knowledge either for multiple edges, placement candidates, or DFG nodes. For each edge or placement candidate, the mapper needs to explore the NoC to establish the routing and need to visit the same network multiple times. Yet, they did not reuse the routing information. Furthermore, simple reuse or routing information memorization cannot be applied as the resource status can change from routing one edge to another edge.

In this paper, we demonstrate that it is possible to simultaneously map multiple nodes and share the routing information among relevant edges. Our approach is shown in Figure 2(d). We first propagate the output value of A along the network without specifying any destination node. Any reachable PEs from the PE containing DFG node A can be a potential placement candidate for node C, which is dependent on node A. Moreover, as the nodes E and F are dependent on node C, by transitivity, they are also dependent on node A. Therefore, if C is placed on a reachable PE from A, we can place E and F on the PEs reachable from C. All these reachable PEs that are potential placement candidates for DFG nodes E and F have been identified during the propagation from A. We can use

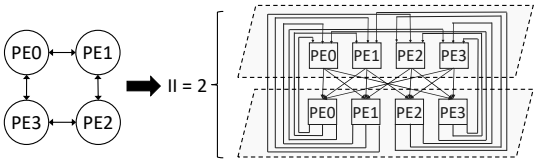

Fig. 3: High-level MRRG example for 2×2 CGRA.

the same propagation information to route $A \rightarrow C$, $C \rightarrow E$, and $C \rightarrow F$. Similarly, we can propagate the output of B and use this information to find potential placement candidates for the nodes D, E, and F, and routing the edges $B \rightarrow D$, $D \rightarrow E$, and $E \rightarrow F$. Finally, we need to conduct backward propagation from node G that has already been mapped, just as we do forward propagation from nodes A and B. The above process identifies the potential placement candidates via forward and backward reachability searches from the already placed ancestor nodes (A and B in the example) and the descendant nodes (G in the example).

However, the placement of a DFG node X needs to satisfy multiple constraints as it needs to be reachable from all the source nodes with which it has dependencies and all the destination nodes that are dependent on this node X. For example, node C should be on the forward propagation routes of nodes A, B, and the backward propagation routes of node G. A simple intersection operation among the propagation routes from the nodes A, B, and G can identify the set of potential feasible placement candidates for node C. Similarly, we can identify the set of potential candidates for nodes D, E, and F. Given these potential candidates for all the nodes we intend to map, we have to select the actual placement candidate for multi-node such that (a) only one DFG node is mapped to a PE candidate, (b) we can route all the data dependencies among these nodes together.

IV. Rewire Algorithm

In this section, we first formulate the mapping problem and then present the Rewire mapper that maps the DFG onto the CGRA. The CGRA mapper first generates a DFG representing the application program and then maps the DFG onto the CGRA with respect to the data dependency. CGRA uses Initiation Interval (II) to evaluate the mapping quality, where II is the number of cycles between consecutive iterations of a loop kernel. The lower the II, the better the performance.

A. Problem Formulation

DFG: We define DFG $D = (V_D, E_D)$ as a directed acyclic graph with V_D representing operations and E_D representing dependencies between operations.

CGRA Graph: CGRA is defined as a graph $G = (V_G, E_G)$. Modulo Routing Resource Graph (MRRG) $H_{II} = (V_H, E_H)$ is a resource graph of the CGRA that is time extended to II cycles [37]. V_H consists of two types of nodes: ALUs (V_H^F) in each PE and ports (V_H^P) in interconnects and Register Files (RFs) [37]. As the CGRA schedule repeats after II cycles, the resources at cycle $II-1$ have connectivity with the resources at cycle 0 in the MRRG. $H^{'} = (V_{H'}, E_{H'})$ is defined as the time extended resource graph of the $G^{'}$ ($V_{H'} \subseteq \mathcal{P}(V_H)$). Figure 3 shows a high-level MRRG example for 2×2 CGRA where we only show the inter-PE links and do not include internal links in the PE.

Problem Definition: Given a kernel and a CGRA, the problem is to construct a time extended MRRG $H_{II} = (V_H, E_H)$ of the CGRA for which there exists a mapping $\phi = (\phi_V, \phi_E)$ from $D = (V_D, E_D)$ to H_{II} which minimizes II. We decompose the problem into three sub-problems: selecting multiple DFG nodes to form a cluster U, propagation for U, and generating the multi-node mapping of U.

Algorithm 1: Rewire Algorithm

```
Input: DFG, CGRA
Output: Valid mapping
1  Sort DFG nodes by topological order;
2  minII = Minimum(recurrenceMII, resourceMII);
3  while mapping is not valid do
4      Generate the initial mapping for current II ;
5      while mapping is not valid do
6          Generate target cluster U;
7          while U is not mapped and is less than α do
8              Propagate for U;
9              Intersect propagation tuples to find placement candidates;
10             if Generate multi-node mapping then
11                 Break;
12             else
13                 Append a node to U;
14         if U are not mapped then
15             Break;
16     II = II + 1;
```

B. Overall Algorithm

Algorithm 1 shows the Rewire algorithm. We first sort DFG nodes by topological order (line 1). The mapper calculates the theoretical Minimum Initiation Interval (MII) based on the hardware resource and inter-iteration data dependency [38] (line 2). Given a DFG and a CGRA, we initiate the mapping process starting from MII. If the mapping is not successful, we increase the II by one and attempt to map again. This process continues until we reach the maximum II (hardware-decided) or exceed the mapping time limit (lines 3-16).

As we mentioned earlier, Rewire takes the initial mapping from conventional approaches [22] (line 2) and focuses on amending the initial invalid mapping to achieve a valid mapping (lines 5-15). Given the invalid initial mapping, Rewire identifies nodes that are non-mapped or have congested routing as ill-mapped nodes. Rewire randomly selects several unmapped connected nodes to let them share the routing information, denoted as U (line 6). We need to limit the size of U. The reason is: (1) too many DFG nodes in U will significantly increase the search space and make it very time-consuming to find suitable placement candidates for U; (2) increasing the number of DFG nodes might not always work as the DFG is not mappable at current II (MII is not always achievable). In practice, we limit the size of U to 15. Given U, Rewire simultaneously propagates the source nodes, which are the parents and children of the cluster U (line 8). Then, Rewire summarizes the propagation information and uses the intersection to generate the placement candidates for each node $v \in U$ (line 9). Rewire uses data dependencies as constraints to prune invalid cluster placement candidates during building the placement of cluster U (line 10). The propagation and mapping generation will be detailed in Section IV-C and Section IV-D.

It is possible that the original U is not mappable due to the limited routing resource and complex data dependencies. Hence, we progressively add the connected node to U (line 13) until we map these nodes or reach the size limit of U (line 7). To append, we select the node that has the least depth-fist search (DFS) distance to the cluster U. Reaching the size limit means we cannot find a valid mapping with current II and need to increase II by one.

C. Routing Propagation

Rewire conducts forward propagation of values from the parents of U ($Parents(U)$) and backward propagation from the children of U ($Children(U)$) across the network. $Parents(U)$ is a set of DFG nodes that have been mapped and have a child node in U, but the node itself does not belong to U, denoted as $Parents(U) =$

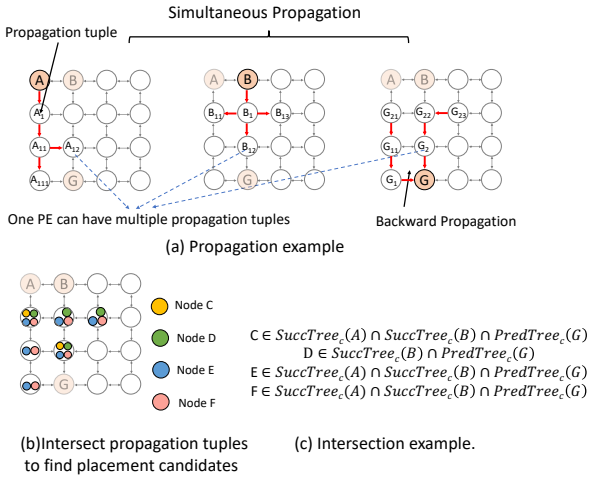

Fig. 4: Propagation and intersection example.

$v \in V \setminus U : \exists u \in U, (v,u) \in E$ and $\phi(v) \neq \emptyset$. Similarly, $Children(U) = v \in V \setminus U : \exists u \in U, (u,v) \in E$ and $\phi(v) \neq \emptyset$. Rewire propagates as long as the network path is not used by current mapping. Once reaching a PE, we will generate a propagation tuple. The propagation tuple contains four essential components: the source node, the propagation direction (forward/backward), the source PE, and the number of routing cycles. Thus, each tuple is associated with a specific PE in the network. The number of routing cycles is the cycle number from the source PE to the current PE.

The propagation tuple is a probe of network utilization that helps Rewire find suitable placement candidates. To keep the only necessary information, when a PE receives a propagation message from an adjacent PE, Rewire generates a new propagation tuple only if no existing tuple at that PE has the identical combination of source node, routing cycle count, and propagation direction. This mechanism prevents redundant exploration while covering all potential routing paths. To determine the number of propagation rounds, we heuristically use the maximum cycle difference between $Parents(U)$ and $Children(U)$ multiplied by three as the number of propagation rounds. When either $Parents(U)$ or $Children(U)$ is empty, we heuristically use the length of the longest path within U multiplied by five. This value allows the Rewire to generate sufficient propagation tuples.

Figure 4(a) provides an example of propagation for the motivating example in Section III. We note that we simultaneously propagate these sources nodes and we show them separately for simplicity. The IDs, like A_{12}, are to distinguish from each other and do not have any special meaning. The simultaneous propagation of multiple source nodes introduces resource contention in the network. Since the objective of propagation is to explore potential routing paths rather than perform final resource allocation, we continue propagation even when hardware resources have been traversed by other propagation tuples. These propagations generate a hierarchical structure where we define the successor tree $SuccTree(v)$ as the set of all propagation tuples originating from node v through forward propagation and the predecessor tree $PredTree(v)$ for backward propagation. We define $Tree(v)$ to represent all propagation tuples propagated from v.

D. Multi-node Mapping Generation

Propagation Information Intersection: After propagation, we first intersect propagation tuples to find placement candidates for DFG nodes in target cluster U. Now, each PE V_H virtually owns multiple propagation tuples, which are from different source nodes and arrive at different cycles. Figure 4(b) shows an example of intersecting these propagation tuples to find placement candidates for the unmapped DFG nodes in Figure 2(a). For a node v in U, PE V_H can be a placement candidate if it has the required propagation tuples for v. The requirement is, for each edge (v,u) (or (u,v)), or for each parent and child, we need to have a corresponding tuple, and these corresponding tuples must arrive at the same cycle to ensure the "right" execution of node v_i. If a parent or child node of v in U is not the source node of propagation, we use DFS to find a source node to represent this parent or child. For example, for the DFG in Figure 2(a), F is not a propagation source node, and we use DFS to find G as the propagation source node. In this example, three edges are connected to C; therefore, a PE can be a placement candidate of C only if the PE has all three corresponding tuples to ensure routing paths. In other words, we need to have three tuples originating from A, B, and G, and these tuples must arrive at the same cycle.

Hence, we formalize the intersection rule as below:

$$PCandidates(v_i) = \{V_H^F | \exists c \in \mathbb{N} : V_H^F \in (\bigcap_{v_j \in Parents(v_i)} SuccTree_c(source(v_j))) \cap (\bigcap_{v_k \in Children(v_i)} PredTree_c(source(v_k)))\} \quad (1)$$

where $SuccTree_c(v)$ represents the successor tree from node v at cycle c, $PredTree_c(v)$ represents the predecessor tree from node v at cycle c, and c is the common arrival cycle for all required tuples. For example, for node C, we can obtain the candidates with:

$$PCandidates(C) = \{V_H^F | \exists c \in \mathbb{N} : V_H^F \in (SuccTree_c(A) \cap SuccTree_c(B) \cap PredTree_c(G))\} \quad (2)$$

Figure 4(c) provides a few simplified examples using intersection to find the placement candidates for unmapped nodes. With the propagation and intersection example, we can find we only need several rounds of propagation to let these DFG nodes find potential placement candidates, even though the process has not yielded the final multi-node mapping yet. In contrast, conventional approaches usually need to invoke the path routing algorithm multiple times to check multiple candidates for only one DFG node placement.

Algorithm 2: Generate multi-node mapping

Input: DFG, CGRA, cluster U, $PCandidates(v_i)$ for each $v_i \in U$
Output: Mapping

1 Sort U by topological order $U = \{v_i | i = 0, ..., m\}$;
2 **foreach** $v_i \in U$ **do**
3 | Sort placement candidates by available execution cycles;
4 **while** *not exceed the time limitation* **do**
| // generate $Placement(U)$
5 | **foreach** v_i ($0 \leq i \leq m$) **do**
6 | | **foreach** v_j ($0 \leq j \leq i-1$) **do**
7 | | | Generate time constraints related to current node v_i;
8 | | select a candidate obeying execution cycle constraints;
9 | **if** *routing verified* **then**
10 | | return the $Placement(U)$;

Multi-node Mapping Generation: Algorithm 2 shows how to generate multi-node mapping. After the intersection of propagation tuples, we generate placement candidates $PCandidates(v_i)$ for each node $v_i \in U$, where placement candidates can execute at different cycles (decided by the arriving cycles of propagation tuples). We utilize the execution cycle information to filter invalid placement for U. We first sort nodes in cluster U by topological order (line 1) and sort placement candidates for each DFG node v_i by their execution cycles (lines 2 and 3). Then, we build placement candidates for U (represented as $Placement(U)$), which need to obey the execution order among nodes in U. For example, for the DFG in

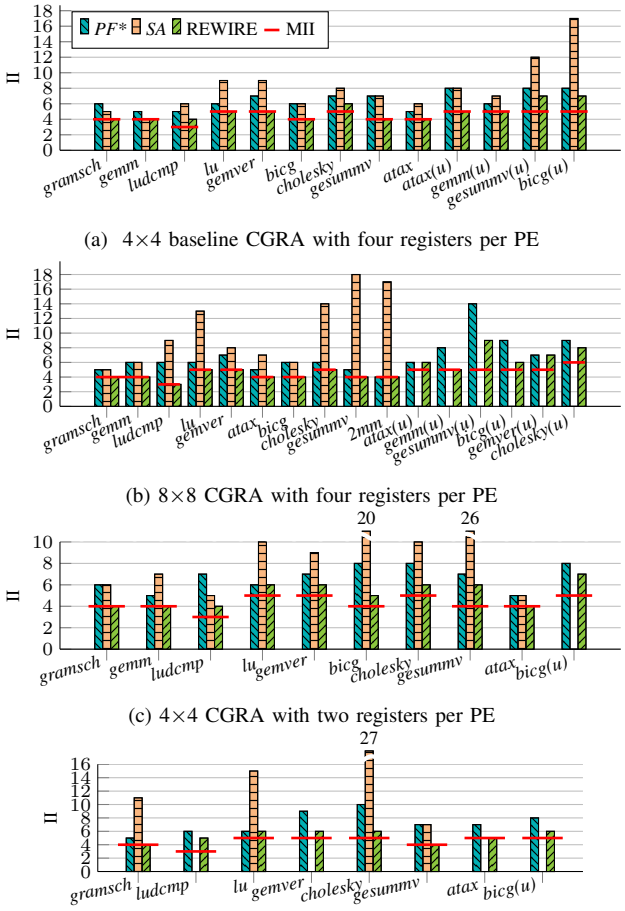

Figure 2(a), the execution cycle of E's placement candidate must be larger than the cycle of C's with respect to the data dependency. As $PCandidates(v_i)$ can have different execution cycles, we need to remove the invalid combinations during $Placement(U)$ generation. Hence, we iterate from v_0 to v_m to build $Placement(U)$ (lines 5-8) and check the execution cycle constraints (lines 6-8) during this process. Moreover, we use an index vector to track these placement candidates and iterate them to ensure we do not explore the same $Placement(U)$. When we add a placement candidate for v_i, we check the cycle execution constraints from v_0 to v_{i-1} if it has any data dependency with v_i. We find that this method is quite effective in pruning invalid $Placement(U)$.

As we mentioned in propagation, the propagation tuple may not always be valid, as we do not check resource contention among tuples during propagation. Hence, we must verify the $Placement(U)$ through routing (lines 9 and 10). If not successfully verified, we keep finding valid $Placement(U)$ (lines 4-10). After propagation, only part of PE can be the placement candidate of the DFG node, while the cycle execution constraints prune most invalid $Placement(U)$, meaning we only need to check a small portion of $Placement(U)$. Our evaluations show that generated $Placement(U)$ has a very high success rate of around 95% for verification. The reason is that the execution cycle constraints have successfully pruned many invalid $Placement(U)$, and the propagation mechanism has already performed a preliminary evaluation of routability.

V. Evaluation

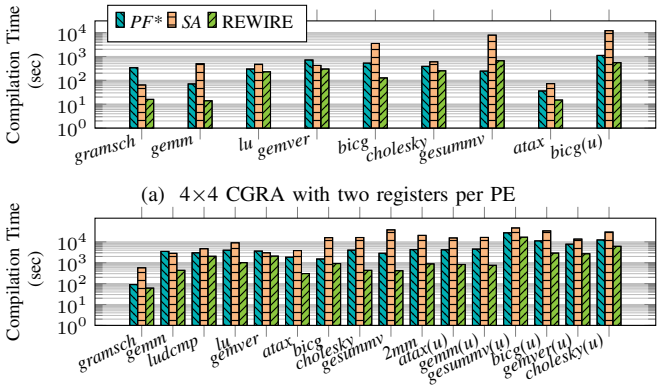
In this section, we evaluate Rewire against two recent CGRA mapping techniques in terms of application performance (iteration interval II) and compilation time. We compare Rewire against two mapping approaches: SA and PF*. Simulated Annealing (SA) has been widely used in different CGRA compilation frameworks [10], [29], [32]. PathFinder is a popular algorithm used by several CGRA mappers [2], [22], [39], [40]. PathFinder and SA are two representative examples of the first type and the second type of mapper as discussed in Section II, respectively. We refer to our fine-tuned implementation of PathFinder with 3K lines of C++ code as PF*. The idea of PF* is to generate an initial mapping by selecting the placement with the minimal routing cost for the edges and then amend the mapping through multiple remapping iterations until a feasible solution is reached. We use the initial mapping of PF* as the initial mapping for Rewire, and then use our multi-node mapping to reach a feasible solution from the initial infeasible mapping.

We evaluate these mappers on the following CGRA architectures: (a) 4×4 CGRA with four registers per PE; (b) 8×8 CGRA with four registers per PE; (c) 4×4 CGRA with two registers per PE; (d) 4×4 CGRA with one register per PE. All the 4×4 CGRAs have two local memory banks, and PEs on the left-most column can access the memory. The 8×8 CGRA have eight local memory banks, and the left-most and right-most PE columns can access the memory, making 16 PEs can access the memory. Registers play a crucial role in buffering data during routing, particularly when the producer and consumer are distant nodes along spatial or temporal dimensions. We evaluate with different numbers of registers to evaluate Rewire's capability to handle different routing resources. 4×4 CGRA with one register per PE is not practical as it has very limited routing resources. Yet, we use it to evaluate the capability to handle extreme cases. We use the PolyBench [41], MachSuite [42] and MiBench [43] for our applications. We also used unrolled versions (unroll factor of 2) of some of these benchmarks to stress the compiler, specially on 8×8 CGRA. The number of DFG nodes varies from 26 to 51 and the average number of DFG nodes is 38. We measure the compilation time on the Intel Xeon Gold CPU (2.60GHz).

(a) 4×4 baseline CGRA with four registers per PE

(b) 8×8 CGRA with four registers per PE

(c) 4×4 CGRA with two registers per PE



(d) 4×4 CGRA with one register per PE

Fig. 5: Comparison on the mapping quality of Rewire with PF* and SA on different benchmarks and CGRA configurations. The lower the II value, the higher the performance. *u* next to a benchmark represents the unrolled version with a factor 2. MII is the theoretically minimal II that may not be achievable in practice. Missing bars for SA for some benchmarks indicate that SA was not successful in mapping those benchmark-architecture configurations. We did not include a benchmark-architecture configuration if none of the three approaches can map it due to inadequate availability of resources, e.g., unrolled loops on architectures with few registers per PE.

A. Quality of Mapping

Figure 5 shows the comparison of the mapping quality for the different approaches (Rewire, PF*, and SA) in terms of the II values on four different CGRA configurations. Recall that II is the number of cycles between starting the execution of consecutive iterations of a loop kernel. The lower II value indicates lower execution time and hence higher performance. MII is the theoretically minimal II which is calculated by resource and inter-iteration data dependencies. However, achieving the MII may not always be possible as complex data dependency constraints are not considered in the theoretical calculation. Nevertheless, we consider a mapping optimal if it achieves the MII. If the difference between the II achieved and MII is one, we call the mapping near-optimal.

This evaluation uses 47 different DFG and architecture combinations. Rewire can achieve superior performance than PF* and SA if not the same on every application and CGRA combination. Both Rewire and PF* successfully map all the combinations, whereas SA

(a) 4×4 CGRA with two registers per PE

(b) 8×8 CGRA with four registers per PE

Fig. 6: Compilation time comparison of Rewire with PF* and SA on 4×4 CGRA with four registers per PE and with two registers per PE.

fails to map 12 combinations. Among the 47 combinations, Rewire delivers optimal or near-optimal mapping in 38 cases. In comparison, PF* and SA achieve optimal or near-optimal mapping for only 15 and 3 cases, respectively. Overall, Rewire delivers an average performance speedup of 1.3x and 2.1x compared to PF* and SA, respectively. The mapping quality difference shows Rewire's ability to handle complex data dependencies across application kernels on different CGRAs.

Rewire is also versatile and scalable to support various CGRA configurations. Rewire consistently achieves 1.33x, 1.31x, 1.29x, and 1.32x performance improvement compared to PF* on 4×4 baseline CGRA with four registers per PE, 4×4 CGRA with one register per PE, 4×4 CGRA with two registers per PE, and 8×8 CGRA with four registers per PE, respectively. This consistency underlines Rewire's ability to achieve superior performance across varied architectures. Moreover, compared to SA, Rewire can achieve 1.58x, 3.25x, 2.10x, and 2.21x performance improvement on these architectures, respectively. The most significant improvement comes from the 4×4 CGRA with one register. This architecture has very limited routing resources to evaluate the capability to handle extreme cases, as mentioned earlier, and a few DFGs can be mapped on the architecture. This improvement also highlights Rewire's capability to handle various architectures. The key factor behind the success of Rewire is its ability to coordinate the mapping of multiple DFG nodes, while PF* and SA make localized and myopic decision, making them struggle to handle intricate data dependencies.

Rewire achieves significant performance improvement from 4×4 CGRA with 4 registers per PE to 8×8 CGRA with 4 registers per PE. Rewire generates optimal mapping for *cholesky*, *ludcmp*, and *gesumv(u)* for the 8×8 CGRA, while fails on 4×4 CGRA to generate mappings due to insufficient hardware resources. This demonstrates the scalability of Rewire to handle larger search space by effectively pruning away infeasible candidates to avoid unnecessary searches.

B. Compilation Time

Figure 6 shows the compilation time comparison among these mappers on 8×8 CGRA with four registers per PE and 4×4 CGRA with two registers per PE. Note that the Y-axis is in log scale. Mappers can explore for a maximum of one hour per II, and can terminate early at each II due to the backtracking limitation (PF*) or no mapping cost improvement after 100 iterations (SA). As mentioned earlier, SA cannot map several benchmarks even after numerous iterations. In those cases, we choose the termination time as the compilation time. We note that the propagation time usually takes less than one second in Rewire, and the most time-consuming step happens at pruning during multi-node mapping generation.

TABLE I: Number of single-node remapping iterations for PF* and SA on 4×4 CGRA with four registers per PE and with one register per PE.

4×4 CGRA with 1 register per PE			4×4 CGRA with 4 registers per PE		
Benchmark	**PF***	**SA**	**Benchmark**	**PF***	**SA**
gramsch	242	1335	gramsch	323	1084
ludcmp	362	1422	ludcmp	315	1494
lu	233	1231	lu	233	1440
gemver	339	1428	gemver	293	1208
cholesky	332	1390	cholesky	332	1116
gesummv	935	1440	gesummv	228	1259
atax	232	1451	atax	242	920
bicg(u)	442	1425	bicg(u)	423	1341

On 4×4 CGRA with two registers per PE, Rewire achieves 4.2x and 13.5x compilation time reduction compared to PF* and SA, respectively. On 8×8 CGRA with four registers per PE, Rewire achieves 2.47x and 6.97x compilation time reduction compared to PF* and SA, respectively. Overall, Rewire achieves significant compilation time reduction compared to other approaches. The main reason is that Rewire maps multiple nodes in one go and does not need numerous iterations to map each node individually and backtrack (remap) if it fails to map future nodes. Moreover, the compilation time on 8×8 CGRA is significantly higher than 4×4 CGRA due to the larger search space, but Rewire can still achieve substantial compilation time reduction compared to the other two approaches, demonstrating the efficiency of the pruning algorithm.

Table I shows the number of iterations for PF* and SA on 4×4 CGRA with four registers per PE and 4×4 CGRA with one register per PE. In each iteration, both methodologies select one node to unmap. As the mappers need to generate a new initial mapping for each explored II value, we use the average number of remapping iterations from the start II to the final mapped II. Both PF* and SA need a significant number of single-node mapping iterations, while Rewire only needs to construct the right cluster of multiple nodes and amend their invalid mappings in one shot. SA needs much more remapping iterations than PF*. The reason is that PF* evaluates all the placement candidates for each single-node remapping and selects the best one, while SA selects one candidate randomly. Thus, PF* has a better chance of success. Moreover, PF* and SA generally need more remapping iterations on CGRA with one register per PE compared to CGRA with four registers per PE. The reason is that the former has fewer routing resources and needs more iterations to find a mapping. Rewire might need multiple iterations to build U as we progressively append the node to U. However, U cannot be bigger than the size of DFG, and we have limited the size to 15, as mentioned previously. Hence, Rewire takes significantly fewer iterations than both methodologies.

In summary, for almost all applications and CGRA combinations, Rewire substantially outperforms PF* and SA in mapping quality (application performance) and compilation time. With the consolidated routing paradigm, Rewire scales with CGRA size and complex DFGs and well handles architectures with limited routing resources.

VI. Conclusion

Existing mapping approaches place and route nodes individually, limiting the ability to comprehensively coordinate multi-node mapping. Rewire presents a consolidated routing paradigm for CGRA mapping that effectively handles complex multi-node dependencies. By mapping multiple nodes in one shot through propagation and consolidation of routing information, our approach achieves significant improvements in both performance and compilation time compared to two popular mappers.

***Abstract*—Measurement-based uncomputation (MBU) is a technique used to perform probabilistic uncomputation of quantum circuits. We formalize this technique for the case of single-qubit registers, and we show applications to modular arithmetic. Using MBU, we reduce Toffoli count and depth by 10% to 15% for modular adders based on the architecture of [1], and by almost 25% for modular adders based on the architecture of [2]. Our results have the potential to improve other circuits for modular arithmetic, such as modular multiplication and modular exponentiation, and can find applications in quantum cryptanalysis.**

I. Introduction

Given an invertible Boolean function $f : \{0,1\}^n \to \{0,1\}^m$, a quantum circuit implementation is given by a unitary gate U_f mapping $|x\rangle_n \mapsto |f(x)\rangle_m$. In general, computing f may require an out-of-place implementation, where U_f maps $|x\rangle_n |0\rangle_m$ to $|x\rangle_n |f(x)\rangle_m$, possibly introducing auxiliary qubits in a garbage state, $|g(x)\rangle_k$, which must be uncomputed to preserve reversibility. As it turns out, out-of-place implementations with garbage often arise in binary arithmetic. For instance, a *ripple carry* addition algorithm computes the carry bitwise from the least significant bits of the addends, leaving the carry in memory. To ensure correctness, the ancillary carry bit must be uncomputed from the registers. Other operations, such as (modular) addition, subtraction, and comparison by a constant, can be built from these adder gates. Efficient quantum arithmetic circuits are pivotal for advancing quantum computing, underpinning numerous key algorithms. Effective implementations of binary arithmetic are fundamental to many quantum algorithms, such as quantum algorithms for factoring [3], [4] and discrete logarithm [5], quantum walks [6], and for algorithms that construct oracles for Grover's search and quantum phase estimation, e.g. [7]–[9]. Therefore, finding cheaper ways of performing uncomputation on qubits storing garbage/intermediate computations is essential for efficient quantum circuit design.

a) Contributions: In this work, we enhance quantum circuits for modular arithmetic, specifically focusing on modular addition two n-bit quantum registers. Our approach has the potential to improve not only modular multiplication and modular exponentiation but also quantum circuits used in cryptographic attacks, see for example [1], [10], [11]. In Section II we formalize the measurement-based uncomputation technique introduced in [12]–[14] providing with Lemma 1 a plug-and-play result that can be applied to any single-qubit garbage. In Section III, we introduce a modular and composable framework to construct arithmetic circuits from other known arithmetic primitives. In particular, we quantify the resource cost for some previously known adder implementation circuits for addition, namely [1], [12], [15], [16]. We also discuss how to compute subtraction, comparison, and modular addition together with their controlled and constant variants. Section IV is dedicated to deriving formal statements for modular addition circuits optimized by MBU. Notably, table V provides resource counts for modular addition, and highlights the cost reductions achieved by using MBU. For the controlled modular adder derived from [15], MBU can reduce the Tof (Toffoli) count by $n + \frac{1}{2}$ gates in expectation. For modular addition by a constant, MBU reduces the Tof count by n gates in expectation (see theorem 4), leading to a 16.7% improvement on the original circuit. We obtain similar improvements for controlled modular addition by a constant. Finally, to our knowledge, we are the first to discuss a quantum circuit to compute whether a given register's value is contained within two other register's values (theorem 6). This circuit is a prime candidate for MBU, leading to a nearly 16.7% reduction in the cost of the circuit.

b) Notation and convention: As in [15], we denote the quantum registers by capital letters A, B, C, etc. Each register is encoded with several qubits; we denote by A_i the i-th qubit of register A. Where necessary, we put the number of qubits in a register as a subscript following the ket representing the register's state, e.g. $|x\rangle_n$ for an n-qubit register. For an n bit string $\mathbf{x} = x_{n-1}x_{n-2}\dots x_0 \in \{0,1\}^n$ we shall often equate it with the decimal number x encoded in binary by $\mathbf{x}$. We denote with $a|_n$ the n bit string encoding the number $a \in \{-2^n, \dots, 0, 1, \dots, 2^{n-1}-1\}$ in the 2's complement notation. For a number $a \in \mathbb{N}$, $|a|$ denotes the Hamming weight of the binary representation of a. We define the function $\mathbf{1}[\mathsf{condition}]$ to be 1 if $\mathsf{condition}$ is true, otherwise is 0. We call *bit string addition* the binary operator $+ : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}^{n+1}$, $(\mathbf{x}, \mathbf{y}) \mapsto \mathbf{s}$ defined bit-wise by $s_i = x_i \oplus y_i \oplus c_i$, where the bit c_i, called i-th carry, is defined recursively by $c_0 = 0$ and $c_{i+1} = \mathrm{maj}(x_i, y_i, c_i)$. The function maj is a logic gate called *majority* defined by

$$\mathrm{maj}(x_i, y_i, c_i) = x_i y_i \oplus x_i c_i \oplus y_i c_i \ , \tag{1}$$

which gives 1 whenever at least half of the inputs (at least two out of three) entries are different 1. We call 1*'s complement* the operator $\overline{\cdot} : \{0,1\}^n \to \{0,1\}^n$, $\mathbf{x} \mapsto \overline{\mathbf{x}}$ defined bit-wise as $(\overline{\mathbf{x}})_i = x_i \oplus 1$. We call 2*'s complement* the operator defined as $\overline{\overline{\mathbf{x}}} = \overline{\mathbf{x}} + \mathbf{1}$, where $\mathbf{1}$ denotes the n bits string $0 \dots 0\,1$. We call *bit string subtraction* the binary operator $- : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}^{n+1}$, $(\mathbf{x}, \mathbf{y}) \mapsto \overline{(\overline{\mathbf{x}} + \mathbf{y})}$. The string $\mathbf{d} = \mathbf{x} - \mathbf{y}$ is given bit-wise by $d_i = x_i \oplus y_i \oplus b_i$, where the bit b_i, called i-th borrow, is defined recursively by $b_0 = 0$ and $b_{i+1} = \mathrm{maj}(x_i \oplus 1, y_i, b_i)$. Let Q be a quantum circuit composed of m gates Q_j from a gateset $\mathcal{G} = \{\mathcal{G}_1, \mathcal{G}_2, \dots, \mathcal{G}_K\}$. Define the gate count $c_i := |\{j \in [m] \mid \mathsf{Q}_j = \mathcal{G}_i\}|$ for $i \in [K]$. We represent the gate counts of Q as $\mathsf{count}(\mathsf{Q}) = \{(\mathcal{G}_i, c_i) \mid i \in [K]\}$. According

Corresponding author: asireesh@ed.ac.uk

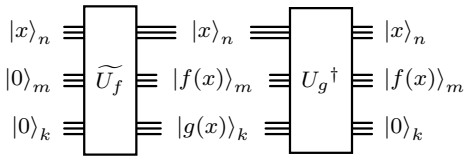
to [17], a Quantum fourier transform QFT_m has a circuit size of $\mathsf{count}(\mathsf{QFT}_m) = \{(\mathsf{H}, m)\} \cup \{(\mathsf{C\text{-}R}(\theta_i), m+1-i) \mid i \in [1, m+1]\}$.

II. Ancillary garbage uncomputation

In this section, we dive deeper into the importance of uncomputation. Consider a quantum circuit U_f computing a Boolean function $f : \{0,1\}^n \to \{0,1\}^m$ between bit strings. When f is invertible (meaning that f is injective and $n = m$) we say that U_f computes f *in-place* if it performs the mapping

$$U_f : |x\rangle_n \mapsto |f(x)\rangle_m \tag{2}$$

for any bit string $x \in \{0,1\}^n$, where we use the subscripts to denote the number of qubits in a quantum register. An in-place implementation is not always possible. In the most general case, one needs to compute f *out-of-place*, meaning that the circuit U_f realises the following mapping



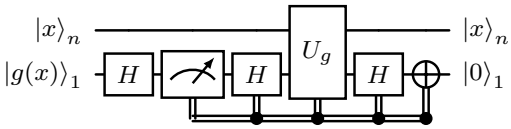
$$U_f : |x\rangle_n |0\rangle_m \mapsto |x\rangle_n |f(x)\rangle_m \ . \tag{3}$$

However, a more realistic implementation of the above gate will, in principle, involve a number k of auxiliary qubits which get mapped in a *garbage* state $|g(x)\rangle$ as follows:

$$\widetilde{U}_f : |x\rangle_n |0\rangle_m |0\rangle_k \mapsto |x\rangle_n |f(x)\rangle_m |g(x)\rangle_k . \tag{4}$$

The auxiliary qubits are entangled with the other registers and must be uncomputed, i.e. restored to their original value, in order to get a reversible out-of-place implementation of f. Such uncomputation can be achieved in several ways. A first solution, due to [18], simply prescribes copying the output $|f(x)\rangle_m$ into an auxiliary m-qubit register via a set of m CNOT gates and then applying $\widetilde{U}_f^\dagger$. This strategy doubles the resource cost of the reversible computation of f, also requiring m more ancillary qubits. Alternatively, one could look for an out-of-place implementation of the garbage function U_g, seeing g as a function of x and $f(x)$. When this unitary is available, one can implement U_f as in figure 1.

Fig. 1: Garbage gate uncomputation.



In principle, invoking the garbage circuit U_g can be quite resource intensive. Therefore, it is necessary to develop techniques to optimize the synthesis of quantum circuits and their uncomputation.

A. Measurement-Based Uncomputation (MBU).

Measurement-based uncomputation (MBU) was developed to efficiently address the challenge of uncomputing Boolean functions. This technique performs uncomputation probabilistically, by measuring the qubits slated for uncomputation on the X basis. Depending on the measurement outcome, the uncomputation circuit may either be executed or considered already completed, which helps to minimize overall quantum resource requirements. MBU has already been applied in various contexts to improve resource efficiency in uncomputation [12]–[14], [19]. However, to our knowledge, ours is the first formalization of this technique, enabling a clearer understanding and easy application in diverse contexts, as we show in Section III.

Lemma 1 (Measurement-based uncomputation lemma)**.** *Let $g : \{0,1\}^n \to \{0,1\}$ be a function, and let U_g be a self-adjoint $(n+1)$-qubit unitary that maps $U_g |x\rangle_n |b\rangle_1 = |x\rangle_n |b \oplus g(x)\rangle_1$.*

Fig. 2: A circuit for measurement-based uncomputing the unitary U_g.

There is an algorithm performing the mapping $\sum_x \alpha_x |x\rangle_n |g(x)\rangle_1 \mapsto \sum_x \alpha_x |x\rangle_n |0\rangle_1$ using U_g, 2 H gates, and 1 NOT gate with $1/2$ probability. It also involves one single-qubit computational basis measurement and a single H gate.

Proof. The algorithm is described in figure 2. We first apply the Hadamard gate on the register G and measure it in the computational basis. Since $g(x) \in \{0,1\}$, the resulting outcome is 0 or 1 with equal probabilities. If we obtain 0, we successfully uncomputed the register, leaving the registers in the state $\sum_x \alpha_x |x\rangle_A |0\rangle_G$. On the other hand, if we get the outcome 1, the state at this point is $\sum_x \alpha_x (-1)^{g(x)} |x\rangle_A |1\rangle_G$. We then apply another Hadamard to G, followed by U_g. This performs a phase kickback, leaving the quantum computer in the state

$$\sum_x \alpha_x (-1)^{g(x)} |x\rangle_A \frac{|0 \oplus g(x)\rangle_G - |1 \oplus g(x)\rangle_G}{\sqrt{2}} = \sum_x \alpha_x (-1)^{g(x) \oplus g(x)} |x\rangle_A |-\rangle_G \ .$$

Applying on G another Hadamard and a NOT gate results in the final state $\sum_x \alpha_x |x\rangle_A |0\rangle_G$. □

Applying the MBU lemma leads to gate costs expressed *"in expectation"*. The expected value is calculated based on a Bernoulli distribution with a probability $p = \frac{1}{2}$. This is because, for any quantum state $\sum_x \alpha_x |x\rangle_n |g(x)\rangle_1$, if $g(x) \in \{0,1\}$, when the last register is measured in the X basis, there is an equal probability of obtaining a $|0\rangle$ or $|1\rangle$ state.

III. Quantum Arithmetic

Early proposals for quantum addition [1], [15], [20], some of which are employed in fault-tolerant algorithms with state-of-the-art resource estimates [4], [21], [22], were inspired by classical circuits for addition, with an emphasis on minimizing the T count and/or the Tof (Toffoli) count, and the number of ancilla qubits. Subsequent approaches have explored more quantum-specific methods of performing arithmetic [2], [16], [23], [24]. All these arithmetic circuits serve as building blocks for more complex operations such as modular addition, multiplication, and exponentiation, to name a few. A comprehensive survey on quantum adders can be found in [11], [25].

We define a *(constant[1], controlled) quantum adder* as any unitary gate that implements the addition of n-bit strings according to circuits in figures 3, 4, and 5. Note that the initial extra qubit, prepared in $|0\rangle$, in the second register is needed to take into account the possible overflow. The circuit can perform unsigned integer addition by interpreting the bit string x as its corresponding decimal number, as well as signed integer addition, using the 2's complement representation. Table I summarizes the gate and qubit counts for various quantum implementations of bit string addition from the literature.

[1]By constant we mean a classically known value employed in the quantum computation.

Draper [16]	3	0	–

TABLE I: Plain adders, gate count.

One can easily construct a controlled quantum adder circuit using an existing n-bit quantum adder. The construction requires $n+s$ ancilla qubits and $r+2n$ Toffoli gates, where s and r are the number of ancilla and Toffoli gates used by the original adder. It involves loading the value $c \cdot x$ in a register initially in the $|0\rangle_n$ state, performing plain addition, and unloading the control using a sequence of Toffoli gates. An improvement can be achieved by implementing Gidney's adder [12] by loading the value $c \cdot x$ via temporary logical-AND and then uncomputing it using measurements. Alternatively, the [15] adder implementation can be easily modified to perform controlled addition with a single ancilla qubit. To do so, it is sufficient to substitute a suitable CNOT in the "unmajority" gate with a Tof gate on the control register. Regarding the Draper implementation [20], circuit symmetries can be exploited to avoid controls on all gates. Only the central adder gate would need to be controlled, whereas the quantum Fourier transforms at the beginning and the end of the circuit remain uncontrolled. In total, this would require a single ancilla and n extra Tof gates. See table II for the gate count of some well-known implementations.

Procedure	Tof Count	Ancillas	CNOT
CDKPM	$3n$	1	$4n+1$
Gidney	$2n$	$n+1$	$7n-1$
	Tof Count	**Ancillas**	QFT_{n+1}
Draper	n	1	3

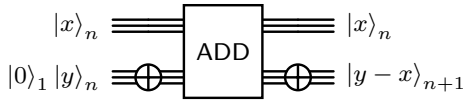

TABLE II: Controlled addition, gate count.

As suggested in [15], one can implement a quantum circuit that adds a classically known constant value a to an n-bit quantum register using any given adder circuit by loading the constant a (via $|a|$ NOT gates) on an ancillary register, performing the addition and then unloading a using the same NOT gates. In the case of Draper's QFT adder, Beauregard [2] introduced a method to add constants without requiring ancillas. Relying on the procedure sketched above, one can obtain a constant controlled adder starting with any plain adder implementation, and using additional $2|a|$ CNOT gates to conditionally Load/Unload the constant value. In [2], they propose another method based on Draper's implementation, which adds controls to rotation gates and achieves the same result without any ancilla qubits, with the circuit's complexity depending on the binary representation of the constant a. In table III we record the gate count for the above implementations.

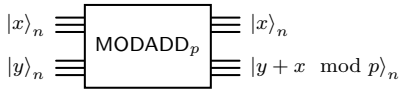
Procedure	Tof Count	Ancillas	CNOT
CDKPM	$2n$	$n+1$	$4n+1+2\|a\|$
Gidney	n	$2n$	$6n-1+2\|a\|$
	QFT_{n+1}	**Ancillas**	$\mathsf{C\text{-}\Phi_{ADD}}(a)$
Draper	2	0	1

TABLE III: Controlled addition by a constant 'a', gate count.

We define a *(controlled) constant quantum subtractor* as any unitary gate that implements the subtraction of the n strings according to the circuits in figures 6,7, and 8. Due to the unitarity of the quantum adder gate and the uniqueness of the adjoint, it follows that $(\mathsf{ADD})^\dagger$ implements a quantum subtractor. Alternatively, one can implement a quantum subtractor directly from the definition of bit-string subtraction as follows.

In principle, a subtractor has the same count of ancillas, Tof gates, and CNOT gates as the corresponding adder implementations. We define a *(controlled, constant) quantum comparator* as any unitary gate that implements the n string comparison according to the circuits in figures 9,10, and 11. Note that $\mathbf{1}[\mathsf{x} > \mathsf{y}]$ coincides with the most

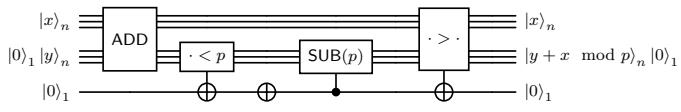
significant bit of $y - x$, i.e. it is 1 when $x > y$ and 0 otherwise. Given a quantum subtractor, one can easily obtain a string comparator reading the sign (i.e. the most significant bit) of the difference. In table IV we record the gate count for comparators with respect to the considered adder implementations. Given any circuit implementing



Procedure	Tof Count	Ancillas	CNOT
CDKPM	$2n$	1	$4n+1$
Gidney	n	n	$6n+1$
	QFT_{n+1}	**Ancillas**	–
Draper	6	1	–

TABLE IV: Comparator, gate count.

the comparison $(x > y)$ one can get the opposite comparison $(x \leq y)$ by simply postcomposing the first circuit with an X gate acting on the target register.



A. Quantum modular addition

Let $x \in \{0,1\}^n, y \in \{0,1\}^n$ be two bit strings, and $p \in \{0,1\}^n$ classically known with $0 \leq x, y < p$. We define a *quantum modular adder* as any unitary gate implementing the n-bit strings *addition modulo* p according to the following circuit:

A modular adder performing the operation, $|x\rangle|y\rangle \mapsto |x\rangle|x+y \pmod p\rangle$, can be decomposed into four separate subroutines [1]: quantum-quantum addition, comparison with a classical constant (by first loading in the constant using a set of X gates into an empty register, using two half subtractors [15] for the comparison, and then unloading the constant), controlled subtraction by a classical constant (by first loading the constant using a set of CNOTs into an empty register, then performing the subtraction using an inverse adder, and finally unloading the constant) and quantum-quantum comparison (using two half subtractor). The following implementation is a slight modification of [1] and [21]. It uses any available combination of adders, (controlled) subtractors (by a constant), and comparators (by a constant).

Fig. 12: Implementation of a modular adder using previous circuits.

The cost estimates for different specific combinations of the required building blocks are subsumed in table V.

IV. Measurement-based uncomputation speed-ups

In this section, we demonstrate the versatility of the MBU lemma in improving modular arithmetic circuits. While the technique is applicable to a wide range of modular arithmetic operations, we focus on a subset of key results to illustrate its impact. Specifically, we highlight their application to modular addition, controlled modular addition, modular addition by a constant, and controlled modular addition by a constant. For instance, in the modular adder architecture of VBE discussed in the previous section, the first three subroutines compute the desired value $|x+y \mod p\rangle$ in the output register, but leave an entangled ancilla qubit. The quantum-quantum comparison is required for the uncomputation of this single ancilla storing the most significant qubit of the adder circuit. Thus, the MBU Lemma can be applied to probabilistically uncompute this garbage qubit, reducing overall costs.

The theorems (thms. 1, 2, 3, 4, 5) detailed in this section represent abstract architectures of modular addition circuits which we optimize with the MBU lemma. Each subroutine in these theorems can be replaced by a specific implementation of a plain adder architecture of one's choice. In table V, we present the savings achieved by the MBU optimized modular adder, using specific plain adder architectures ([1], [12], [15], [16]) for the subroutines. Using our technique, we can derive similar results (e.g. between 15% to 25% reduction in gate count) for modular addition by a constant, controlled modular addition, and controlled modular addition by a constant.

Theorem 1 (MBU modular adder - VBE architecture)**.** *Let* $\mathsf{Q}_{\mathsf{ADD}}$ *be a quantum circuit that performs a quantum addition using* s_{ADD} *ancillas, and* r_{ADD} Tof *gates;* $\mathsf{Q}_{\mathsf{COMP}}(p)$ *be a quantum comparator using* s_{COMP} *ancillas,* r_{COMP} Tof *gates;* $\mathsf{C\text{-}Q}_{\mathsf{SUB}}(p)$ *be a quantum circuit that performs a (controlled) subtraction by a constant* p *using* $s_{\mathsf{C\text{-}SUB}}$ *ancillas, and* $r_{\mathsf{C\text{-}SUB}}$ Tof *gates;* $\mathsf{Q}'_{\mathsf{COMP}}$*: be a quantum comparator using (*s'_{COMP} *ancillas,* r'_{COMP} Tof *gates). There is a circuit,* $\mathsf{Q}_{\mathsf{MODADD}_p}$*, performing the* n*-bit modular addition operation using* $r = (r_{\mathsf{ADD}} + r_{\mathsf{COMP}} + r_{\mathsf{C\text{-}SUB}} + (r'_{\mathsf{COMP}}/2))$ Tof *gates in expectation and* s *ancillas with:*

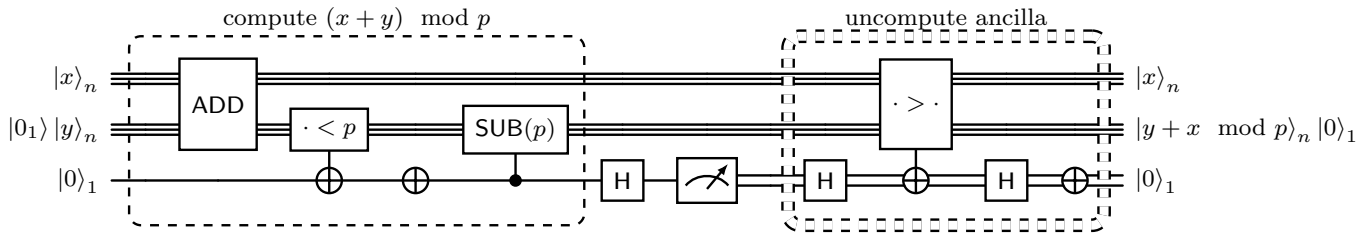
$$s = 2 + \max(s_{\mathsf{ADD}}, s_{\mathsf{COMP}}, s_{\mathsf{C\text{-}SUB}}, s'_{\mathsf{COMP}}) \ .$$

Proof. The first three subroutines map $|0\rangle_s |x\rangle_n |y\rangle_n$ to

$$|0\rangle_{s-1} |x\rangle_n |x+y \mod p\rangle_n |\mathbf{1}[x+y \geq p]\rangle_1 \ .$$

The comparator qubit storing $\mathbf{1}[x+y \geq p]$ is finally supposed to be uncomputed using $\mathsf{Q}'_{\mathsf{COMP}}$. We can apply the MBU lemma on the comparator qubit and the uncomputation subroutine $\mathsf{Q}'_{\mathsf{COMP}}$, thus halving the cost of $\mathsf{Q}'_{\mathsf{COMP}}$ in expectation. Therefore, we finally get a cost of $r = (r_{\mathsf{ADD}} + r_{\mathsf{COMP}} + r_{\mathsf{C\text{-}SUB}} + (r'_{\mathsf{COMP}}/2))$ Tof gates in expectation, and the same ancilla count of the modular addition implementation. □

By suitably substituting certain adder gates with the corresponding controlled version, one obtains a routine for controlled modular arithmetic.



Theorem 2 (MBU controlled modular adder - VBE architecture)**.** *Let* $\mathsf{C\text{-}Q}_{\mathsf{ADD}}$ *be a quantum circuit that performs a quantum (controlled) addition using* $s_{\mathsf{C\text{-}ADD}}$ *ancillas, and* $r_{\mathsf{C\text{-}ADD}}$ Tof *gates;* $\mathsf{Q}_{\mathsf{COMP}}(p)$ *be a quantum comparator by a constant* p*, using* s_{COMP} *ancillas,* r_{COMP} Tof *gates;* $\mathsf{C\text{-}Q}_{\mathsf{SUB}}(p)$ *be a quantum circuit that performs a quantum subtraction by a constant* p*, using* $s_{\mathsf{C\text{-}SUB}}$ *ancillas, and* $r_{\mathsf{C\text{-}SUB}}$ Tof *gates;* $\mathsf{C\text{-}Q}'_{\mathsf{COMP}}$*: be a controlled quantum comparator using* $s'_{\mathsf{C\text{-}COMP}}$ *ancillas and* $r'_{\mathsf{C\text{-}COMP}}$ Tof *gates. There exists a circuit* $\mathsf{C\text{-}Q}_{\mathsf{MODADD_p}}$ *that implements an* n*-bit controlled quantum modular addition using* $r = (r_{\mathsf{C\text{-}ADD}} + r_{\mathsf{COMP}} + r_{\mathsf{C\text{-}SUB}} + (r'_{\mathsf{C\text{-}COMP}}/2))$ Tof *gates in expectation and* $s = 2 + \max(s_{\mathsf{C\text{-}ADD}}, s_{\mathsf{COMP}}, s_{\mathsf{C\text{-}SUB}}, s'_{\mathsf{C\text{-}COMP}})$ *ancillas.*

Proof. The first three subroutines in figure 13 map $|0\rangle_s |c\rangle_1 |x\rangle_n |y\rangle_n$ to

$$|0\rangle_{s-1} |c\rangle_1 |x\rangle_n |c \cdot x + y \mod p\rangle_n |\mathbf{1}[c \cdot x + y \geq p]\rangle_1 \ .$$

The comparator qubit storing $\mathbf{1}[c \cdot x + y \geq p]$ is finally supposed to be uncomputed using $\mathsf{C\text{-}Q}'_{\mathsf{COMP}}$. We can apply the MBU lemma here on the comparator qubit and the uncomputation subroutine $\mathsf{C\text{-}Q}'_{\mathsf{COMP}}$, thus

Fig. 13: Implementation of a MBU modular addition. The double dotted lines represent the non-computation of the ancilla, controlled on the measurement value.

halving the cost of C-$\mathsf{Q}'_{\mathsf{COMP}}$ in expectation. Therefore, we finally get a cost of $r = (r_{\text{C-ADD}} + r_{\mathsf{COMP}} + r_{\text{C-SUB}} + (r'_{\text{C-COMP}}/2))$ Tof gates in expectation, and the same ancilla count as the controlled modular addition implementation. □

Similarly, one can get the circuit implementation of modular addition with a constant.

Theorem 3 (MBU modular addition by a constant - VBE architecture)**.** *Let* $\mathsf{Q}_{\mathsf{ADD}}(\mathsf{a})$ *be a quantum circuit that performs a constant quantum addition using* s_{ADD} *ancillas, and* r_{ADD} Tof *gates;* $\mathsf{Q}_{\mathsf{COMP}}(p)$ *be a quantum comparator using* s_{COMP} *ancillas,* r_{COMP} Tof *gates;* C-$\mathsf{Q}_{\mathsf{SUB}}(p)$ *be a quantum circuit that performs a (controlled) subtraction by a constant* p *using* $s_{\text{C-SUB}}$ *ancillas, and* $r_{\text{C-SUB}}$ Tof *gates;* $\mathsf{Q}'_{\mathsf{COMP}}(a)$*: be a constant quantum comparator using (*s'_{COMP} *ancillas,* r'_{COMP} Tof *gates). There exists a circuit* $\mathsf{Q}_{\mathsf{MODADD_p}}(a)$ *that implements an* n*-bit quantum modular addition by a constant using* $r = (r_{\mathsf{ADD}} + r_{\mathsf{COMP}} + r_{\text{C-SUB}} + (r'_{\mathsf{COMP}}/2))$ Tof *gates and* $s = 2 + \max(s_{\mathsf{ADD}}, s_{\mathsf{COMP}}, s_{\text{C-SUB}}, s'_{\mathsf{COMP}})$ *ancillas.*

Proof. The first three subroutines map $|0\rangle_s\,|x\rangle_n$ to

$$|0\rangle_{s-1}\,|x\rangle_n\,|x+a \mod p\rangle_n\,|\mathbf{1}[x+a \geq p]\rangle_1 \ .$$

The comparator qubit storing $|\mathbf{1}[x+a \geq p]\rangle_1$ is finally supposed to be uncomputed using $\mathsf{Q}'_{\mathsf{COMP}}(a)$. We can apply the MBU lemma here on the comparator qubit and the uncomputation subroutine $\mathsf{Q}'_{\mathsf{COMP}}(a)$, thus halving the cost of $\mathsf{Q}'_{\mathsf{COMP}}(a)$ in expectation. Therefore, we finally get a cost of $r = (r_{\mathsf{ADD}} + r_{\mathsf{COMP}} + r_{\text{C-SUB}} + (r'_{\mathsf{COMP}}/2))$ Tof gates in expectation, and the same ancilla count as the constant modular addition implementation. □

Theorem 4 (MBU modular adder by a constant - in Takahashi Architecture [26])**.** *Let* $x \in \{0,1\}^n$*. Assume to know classically* $p, a \in \{0,1\}^n$ *with* $0 \leq a, x < p$*. Also, assume we have access to the following subroutines:* $\mathsf{Q}_{\mathsf{SUB}}(\mathsf{a})$ *be a quantum circuit that performs a constant quantum subtraction using* s_{SUB} *ancillas, and* r_{SUB} Tof *gates;* C-$\mathsf{Q}_{\mathsf{ADD}}(p)$ *be a quantum circuit that performs a (controlled) addition by a constant* p *using* $s_{\text{C-ADD}}$ *ancillas, and* $r_{\text{C-ADD}}$ Tof *gates;* $\mathsf{Q}_{\mathsf{COMP}}(a)$ *be a classical comparator using* s_{COMP} *ancillas,* r_{COMP} Tof *gates. Then, there exists a circuit* $\mathsf{Q}_{\mathsf{MODADD_p}}(a)$ *that implements quantum modular addition by a constant using* $r = (r_{\mathsf{SUB}} + r_{\text{C-ADD}} + (r_{\mathsf{COMP}}/2))$ Tof *gates in expectation and* $s = 1 + \max(s_{\mathsf{SUB}}, s_{\text{C-ADD}}, s_{\mathsf{COMP}})$ *ancillas.*

Proof. As seen in the Takashi constant modular adder [26], the first two subroutines map $|0\rangle_s\,|x\rangle_n$ to

$$|0\rangle_{s-1}\,|x\rangle_n\,|x+a \mod p\rangle_n\,|\mathbf{1}[x+a < p]\rangle_1 \ .$$

The comparator qubit storing $|\mathbf{1}[x+a < p]\rangle_1$ is finally supposed to be uncomputed using $\mathsf{Q}_{\mathsf{COMP}}(a)$ and a NOT gate. We can apply the MBU lemma here on the comparator qubit and the uncomputation subroutine $\mathsf{Q}_{\mathsf{COMP}}(a)$, thus halving the cost of $\mathsf{Q}_{\mathsf{COMP}}(a)$ in expectation. Therefore, we finally get a cost of $r = (r_{\mathsf{SUB}} + r_{\text{C-ADD}} + (r_{\mathsf{COMP}}/2))$ Tof gates in expectation, and the same ancilla count of the [26] constant modular adder. □

Theorem 5 (MBU controlled modular adder by a constant - VBE architecture)**.** *Let* C-$\mathsf{Q}_{\mathsf{ADD}}(\mathsf{a})$ *be a quantum circuit that performs a controlled addition by a constant using* $s_{\text{C-ADD}}$ *ancillas, and* $r_{\text{C-ADD}}$ Tof *gates;* $\mathsf{Q}_{\mathsf{COMP}}(p)$ *be a quantum comparator using* s_{COMP} *ancillas,* r_{COMP} Tof *gates;* C-$\mathsf{Q}_{\mathsf{SUB}}(p)$ *be a quantum circuit that performs a (controlled) subtraction by a constant* p *using* $s_{\text{C-SUB}}$ *ancillas, and* $r_{\text{C-SUB}}$ Tof *gates;* C-$\mathsf{Q}'_{\mathsf{COMP}}(a)$*: be a controlled constant quantum comparator using (*$s'_{\text{C-COMP}}$ *ancillas,* $r'_{\text{C-COMP}}$ Tof *gates). There exists a circuit* C-$\mathsf{Q}_{\mathsf{MODADD_p}}(a)$ *that implements an* n*-bit controlled quantum modular addition by a constant using* $r = (r_{\text{C-ADD}} + r_{\mathsf{COMP}} + r_{\text{C-SUB}} + (r'_{\text{C-COMP}}/2))$ Tof *gates and* $s = 2 + \max(s_{\text{C-ADD}}, s_{\mathsf{COMP}}, n + s_{\text{C-SUB}}, s'_{\text{C-COMP}})$ *ancillas.*

Proof. A controlled modular adder by a constant in VBE architecture, the first three subroutines map $|0\rangle_s\,|c\rangle_1\,|x\rangle_n$ to

$$|0\rangle_{s-1}\,|c\rangle_1\,|x\rangle_n\,|x+c\cdot a \mod p\rangle_n\,|\mathbf{1}[x+c\cdot a \geq p]\rangle_1 \ .$$

The comparator qubit storing $|\mathbf{1}[x+c\cdot a \geq p]\rangle_1$ is finally supposed to be uncomputed using C-$\mathsf{Q}'_{\mathsf{COMP}}(a)$. We can apply the MBU lemma here on the comparator qubit and the uncomputation subroutine C-$\mathsf{Q}'_{\mathsf{COMP}}(a)$, thus halving the cost of C-$\mathsf{Q}'_{\mathsf{COMP}}(a)$ in expectation. Therefore, we finally get a cost of $r = (r_{\text{C-ADD}} + r_{\mathsf{COMP}} + r_{\text{C-SUB}} + (r'_{\text{C-COMP}}/2))$ Tof gates in expectation, and the same ancilla count of a controlled constant modular adder. □

Finally, we introduce a new quantum arithmetic subroutine called the two sided comparison circuit which checks if a register $|x\rangle$ has a value in the range specified by two other quantum registers $|y\rangle$ and $|z\rangle$, and also show how its cost can be further reduced with MBU. Compared to a non-MBU implementation, we save 16.5% for the Tof gate cost.

Theorem 6 (Two-sided comparator)**.** *Let* $x, y, z \in \{0,1\}^n$*, and* $t \in \{0,1\}$ *Let us assume we have access to* $\mathsf{Q}_{\mathsf{COMP}}$*, with*

$$|x\rangle_n\,|y\rangle_n\,|t\rangle_1 \xmapsto{\mathsf{Q}_{\mathsf{COMP}}} |x\rangle_n\,|y\rangle_n\,|t \oplus \mathbf{1}[x<y]\rangle_1$$

[1]We denote by $|p|$ the Hamming weight of the bit string of the number p expressed in binary expansion. PCQFT stands for "partially-classical" quantum Fourier transform, where each controlled rotation in the QFT is replaced by a classically controlled rotation. Results with MBU are considered "in expectation". Draper (Expec) represents the repeated use of the Draper addition circuit. In expectation, the cost of the first QFT and last IQFT become negligible compared to the rest of the circuit.

TABLE V: Cost of modular addition using different plain adder circuits in the VBE architecture of modular addition.

using s_{COMP} ancillas and r_{COMP} Tof gates. Assuming we also have access to $\mathsf{C\text{-}Q}'_{\mathsf{COMP}}$, with

$$|c\rangle_1 |x\rangle_n |y\rangle_n |t\rangle_1 \xmapsto{\mathsf{C\text{-}Q}'_{\mathsf{COMP}}} |c\rangle_1 |x\rangle_n |y\rangle_n |t \oplus c \cdot \mathbf{1}[x<y]\rangle_1$$

using $s'_{\mathsf{C\text{-}COMP}}$ ancillas and $r'_{\mathsf{C\text{-}COMP}}$ Tof gates. Then, there exists a circuit that performs the operation $\mathsf{Q}_{\mathsf{IN_RANGE}}$

$$|x\rangle_n |y\rangle_n |z\rangle_n |t\rangle_1 \xmapsto{\mathsf{Q}_{\mathsf{IN_RANGE}}} |x\rangle_n |y\rangle_n |z\rangle_n |t \oplus \mathbf{1}[x \in (y,z)]\rangle_1$$

using $s = 1 + s_{\mathsf{COMP}}$ ancillas and $r = 1.5r_{\mathsf{COMP}} + r'_{\mathsf{C\text{-}COMP}}$ Tof gates.

Proof. We begin by first checking if $y < x$. Applying $\mathsf{Q}_{\mathsf{COMP}}$ to the state $|0\rangle_s |x\rangle_n |y\rangle_n |z\rangle_n |t\rangle_1$ one gets

$$|0\rangle_{s-1} |x\rangle_n |y\rangle_n |z\rangle_n |\mathbf{1}[y<x]\rangle |t\rangle_1 \ .$$

Next we compute whether $x < z$ controlled on $\mathbf{1}[y < x]$, and store the output in our target. We know that $\mathbf{1}[x \in (y,z)] \equiv (\mathbf{1}[y<x] \cdot \mathbf{1}[x < z])$, and since we have both the comparator values stored in memory mapping the previous state to

$$|0\rangle_{s-1} |x\rangle_n |y\rangle_n |z\rangle_n |\mathbf{1}[y<x]\rangle_1 |t \oplus \mathbf{1}[x \in (y,z)]\rangle_1 \ .$$

We finally uncompute the intermediate value $\mathbf{1}[y < x]$ using $\mathsf{Q}_{\mathsf{COMP}}$ obtaining the state

$$|0\rangle_s |x\rangle_n |y\rangle_n |z\rangle_n |t \oplus (\mathbf{1}[y<x] \cdot \mathbf{1}[x<z])\rangle_1 \ .$$

Therefore, we obtain a cost of $r = 2r_{\mathsf{COMP}} + r'_{\mathsf{C\text{-}COMP}}$. This cost can be decreased by applying the MBU lemma on the $\mathsf{Q}_{\mathsf{COMP}}$ uncomputing $\mathbf{1}[y < x]$, thus leading to a cost of $r = 1.5r_{\mathsf{COMP}} + r'_{\mathsf{C\text{-}COMP}}$. □

V. Conclusions

Through this work, we aim to emphasize the importance of enhancing existing subroutines in known quantum algorithms, as these optimizations play a crucial role in refining resource estimates for algorithms with substantial practical applications. In modular arithmetic circuit, the efficiency of the circuit highly depends on the specific plain adder used in the implementation (e.g. [1], [12], [15], [16]). This can be seen by comparing the gate counts of various modular addition implementations in the columns "w/o MBU" in table V. The flexibility of our formalization for (controlled) quantum modular addition (by a constant) allows us to select any plain adder circuit for each of its four subroutines. An interesting variant we discovered optimizes the use of available ancilla qubits by applying the Gidney adder solely for the initial addition and final comparison steps, while using the CDKPM adder for constant subtraction and constant comparison. This approach results in a lower Tof count than a modular adder fully based on CDKPM adders ($6n$ vs. $8n$) and reduces the logical qubit count compared to a fully Gidney-based modular adder ($3n+2$ vs. $4n+2$). In section. II-A, we introduced the MBU lemma. We then applied MBU to different modular addition architectures to show the savings in Tof gate counts (see thms. 1, 2, 3, 4, 5). As seen in table. V, when comparing the Tof gate costs of the original implementations and their MBU optimized versions, we saw savings anywhere from $15-25\%$ in the gate costs. We stress that our techniques can similarly improve modular addition by a constant, controlled modular addition, and controlled modular addition by a constant.

This work opens up numerous promising research directions. First, the MBU Lemma can be studied and applied in the multi-qubit setting. Our improved circuit for modular addition can be plugged in the vast literature of quantum modular arithmetic subroutines, leading to savings in the gate count, see e.g. [27]–[30]. However, approximate modular addition techniques such as the coset representation [14] seem to currently be the dominant approach in scenarios that involve a large number of repeated additions, hence making a fruitful application of MBU in this setting non-trivial. Last but not least, we leave for future research the exploration of the resource implications of our new modular addition circuits when employed as subroutines in quantum algorithms.

***Abstract*—Generating diverse VLSI layout patterns is essential for various downstream tasks in design for manufacturing, as design rules continually evolve during the development of new technology nodes. However, existing training-based methods for layout pattern generation rely on large datasets. In practical scenarios, especially when developing a new technology node, obtaining such extensive layout data is challenging. Consequently, training models with large datasets becomes impractical, limiting the scalability and adaptability of prior approaches.**

To this end, we propose PatternPaint, a diffusion-based framework capable of generating legal patterns with limited design-rule-compliant training samples. PatternPaint simplifies complex layout pattern generation into a series of inpainting processes with a template-based denoising scheme. Furthermore, we perform few-shot finetuning on a pretrained image foundation model with only 20 design-rule-compliant samples. Experimental results show that using a sub-3nm technology node (Intel 18A), our model is the only one that can generate legal patterns in complex 2D metal interconnect design rule settings among all previous works and achieves a high diversity score. Additionally, our few-shot finetuning can boost the legality rate by 1.87X compared to the original pretrained model. As a result, we demonstrate a production-ready approach for layout pattern generation in developing new technology nodes.

I. Introduction

Generating synthetic pattern libraries is an essential and high-value element in technology development. However, this process faces significant challenges at advanced technology nodes. Engineers must first understand hundreds of design rules (DRs), and then create or modify pattern generators accordingly, resulting in lengthy turnaround times and substantial engineering effort. Moreover, this becomes more challenging as the DRs are constantly changing at the early stage of technology development. Each new DR set requires diverse patterns to support many downstream tasks, such as optical proximity correction (OPC) elements [1], [2], [3], [4], [5], [6], hotspot detection [7], [8], [9], [10], [11], design rule manual qualification [12]. These tasks require a wide spectrum of patterns to test/improve their methodologies and avoid unanticipated patterns that cause systematic failure.

Before the rise of machine learning, several rule/heuristic-based methods [13], [14], [15] were proposed to generate synthetic layout patterns. However, these heuristic methods demanded substantial engineering effort during development, as they required hundreds of design rules to be converted into algorithmic constraints. Moreover, these methods were often closely coupled with the DR set of a specific technology node, resulting in considerable time and effort to adjust them for new technology nodes. More recently, leveraging recent advances in generative models [16], [17], a number of training-based ML methods such as GANs, Transformers, TCAEs, and Diffusion models [18], [19], [20], [21], [22], [23] have been proposed with the promise of reduced engineering effort and high pattern diversity.

Despite these advancements, their practical application remains limited due to their dependence on large training datasets of clean DR layout samples. This limitation becomes particularly challenging in the early stage of technology node development. During this stage, design rules are continuously changing, and very few realistic layout patterns are available. Creating these thousands of training samples often requires rule-based methods to be coded as a pre-requisite, which demands significant time and effort. These constraints significantly restrict the deployment of training-based methods in critical Design for Manufacturability (DFM) applications.

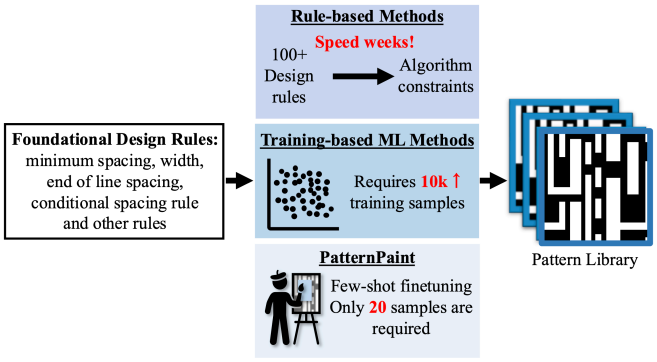

Fig. 1: Comparison between rule-based methods, training-based methods [19], [23], and our PatternPaint for layout pattern generation.

Additionally, these works have been demonstrated only in over-simplified academic design rule settings, rather than being tested in close-to-realistic scenarios. Due to the simplicity of the rule set, they decompose layout generation into generating pattern topologies (a blueprint of a layout pattern consisting only of the shape of patterns) and using a nonlinear solver to convert the topology into DR-clean layout patterns. However, this decomposition becomes unrealistic due to the following reasons. First, the solver's runtime grows exponentially with both the number of designs and pattern size. Second, when the DR set includes discrete constraints, the problem transforms into a mixed integer programming problem, resulting in significantly lower legality rates using the original nonlinear setting.

To address these challenges, we propose PatternPaint, a few-shot inpainting framework capable of generating legal patterns. Our unique advantage is highlighted in Figure 1. Our framework primarily targets single metal layer pattern generation to support DFM tasks, such as pattern feasibility analysis using OPC models. PatternPaint simplifies layout generation into a series of inpainting processes, which naturally exploit design rule information encoded in neighboring regions of existing patterns. PatternPaint operates at the pixel level through a customized template-based denoising scheme, bypassing the need for solver-based legalization.

Our contributions are outlined as follows:

- We present PatternPaint, the first few-shot pattern generation framework that leverages inpainting to drastically reduce training sample requirements for legal pattern generation.
- We decompose layout pattern generation into a series of inpainting processes with a novel template-based denoising scheme specifically designed for layout patterns. Our denoise method outperforms the conventional denoising method [24] by achiev-

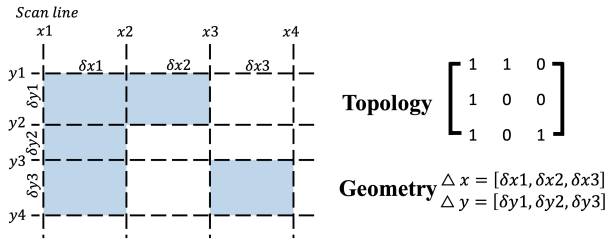

Fig. 2: Squish Pattern Representation.

ing a tenfold increase in legal pattern generation.

- **Validation on industrial PDKs:** PatternPaint is the first ML approach validated on an industrial PDK Intel 18A with full-set sign-off DR settings. Using only 20 starter samples, PatternPaint generates over 4000 DR-clean patterns, while prior ML solutions fail to deliver DR-clean patterns by training with 1k samples.

II. Preliminaries

A. Diffusion model

Diffusion models [25] are generative models that operate through forward and reverse diffusion processes. The forward process gradually adds Gaussian noise to data over T timesteps:

$$q(x_t|x_{t-1}) = \mathcal{N}(x_t; \sqrt{1-\beta_t}x_{t-1}; \beta_t\mathbf{I}) \quad (1)$$

$$q(x_1, ..., x_T|x_0) = \prod_{t=1}^{T} q(x_t|x_{t-1}) \quad (2)$$

where x_0 is the original sample, x_t represents noise-corrupted samples, and β_t controls the noise schedule. As T increases, the data distribution approaches Gaussian:

$$q(x_T) \approx \mathcal{N}(x_t; 0; \mathbf{I}) \quad (3)$$

The reverse process generates samples by learning to denoise:

$$p_\theta(x_0) = \int \prod_{t=1}^{T} p_\theta(x_{t-1}|x_t) dx_{1:T} \quad (4)$$

$$p_\theta(x_{t-1}|x_t) = \mathcal{N}(x_{t-1}; \mu_\theta(x_t, t); \sum_\theta(x_t, t)) \quad (5)$$

where θ represents neural network parameters trained to minimize the objective:

$$L = \sum_{t=0}^{T} D_{KL}(q(x_t|x_{t+1}, x_0)||p_\theta(x_t|x_{t+1})), t \in [1, T-1] \quad (6)$$

For inpainting tasks [26], this process is conditioned on known image regions to fill masked areas consistently with the surrounding content. We found this characteristic aligns well with VLSI layout pattern generation, as design rule information is largely encoded in neighboring regions. By conditioning the generation on legal neighboring layouts, our model naturally learns to produce design-rule-compliant patterns. In later sections, we demonstrate how this approach significantly reduces training sample requirements while enriching pattern libraries.

B. Squish representation

Standard layout patterns are typically composed of multiple polygons, presenting a sparse informational structure. To efficiently represent these patterns, majority of existing training-based methods [21], [18], [19], [27], [23] use "Squish" pattern [28], [29] to address these issues by compressing a layout into a concise pattern topology matrix alongside geometric data $(\triangle_x, \triangle_y)$, as illustrated in Fig. 2. This process involves segmenting the layout into a grid framework using a series of scan lines that navigate along the edges of the polygon.

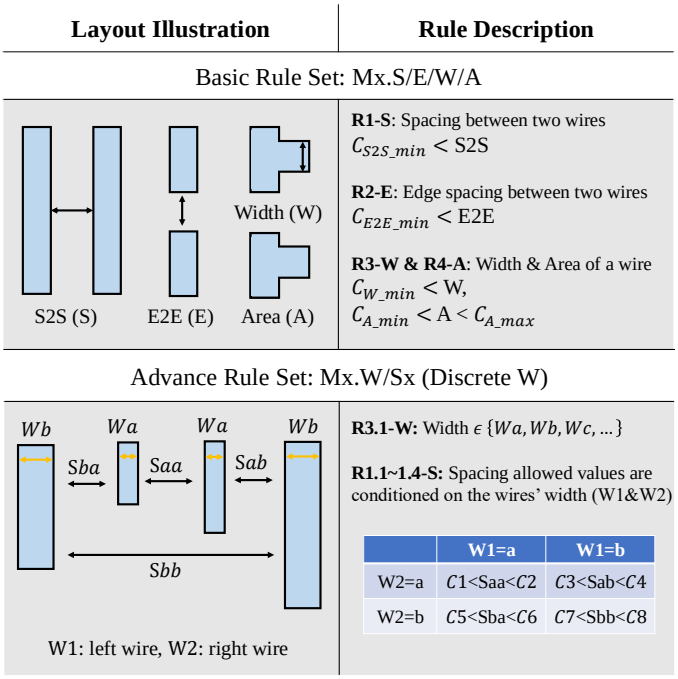

Fig. 3: Illustration of metal layer design rules. A selected set of design rules used in PatternPaint evaluation is shown as the advance rule set. (1) Basic Rule Set: Spacing (R1-S,R2-E)/ Width (R3-W)/ Area (R4-A) of Mx layer metal element. (2) Advance Rule Set: (R3.1-W) Only a set of discrete widths is allowed. (R1.1 1.4-S), the allowed spacing range is different depending on the neighboring metal widths.

The distances between each adjacent pair of scan lines are recorded in the $\triangle$ vectors. The topology matrix itself is binary, with each cell designated as either zero (indicating an absence of shape) or one (indicating the presence of a shape).

Existing training-based methods focus on topology generation, leaving the geometry vector solved by a nonlinear solver. We refer to all the prior approaches that use squish representation as **squish-based** solutions. However, these solvers lack scalability and cannot handle advanced design rules effectively. To overcome these limitations, PatternPaint switches to a simpler **pixel-based** representation where $\triangle x_i, \triangle y_i$ are pre-defined with fixed physical widths (e.g., 1nm × 1nm rectangles per pixel).

C. Related Works

Recent years, the development of training-based ML solutions for layout pattern generation has emerged. DeePattern [18] pioneered this field by using a Variational Autoencoder (VAE) [30] model to generate 1D layout patterns for 7nm EUV unidirectional settings with fixed metal tracks. This method employed a squish representation and a nonlinear solver to solve for the geometry vectors. Then, CUP [21] expanded the approach to 2D pattern generation, creating a large 2D academic layout pattern dataset containing 10k of training samples for a simple design rule setting (minimum width, spacing, and area). Under this dataset, LayouTransformer [20] introduced transformer-based sequential modeling, and DiffPattern [19] employed discrete diffusion methods. Additional explorations include transferability [27], free-size pattern generation [23], and controllable generation [22].

All existing ML works have been demonstrated only in basic DR settings. In contrast, PatternPaint addresses a full set of industrial standard DRs. As shown in Figure 3, the advanced rule set introduces significantly more complex constraints. Under these complex rules, the nonlinear solver-based legalization used in existing state-of-the-art methods [19], [23] becomes unscalable due to the presence of

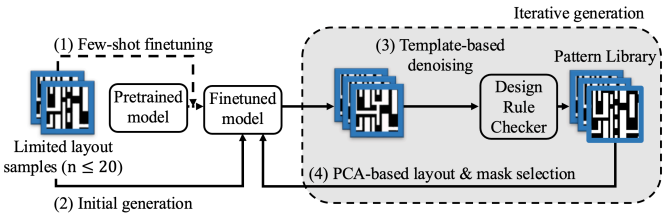

Fig. 4: PatternPaint framework. It consists of: (1) few-shot finetuning, (2) initial generation, (3) template-based denoising for layout refinement, followed by a design rule checking validation, and (4) PCA-based layout & mask selection to select the next inpainting samples for iterative generation. This approach enables efficient pattern generation while ensuring design rule compliance.

discrete widths and upper bounds on spacing. This scalability issue is evident in [23], where lower success rates are observed as pattern sizes increase. PatternPaint's pixel-based approach overcomes these limitations, enabling efficient pattern generation under more realistic and complex design rule constraints. The limitation of the solver is further discussed in Section VI.

III. Problem Formulation

In this section, we formalize the pattern generation problem and its evaluation criteria. The objective is to produce diverse, realistic layout patterns from a small set of existing designs while ensuring compliance with rigorous design rules. We use a variety of metrics for quantitative evaluation.

(1) Legality: A layout pattern is legal iff it is DR-clean.

(2) Entropy H_1: As detailed in [19], the complexity of a layout pattern is quantified as a tuple (C_x, C_y) representing the count of scan lines along the x-axis and y-axis, respectively, each reduced by one. Then, we can obtain

$$H_1 = \sum_{i,j} P(C_{x_i}, C_{y_j}) log P(C_{x_i}, C_{y_j})$$

where $P(C_{x_i}, C_{y_j})$ is the probability of encountering a pattern with complexities C_{x_i} and C_{y_j} within the library. This metric only focuses on topology diversity without considering any geometric information from actual patterns.

(3) Entropy H_2: To further examine the diversity of actual patterns with their geometric information included, we introduce H_2. For each unique combination of $\triangle x$ and $\triangle y$ (defined in Section II-B) presented in the library, we record their probability $P(\Delta_{x_i}, \Delta_{y_j})$ of having a pattern with the same $\Delta_{x,y}$ matrix within the library.

$$H_2 = \sum_{i,j} P(\Delta_{x_i}, \Delta_{y_j}) log P(\Delta_{x_i}, \Delta_{y_j})$$

Since we target on pixel level generation, H_2 serves as the main metric to evaluate generation performance.

Based on the aforementioned evaluation metrics, the pattern generation problem can be formulated as follows.

Problem 1 (Pattern Generation). *Given a set of design rules and existing patterns, the objective of pattern generation is to synthesize a legal pattern library such that H_2 of the layout patterns in the library is maximized.*

IV. PatternPaint

A. Overview

As illustrated in Figure 4, PatternPaint integrates four key components to achieve efficient layout pattern generation: (1) few-shot finetuning, (2) initial generation, (3) template-based denoising and (4) PCA-based layout & mask selection. In the following sections, we detail how these components work together to produce diverse and legal layout patterns.

B. Few-shot Finetuning

PatternPaint adapts a pretrained text-to-image diffusion model to VLSI layouts through few-shot finetuning using the limited available layout samples. During finetuning, we fixed the text encoder and only finetuned on the image diffusion model. This finetuning shares a similar training objective with Equation (6) but starts from the θ' in the pretrained diffusion neural network. The training objectives then become

$$\begin{aligned} L = & D_{KL}(q(x_T|x_0)||p_{\theta'}(x_T)) - log p_{\theta'}(x_0|x_1) \\ & + \sum_{t=2}^{T} D_{KL}(q(x_t|x_{t+1}, x_0)||p_{\theta'}(x_t|x_{t+1})) \\ & + \lambda L_{prior} \end{aligned} \tag{7}$$

where x_0 is selected from the limited n layout patterns at the finetuning stage, L_{prior} represents the prior preservation loss calculated on a set of class-specific images generated before training, and λ is a weighting factor that balances the influence of prior preservation. The L_{prior} helps serve as a regularization term to enable the model to learn very sparse samples while avoiding overfitting. The class-specific images are obtained by giving a fixed prompt to a text-to-image pretrained model. The interested reader is referred to [31], [32] for details.

C. Initial Pattern Generation

After finetuning, PatternPaint begins the initial generation phase using the n starter patterns from finetuning. Unlike prior approaches that generate entire patterns at once, our method decomposes generation into localized inpainting processes, mimicking how human engineers make targeted adjustments while preserving surrounding structures.

The generation process requires two inputs: (1) starter patterns that provide design rule context and (2) mask images that specify regions for variation. A masked image x_0^{masked} is created by applying the mask to a starter pattern, where masked regions (region replaced with Gaussian noise) are set to be predicted while unmasked regions remain unchanged. We provide 10 predefined masks (illustrated in Figure 6), though users can customize masks to target specific regions of interest. For each starter pattern-mask combination, the model generates multiple variations, producing a total of $n \times 10 \times v$ patterns in the initial iteration, where n is the number of starter patterns and v is the number of variations generated during inpainting.

Inpainting. During inpainting, the model predicts the masked regions while conditioning on the known pixels. The reverse diffusion process is modified as:

$$p_\theta(x_{t-1}|x_t, x_0^{masked}) = N(x_{t-1}; \mu_\theta(x_t, x_0^{masked}, t), \sum_\theta(x_t, x_0^{masked}, t)) \tag{8}$$

The mean and covariance now also depend on the original masked image x_0^{masked}, conditioning the reverse process on the known pixels. We also follow the inference scheme mentioned in [32] that only generates masks with about 25% region of its target image size.

D. Template-based Denoising and DR Checking

The inpainting process, while effective for generating a big set of pattern variations, introduces noise along polygon edges due to the lossy nature of latent diffusion models. This edge noise can significantly alter pattern dimensions and lead to design rule violations.

To address this challenge, we propose automated template-matching denoising, listed in Algorithm 1, inspired by the fact that only a sub-region of an image is changed during inpainting and the scan lines of the starter pattern (pre-inpainting) are known. We use the

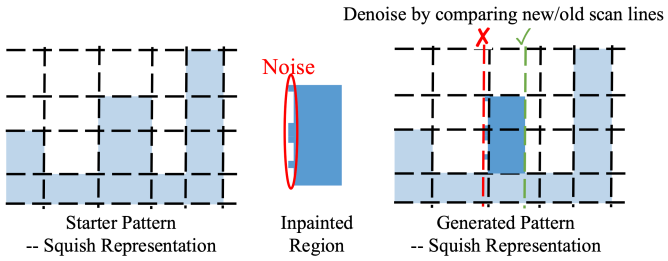

Fig. 5: Illustration of Template-based Denoising. Noise at the edge is reduced by comparing new scan lines with the original scan lines (black). Here, green scan line is preserved since it is larger than a predefined threshold, and red scan line is removed.

Algorithm 1 Template-based Denoising

Input: Generated noisy image I_g, template (noise-free) image I_t, and threshold T
Output: Denoised output image I_o

$L_g \leftarrow$ *extract_squish_lines*(I_g)
$L_t \leftarrow$ *extract_squish_lines*(I_t)
Cluster L_g into subsets $C_1, C_2, \ldots, C_n$ such that for each cluster C_i, $\|L_g(i) - L_g(j)\| \leq T$
for each cluster C_i
    $l_{\text{match}} \leftarrow$ single scan line from L_t that minimizes $\|l - C_i\|$
    if $\|l_{\text{match}} - C_i\| \leq T$
        Replace C_i with l_{match} ▷ Replace cluster with matched scan line from template
    else
        Randomly select $L_{\text{random}} \in C_i$ and replace the cluster with L_{random}
Construct the topology matrix M from the modified L_g
$I_o \leftarrow$ *reconstruct_image*(M, L_g)
return I_o

squish representation mentioned in Section 2.2, where we first extract scan lines from the noisy generated pattern (post-inpainting) and cluster similar lines within a predefined threshold. We then compare them to scan lines from the template (starter pattern). For each cluster, a parent scan line is chosen if available; otherwise, a line is randomly selected from within the cluster. This method is very effective, and we observe that it significantly increases the number of patterns passing DR checks. Figure 5 also gives an intuitive example of denoising is performed by neglecting unnecessary scan lines due to edge noise but still preserving the scan lines. Denoising is performed by extracting the topology matrix using the designated scan lines and reconstructing the pattern again. A quantitative evaluation of this template-based denoising is shown in later Section VI and Table III.

E. PCA-based layout & mask selection

After the initial generation, a vast set of pattern variations is obtained. To produce more new and diverse layout patterns, iterative generation is employed, altering only a sub-region of the image in each iteration. For each iteration, we adopt a PCA-based approach to pick k representative samples from the existing pattern library, followed by a mask selection scheme using two mask sets.

1) PCA-based layout selection: As described in Algorithm 2, we propose a PCA-based layout selection scheme to pick representative layouts for the next iteration generation. PCA reduction provides a qualitative means to illustrate the diversity of a given layout pattern library [14]. The input samples are DR-clean layout clips. We first apply PCA to decompose images into several most representative components. To preserve most of the information in the dataset, we push the PCA to have explained_varaince (0.9, meaning 90% of the explained variance is preserved in the dimension-reduced components. Then, an iterative selection is performed to ensure that diverse samples are extracted from the existing library while meeting density constraints. The constraints can be easily integrated with other requirements such as specific pattern shapes or other interesting features and perform layout pattern generation in a more controlled setting.

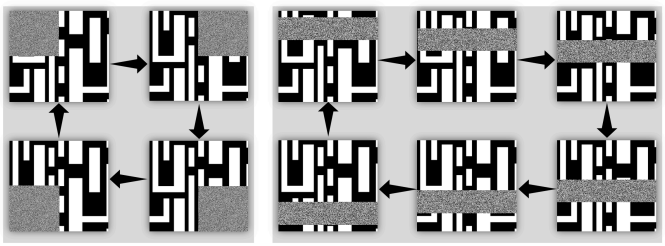

Fig. 6: Predefined mask sets for pattern generation: default masks (left) and horizontal masks (right). Horizontal masks are customized for our dataset since we primarily focus on vertical track layout generation. Mask in each set is selected sequentially during iterative generation.

Algorithm 2 PCA-based Representative Layout Selection

Input: Dataset $X \in \mathbb{R}^{n \times d}$, target samples k, constraints C
Output: Selected samples $S \subset X$

$X_{pca} \leftarrow \text{PCA}(X)$ ▷ Dimensionality reduction
$I_s \leftarrow \{\}$, $I_r \leftarrow \{1, \ldots, n\}$ ▷ Selected and remaining indices
$i_0 \leftarrow \text{random}(I_r)$ ▷ Initial random sample
$I_s \leftarrow I_s \cup \{i_0\}$, $I_r \leftarrow I_r \setminus \{i_0\}$
for $t \leftarrow 1$ to $k-1$
    for $i \in I_r$
        $d_i \leftarrow \sum_{s \in I_s} \|X_{pca}[i] - X_{pca}[s]\|$ ▷ Sum of distances
    $i^* \leftarrow \arg\max_{i \in I_r} d_i$ s.t. $C(X[i])$ ▷ Farthest point
    $I_s \leftarrow I_s \cup \{i^*\}$, $I_r \leftarrow I_r \setminus \{i^*\}$
return $X[I_s]$

2) Mask selection: As illustrated in Figure 6, our framework defined two mask sets (10 masks total) to guide pattern generation. The default mask set enables general pattern variations through targeted modifications, including metal wire modification and inter-track connections. The horizontal mask set is specifically designed for vertical track layouts to enhance exploration of end-to-end design rules and inner-track interactions. For horizontal track layout generation, a vertical mask set shall also be proposed.

For each selected layout, we generate its mask following a predefined sequential schedule within each set. For example, when a pattern undergoes modification in one region (e.g., top-left in the default mask set), subsequent iterations target adjacent regions (e.g., top-right) following the predefined sequence. This sequential approach preserves features generated in previous iterations while providing rich contextual information for the inpainting model through newly generated patterns.

F. Iterative Generation

As illustrated in the grey region of Figure 4, the final iteration generation process then integrates Algorithm 2 to select representative layouts from the existing pattern library with a mask provided by its own mask set. Our framework keeps performing iterative generation until the desired diversity is reached or the sample budget is exceeded. When the iterations are completed, a diverse pattern library within the given DR space can be generated.

V. Experimental Results

A. Experimental Setup

We validate PatternPaint on Intel 18A technology node with all generated patterns verified through industry-standard DR checking. The dataset contains 20 starter patterns.

Model setting: We experiment on two pre-trained models, including stablediffusion1.5-inpaint (PatternPaint-sd1-base) and stablediffusion2-inpaint (PatternPaint-sd2-base) [32].

Finetuning details: We adhered to the procedure described in DreamBooth [31] to finetune the inpainting model with 20 layout patterns. The learning rate is set to 5e-6. For PatternPaint-sd1-base (PatternPaint-sd2-base), we denote its fine-tuned model as PatternPaint-sd1-ft (PatternPaint-sd2-ft). Experiments are performed on one Nvidia A100 GPU and one Intel(R) Xeon(R) Gold 6336Y CPU@2.40GHz. Finetuning time takes around 10 minutes. The average time for generating is 0.81 seconds and 0.21 seconds for denoising per sample.

Baseline methods: We conducted comparisons using two state-of-the-art methods, CUP [21] and DiffPattern [19]. Since 20 patterns in our dataset are not enough to train diffusion-based and VCAE-based solution, we further obtain 1000 samples from a commercial tool with a size of 512 x 512 pixels to train CUP [21] and DiffPattern [19] in squish representation [29]. The topology size for these experiments was set to 128 x 128 pixels. DiffPattern, which employs a non-linear solver-based legalization process, initially supported only three basic design rules. However, this is inadequate for Intel 18A, which includes constraints such as discrete values for certain line widths. We tried our best to improve this solver to accommodate a subset of the design rules that involve max-spacing, max-width, and discrete values for certain line widths. After this improvement, legal layout patterns started to appear. We implemented this nonlinear solver using scipy package, and the maximum iteration count is set to 10^8.

Initial generation: Since previous works are one-time generation methods, to establish a fair comparison, we also present the results of the first stage of PatternPaint, initial generation, into performance comparison. For each initial pattern, each model generated 100 layout patterns per mask. In total, we generate 20,000 patterns. The performance of the initial generation across 4 models is denoted as (model-name)-init.

Iterative generation: Following the initial generation, we created a library of unique patterns with substantial variation. We then perform iterative pattern generation, as described in section IV-E, to check if diversity increased through this process. We designated the unique patterns from experiment 1 (Table 1) as our first iteration. For subsequent iterations, we conducted PCA analysis to select 100 of the most sparse representative samples, with the density constraint set at 40% for the selected patterns. For each iteration, we generated 5000 samples out of the 100 patterns, adding only clean and new samples to our existing pattern library. We performed 6 iterative generations and collected 50000 generated patterns in total. The performance of iterative generation across 4 models is denoted as (model-name)-iter.

B. Comparison of Pattern Generation

The evaluation results of the initial generation are shown in Table I. 10% of the layout patterns generated by PatternPaint are legal and show better H_1 and H_2 than with the starter patterns. Compared with other baselines, CUP is unable to generate legal patterns, and DiffPattern only generated four legal patterns.

The effectiveness of the proposed fine-tuning process is evident when comparing PatternPaint-sd1-base-init (and PatternPaint-sd2-base-init) with their fine-tuned counterparts, PatternPaint-sd1-ft-init (and PatternPaint-sd2-ft-init). Fine-tuned models show improvements in the number of legal patterns, unique patterns, and the main metric H_2. The results of iterative generation are in Figure 7. As iterations proceed, both the unique pattern count and H_2 increase, further highlighting the gap between baseline models (PatternPaint-sd1-base, PatternPaint-sd2-base) and fine-tuned models (PatternPaint-sd1-ft, PatternPaint-sd2-ft), with the latter consistently outperforming the former. This validates that our fine-tuning process demonstrates significant model improvements.

TABLE I: Performance comparison for layout pattern generation.

Method	**Generated Patterns**	**Legal Patterns**	**Unique Patterns**	H_1	H_2
Starter patterns	-	20	20	3.68	4.32
CUP [21]	20000	0	0	0	0
DiffPattern [19]	20000	4	4	2	2
PatternPaint-sd1-base-init	20000	1251	928	5.06	9.78
PatternPaint-sd2-base-init	20000	1479	861	5.15	9.60
PatternPaint-sd1-ft-init	20000	2336	1728	4.65	10.49

PatternPaint-sd2-ft-iter	50000	5982	4616	4.11	**12.01**

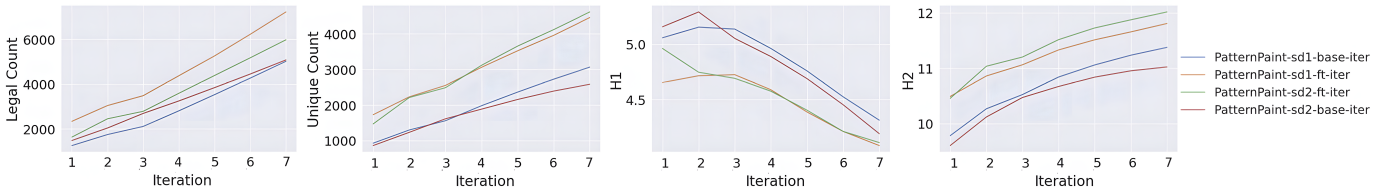
TABLE II: Runtime comparison with our method and DiffPattern.

Method	Avg Runtime (s)
PatternPaint (Inpainting)	0.81
PatternPaint (Denoising)	0.21
DiffPattern	38.04

We observe a slight decrease in H_1 as the iterative process proceeds, which can be attributed to the fact that H_1 primarily focuses on topology diversity. Since our framework alters only a sub-region of a given layout at a time, this results in several replicated topologies with adjustments limited to physical width, leading to the observed decrease in H_1. However, many DFM studies, such as OPC recipe development, benefit not only from topology diversity but also from variations in physical width combined with a given topology. This is captured by our key metric H_2, which considers both topology and physical dimensions. As iterations progress, more patterns with higher diversity are generated, including variations in physical widths and connection types. These diverse patterns can be used in yield analysis of metal patterns as well as finetuning OPC recipes, addressing the critical needs for real-world DFM applications.

Figure 8 visually represents the variations generated by our proposed methods. The starter pattern is depicted in (a), (b-f) show the generated patterns. We observed that the proposed methods explored a wide range of variations, demonstrating the models' awareness of tracks. For example, in (f), the model attempts to disconnect from an adjacent thick track and establish a connection with a farther one. In (e), more complex changes were made, forming connections with even farther tracks and upper objects. These alterations enrich the pattern library and represent a unique feature of the ML-based method. Achieving such inter-track alternations with a rule-based method would require significant engineering effort, making it nearly impossible without advanced techniques coded for the given DR set.

Table II exhibits the runtime comparison with DiffPattern. Note that we omit the comparison with CUP because it is unable to give a feasible solution. The runtime for DiffPattern is 30× longer than PatternPaint due to the time-consuming solver-based legalization process. Overall, these results demonstrate the effectiveness of PatternPaint to generate legal patterns and indicate that the solver-based solution is not suitable for industrial DR settings.



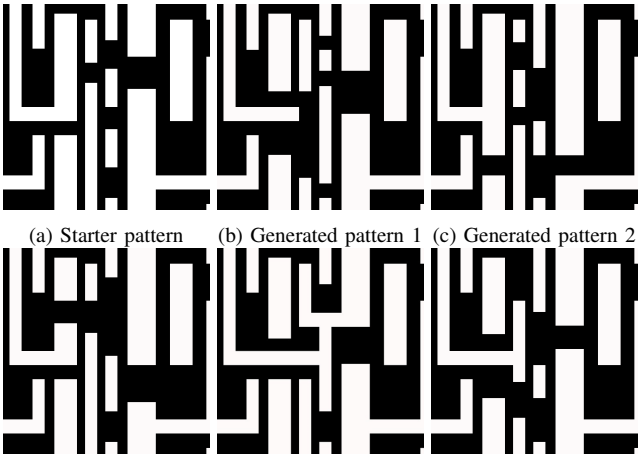


Fig. 7: Experimental results for iterative generation process using four metrics: legal pattern counts, unique pattern counts, H_1, and H_2.

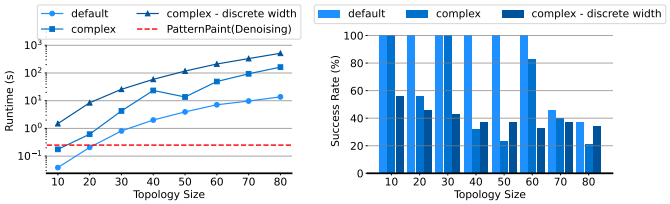

Fig. 9: Runtime and success rate analysis of non-linear solver under three design rule settings: default, complex, and complex-discrete width. Results show exponential runtime growth and declining success rates with increasing topology size.

VI. Ablation Study

We conduct comprehensive ablation studies to validate two key aspects: (1) the limitations of solver-based approaches with increasing design rule complexity, and (2) the effectiveness of our template-based denoising scheme.

1) Impact of Design Rule Complexity: We evaluate three progressively design rule settings to illustrate the solver limitations as shown in Figure 9. The *default* setting follows the academic design rule set of [19], including basic constraints such as minimum width/spacing and area checks. The *complex* setting extends this by differentiating horizontal and vertical directions for width and spacing checks, including their minimum and maximum values. The *complex-discrete* setting further restricts width values to discrete sets. We observe two critical limitations of this non-linear solver. First, the solver's runtime increases significantly from default to complex-discrete settings, showing exponential growth with topology size, significantly exceeding PatternPaint's denoising time. Second, despite the existence of legal solutions, the solver's success rate deteriorates with rule complexity. For topologies larger than 60×60, all settings achieve less than 50% success rate. This scalability issue is also evident in [23], where lower success rates are observed as pattern sizes increase.

TABLE III: Comparison of the pattern generation success rate (S%) using PatternPaint with different denoising schemes: our template-based denoising, OpenCV non-local means filter [24], and without denoising.

Method	W/ Template-based Denoise (S↑)	W/ OpenCV Denoise Filter [24] (S↑)	W/o Denoise (S↑)
PatternPaint-sd1-base	6.25	0.12	0
PatternPaint-sd1-ft	11.68	1.04	0
PatternPaint-sd2-base	7.40	0.24	0
PatternPaint-sd2-ft	8.15	0.76	0
Average	**8.37**	**0.86**	**0**

2) Effectiveness of Template-based Denoising: Table III evaluates the effectiveness of our template-based denoising scheme in the PatternPaint framework. We compare the template-based denoising scheme with a widely used denoising filter, the non-local means filter [24] implemented in OpenCV. We also show the DRC results without any denoising activity. The generation success rate is calculated by legal patterns divided by total generated patterns. The results show that no patterns can be directly used without denoise. Our template-based denoising significantly outperforms the OpenCV non-local means filter [24], with an average of 9.7x generation success rate improvement. The fine-tuned versions of PatternPaint achieve the highest success rates when combined with template-based denoising, reaching 11.68%. These findings validate the effectiveness of the template-based denoising scheme in maximizing pattern generation efficiency, especially when combined with fine-tuning techniques.

VII. Conclusion

In this paper, we propose PatternPaint, an automated few-shot pattern generation framework using diffusion-based inpainting. We develop our own unique template-based denoising scheme to tackle noise and propose a PCA-based sample selection scheme for iterative pattern generation. In the initial round of the iterative generation process, thousands of DR clean layouts are generated on the latest Intel PDK and checked through an industry-standard DR checker. In later iterations, by measuring entropy, we observed that pattern diversity improves. Our work, PatternPaint, has its unique benefits with little to no human effort in loop and is the first can perform pattern generation in a few-shot learning scenario. In future work, we will improve PatternPaint to support larger size pattern generation and explore further finetuning the pre-trained models using legal samples collected from PatternPaint enriched pattern library. We also plan to evaluate the explored design rule space against product-level layout patterns and demonstrate the application of PatternPaint-generated patterns on yield learning test chips for future PDK development and DFM studies on Intel silicon.

***Abstract*—Quantum graph states are critical resources for various quantum algorithms, and also determine essential interconnections in distributed quantum computing. There are two schemes for generating graph states — *probabilistic scheme* and *deterministic scheme*. While the all-photonic *probabilistic scheme* has garnered significant attention, the emitter-photonic *deterministic scheme* has been proved to be more scalable and feasible across several hardware platforms.**

This paper studies the GraphState-to-Circuit compilation problem in the context of the *deterministic scheme*. Previous research has primarily focused on optimizing individual circuit parameters, often neglecting the characteristics of quantum hardware, which results in impractical implementations. Additionally, existing algorithms lack scalability for larger graph sizes. To bridge these gaps, we propose a novel compilation framework that partitions the target graph state into subgraphs, compiles them individually, and subsequently combines and schedules the circuits to maximize emitter resource utilization. Furthermore, we incorporate *local complementation* to transform graph states and minimize entanglement overhead. Evaluation of our framework on various graph types demonstrates significant reductions in CNOT gates and circuit duration, up to 52% and 56%. Moreover, it enhances the suppression of photon loss, achieving improvements of up to $\times$1.9.

I. Introduction

Quantum information processing has the potential to revolutionize computation, communication, cryptography, sensing, and imaging. Within quantum information, entanglement plays a vital role as it serves as the foundation for interconnections between qubits. *Graph state* – a highly entangled quantum state, is the critical resource for quantum error correction (QEC) [1], measurement-based quantum computing (MBQC) [2], and various other applications. Moreover, it enables distributed quantum computing [3], [4] and quantum networking [5], acting as a paradigm for non-local qubit interactions. For instance, the *Bell state* is a special case of a graph state.

Before graph states can be utilized for various applications, they must first be generated on quantum computers or quantum network nodes. Graph state generation has predominantly focused on the *probabilistic scheme* [6], which relies on a sequence of *fusion gates* and photon interference. This all-photonic approach is widely studied for its relevance in optical quantum computing. Several previous compilation studies [7], [8], [9] for photonic MBQC are rooted in the *probabilistic scheme*. However, such approach suffers from an exponential demand for resources, severely limiting the scalability of the target graph states. Additionally, the randomness and uncertainty associated with fusion gates significantly increase the complexity of the compilation algorithms.

An alternative hardware solution is the *deterministic scheme*, where *photon qubits* are directly generated by emitters [10]. In this scheme, a set of interacting *emitter qubits* is employed to induce entanglement among photon qubits as they are emitted. Owing to better scalability and advancements in engineering, the *deterministic scheme* is attracting increasing attention. Emitter-based graph states have been demonstrated across various hardware platforms, including silicon quantum dots [11], [12], nitrogen vacancy (NV) color centers [13], [14], and Rydberg atoms [15], achieving scales of up to 14 qubits [16].

The generation process of an emitter-based graph state could be formalized by a quantum circuit model. Constructing the quantum circuit for the generation of a specific graph state can be referred to as the **GraphState-to-Circuit compilation** — which is the problem we focus on in this paper. Such a compilation task has distinct constraints compared to previous quantum compilers designed for superconducting [17], [18], [19], [20], [21], [22], trapped-ion[23], all-photonic [7], Bosonic quantum [24], or neutral atom [25] platforms. Shown in Figure 1.a, the circuit model for graph state generation [26], [27] contains two types of qubits: *emitter qubit* and *photon qubit*. Entanglement is created via emitter-emitter interactions (e.g., emitter-emitter CNOTs), and the entanglement connections are transduced to photons through the photon emission process. However, for the purpose of being *deterministic*, photon-photon interactions are not allowed, which significantly differentiates this approach from the all-photonic *probabilistic scheme*. Moreover, the gates for different types of qubits are implemented based on completely different physical operations, leading to significantly varying gate durations. These particular constraints necessitate a specific compiler.

A series of research efforts attempt to address the compilation problem for emitter-based graph state generation. Li et al. [26] propose a method to minimize the emitter resources required for graph state generation. However, their approach does not consider circuit depth and suffers from photon loss issues due to the prolonged hardware operations of emitter CNOTs. Kaur et al. [28] explore loss-aware generation for repeater graph states (RGS), but their method does not fully exploit resource utilization for arbitrary graph states. Ghanbari et al. [27] leverage *local complementation* to optimize graph states and reduce generation overhead. Nevertheless, finding the optimal *local complementation* is #P-complete [29], which limits the scalability of this optimization. Furthermore, none of these works provide a feasible compilation scheme for large-scale graphs. Hindered by high complexity and an exponential solution space, optimal solutions for random graph states can only be achieved at the scale of a few qubits.

To address the above limitations, we propose a novel compilation framework for the graph state generation task, adopting a divide-and-conquer strategy to tackle the scalability problem. First, we partition the graph state into subgraphs, enabling optimal compilation for each subgraph with low overhead, while integrating *local complementation* for optimization. Next, we compile the subgraphs based on a comprehensive objective function that accounts for the characteristics of actual quantum computing hardware. Finally, during subgraph recombination, we design a circuit scheduling scheme to exploit emitter reuse among subgraphs, thereby maximizing qubit

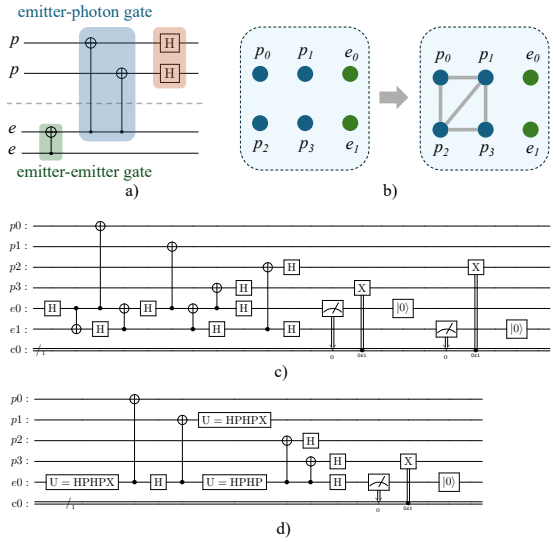

Fig. 1: The background on GraphState-to-Circuit Compilation. a) The constraints of a *deterministic* graph state generation, with p as photon and e as emitter. For deterministic purpose, only emitter-emitter CNOT in green and emitter-photon CNOTs (emissions) in blue are allowed. b) Generation of a graph state on photon qubits p_0 - p_3. c) The circuit for generating the graph state in b), as a result of compilation. d) An optimized circuit for the same graph state, with fewer emitters utilization and fewer CNOTs engaged compared to c).

resource utilization and reducing photon loss accumulation during generation. Our framework is evaluated on various types of graph states and compared with the best-known method [30]. It outperforms the baseline, achieving on average a 30% (up to 52%) reduction in emitter-emitter CNOTs, a 38% (up to 56%) reduction in circuit duration, and a suppression of photon loss by $\times$1.4 (up to $\times$1.9).

Our key contributions are as follows:

1) We are the first to study emitter-based graph state generation from a quantum compiler perspective. We formulate the compilation constraints, perform a comprehensive analysis of previous methods, and identify the objectives to consider based on realistic hardware implementations.
2) We propose a scalable compilation method by partitioning the target graph state into subgraphs and compiling these subgraphs. This method incorporates *local complementation* to reduce the critical overhead – emitter-emitter CNOT.
3) We design a scheduling scheme that maximizes the utilization of emitter qubit resources. It minimizes circuit duration, thereby reducing the accumulation of photon loss.

II. Background

A. Quantum Graph State

A quantum graph state $|G\rangle$ is a specific type of multipartite entanglement state that is intrinsically associated with a graph $G = (V, E)$, where V is the set of vertices and E is the set of edges connecting these vertices. In graph G, a vertex v represents a physical qubit, whereas an edge e indicates the entanglement between the two qubits. The formal definition of a graph state $|G\rangle$ is given by:

$$|G\rangle = \prod_{(i,j)\in E} CZ_{(i,j)} \, |+\rangle^{\otimes |V|} \tag{1}$$

Here, $|+\rangle^{\otimes |V|}$ denotes the tensor product of $|V|$ copies of $|+\rangle$ state at all the vertices of G, and $CZ_{(i,j)}$ is the controlled-Z gate operation applied to the pair of qubits corresponding to the edge $(i, j) \in E$.

Typically, the generation of a graph state is achieved through two steps: 1) Prepare a set of qubits in initial states, corresponding to all the vertices in V; 2) For each pair of qubits where the entanglement is desired, apply a CNOT/CZ interaction. Note that for a graph state, all CNOT/CZ gates are commutable, allowing them to be arranged in arbitrary sequences or applied in parallel, providing abundant flexibility for circuit scheduling. Here we provide an example of graph state, shown on the right side of Figure 1.b), representing the entanglement among photon qubits p_0, p_1, p_2, p_3.

B. Emitter-Based Graph State Generation

Problem Formulation. Here we provide a description of the circuit model for emitter-based graph state generation, including all elementary operations required for the process, as illustrated in Figure 1.a-c, and an example of optimization in Figure 1.d:

1) Two types of qubits are involved: *emitter qubit* and *photon qubit*. Emitter qubits are initialized to state $|0\rangle$, while photon qubits do not exist physically before emission and are represented as $|0\rangle$.
2) Entanglement is induced by emitter-emitter CNOT, and the entanglement connection are transduced to emitted photon via emission process.
3) The emission of a photon is modeled by an emitter-photon CNOT between the emitter and emitted photon, being always the first gate applied on each photon qubit.
4) For *deterministic* purpose, the photon-photon interactions are not allowed. Only single-qubit gates and measurement can be applied on emitted photon qubits.
5) The final result should be a graph state entangled across n photons (n = size of the graph), while all emitters return to $|0\rangle$ state upon completion.

Hardware Characteristic. The emission and entanglement operations are implemented differently across hardware platforms. Here we use the quantum dots platform [10], [31] as an example. The emitter-emitter CNOT is realized through electron exchange coupling between quantum dots, with a gate time of 1-10 ns and a fidelity $\geq$0.99. In contrast, the emitter-photon CNOT (emission) has a significantly shorter duration of $\sim$0.1 ns. Given this distinction in gate time, circuit scheduling for emitter-based graph state generation becomes a non-trivial problem.

C. Time-Reversed Model for Graph State Generation

Our compilation algorithm is built upon a **time-reversed model** introduced in previous work [26]. In this time-reversed context, photon emission is replaced with a hypothetical "photon absorption", while emitter-emitter interaction correspond to "disentangling" between emitters. Using these reversed operations, we can derive

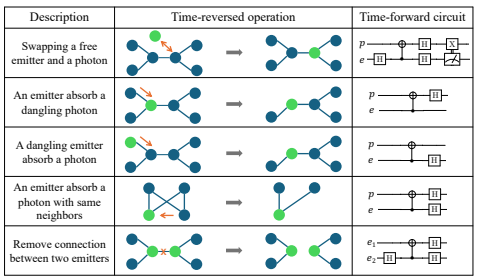

Fig. 2: Operations of the time reversed graph reduction model.

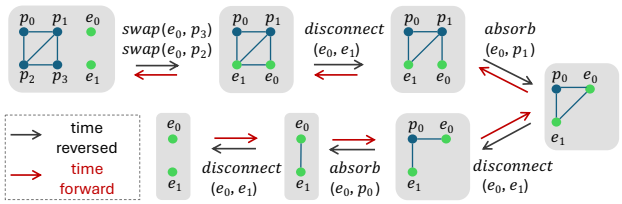

Fig. 3: An example of the time-reversed reduction sequence (black arrows), corresponding to the circuit in Figure 1.c (red arrows).

a virtual sequence that reduces a target graph state to initial state. Hence, reversing this sequence yields the required circuit to generate target state from initial state. We specify the following reversed operations [28], which are also illustrated in Figure 2:

a) Swapping with free emitter: An arbitrary photon in the graph state can be replaced by a free emitter in $|0\rangle$ state.

b) Photon absorption: If an emitter is entangled with a photon in the graph, it can absorb the photon under certain conditions. The specific conditions for photon absorption are illustrated in Figure 2.

c) Emitter disentangle: Remove the entanglement connection (represented as an edge in the graph) between two emitters.

Based on these operations, our compiler determines the optimal time-reversed reduction sequence of target graph state (e.g. Figure 3), then reverses this sequence to generate the desired circuit. We recommend Kaur et al. [28] for a more comprehensive background.

D. Optimizing Graph State via Local Complementation

By applying local Clifford (LC) gates to a graph state, it can be transformed into a set of alternative graph states that are LC-equivalent with original graph state. Hence, generation of the target graph state can be redefined as generating an LC-equivalent graph state. If the LC-equivalent graph has fewer edges, this transformation can reduce the entanglement overhead, with the only cost being the addition of single-qubit gates to the circuit.

Finding LC-equivalent graph state can be formalized as applying *local complementation* to the graph [27], [29]. Specifically, local complementation of a vertex v in the graph modifies the edges within the neighborhood on v. In the neighborhood of v, edges that are present will be removed, and edges that are missing will be added (Figure 4). A proper local complementation of target graph state can significantly reduce the entanglement overhead. However, determining the optimal local complementation has been proven to be #P-complete [32], making it infeasible to solve in polynomial time.

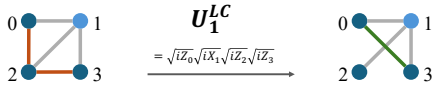

Fig. 4: Leveraging local complementation to optimize the graph state. In this example, a Clifford unitary is applied on photon 1 (U_1^{LC}), leading to a local complementation of the corresponding vertex 1, acting on neighborhood vertices 0, 2, 3.

III. Motivation

A. Challenges and Solution

Given the constraints and optimization opportunities, GraphState-to-Circuit compilation is a complex and non-trivial task. In this section, we discuss the associated challenges and propose our solution.

Challenge 1: There is an exponential overhead in searching the optimal circuit of graph state generation. Additionally, finding the best local complementation for target graph state is a #P-complete problem. As a result, the compilation is **not scalable**.

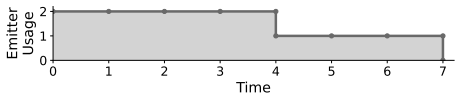

Fig. 5: The emitter usage number over time (timescale simplified), for a graph state generation circuit.

As we mentioned in Section II.A, the commutation of CNOT/CZ in graph state generation allows photon emission in an arbitrary sequence. As a result, the compilation overhead grows exponentially when exhaustively searching all possible circuits. For the state-of-the-art compiler GraphiQ [30], the runtime exceeds 10^3 seconds when solving a linear cluster state with more than 10 qubits. Furthermore, when realistic optimization targets such as circuit duration and loss rate are considered instead of simply minimizing the #CNOT, the runtime becomes even worse.

Solution: We partition the target graph state into several subgraphs, each with a feasible size for finding the optimal generation circuit. These subgraphs are treated as *leaves* and are compiled separately with designated optimization. Meanwhile, those inter-subgraph entanglements are treated as *stems*, compiled into an independent circuit and integrated into the final result.

Challenge 2: In hardware-aware scenarios, there are **various factors affecting the quality** of compiled circuits.

Based on the hardware characteristic of quantum dots emitter in Section II.B, several optimization targets must be considered: 1) A limited number of emitters, leading to prolonged circuit execution; 2) Accumulation of photon loss over time, which may render photons unusable; 3) Imperfect emitter-emitter CNOTs, affecting fidelity of the target state. Previous research has only considered one of these factors [26], resulting in impractical outcomes.

Solution: We construct a cost function that combines multiple optimization objectives. Specifically, we extract the gates duration based on hardware settings, and use them to calculate the photon loss duration of generation circuit as the cost function.

Challenge 3: When an emitter is entangled in the graph state, it may remain idle due to the lack of available operations. This results in **insufficient utilization of emitters**, thereby increasing the circuit duration.

Figure 5 provides an example of the emitter usage curve of a circuit, illustrating the number of utilized emitters during the generation process. It can be observed that, for certain parts of the circuit, the utilization of emitters does not reach the maximum capacity. In other words, the emitter resources are not fully utilized. This under-utilization becomes more pronounced as the scale of the target graph state increases, resulting in a generation circuit with significantly longer duration.

Solution: We schedule the subgraphs circuits by arranging them on the timeline. Based on the emitter utilization curve of each subgraph, we can share emitter qubits among different subgraphs, ensuring maximum utilization of emitters at every time slot. Briefly, we exploit the circuit-level parallelism and emitter reuse.

B. Insight: Divide-and-Conquer

The framework we propose adopts a *divide-and-conquer* strategy, inspired by the natural *stem-leaf* structure of a tree graph, but also applies to arbitrary graph structure. A straightforward illustration of this *stem-leaf* structure can be find in the left part of Figure 6. By partitioning the target graph state into several subgraphs [33],

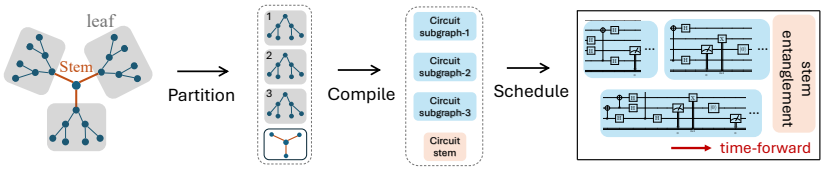

Fig. 6: The overview of our framework.

we treat the entanglements within each *leaf* as sub-problems, and finally recombine them through the compilation of inter-subgraph entanglements as the *stem*. The overview of framework is in Figure 6.

Our insight within this strategy is that finding the global optimal solution of graph state generation circuit is highly complex. However, optimizing each sub-problem individually can reduce overhead and achieve a local-minimum. Another challenge is determining an appropriate partitioning scheme for any graph state, which will be discussed in Section IV.A. Additionally, our circuit scheduling approach reduces redundancy by treating each subgraph as a coarse-grained basic unit.

IV. Framework Design & Implementation

A. Graph State Partitioning

We present the design of the first part in our compilation framework, where the target graph state is partitioned into subgraphs. To find an appropriate partitioning scheme, the following considerations should be addressed:

Reduce interconnections among subgraphs. The target graph state is partitioned into subgraphs, and each subgraph is compiled with lower runtime overhead. After obtaining the optimal generation circuit for each subgraph, they need to be connected via inter-subgraph entanglements (edges). In the resulting circuit that combines all subgraphs, these inter-subgraph entanglements will be compiled into emitter-emitter CNOTs, which are expensive operations on the hardware. Thus, the objective of graph state partitioning is to minimize the number of interconnection edges among different subgraphs.

Optimize graph partitioning with local complementation. Taking the graph state in Figure 7 as an example, normally at least 5 interconnecting edges must be cut to divide it into two subgraphs, shown in (a). However, by applying local complementation on vertices α and β, only 1 interconnecting edge remains for the partitioning, shown in (b). Thus, finding the appropriate local complementation is crucial not only for reducing the overall number of edges, but also for minimizing the partitioning cost. Due to the exponential search space for local complementations, we limit the number of LC operations to l, resulting in a depth-limited search. This restriction not only simplifies the search process, but also limits the additional circuit depth introduced by the local complementation operations.

Graph state partition searcher with depth-limited LC. We leverage a mix integer programming (MIP) solver to simultaneously find the best local complementation and graph partitioning solution. Our MIP model is described as follows:

a) Constant Parameters: Given the target graph state $G = (V, E)$, the vertices are represented as $v \in V$ and the edges as $e \in E$. Assuming the number of local complementation (LC operations) is limited to l, we define a sequence $1, 2, \ldots, l$ to mark the status of the graph state at each step. The subgraphs partitioned from G are represented as the set $\{g\}$, with size limitation $|g| \leq g_{max}$. Additionally, the total number of subgraphs is given by $\lceil |G|/g_{max} \rceil$.

Fig. 7: LC optimization for graph state partitioning.

b) Variables: First, we define our edge status in each step t by $e_{v_1,v_2,t}$ $(t \in 1, \ldots, l)$, and vertices in each subcircuit by $y_{v,g}$:

$$e_{v_1,v_2,t} = \begin{cases} 1, \text{ if vertex } v_1, v_2 \text{ are adjacent at step } t \\ 0, \text{ otherwise} \end{cases}$$

$$y_{v,g} = \begin{cases} 1, \text{ if vertex } v \text{ is partitioned in subgraph } g \\ 0, \text{ otherwise} \end{cases}$$

Then, we set the local complementation in each step as $x_{v,t}$.

$$x_{v,t} = \begin{cases} 1, \text{ if local complementation applied on } v \text{ at step } t \\ 0, \text{ otherwise} \end{cases}$$

c) Constraints: For local complementation, we only apply it on single vertex at each step (or skip this step), thus we have:

$$\sum_{v \in V} x_{v,t} \leq 1, \quad \forall t \in \{1, ..., l\} \tag{2}$$

Most importantly, the local complementation at step t will add or remove the edges, resulting in a change at step $t+1$. Suppose the local complementation is applied to vertex v_0 ($x_{v_0,t} = 1$), and v_1, v_2 being two of its adjacent vertices ($e_{v_0,v_1,t} = e_{v_0,v_2,t} = 1$). Then, there should be a change to the edge e_{v_1,v_2} from step t to $t+1$:

$$x_{v_0,t} * e_{v_0,v_1,t} * e_{v_0,v_2,t} \leq |e_{v_1,v_2,t} - e_{v_1,v_2,t+1}| \tag{3}$$

In addition, the size of each subgraph is restricted by:

$$\sum_{v \in V} y_{v,g} \leq g_{max}, \quad \forall g \in \{g\} \tag{4}$$

d) Objective Function: Since we hope to minimize the interconnecting edges among subgraphs, our objective function is the number of such edges, represented by K. We use $\sum_{\forall g \in \{g\}} y_{v_1,g} * y_{v_2,g}$ to determine if v_1, v_2 are in the same subgraph, then we have:

$$K = \sum_{\forall v_1, v_2 \in V} e_{v_1,v_2,l} * (1 - \sum_{\forall g \in \{g\}} y_{v_1,g} * y_{v_2,g}) \tag{5}$$

Overall, the MIP model can be formulated as

$$minimize\ objective\ \ K(Eq.\ 5)$$
$$s.t.\ constraint\ Eqs.\ (2,\ 3,\ 4)$$

B. Optimizing Circuit Depth for Subgraph Generation

Optimizing Targets. In this section, we introduce our compilation method for the subgraphs. Unlike previous works that focus on optimizing either the minimal emitter resource [26] or #CNOT [30], we propose a novel compilation method emphasizing the suppression of photon loss, informed by the practical constraints of current hardware platforms. Our optimization targets are outlined below:

a) Number of emitter-emitter CNOTs: Considering gates durations on hardware, emitter-emitter CNOTs are typically more challenging to implement than other operations. As discussed in the quantum dot example in Section II.B, the emitter-emitter CNOT time is more than $10\times$ longer than that of the emitter-photon CNOT, constituting the primary contributor to the overall circuit duration.

b) Photon loss duration: Another critical problem in graph state generation is the loss of photon qubits. From the moment a photon is emitted until the entire graph state is fully generated, the photon accumulates loss, reducing the fidelity of the final graph state. Minimizing the existing time of photons can suppress the probability of photon loss. Specifically, given two circuits with the same depth (duration), we prefer the circuit that delays photon emission operations as much as possible.

Compilation Strategy. Based on the time-reversed model, our compilation of each subgraph involves the following steps:

① We search for the graph state reduction sequence, utilizing the reduction operations detailed in Section II.C, considering the maximum number of available emitter ne_{limit}. A heuristic-based depth-first searching is performed to find reduction sequences requiring the minimal number of *emitter disentangle* operations, which corresponds to circuits with minimal emitter-emitter CNOTs. The degree of vertices is used as heuristic, prioritizing the reduction of lower-degree vertices to ensure that more entanglements are created by photon emissions rather than emitter-emitter CNOTs. Additionally, we truncate the operation sequences with a high number of emitter-emitter CNOTs to reduce the searching overhead.

② After obtaining a set of candidate sequences with minimal number of emitter-emitter CNOTs, these sequences are translated into circuits, and the one with the minimal photon loss duration is selected. Specifically, the average photon loss duration ($\overline{T}_{loss}$) is calculated by:

$$\overline{T}_{loss} = \frac{1}{n} \sum_{p=p_1,\ldots,p_n} M_{circ_end} - M_{emit}(p)$$

where $M_{\text{circ_end}}$ represents the circuit ending time, and $M_{\text{emit}}(p)$ represents the emission time of photon p.

Flexible Resource Constraint. We adopt a flexible resource constraint, enabling the generation of optimal circuits under varying numbers of available emitters. For a subgraph g, the minimal number of required emitters, ne_{min}, is calculated using entanglement entropy theory [26]. The subgraph is then compiled with different available emitter limits: $ne_{\text{limit}} = ne_{\text{min}}, ne_{\text{min}}+1, ne_{\text{min}}+2$, respectively, to generate circuits for each scenario. This approach enhances parallelism within the subgraph when additional emitter qubits are available, facilitating qubit reuse, which will be discussed further in the next subsection.

C. Subgraph Recombination & Circuit Scheduling

Finally, we combine the generation circuits corresponding to each subgraph and schedule these subcircuits. In this step, inter-subgraph entanglements are added to the overall circuit to connect all components. This process is illustrated in Figure 8.

Circuit Scheduling Strategy. Our scheduling scheme adopts the *as-late-as-possible* strategy from Qiskit [34], appending subgraph circuits starting from the latest possible time and working gradually backward. When selecting circuits to schedule, we prioritize subcircuits with more photon qubits and shorter execution times (placing them later), and deprioritize subcircuits with fewer photon qubits and longer execution times (placing them earlier). The priority coefficient for a subgraph circuit is calculated as: $P_c = \frac{n_p^c}{T_c}$, where n_p^c is the number of photons in it, and T_c is its duration. This strategy ensures that more photons are emitted as late as possible, minimizing the time lasting for photon loss.

Emitter Qubit Reuse. The timestamp for a subgraph circuit c is determined based on its emitter qubit usage curve. When inserting c into the timeline of overall circuit C, we shift c as late as possible, while ensuring that the total emitter usage in C does not exceed the maximum emitter limit Ne_{limit} at any moment. This approach is analogous to playing Tetris, where the pieces (subcircuits c) are shifted downward (later in time) as far as possible, while being constrained by the walls (the Ne_{limit}), as shown in Figure 8.

Full Utilization of Emitter Qubits. To maximize the circuit parallelism in Ne_{limit} constraint, we aim to utilize any remaining (unused) emitter qubits at each time slot. This approach works in conjunction with the *flexible resource constraint* policy in Section IV.B. For example, if no additional subgraph circuit c can fit within a given time period, but the total emitter usage does not fully reach Ne_{limit}, we relax the ne_{limit} constraint from ne_{min} to $ne_{\text{min}}+1$ for the circuits already scheduled in that period. This ensures full utilization of emitter qubit resources, ultimately reducing circuit duration.

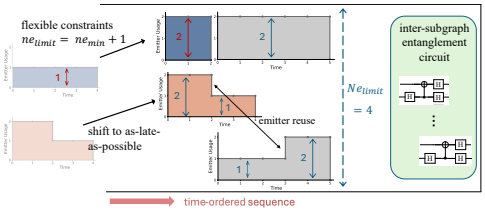

Fig. 8: Our scheduling scheme. The blocks are emitter usage curve for each subgraph, and the width is restricted by total emitters Ne_{limit}.

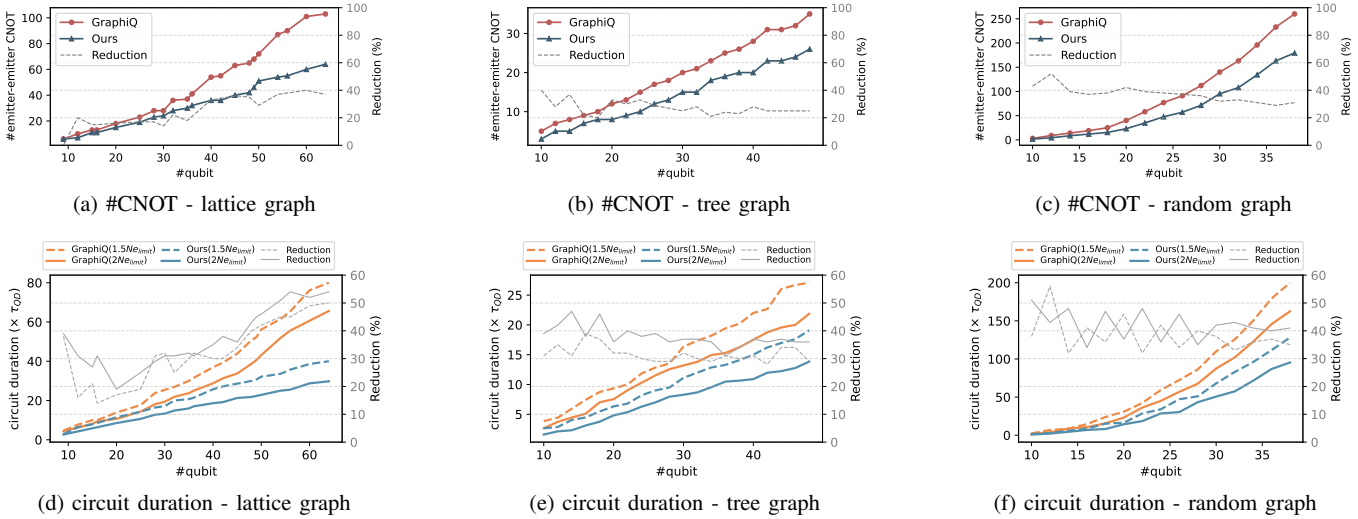
V. Evaluation

We evaluate our framework on various benchmarks using several hardware-realistic metrics and compare our results with the state-of-the-art graph state generation framework, GraphiQ [30].

A. Experimental Setup



Benchmarks. The graph states we tested (Figure 9) are selected from popular quantum applications: 1) *Lattice graph* is a two-dimensional (2D) square grid structure, which is basic element for MBQC [8]; 2) *Tree graph* is a connected acyclic graph, which is particularly useful as it constitutes the quantum routers in quantum random access memory (QRAM) [35], while it's also vital to the tree code [36] in quantum error correction; 3) *Random graph* is generated by the Waxman graph structure [37], which covers most of the possible communication topologies for distributed quantum computing and quantum network [38].

Experiment Platform. All compilation and simulation are executed on a CentOS 7 server featuring dual Intel Xeon 8255C CPUs (48 logical cores) and 384GB memory. The Python version is 3.10.0. Our framework is built based on GraphiQ[30] and Qiskit [34].

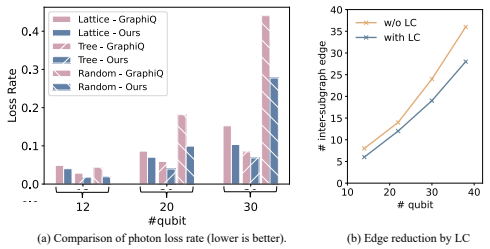
Hardware Model. We select the silicon quantum dot (QD) emitter [10] as our hardware model for simulation. However, it can be easily adapted to other hardware platform, e.g. SiV color centers [39], NV color centers [14] and Rydberg atoms [15], just by changing the configurations of gate characteristic. In QDs hardware, an emitter-emitter CNOT is realized by electron exchange coupling between two QDs, with coefficient J as the exchange interaction strength. Within a time period $\tau_1 = \pi/2J$, the interaction Hamiltonian yields a $\sqrt{SWAP}$ gate, enabling the entangling between emitters. Then, a emitter-emitter CNOT consists of two $\sqrt{SWAP}$ interleaved by two $R_x \otimes R_x$, while each of them take τ_1 as evolution time. Hence, we

Fig. 9: The types of graph in our benchmarks.

(a) #CNOT - lattice graph (b) #CNOT - tree graph (c) #CNOT - random graph

(d) circuit duration - lattice graph (e) circuit duration - tree graph (f) circuit duration - random graph

Fig. 10: Evaluation: reduction of emitter-emitter CNOTs and circuit duration.



represent the period of emitter-emitter CNOT as $\tau_{QD} = 4\tau_1 = 2\pi/J$. The timescale of τ_{QD} depends on J in hardware system, while it is commonly set to $2\pi \times$ 1GHz and thus $\tau_{QD} =$ 1ns. On the other hand, we set the time period for photon emission as $0.1\tau_{QD}$ based on cavity enhancement [40].

Algorithm Configuration & Baseline. In our framework, we use Gurobi [41] as the MIP solver for graph state partitioning. For the graph partitioning search algorithm in Section IV.A, we set a 20-minute timeout for MIP solver, using the best solution found within this time. In MIP model, we limit the size of subgraph $g_{max} = 7$ and maximum length of LC sequence to $l = 15$. Note that the compilation runtime for each subgraph is relatively low (< 100 seconds), owing to the constrained subgraph size. For baseline GraphiQ, we select its *AlternateTargetSolver* and modify it to include a 30-minute timeout, instead of searching exhaustively.

B. Result

1) # Emitter-emitter CNOTs: As the emitter-emitter CNOT being a critical component of graph state generation circuit, we compare its count in the compilation of graph state in varying sizes. The results are shown in Figure 10.(a)-(c) for three types of graphs. Our compilation framework consistently reduces the #CNOT compared to GraphiQ across all graph states, with average reductions of 25%, 28%, 37% (maximum 40%, 39%, 52%) for lattice, tree, and random graphs, respectively. Furthermore, as the size of the graph state increases, the reduction rate grows for lattice graphs and remains steady for the others, demonstrating the scalability of our method.

2) Circuit Duration: The time unit we use for calculating duration is τ_{QD} introduced in last subsection, with its realistic value dependent on hardware. We compare circuit durations under two emitter resource settings: $Ne_{limit} = 1.5Ne_{min}$ and $Ne_{limit} = 2Ne_{min}$ (Ne_{min} is the minimal #emitter required for target graph).

(a) Comparison of photon loss rate (lower is better). (b) Edge reduction by LC

Fig. 11: Evaluation: photon loss suppression and LC optimization.

Our results in Figure 10.(d)-(f) show that our compilation framework reduces circuit duration significantly. For $Ne_{\text{limit}} = 1.5Ne_{\text{min}}$, the average reduction percentages are 33%, 32%, and 39% (maximum 50%, 39%, and 56%). For $Ne_{\text{limit}} = 2Ne_{\text{min}}$, the average reductions are 38%, 38%, and 43% (maximum 54%, 47%, and 51%).

For the same graph state, circuit duration reduction rates are consistently higher than #CNOT reduction rates. Additionally, the duration reduction rate generally increases when the emitter resource setting Ne_{limit} is raised from $1.5Ne_{\text{min}}$ to $2Ne_{\text{min}}$. This highlights the benefits of circuit parallelism, with its impact becoming more pronounced as more emitter resources are made available.

3) Photon Loss: We assess the photon loss rate of final graph state generated by circuit, based on realistic hardware settings. Given the electron spin coherence time $T_2 \sim$ 1s, we set the photon loss rate to 0.5% per time period τ_{QD}. Our simulations ($Ne_{limit} = 1.5Ne_{min}$) are performed using GraphiQ, and the results are given in Figure 11.(a). Our framework improves the baseline by $\times$1.3, $\times$1.4, and $\times$1.9 on average for three types of graph, respectively.

4) Local Complementation: We compare the average number of inter-subgraph edges with and without local complementation optimizing in Figure.11.(b) (by setting LC sequence $l = 15$ or 0), to illustrate the benefits of local complementation. In this experiment, we use random (Waxman) graphs as the benchmark.

VI. Conclusion

We propose a novel compilation framework for emitter-photonic graph state generation, leveraging a divide-and-conquer strategy. The framework partitions the graph state into subgraphs, compiles them separately, and then recombines them using circuit scheduling. Tested on various graph states, our framework shows reductions in #CNOT and circuit duration, taking hardware constraints into account.

***Abstract*—With the rising demand for ultra-low-cost and flexible electronics in applications like smart packaging and wearable health monitoring, printed electronics provide an affordable, adaptable, and customizable alternative to conventional silicon. However, these systems often rely on printed batteries or energy harvesters with limited power capacity, making strict power budgets critical. Printed neuromorphic circuits (pNCs) are promising for their analog signal processing, reduced circuit complexity, and energy efficiency in low-power environments. Nonetheless, maintaining robust performance under strict power constraints remains challenging, necessitating advanced optimization techniques. In this work, we propose an augmented Lagrangian approach to enforce task-specific power constraints in pNCs, validated across 13 benchmark datasets. Our method preserves accuracy within strict power budgets while achieving Pareto-optimal power-accuracy trade-offs in a single training run. In contrast, the penalty-based method, which serves as the baseline, requires up to 150 runs per dataset to generate the Pareto front. For low-power scenarios ($\approx 20\%$ of the original power), our method demonstrates a $52\times$ improvement in accuracy-to-power ratio over the baseline. At higher power budgets ($\approx 80\%$ of the original power), it achieves a $59\times$ improvement, maintaining competitive performance. Experimental results demonstrate that our approach achieves 81.82% accuracy with p-tanh activation function (AF) at high power budgets and excels with p-Clipped_ReLU AF under low power constraints. This highlights the computational efficiency and effectiveness of our approach for power-constrained circuit design.**

I. Introduction

Although silicon-based electronics have witnessed continual advancements in power efficiency and transistor density, their adoption in numerous consumer edge applications such as smart packaging [1], smart bandages [2, 3], wearable devices, and other disposable electronics for consumer use [4]–[7] (as shown in Fig. 1[1]) remains a challenge. Even the most affordable traditional silicon-based electronics, such as Application-Specific Integrated Circuits (ASICs) [8] and microcontrollers [9], struggle to achieve the desired cost efficiency and adaptability for these resource-constrained applications. In this context, printed electronics (PE) emerge as a highly flexible [10, 11], biodegradabele [12] and cost-effective solution, through its additive manufacturing processes, thus enabling highly bespoke circuits at ultra-low costs. Furthermore, many of these applications must operate within a prescribed power budget to ensure a sufficient battery life, making energy efficiency [13] as crucial as cost and flexibility. So, by carefully selecting materials, substrates, and various optimization strategies [13], printed devices can also exhibit high flexibility [10, 11] and biocompatibility [12], making them ideal for constrained environments.

Fig. 1. Target application domains of printed electronics: (a) smart fruit package, (b) smart milk carton, (c) smart food packaging, (d) smart bandages.

Incorporating printed computing circuits is essential to equip printed devices with the basic capacity to process sensor data, such as performing classification tasks. Among various computing paradigms, analog computing is often chosen for PE due to its ultra-low cost and high flexibility in these applications. This approach allows for a reduction in device components, thus avoiding the expensive analog-digital converters (ADCs), and simplifies the execution of multiply-accumulate (MAC) operations. Analog neuromorphic circuits [14] stand out as an effective choice due to their expressiveness [15], using simplified circuit primitives, and benefit from machine learning (ML)-driven off-device design and optimization, making them highly suitable for resource-limited PE applications [13]. Moreover, the agile manufacturing process of PE allows highly tailored circuit designs that can meet the specific functional and physical requirements of target applications, reducing material waste, minimizing design iterations, and enabling rapid prototyping, making it ideal for ultra-low-cost, flexible solutions in constrained environments. A key advantage of this approach is the ability to treat critical components of printed analog neuromorphic circuits (pNCs), such as AFs, as learnable parameters, allowing the adaptation of both the shape and hardware realization of AFs, directly linking ML-optimized parameters to physical circuit characteristics.

Low-power electronics design remains a critical focus area due to its potential to extend device runtime and minimize its uses on high-capacity power sources. This is particularly important for portable and edge devices. While traditional electronics has extensively explored low-power solutions [13, 16, 17] these methods generally operate under soft power constraints, where reducing power consumption is desirable but not mandatory. In contrast, many target applications, especially power harvesters, wearable health monitoring devices, operate within strict power and energy envelopes that demand hard constraints arising

♣Authors contributed equally to this work.
[1]Images are generated by the DALL-E AI tool.

from different physical limitations like weight, cost, reliability over extended periods etc. This distinction is pivotal, as soft constraint solutions often fail to meet the rigid power requirements of such applications. In real-world scenarios, strict power constraints are crucial. For example, wearable health devices, such as ECG or glucose monitors, must operate continuously on compact batteries with limited capacity, requiring precise power management to ensure reliable functionality over their intended lifespan. Disposable medical sensors designed for short-term vital monitoring must similarly adhere to minimal power budgets. Supply chain IoT smart labels, tasked with tracking perishable goods' conditions like temperature over extended transit times, rely on small, non-rechargeable batteries. In outdoor applications such as GPS trackers powered by flexible solar panels, strict power limits must be maintained to guarantee performance in intermittent sunlight conditions.

In this work, we introduce an approach for designing pNCs under strict power constraints at the algorithmic level while ensuring high accuracy. Leveraging the augmented Lagrangian approach together with a surrogate power model of the circuit, we integrate strict power budgets directly into the optimization process, ensuring power consumption stays within pre-defined limits. In short, the contributions of this work are:

- We propose an algorithmic framework based on the augmented Lagrangian method that enables training under strict power constraints while improving classification accuracy in a single training run, in contrast to penalty-based methods, which require multiple runs to approximate Pareto-optimal results.
- We developed data-driven surrogate power models for four different AFs, demonstrating that the choice of activation function and its learnable parameters have a significant impact on power consumption in pNCs.

Experiments show high accuracy within strict power budgets: p-tanh reaches 81.82% accuracy at 80% power, p-Clipped_ReLU maintains 74.65% at 20%, and p-ReLU reduces device count by up to 37% at low power budgets, highlighting its efficiency in power-constrained environments. Unlike the penalty-based approach, which requires numerous training runs to approximate the Pareto front, the augmented Lagrangian method achieves competitive results within a single training run, significantly reducing computational time and effort. This efficiency makes our approach more practical for circuit design applications.

The rest of this paper is structured as follows: Sec. II introduces PE, printed neuromorphic circuits (pNCs), and related works. Sec. III describes the development of power models and their integration into the design objective of the pNCs. In Sec. IV, the proposed approach is evaluated and discussed. Finally, Sec. V concludes this work and discusses possible future works.

II. Preliminaries

A. Printed Electronics

Printed solution-processed electronics (PE) is an additive manufacturing approach that requires less printing process steps

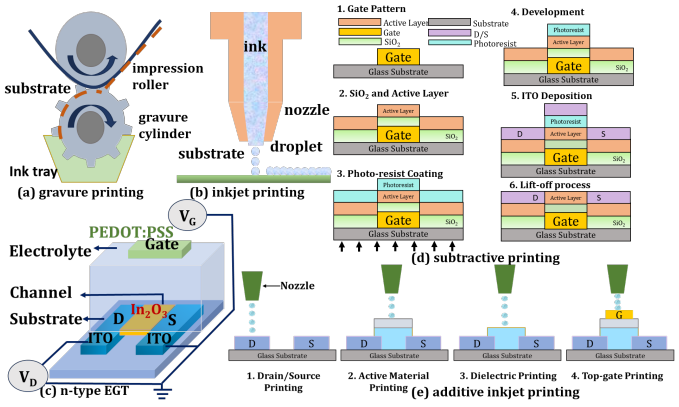

Fig. 2. Schematic of typical printing technologies: (a) gravure printing and (b) inkjet printing (c) a printed nEGT (d) Subtractive and (e) Additive printing process of PE.

than traditional silicon electronics, resulting in lightweight, ultra-low cost and flexible circuits. By selecting appropriate printing technologies, PE devices can be tailored to different production volumes and precision requirements. Furthermore, a wide range of printing materials enables important features for next-generation electronics, such as flexibility [10] and biocompatibility [12]. These makes PE a competitor in IoT applications like wearables [18], RFID [19], disposable electronics [20], energy harvesters, and implantable sensors [21].

Although vacuum-deposited methods achieve the best performance, simpler solution processes, such as spin-coating and inkjet printing are gaining popularity for their cost-effectiveness. PE technologies are categorized as either replication printing (e.g., gravure) for high-volume needs or jet printing (e.g., inkjet) for low-volume, bespoke fabricated circuits.

Most printed FETs are organic in nature and uses P-type materials that require high voltages (≥ 25V) [22]. This restricts their use in low-power applications. In contrast, inorganic N-type Electrolyte-Gated Transistors (nEGTs) offer higher electron mobility, enabling sub-1V operation [23], making nEGTs ideal for low-power devices reliant on small batteries or energy harvesters.

B. Printed Analog Neuromorphic Circuits

In the analog computing paradigm, neuromorphic computing has emerged as a preferred solution and is largely driven by advancements in artificial intelligence (AI), where artificial neural networks (ANNs) have outperformed in solving complex tasks [24].

1) Hardware Primitives: Fig. 3 (a) illustrates the circuit schematic of a pNC with 4-3-3 topology. Fig. 3(b) shows a 3-input, 3-output printed neuron, composed of a crossbar array and printed activation circuits (indicated in red). Additional circuits (highlighted in blue) are incorporated to handle negative weights, $\text{neg}(\cdot)$, by connecting resistors to either V_{in}^i or $\text{neg}(V_{\text{in}}^i)$, based on the sign of the corresponding weights. Figures 3(c)-(f) illustrate the schematics of various printed activation circuits. In the following sections, we provide a comprehensive overview of these circuit primitives.

a) Crossbar array: The array in Fig. 3 (b) illustrates a basic resistor crossbar architecture in pNCs, emulating weighted-sum operations of ANNs [14]. Using Kirchhoff's law [25] and

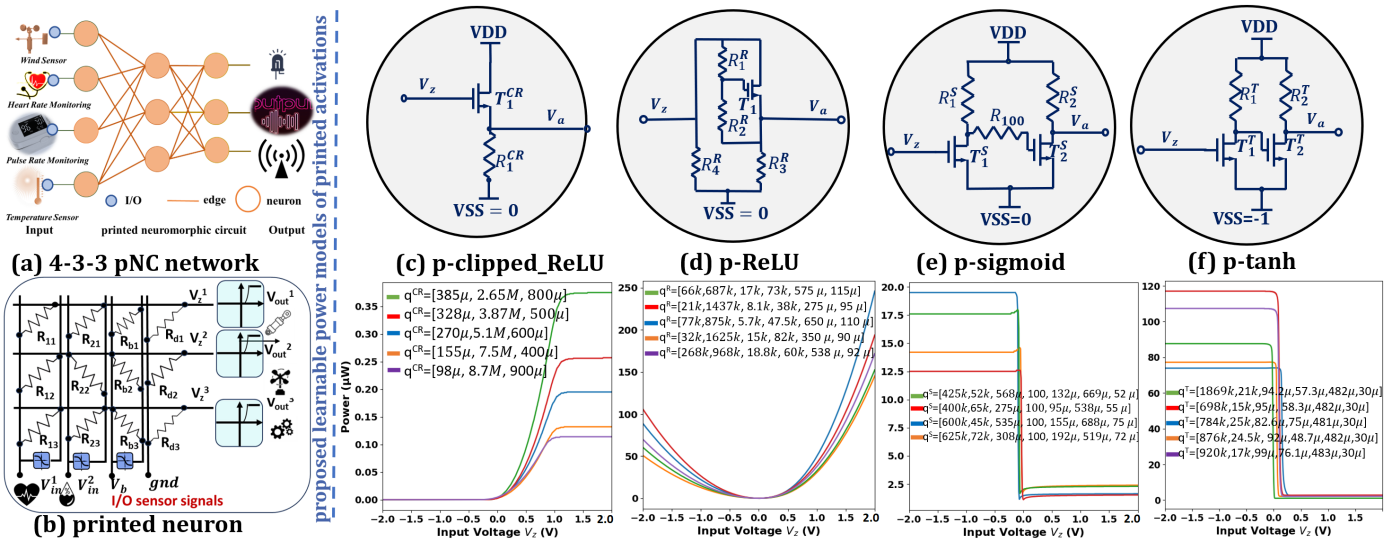

Fig. 3. Schematic of printed neuromorphic circuits. (a) Example of a 4-3-3 pNC network, (b) 3-input-3-output printed neuron based on crossbar array; surrogate power models of: (c) p-clipped_ReLU, (d) p-ReLU, (e) p-sigmoid and (f) p-tanh activation circuit.

expressing resistance as conductance ($g = 1/R$), the output voltage V_z^1 is calculated as

$$V_z^1 = \sum_j \frac{g_{j1}^C}{G_1} V_{in}^j + \frac{g_{b1}^C}{G_1},$$

where G_1 is the summed conductance of the first row in the crossbar, i.e., $\sum_i g_{i1}^C + g_{b1} + g_{d1}$. Here, V_z^1 represents a weighted sum of input voltages V_{in}^j, with conductance values defining weights and bias, enabling control over weights and biases by adjusting these conductance values.

The resistive nature of the crossbar array enables a direct analytical power model using the electronic power formula. For each resistor, the power is calculated as

$$P = \frac{\Delta V^2}{R} = \Delta V^2 \cdot g,$$

where ΔV is the potential difference across the resistor. Therefore, the power consumption of the crossbar, excluding negative weight circuits, is expressed as

$$\boldsymbol{P}^C = ((\tilde{\boldsymbol{V}}_{in} \odot \mathbb{1}_{\{\boldsymbol{\Theta} \geq 0\}} + \text{neg}(\tilde{\boldsymbol{V}}_{in}) \odot \mathbb{1}_{\{\boldsymbol{\Theta} < 0\}}) - \tilde{\boldsymbol{V}}_z)^2 \odot |\boldsymbol{\Theta}|,$$

Here, $\boldsymbol{\Theta} \in \mathbb{R}^{(M+2)\times N}$ is a matrix of learnable parameters for the crossbar array, where M and N denote the number of inputs and outputs, respectively. Each element in $\boldsymbol{\Theta}$ represents a surrogate conductance θ, where the absolute value $|\theta|$ encodes the physical conductance g of the corresponding resistor. Meanwhile, the sign of θ specifies whether a negative weight circuit must be pre-connected to emulate a negative weight. The operation $(\cdot)^2$ denotes an element-wise square, and $\mathbb{1}_{\{\cdot\}}$ is the element-wise indicator function that outputs 1 for true conditions and 0 otherwise. Each element in the matrix $\boldsymbol{P}^C$ represents the power of the corresponding resistor. Thus, the total power of the crossbar is given by

$$\mathcal{P}^C = \mathbf{1}_{M+2}^\top \cdot \boldsymbol{P}^C \cdot \mathbf{1}_N,$$

where $\mathbf{1}_{M+2}$ and $\mathbf{1}_N$ are vectors of ones.

b) Printed non-linear transformation circuits: In crossbar resistor arrays, conductances represent only positive weights. To incorporate negative weights, some resistors are paired with inverter-based circuits [13], as shown in Fig. 3(b) (indicated by blue boxes), which emulate negative weights by inverting the input voltages V_i. After passing through the crossbar, signals are processed by printed AFs, shown in Fig. 3 (c-f) (top). These printed AFs simulate the standard AFs in ANNs, introducing the non-linearity necessary for modeling complex functions. It should also be noted that a significant portion of the overall power is often consumed by AFs, whose non-linear behaviors make the modeling and optimization more complex. The power consumption of these circuits depends on physical parameters like transistor size, resistor values, and input voltage, requiring surrogate models ($\mathcal{P}^N$ and $\mathcal{P}^T$) trained on the SPICE simulation data [13]. This is further complicated as AFs are learnable parameters, meaning that their shapes are adapted during optimization, influencing both accuracy and power.

C. Power-Constrained Electronic Design

While traditional neuromorphic computing has made significant strides in low-power design [26], most existing methods rely on best-effort power optimization with soft constraints, where minimizing power is desirable but not mandatory [27, 28]. However, many real-world applications require strict (hard) power constraints to ensure reliable operation within predefined energy budgets. For example, wearable health devices, disposable medical sensors, and IoT smart labels depend on limited power sources like small batteries or energy harvesters, making it critical to enforce precise power budgets.

Our work directly addresses this gap by modeling and optimizing strict power constraints during the training of pNCs. Unlike soft constraints, where achieving optimal power-performance trade-offs is the goal, we enforce hard constraints to achieve the best accuracy and efficiency without exceeding the predefined power budget. This approach integrates AFs as learnable parameters and uses SPICE simulation for accurate

power estimation, ensuring a robust and practical methodology for power-constrained electronic design.

III. Methodology

To enable training under strict power constraints, we propose a training framework based on the augmented Lagrangian method. The primary objective is to maximize classification accuracy given the circuit parameters $\boldsymbol{\theta}$ and $\boldsymbol{q}$, while ensuring that power consumption below a predefined limit. Formally, this can be described by

$$\underset{\boldsymbol{\theta},\boldsymbol{q}}{\text{minimize}}\ \mathcal{L}(\mathcal{D},\boldsymbol{\theta},\boldsymbol{q})\ \text{s.t.}\ c(\boldsymbol{\theta},\boldsymbol{q}) = P(\boldsymbol{\theta},\boldsymbol{q}) - \overline{P} \leq 0, \quad (1)$$

where $\mathcal{L}(\mathcal{D},\boldsymbol{\theta},\boldsymbol{q})$ denotes the cross-entropy loss on the training data $\mathcal{D}$, which ensures high classification accuracy, and $c(\boldsymbol{\theta},\boldsymbol{q}) = P(\boldsymbol{\theta},\boldsymbol{q}) - \overline{P}$ represents the constraint function, ensuring that the estimated power consumption $P(\boldsymbol{\theta},\boldsymbol{q})$ remains within the strict task-specific upper limit $\overline{P}$. Evaluating the power contraint $c(\boldsymbol{\theta},\boldsymbol{q})$ requires accurate power estimation. Furthermore, since we will require derivatives through the contraint in the training procedure described later, we require a differentiable power model $P(\boldsymbol{\theta},\boldsymbol{q})$.

A. Surrogate power Modeling for Power Estimation

To simplify power analysis for resistor crossbar arrays, we adopt analytical solutions derived in [13]. However, modeling power consumption for nonlinear circuits, such as printed activation circuits (AFs), is more complex. We address this by approximating power consumption through SPICE simulations using the pPDK [29]. For each AF (p-ReLU, p-clipped ReLU, and p-sigmoid), we run 10,000 SPICE simulations, revealing distinct power behaviors as illustrated in Fig. 3 (c)-(f) (bottom). For instance, in p-clipped_ReLU, power spikes near a threshold as transistors conduct more current, then stabilizes due to the clipping effect; p-ReLU exhibits a smooth increase in power with input voltage, reflecting its unbounded nature; and p-sigmoid shows asymmetric power patterns due to higher current demands at negative voltages. Thus, the choice of AFs and their learnable parameters $q^{\mathrm{AF}} = [\mathbf{R}, \mathbf{W}, \mathbf{L}]$ (representing vectors of resistance, transistor widths, and transistor lengths) significantly impacts power consumption in pNCs.

To model learnable AFs, we define a feasible design space, $\mathbb{Q}^{\mathrm{AF}}$, with specified bounds for each parameter $\boldsymbol{q}^{\mathrm{AF}}$. We sample 10,000 circuit configurations using a Sobol sequence and simulate their power consumption using SPICE.

Based on this data, we train a 15-layer ANN for each AF as a surrogate model to map the corresponding physical variables $\boldsymbol{q}^{\mathrm{AF}}$ to power consumption, $\mathcal{P}^{\mathrm{AF}}(\boldsymbol{q}^{\mathrm{AF}})$. To enhance accuracy, data normalization and hyperparameter tuning are applied. This surrogate model provides efficient power estimation, enabling the total power calculation and analysis of the impact of AF configurations on power.

B. Power Estimation for a Printed Neuron

We estimate the power consumption of each printed neuron using the power of the crossbar ($\mathcal{P}^{C}$) and surrogate power models for its components: $\mathcal{P}^{\mathrm{AF}}$ and $\mathcal{P}^{\mathrm{N}}$, corresponding to the AF and negation circuits, respectively. To calculate the total power consumption, we determine N^{AF} and N^{N} [13], which represent the counts of AFs and negation circuits, respectively.

a) Counting Activation Circuits.: Initially, N^{AF} is calculated using an indicator function:

$$N^{\mathrm{AF}} = \mathbf{1}_N^{\top} \cdot \text{row max}\left\{\mathbb{1}_{\{|\boldsymbol{\theta}|>0\}}\right\}, \quad (2)$$

where $\mathbf{1}_N \in \mathbb{R}^N$ is a vector of all ones, $\mathbb{1}_{\{|\boldsymbol{\theta}|>0\}}$ assigns 1 to active circuits and 0 otherwise, and row max$(\cdot)$ returns the row-wise maximum values, as each row in $\boldsymbol{\theta}$ corresponds to a single activation circuit. If all elements in a row of surrogate conductances are zero, the corresponding activation circuit does not need to be printed or activated. This calculation ensures that any row with at least one non-zero conductance is counted only once. However, this piecewise constant function is non-differentiable, limiting its utility for gradient-based optimization.

b) Soft Count for Differentiability: For optimization, we replace $\mathbb{1}_{\{|\boldsymbol{\theta}|>0\}}$ in Eq. (2) with a sigmoid function $\sigma(|\boldsymbol{\theta}|)$ for gradient computation, defining $N_{\text{soft}}^{\mathrm{AF}}$ as

$$N_{\text{soft}}^{\mathrm{AF}} = \mathbf{1}_N^{\top} \cdot \text{row max}\left\{\sigma(|\boldsymbol{\theta}|)\right\}.$$

This relaxation allows gradient-based updates for N^{AF} by providing smooth gradients with respect to $\boldsymbol{\theta}$, as was previously done for N_{soft}^{N} in [13].

c) Final Power Estimation.: During the backward pass, the soft count facilitates gradient-based optimization. However, the final power estimation for a neuron is determined using the indicator function, as shown below:

$$\mathcal{P} = \mathcal{P}^{C} + N^{N} \cdot \mathcal{P}^{N} + N^{\mathrm{AF}} \cdot \mathcal{P}^{\mathrm{AF}}.$$

Power estimation in pNCs is influenced directly by the learnable parameters $\boldsymbol{q}^{\mathrm{N}}$, $\boldsymbol{q}^{\mathrm{AF}}$, and $\boldsymbol{\theta}$. Additionally, $\boldsymbol{\theta}$ indirectly affects the number of active elements in the circuit, which further impacts the total power consumption $P(\boldsymbol{\theta},\boldsymbol{q})$. In multi-neuron configurations, the output voltage of each neuron serves as the input for the subsequent neuron, with the final neuron's output representing the overall pNC output. The total power consumption is determined by summing the contributions from all neurons.

C. Power-constrained Training

To respect the constraints in training with Eq. (1), we require an adapation of the classic training procedure towards methods that can handle constraints. One such method that integrates particularly well backpropagation-based training schemes is the augmented Lagrangian method, see e.g. [30, 31]. It can be motivated by solving a sequence of unconstrained problems that converge to the solution of the constrained problem. Specifically, the method alternates between solving

$$\underset{\boldsymbol{\theta},\boldsymbol{q}}{\text{minimize}} \quad \max_{\lambda \geq 0}\ \mathcal{L}(\mathcal{D},\boldsymbol{\theta},\boldsymbol{q}) + \lambda \cdot c(\boldsymbol{\theta},\boldsymbol{q}) - \frac{1}{2\mu}(\lambda - \lambda')^2, \quad (3)$$

and updates to the Lagrange multiplier estimate λ' by

$$\lambda' \leftarrow \max\{0, \lambda' + \mu \cdot c(\boldsymbol{\theta},\boldsymbol{q})\}. \quad (4)$$

The parameter $\mu \in \mathbb{R}^{+}$ is a hyperparameter that controls the speed of convergence and influences the stability of the method.

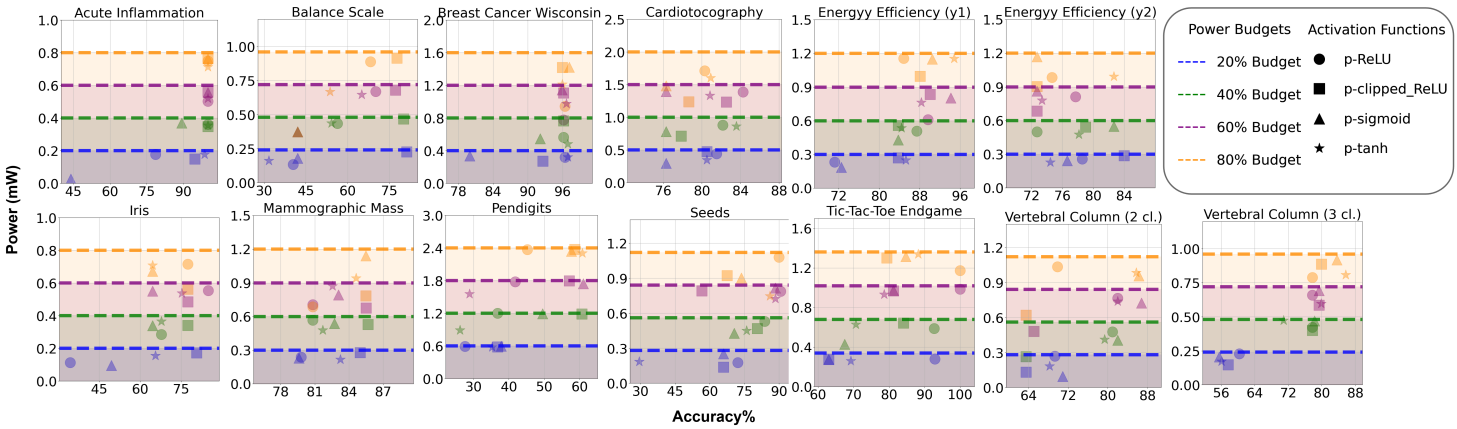

Fig. 4. Scatter plot showing the accuracy and power consumption for 13 datasets using four AFs (p-ReLU, p-clipped ReLU, p-sigmoid, p-tanh) under defined power budgets (20%, 40%, 60%, 80%). Each marker represents an AF, and dashed lines indicate the power budget thresholds. The goal is to achieve high accuracy while ensuring that power consumption stays below the specified budget constraints.

The minimization in Eq. (3) may be performed using classic backpropagation based training. The inner maximization over λ can be solved analytically for a given λ', details see [32]. After solving Eq. (3), the update of λ' in Eq. (4) adjusts the estimate for the Lagrange multiplier, encouraging the constraints to hold for the next minimization attempt. To save computation time, $\boldsymbol{\theta}$ and $\boldsymbol{q}$ should be warmstarted with the last solution obtained. The alternations of these steps can be stopped when a sufficiently good feasible solution is obtained.

IV. Evaluation

A. Experiment Setup

1) Dataset and Training Setup: To evaluate the proposed power-constrained training approach, we implemented the proposed method[2] using PyTorch [33] and tested it on 13 benchmark datasets used in prior studies [13, 34, 35]. The datasets were split into training (60%), validation (20%), and test (20%) sets to ensure consistent evaluation. Training used full-batch gradient descent with the Adam optimizer [36], starting with an initial learning rate of 0.1. Early stopping was applied to prevent overfitting by halving the learning rate after 100 epochs without improvement on the validation set and stopping training if the power constraint was violated. For the selection of μ, RayTune [37] was used. All pNCs were trained with a consistent topology (#$inputs$-3-#$outputs$) and randomly initialized parameters for each AF.

Following the primary training phase, a fine-tuning step was conducted to enhance accuracy while strictly adhering to power constraints. During this process, masks m^C were generated to deactivate inactive components, such as resistors with zero conductance and unused AFs. Similarly, masks m^N were introduced for negation circuits to enforce positive weights where necessary. These masks effectively pruned redundant hardware components, reducing power consumption. The model was then retrained using cross-entropy loss, optimizing accuracy without violating the power constraints. This mask-based adjustment ensured a trade-off between accuracy and power, even under stringent budget limitations.

[2]Code is available at https://github.com/KIT-Neuromorphic-Computing/Power-Constrained-PNC.

2) Benchmark Circuit Design Setup: All experiments at the simulation level were conducted using pPDK [29], while the functionality of printed neuromorphic hardware has been validated in previous work [14, 38].

3) Algorithm Benchmarking: To benchmark the proposed method, we compared its results to a Pareto front generated by traditional penalty-based optimization with p-tanh AFs [13]. For the baseline, we uniformly sampled 50 μ values in the range $[0, 1]$ and trained each model 10 times (using 10 different seeds) to generate the Pareto front. For the augmented Lagrangian approach, power constraints were set at 20%, 40%, 60%, and 80% of the maximum power observed during unconstrained training. This setup allowed for a comprehensive evaluation of the trade-offs between power and classification accuracy.

B. Result

To evaluate the effectiveness of our power-constrained training approach, we compared the results with a penalty-based method [13]. Four neural networks, each using a different AF (p-ReLU, p-Clipped_ReLU, p-sigmoid, and p-anh), were trained under four power budgets: 20%, 40%, 60%, and 80% of the maximum power consumption derived from unconstrained power training. The top three models per dataset were selected based on test accuracy. As shown in Fig. 4, each point represents classification accuracy and power consumption for a dataset. Marker shapes indicate AFs (circles for p-ReLU, squares for p-Clipped_ReLU, triangles for p-sigmoid, and stars for p-tanh), and marker colors represent power budgets, aligned with horizontal dashed lines for power thresholds. The x-axis shows accuracy (percentage), and the y-axis shows power (milliwatts).

Tab. I summarizes the average performance metrics across 13 datasets, comparing power consumption, accuracy, and device count among the proposed AFs (p-ReLU, p-Clipped_ReLU, p-sigmoid, and p-tanh). On the right side of the table, the results for the penalty-based baseline method [13] are presented, showing accuracy and power under different scaling factors α (0.25, 0.5, 0.75, and 1), which indicate the trade-off between power and accuracy. Additionally, for the baseline method, we generated a Pareto front (pink curve) using 500 penalty-based runs, varying the scaling factor α over the range $[0, 1]$. Fig. 5

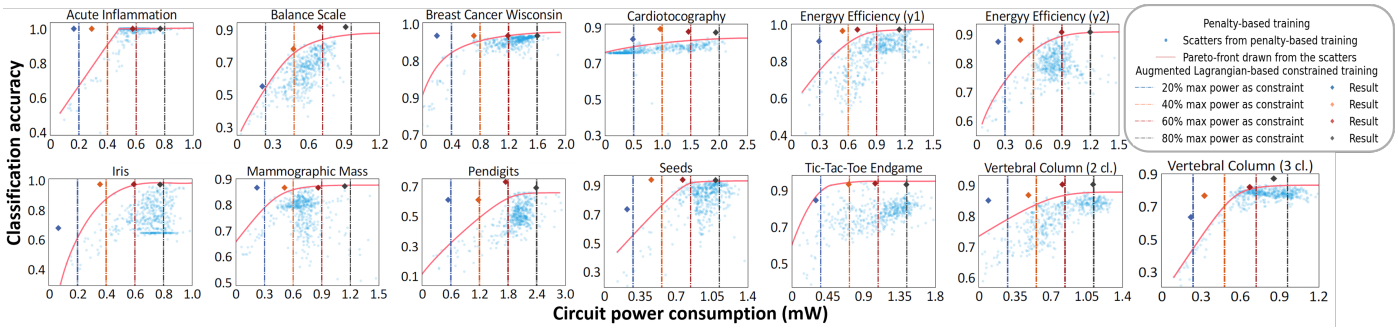

Fig. 5. Classification accuracy and power consumption of pNCs using exemplary p-tanh AF from penalty-based and Augmented Lagrangian-based training approaches. The blue scatters are the results of penalty-based training, while the pink curves are Pareto fronts drawn from the scatters. The vertical lines indicate the power constraints in the augmented Lagrangian approach, whereas the rhombus with the same color refers to the results from the augmented Lagrangian

compares the optimal solutions found by our method in a single training run against this Pareto front. Vertical dashed lines highlight power constraints, demonstrating that our method efficiently achieves power-constrained optima, often matching or surpassing the Pareto front with significantly fewer training runs.

C. Discussion

Our experimental results demonstrate the effectiveness of the augmented Lagrangian approach in achieving high accuracy while adhering to defined power constraints across various datasets. As shown in Fig. 4, all results lie below the defined power levels, confirming the method's capability to enforce power limits effectively. Notably, at 20% of the power budget, accuracy decreases compared to higher power budgets, highlighting the trade-off between power and performance. As shown in Tab. I, the baseline demonstrates high accuracy at $\alpha = 0.25$ but with higher power consumption, while $\alpha = 1$ reduces power at the cost of accuracy. In contrast, the proposed method achieves a balanced trade-off between power and accuracy across power budgets in a single training run. Furthermore, it delivers results comparable to or better than the Pareto front obtained from penalty-based objectives (Figure 5) without the need for extensive hyperparameter tuning.

The success of this approach is due to two main factors. First, by directly incorporating power constraints into the training objective, the augmented Lagrangian method avoids the instability often caused by high power penalties in penalty-based methods. Second, this explicit formulation focuses on achieving the best feasible accuracy for each specified power budget without unnecessarily minimizing power further.

Compared to penalty-based methods, which often create ill-conditioned optimization problems and fail to align with optimal power-accuracy trade-offs, the augmented Lagrangian method dynamically enforces constraints while maintaining accuracy. This ensures a balanced solution on the Pareto front with fewer computational resources.

Analyzing individual AFs reveals trade-offs between accuracy and device count. For example, p-tanh achieves up to 81.82% accuracy at an 80% power budget, but requires an average of 58 devices, whereas p-ReLU achieves 80.42% accuracy with only 37 devices—a 36% reduction. This makes p-ReLU particularly suitable for hardware-limited applications. These findings demonstrate that such trade-offs persist even under strict power constraints, with reduced device counts contributing to lower power consumption.

V. CONCLUSION

In this work, our objective is to introduce a methodology for power-constraint training of analog printed neuromorphic circuits. This is implemented by an augmented Lagrangian approach which leveraged the surrogate power models for activation function circuit primitives. The approach achieved en par to superior performance to penalty based methods across 13 benchmark datasets, while requiring fewer training time to find suitable pNCs. We additionally developed power models for four printed AFs, enabling analysis of power and accuracy trade-offs. While p-tanh achieves higher accuracy, p-ReLU minimizes device count, proving beneficial for resource-limited applications. Due to the flexibility of the proposed approach, future works may explore its applicability to additional circuit components and constraints.

Graph in the Vault: Protecting Edge GNN Inference with Trusted Execution Environment

Ruyi Ding*, Tianhong Xu*, Aidong Adam Ding, Yunsi Fei
Northeastern University
{ding.ruy, xu.tianh, a.ding, y.fei}@northeastern.edu

***Abstract*—Wide deployment of machine learning models on edge devices has rendered the model intellectual property (IP) and data privacy vulnerable. We propose GNNVault, the first secure Graph Neural Network (GNN) deployment strategy based on Trusted Execution Environment (TEE). GNNVault follows the design of "partition-before-training" and includes a private GNN rectifier to complement with a public backbone model. This way, both critical GNN model parameters and the private graph used during inference are protected within secure TEE compartments. Real-world implementations with Intel SGX demonstrate that GNNVault safeguards GNN inference against state-of-the-art link stealing attacks with a negligible accuracy degradation ($< 2\%$).**

I. Introduction

On-device machine learning has emerged as an important paradigm for tasks requiring low latency and high privacy [1]. Applications like Apple's CoreML [2] and Huawei's MindSpore [3] enable user personalization on local devices. This trend has also extended to Graph Neural Networks (GNNs) [4], [5], ensuring the privacy of user data during inference for tasks such as community detection [6], e-commerce personalization [7], and recommender systems [8]. However, local GNN inference grants users significant privileges to local models and data, introducing additional security vulnerabilities [9].

There are two primary security threats to inference on local devices: model intellectual property (IP) theft and data privacy breach. Valuable model IP includes the hyper-parameters, trained parameters, and model's functionality [10]. Data privacy issues involve attacks such as membership inference [11] and link stealing attack [12], which can exploit the white-box accessibility of local models. Existing defenses, including watermarking [13], non-transferable learning [14], and homomorphic encryption [15], are often passive, inaccurate, or computation-expensive. Recently, studies have begun leveraging Trusted Execution Environments (TEEs) to protect local models and data [16], [17], by partitioning them into slices and deploying critical components within secure compartments.

However, current TEE-based secure deployment mainly targets datasets for tasks such as computer vision and large language models, which is not applicable to GNN inference. Specifically, GNN operations require updating the graph node representations (i.e., embeddings) based on information from their neighboring data points. Thus, *the entire graph data, including node features and their connectivity (adjacency matrix), has to be stored locally during inference*, posing additional challenges for data privacy. Moreover, TEEs have limited memory capacities, while large graphs require significant storage for node features. To bridge this gap, we propose a new method for local GNN deployment, GNNVault, which effectively preserves both critical model parameters and the most important structural information (i.e., edges) using TEE.

GNNVault employs the "partition-before-training" strategy [16], where the GNN model is designed with a public backbone and a private GNN rectifier. Specifically, the public backbone is computation-intensive but inaccurate, which is trained with a substitute graph and deployed in the untrusted environment. The GNN rectifier leverages the real private graph structure to rectify the backbone's node embeddings. It is designed to be much smaller and resides within the TEE. Our experiments show that GNNVault achieves performance comparable to the original unprotected GNN while preventing information leakage of private parameters and edges. We also evaluate our design on a real system using Intel SGX, demonstrating the low overhead of GNNVault.

Our Contributions: We propose GNNVault, the first secure deployment framework designed specifically for graph neural networks. Our work makes the following contributions:

1) We propose various communication schemes between public backbones and private rectifiers in GNNVault, and evaluate the performance and implementation cost of rectifiers.
2) Software evaluation demonstrates that GNNVault achieves a high inference accuracy with a small rectifier inside TEE while protecting critical model parameters and edge data.
3) We implement a real-world deployment using Intel SGX to run GNNs locally. Experimental results show that the introduction of the enclave increases a small inference overhead and negligible accuracy degradation (less than 2%), demonstrating the effectiveness of GNNVault.
4) We conduct a security analysis with link stealing attacks on the intermediate data communicated from the public backbone to the rectifier, showing that no private edge information is leaked in the untrusted environment.

II. Background

A. Graph Neural Network

GNNs process graph-structured data, which contains relational information between nodes (or edges). Without loss of generality, we follow the common GNN definition [18]: a graph $G = (V, E)$ consists of the node set V with n nodes, each with a feature represented by a d-dimensional vector,

denoted as $X \in \mathbb{R}^{n \times d}$. The set of edges E is depicted by an adjacency matrix $A \in \{0,1\}^{n \times n}$, indicating the existence of connections between nodes in G. A GNN model is a function $f(X, A)$ to summarize global information in the graph for downstream tasks including node classification [19], community detection [6], and recommender systems [20]. The forward propagation of GNN layer k can be written as

$$H^{(k)} = \sigma(\hat{A}H^{(k-1)}W^{(k)}) \tag{1}$$

where $H^{(k)} \in \mathbb{R}^{N \times d^{(k)}}$ is the matrix of node embedding at layer k, $\hat{A}$ is the adjacency matrix with self-loops normalized with degree matrix, $W^{(k)} \in \mathbb{R}^{d^{(k-1)} \times d^{(k)}}$ is the learnable weight matrix, and σ is an activation function. Note that GNN operations require $\hat{A}$ through message passing during the inference process, which causes edge data privacy concerns.

B. Model Deployment in Trusted Execution Environments

A TEE, such as Intel SGX or ARM TrustZone, protects code and data within it, ensuring their confidentiality and integrity with hardware support against strong adversaries including a malicious host operating system. The increasing demand for edge AI applications, e.g., those that require real-time responses or rely on local data or private data, has led to a trend of using TEEs for IP protection and privacy preservation. Previous works focus on securely deploying DNNs by isolating the non-linear layers [21] or by partitioning the model and placing the final dense layers inside the TEE [22]. Recently, Zhang et.al [16] also consider the privacy of training data and propose a "partition-before-training" strategy against membership inference attack [11]. Additionally, Liu et al. [17] design a deployment strategy that only allows single-directional data flow from the untrusted environment to the enclave. However, all previous works only focus on local DNN's IP and data privacy, which are not applicable to the secure deployment of a GNN on the edge. Our proposed method, GNNVault, bridges this gap by protecting the security of trained GNNs and private edge data using TEEs.

III. Problem Statement

A. Deploying GNN locally Causes Vulnerabilities

Deploying GNNs on local devices requires access to graph data in addition to the trained model, which introduces unique security and privacy challenges. Similar to DNN deployment, the IP of the well-performed local model, including its trained weights and biases, is valuable asset that must be protected against model extraction attacks. Beyond the model IP, local GNN inference raises additional privacy concerns due to the nature of GNN architecture. Specifically, during the message-passing phase of GNN inference, target nodes aggregate information from neighboring nodes to update their embeddings. This process involves accessing sensitive edge data, such as user-product interactions in recommender systems. In our work, we will address the GNN IP infringement and edge data breach vulnerability during GNN deployment.

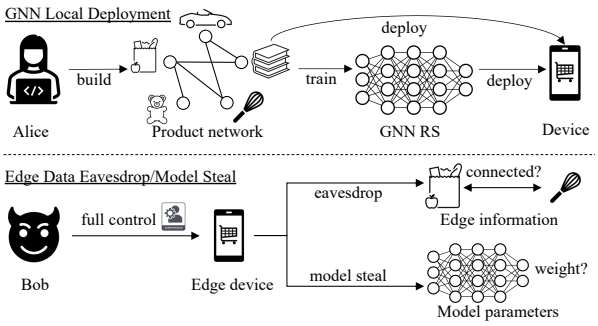

Fig. 1. **Motivation Example:** Alice (victim) builds a graph of products and trains a GNN RS. She deploys both edge data and RS on local devices. Bob (attacker) accesses this device and steals the edge data and model parameters.

B. Edge Privacy is Valuable

Membership inference attack is the most common data privacy threat to machine learning models [11], where the goal is to determine whether a given data point belongs to the training set. However, in the context of GNNs, edge data raises additional privacy concerns. Link stealing attacks [12], [23] aim to infer the connectivity between any pair of given nodes. In this work, we focus on the adjacency information (edges), while considering the node features as public. A real-world example is illustrated in Fig. 1, where Alice (victim) deploys a recommender system (RS) on local edge devices. In such a product graph, the node features are public attributes of the products—such as price, user reviews, or categories—that are available to any user. However, the internal relationships between products require intensive learning from user behavior data, which is valuable IP for the model vendor. Therefore, safeguarding the node connectivity information during GNN local inference is of great importance.

C. TEE Has Memory Restrictions

The introduction of TEE greatly enhances data security and privacy with secure compartments. However, TEE platforms face significant memory limitations, a critical constraint for secure computation. For instance, for Intel SGX trusted enclaves, the physical reserved memory (PRM) is limited to 128MB, with 96 MB of it allocated to the Enclave Page Cache (EPC) [24]. Excessive memory allocation will lead to frequent page swapping between the unprotected main memory and the protected enclave, which can cause high overhead and additional encryption/decryption to ensure data integrity [25]. This memory constraint poses a significant challenge for deploying GNN models and the entire graph (including node features and adjacency information) within the secure enclave, which often far exceed the PRM limitation of enclaves.

IV. Our Approach: GNNVault

A. Threat Model

Our work aims to protect both GNN model parameters and the edge data during inference, specifically using the TEE of Intel SGX. Unless specified, we consider node classification as the primary downstream task.

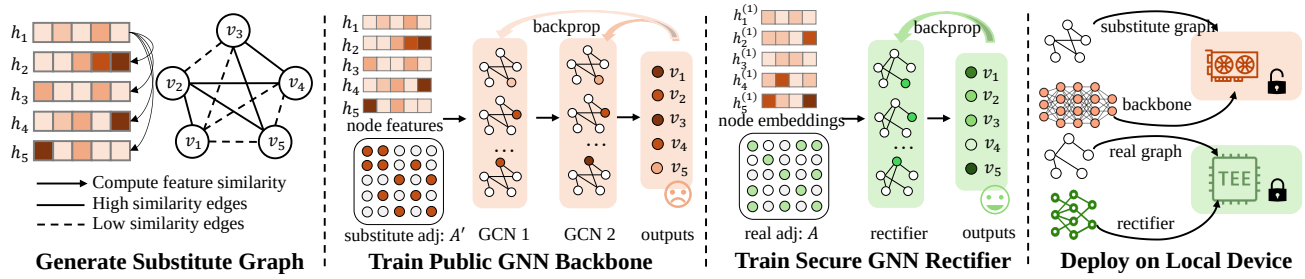

Fig. 2. **Overview of GNNVault.** GNNVault can be summarized into four steps: 1. generate a substitute graph based on the similarity between the node features; 2. train the GNN backbone with the substitute adjacency matrix; 3. freeze the backbone and train the secure recalibration rectifier using real adjacency information; 4. deploy the backbone and substitute graph in untrusted environments (in brown) and deploy the real graph and rectifiers on enclaves (in green).

Attacker's Goal. We assume there are "honest-but-curious" attackers such as users of local ML systems. Specifically, these passive attackers are curious about sensitive data but do not intend to corrupt the system's integrity and functionality. Their objective is to extract confidential graph structural information, represented by the adjacency matrix, and to steal the parameters of highly accurate GNNs present on the device.

Attacker's Capability. The attacker has full control over the victim system, enabling them to query the GNN model with any chosen node to obtain the model output results. Additionally, they can observe any computation and intermediate results in the untrusted environment, such as the public part of the GNN model or the intermediate node embeddings. However, any data and operations within the enclaves remain sealed and inaccessible to the attacker. Other attacks against TEE, e.g., side-channel attacks, are out of the scope of this work.

Attacker's Knowledge. We assume the attacker lacks knowledge of the adjacency matrix, which represents confidential relationships between any two nodes in the graph (e.g., hidden correlations between customers and products in recommender systems or private connections between users in social networks). The node features, however, are considered public knowledge such as product attributes or user profiles.

Defender's Goal. The defender, a model provider such as Apple or Amazon, is responsible for the design and deployment of the GNN model on the local device, aiming to protect both the highly accurate GNN model and the private adjacency matrix information. This involves designing the GNN structure and establishing the secure deployment of the trained model and graph data on the inference platform.

B. Overview of GNNVault

GNNVault employs the design strategy known as *partition-before-training* [16], to completely avoid using the private edge data during training of the public backbone. To maintain the model performance, a GNN rectifier is designed to use the real adjacency matrix, which is lightweight and securely protected within the TEE. Furthermore, to prevent information leakage through intermediate data transfer, GNNVault allows only one-way communication from the untrusted environment to the enclave. As illustrated in Fig. 2, GNNVault can be summarized in four steps: (1) generate substitute graph(s); (2) train the public backbone; (3) train the private rectifier; (4) securely deploy the data and models.

C. Public GNN Backbone

The backbone is trained with public data, aiming to provide sufficient pre-computation during the inference process. Unlike the backbones for DNNs or LLMs in [16], which are open-source pre-trained models, GNNs are more dataset-specific and cannot directly leverage such models. Therefore, our GNNVault uses a pre-trained neural network backbone that utilizes public node features. We generate a substitute adjacency matrix based on node similarity and train this backbone for the target tasks (node classification).

Substitute Adjacency Matrix: To enable the backbone model to capture message passing between nodes, we design it as a GNN with a substitute adjacency matrix. This substitute adjacency is computed based on the similarity between nodes:

$$A'(i,j) = \begin{cases} 1 & \text{if } F(i,j) \geq \tau \text{ for each } j \neq i \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

Here, $F(i,j) = \text{sim}(x_i, x_j)$ represents the similarity measure computed between two node features, such as cosine similarity $\frac{x_i \cdot x_j}{|x_i||x_j|}$. Based on this similarity, we determine the connected edges using a threshold τ. Alternatively, connectivity can be computed using the k-nearest neighbors, where we connect the top-k similar nodes to construct the adjacency matrix.

Training the Public Backbone: The public backbone consists of GCN layers trained with the substitute adjacency matrix A' and the public node features X. Each GCN layer k projects the high-dimensional features (embeddings) from $\mathbb{R}^{N \times d^{(k)}}$ to a lower-dimensional space $\mathbb{R}^{N \times d^{(k+1)}}$ through the message passing procedure. However, due to the loss of spatial information from the real adjacency matrix, this public backbone often exhibits lower accuracy. Therefore, the other component, a private rectifier, aims to recalibrate the embeddings in $\mathbb{R}^{N \times d^{(k+1)}}$ with real adjacency to achieve higher accuracy.

D. Secure GNN Rectifier

With the public backbone trained using the substitute adjacency matrix, the node embeddings are passed from the backbone to the GNN rectifier to rectify the misinformation from A'. The rectifier is designed with GCN layers that take the outputs of the backbone as inputs, along with the true adjacency matrix for rectification. Notably, the embeddings are often in a lower-dimensional latent space compared to the original node features. Therefore, a rectifier layer will be

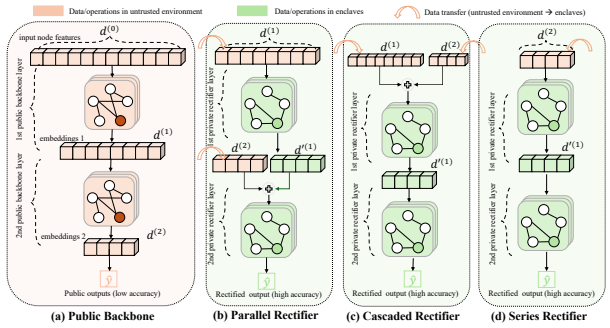

Fig. 3. **Backbone and GNN Rectifier Designs:** (a). Public GNN backbone; (b). Parallel rectifier; (c). Cascaded rectifier; (d) Series rectifier.

smaller than the corresponding backbone layer, so that it can fit into the enclave. During the training process of the rectifier, we freeze the pre-trained GNN backbone and adjust the rectifier parameters using cross-entropy loss for node classification.

How to process node embeddings from the backbone will result in various rectifier sizes and rectification performances. We consider three communication schemes (data flows) and the corresponding rectifiers, as shown in Fig. 3:

Parallel Rectifier: Layers of the public backbone and layers of the rectifier run layer-by-layer in parallel. We aim to rectify the node embeddings right after each message-passing with the substitute adjacency matrix. Our experiment shows that the parallel rectifiers have the best accuracy (Sec. V-B1).

Cascaded Rectifier: This design allows the backbone to run first, and then we concatenate all GCN layer outputs from the untrusted environment as input to the rectifier, which provides the rectifier a global view of the node embeddings but introduces additional computational requirements.

Series Rectifier: In this design, we utilize only the final layer from the backbone as input to the rectifier. This approach uses the smallest input space and results in lower memory consumption and faster response time.

E. Deployment of GNN on TEE

As shown in Fig. 2, we deploy the public backbone and substitute graph in the untrusted environment, where the model can benefit from acceleration from GPUs. We safeguard the real adjacency information and GNN rectifiers inside the secure enclaves to prevent edge privacy breaches and model stealing attacks. The true adjacency matrix will be saved in the Coordinate (COO) format, which maintains only the non-zero elements with their indices for memory efficiency, with the pre-computed degree matrix, to accelerate the normalization process. During the inference phase, each layer of the rectifier's output will be stored internally within the enclave, preventing intermediate data from leaking to the untrusted environment. Logits have been shown to contain additional privacy information such as data membership and link connectivity [12], [11]. Therefore, we also require the final output to be label-only, i.e., the logits are kept inside the enclave and only the output class is available to users.

V. Experimental Validation

A. Experiment Setup

Datasets: We focus on semi-supervised learning tasks for node classification with GNNs on multiple datasets at different scales, as shown in Table I. Specifically, we evaluate GNNVault on three standard datasets in [26], two larger graphs *Amazon Computer* and *Photo* in [27], and *CoraFull* [28] which has many classes (70). Table I shows the memory requirement for a dense adjacency matrix. To train the GNN, we follow the common practice: using 20 labeled node per class [27], and the unlabeled nodes are used as the testing set. If not specified, we use KNN with k=2 as substitute graphs in backbones, which are chosen based on the ablation study in V-B4.

TABLE I
Dataset Used in GNNVault Validation

Dataset	# Node	# Edge	# Feature	# Class	Dense A (MB)
Cora [26]	2,708	10,556	1,433	7	167.85
Citeseer [26]	3,327	9,104	3,703	6	253.35
Pubmed [26]	19,717	88,648	500	3	8898.01
Computer [27]	13,752	491,722	767	10	4328.56

CoraFull [28]	19,793	126,842	8,710	70	8966.74

Models: We evaluate GNNVault on three different GNN structures based on dataset features space size: $\mathcal{M}_1$ has as a 3-layer GCN backbone with output channel size as $(128, 32, \mathcal{C})$ and a rectifier $(128, 32, \mathcal{C})$, which is designed for a smaller dataset including Cora, Citeseer, Pubmed, where $\mathcal{C}$ is the label space size. $\mathcal{M}_2$ has wider output channels (256) for both the backbone and the rectifier, which is used for the case when the model has a high-class number, such as CoraFull. We also test a larger and deeper design $\mathcal{M}_3$ with a backbone $(256, 64, 32, 16, \mathcal{C})$ and rectifier $(64, 32, \mathcal{C})$. Different rectifiers may have various input channel sizes, as shown in Fig. 3.

Metrics: We first compute the accuracy of the original GNN model, which has the same architecture as the backbone but uses the real adjacency matrix and therefore has different parameters, denoted as p_{org}. The difference between the classification accuracy of the public backbone in the normal world, denoted as p_{bb}, and the accuracy of the GNN rectifier, denoted as p_{rec}, measures the *protection performance*. We also compare the size of the public backbone and private rectifier in terms of the number of model parameters, denoted as θ_{bb}, and θ_{rec}. To show accuracy degradation, we utilize the difference between p_{rec} and p_{org} and the silhouette score to show the node's clustering performance [29].

Platform: We run the training procedure and the software evaluation process on Ubuntu 18.04.6 with NVIDIA TITAN RTX. We also follow a similar setting to [16] as a real-world case study on an SGX-enabled Intel Core i7-7700, running Ubuntu 20.04.6 and utilizing Intel SGX SDK and PSW.

B. Software-based Validation

1) Evaluation of GNNVault Performance: The performance of GNN deployment using TEE on a local device can be evaluated using the following attributes: 1. Accuracy degradation (p_{org} - p_{rec}) (lower is better); 2. Protection performance $\Delta p = p_{\text{rec}} - p_{\text{bb}}$ (higher is better); 3. The model size inside

the enclave θ_{rec} (smaller is better). In Table II, we present the performance of GNNVault on three rectifier designs, following the experimental setups described in Section V-A. Among the three rectifier designs, the parallel rectifier achieves the highest accuracy on three datasets and ranks second-best in others, and it also offers the highest protection. The cascaded rectifier has the largest model size but shows lower accuracy, as the input GCN layer may not handle all complex inputs together well. The series rectifier has the smallest size inside the TEE, as it only requires the final node embedding from the backbone as input, and yet it still achieves good performance overall.

2) Evaluation of Different Backbones: GNNVault's backbones show low accuracy when using the substitute graph, indicating that our design effectively prevents malicious attackers from accessing any high-precision models in untrusted environments. We then compare the performance of GNNVault using different types of backbones: the DNN backbone (an MLP using only node features), and the GNN backbones with three different ways to generate the substitute graph: random (the graph is randomly generated), cosine (the graph is generated based on cosine similarity), and KNN (the graph is generated using the KNN algorithm). For the GNN-based backbones, we sample the graph density to match that of the original graph. Among all four types of backbones, the cosine and KNN methods demonstrate the best performance, while the GNN with a random graph shows the lowest accuracy. Specifically, the random graph incorporates too much misinformation, degrading the embedding performance of the backbone model and making rectification difficult. Moreover, compared with the DNN model, the GNN backbones using cosine similarity and KNN substitute graphs enable the backbone not only to extract information from the node features but to gather additional information from similar nodes via message passing. This additional information enhances the rectification process when using the correct adjacency information.

3) Rectifier Interpretation: To illustrate the rectification process, we visualize the node latent space of a parallel GNNVault applied to the Cora dataset, which contains 7 classes. In Fig. 4, we illustrate how the latent space changes layer-by-layer between the backbone and the rectifier using t-SNE [30]. The rectifier layer significantly improves the clustering performance by gradually incorporating the real adjacency matrix, ultimately approaching the original model's performance. Additionally, we plot the silhouette score of each layer's embeddings to numerically assess their clustering performance. The results show that the rectifier's scores (green line) become close to those of the original GNN (gray line), while the backbone model's scores (orange line) remain low.

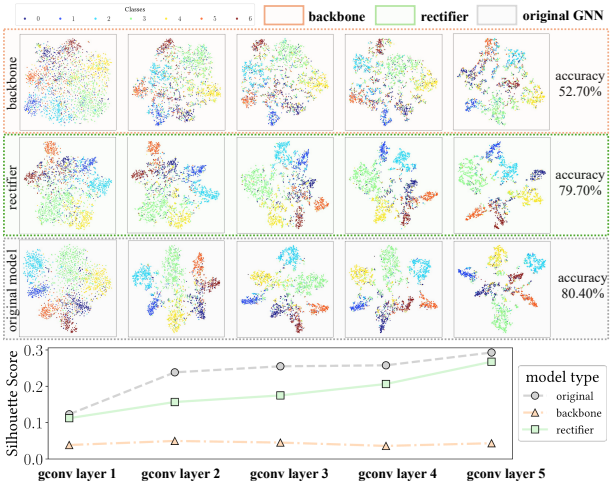

Fig. 4. **Visualization of the node embeddings.** We visualize the embedding latent space for parallel GNNVault on Cora dataset using the same structure for the original GNN, backbone and rectifier as $\mathcal{M}_2$. The line chart shows the Silhouette Score of the clustering performance**(the higher the better).**

4) Ablation Study: We evaluate the impact of different hyperparameters on GNNVault's performance, as shown in Fig. 5. Specifically, we vary the number of neighbors in the KNN-based substitute graph, adjust the cosine similarity threshold for the cosine similarity graph, and change the percentage of random edges (relative to the number of real edges) for the random substitute graph. For the KNN method, the performance remains stable because the algorithm consistently connects similar nodes based on their features. Increasing k primarily affects the density of the substitute graph without significantly impacting performance. We select k=2 as the number of edges for it is close to the real graph for most of the datasets. In contrast, selecting a low cosine similarity threshold for the cosine similarity graph can connect unrelated nodes, which adversely affects GNNVault's performance (when the cosine similarity threshold is $\leq$ 0.2). As we increase the

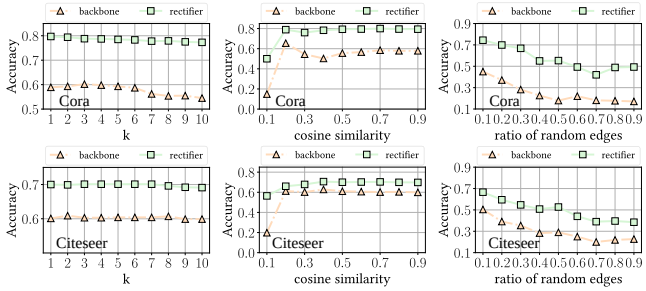

Fig. 5. Impact of hyperparameters of different substitute graphs

number of random edges in the substitute graph, the performance of both the backbone and the rectifier decreases as more structural noise is introduced. Notably, when we use an extremely small number of edges, random GNNVault's accuracy approaches that of the DNN backbone.

C. Real-world Implementation

1) Implementation Details: We implemented GNNVault on a desktop PC equipped with an Intel Core i7-7700 (3.60GHz) processor. The public backbone in the untrusted environment is developed using PyTorch 2.4.1, while the rectifier is implemented in C++ with Intel SGX SDK 2.25. To optimize the computation within the rectifier, we leveraged the Eigen linear algebra library to efficiently handle matrix operations, achieving approximately 20% speed up for large models [31].

2) Inference Overhead and Memory Usage: The inference time of GNNVault comprises of the backbone execution time, data transfer time, and the rectifier execution time. In Fig. 6 (top), we present a breakdown of the inference time, for three rectifier designs and different GNN models: $\mathcal{M}_1$ (Cora), $\mathcal{M}_2$ (CoraFull), and $\mathcal{M}_3$ (Amazon Computer). The parallel and cascaded rectifiers transfer all intermediate node embeddings from the normal world to the secure world, resulting in higher latency due to data transfer and execution inside the TEE. The series rectifier exhibits the smallest overhead since it only requires the last layer's embedding, leading to an overhead of approximately 52% to 131% compared with running an unprotected GNN with CPU. Note that the backbone can be accelerated using GPUs to further increase the inference speed.

We also present the enclave runtime memory usage required for different GNNVault configurations, as shown in Fig. 6 (bottom). As mentioned before, the memory allocated in the trusted enclave is limited by SGX's PRM and EPC. Therefore, it is essential to ensure that the rectifier operates effectively within the enclave's secure boundaries and does not exceed the recommended limits. The enclave memory usage is primarily for each layer's input features, adjacency matrix, and model parameters. Notably, the highest memory usage across all models and rectifier designs remains at only 41.6MB, well within the 96MB EPC threshold. This confirms the feasibility of running these configurations securely within the enclave. In contrast, the backbone's runtime memory usage for the three models significantly exceeds 128MB, underscoring the impracticality of executing a complete GNN model within the enclave due to memory constraints.

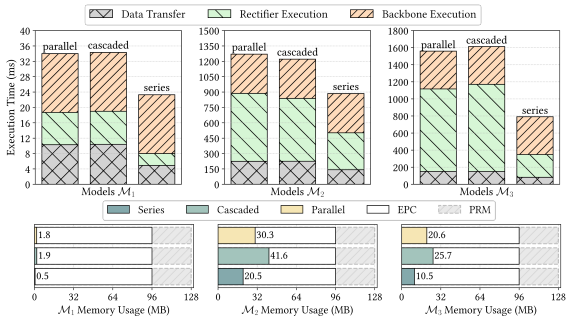

Fig. 6. GNNVault Inference Time Breakdown and Memory Usage

D. Security Analysis using Link Stealing Attacks

Link stealing attacks [12], [23] aim to infer the adjacency matrix by exploiting the similarity between node embeddings, based on the assumption that GNN layers produce more similar embeddings for connected nodes than for unconnected ones. GNNVault isolates the private graph within the secure world and ensures one-directional communication from the normal world to the secure world. To verify the effectiveness of this isolation, we conduct link stealing attacks using six different similarity metrics and present the attack ROC-AUC scores in Table IV using all intermediate embeddings. A higher AUC score indicates greater leakage of private graph information. We use the attack performance on a DNN model with pure node features as the baseline ($\mathcal{M}_{\text{base}}$). The unprotected GNN ($\mathcal{M}_{org}$) shows very high AUC scores using all similarity metrics on both datasets, but with our GNNVault ($\mathcal{M}_{gv}$), the attack performance decreases to the level of the $\mathcal{M}_{base}$.

VI. CONCLUSIONS AND FUTURE WORK

In this paper, we propose a novel secure GNN deployment strategy called GNNVault. Our approach involves strict isolation, training a public backbone model using only public data, and training a rectifier on private data to rectify the results from the backbone. The two spited models and their corresponding graph data are deployed in the untrusted environment and secure enclave, respectively. This method effectively safeguards sensitive adjacency information during GNN inference on edge devices. Given the growing trend of GNN local deployment, ensuring data privacy in such settings is of paramount importance. As part of our future work, we plan to explore and implement our strategy with additional GNN architectures, including GraphSAGE and GAT, to further enhance the security and broaden applicability.

***Abstract*—For collaborative inference through a cloud computing platform, it is sometimes essential for the client to shield its sensitive information from the cloud provider. In this paper, we introduce Ensembler, an extensible framework designed to substantially increase the difficulty of conducting model inversion attacks by adversarial parties. Ensembler leverages selective model ensemble on the adversarial server to obfuscate the reconstruction of the client's private information. Our experiments demonstrate that Ensembler can effectively shield input images from reconstruction attacks, even when the client only retains one layer of the network locally. Ensembler significantly outperforms baseline methods by up to 43.5% in structural similarity while only incurring 4.8% time overhead during inference.**

I. Introduction

Deep learning models have achieved exceptional performance across critical domains [1], but their increasing size poses challenges for computationally constrained edge devices like mobile phones [2, 3]. When the model's size and complexity exceed the computational ability of the edge devices, a prevalent solution to reduce the workload on these resource-limited edge devices is through collaborative inference (CI) [4], as shown in the left side of Fig. 1. During inference, the client (edge device) computes the first few layers of the network and sends the intermediate features to the server (cloud), where the server computes the computationally expensive layers and returns the features or the results back to the client. However, this raises concerns about the privacy of sensitive client data, especially when the cloud server may be adversarial and tasks involve sensitive information like medical or facial data [5]. Consequently, there is a growing need for secure, accurate, and efficient machine learning frameworks that enable privacy-preserving collaboration between edge devices and cloud servers.

During CI, a classical yet powerful attack on the client's sensitive data is through model inversion attacks (MIA). As shown in the right side of Fig. 1, an adversarial server aims to inverse the client's private network to reconstruct the private input through intermediate features. We will elaborate on the details of MIA in Section II. He et. al. show that the client's data is especially vulnerable when the client retains only one

The research was supported in part by the National AI Institute for Exceptional Education (NSF Award #2229873), Center for Early Literacy and Responsible AI (IES Award #R305C240046), FuSe-TG (NSF Award #2235364) and SaTC (NSF Award #2329704). The opinions expressed are those of the authors and do not represent views of any sponsors.

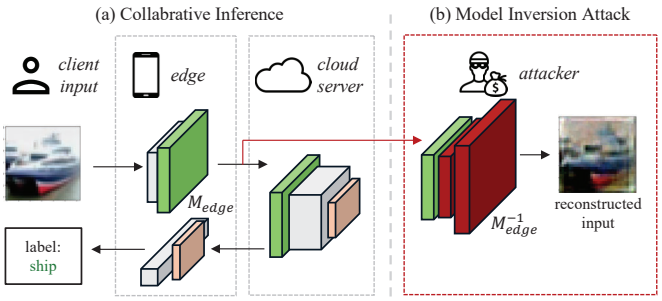

Fig. 1. An illustration of (a) collaborative inference, where the client offloads computation to the server; and (b) model inversion attack, where the adversarial server builds a decoder M_{edge}^{-1} to decode the client's input from the intermediate features computed by the client's private network M_{edge}.

single convolutional layer [4]. While the client can potentially keep more privacy as it keeps more layers, such a method is less practical in the real world due to the limitations of the computational power of edge devices. Shredder [4] uses a noise injection layer before the client sends out computed results to reduce mutual information between client and server while maintaining good classification accuracy. Nevertheless, Preva [5] demonstrates that Shredder falls short in safeguarding facial images from recovery. Through experimentation with the noise injection layer proposed by Shredder on a shallow layer, we observed significant accuracy drops with combined multiplicative and additive noise. On the other hand, simple additive noise with about a 3% drop in accuracy failed to protect images from recovery.

The failure of Shredder [6] could be attributed to two factors: the client's computational limit and the server's knowledge of the partial weights. To ensure the best defense, Shredder requires the noise injection layer to be very deep, but that results in the client taking heavy computation work and is less practical. Meanwhile, a shallow noise injection layer leaves most of the weights to the server. With rich information about public model weights available, the server can learn a strong and accurate representation of the private network held by the client, which leads to a successful MIA. Thus, the key challenge behind a practical CI framework is to defend against an adversarial server's reconstruction ability when the client only holds a minimal portion of the network.

To address the current deficiencies in privacy-preserving edge-cloud collaborative inference scenarios, in this work,

we propose a novel mechanism of "selective ensemble." Our intuition is as follows. Since the reconstruction ability of the adversarial server is powerful, it may be wiser to hide the client's private model than to defend it directly against the model reconstruction attack. We propose to leverage model ensemble on the cloud and secret private masking on the user side to achieve a "Schrödinger's model," where a reconstruction attack can lead to a successful, but different, shadow network than the client's true network.

Based on the above analysis, we propose *Ensembler*, a novel and secure CI framework designed to substantially increase the adversary's effort required to recover the client's input. The proposed architecture consists of multiple parallel networks, but only a subset of them is actually activated by the client during inference. An existing MIA on the network will lead to a seemingly successful reconstruction, but such reconstruction does not represent the client's real network weights. We make the following contributions in this paper:

- We identify and address the key challenge in practical private collaborative inference, i.e., when the model split location between the client and the server is shallow, a direct defense fails to work.
- We reveal that a secret selection of a subset of the networks in an ensemble architecture can be useful for defending against model inversion attacks.
- We propose *Ensembler*, a standalone framework that can not only significantly increase the adversary server's reconstruction difficulty but also be seamlessly integrated with existing complex algorithms to construct practical and private inference architectures.

To verify the effectiveness of *Ensembler*, we conduct experiments on multiple datasets. Compared to models without using model ensemble, when defending against MIA, *Ensembler* achieves up to 43.5% decrease in structural similarity and 40.5% decrease in peak signal noise ratio. In addition, compared to the previous popular approach, Shredder [6], *Ensembler* better protects the client's sensitive information with a 10.7% decrease in peak signal noise ratio, highlighting its effectiveness even as a standalone framework.

II. Background

A. Collaborative Machine Learning

The development of mobile graphic processing units (GPUs) has ushered in a new era where machine learning tasks are increasingly deployed with a portion of the computation being handled by edge devices. Related areas include federated learning, where multiple edge devices jointly train a DL model [7, 8]; split learning, where a DL model is split into two or more parts, and the client and server jointly train it [9]; and collaborative inference, where a DL model is split, with only a portion deployed on the server to provide services [4, 10]. In this paper, we will focus on the inference part and assume that the training phase of DL models is secure. Though the training phase is sometimes also susceptible to adversarial attacks aimed at stealing sensitive information [11, 12], private inference is still more prevalent in most practical scenarios.

There have been multiple works addressing this formidable challenge of safeguarding the client's sensitive information in collaborative inference scenarios. [13, 14] provides an extensive discussion on different algorithmic and architectural choices and their impacts on privacy protection. For simplicity and without loss of generalization, we will group existing approaches into two categories in this paper: encryption-based algorithms that guarantee privacy at the cost of thousands of times of time efficiency [15, 16, 17, 18], and perturbation-based algorithms that operate on the intermediate layers of a DL architecture, introducing noise to thwart the adversary's ability to recover client input [6, 10, 5, 19]. Since perturbation-based algorithms directly operate on the intermediate outputs from the client, they incur minimal additional complexity during the inference process. As opposed to guaranteed privacy provided by encryption-based algorithms, perturbation-based algorithms suffer from the possibility of privacy leakage, meaning sensitive private information may still be recoverable by the adversarial server despite the introduced perturbations, but they are nonetheless more practical to use due to the less additional costs associated with the methods.

B. Threat model

In this paper, we consider the collaborative inference task between the client and the server, which acts as a semi-honest adversarial attacker that aims to steal the raw input from the client. Formally, we define the system as a collaborative inference on a pre-trained DNN model, $\mathbf{M}(x, \theta)$, where the client holds the first and the last few layers (i.e. the "head" and "tail" of a neural network), denoted as $\mathbf{M}_{c,h}(x, \theta_{c,h})$ and $\mathbf{M}_{c,t}(x, \theta_{c,t})$. The rest of the layers of DNN are deployed on the server, denoted as $\mathbf{M}_s(x, \theta_s)$. θ is the trained weights of M, where $\theta = \{\theta_{c,h}, \theta_s, \theta_{c,t}\}$. The complete collaborative pipeline is thus to make a prediction of incoming image x with $\mathbf{M}_{c,t}[\mathbf{M}_s[\mathbf{M}_{c,h}(x)]]$.

During the process, the server has access to θ_s and the intermediate output $\mathbf{M}_{c,h}(x)$. In addition, we assume that it has a good estimate of the DNN used for inference. That is, it has auxiliary information on the architecture of the entire DNN, as well as a dataset in the same distribution as the private training dataset used to train the DNN. However, it does not necessarily know the hyper-parameters, as well as the engineering tricks used to train the model. Since the server is a computation-as-a-service (CaaS) provider, it is assumed to have reasonably large computation resources. While it is powerful in computing, the server is restricted from querying the client to receive a direct relationship between raw input x and intermediate output $\mathbf{M}_{c,h}(x)$.

To reconstruct raw input x from the intermediate output $\mathbf{M}_{c,h}(x)$, the server adopts a common model inversion attack [4, 5, 20]. To obtain x's reconstruction, MIA aims to obtain the inverse of $\mathbf{M}_{c,h}$, which will be denoted as $\mathbf{M}_{c,h}^{-1}$. The server constructs a shadow network $\tilde{\mathbf{M}}(x, \tilde{\theta_{c,h}}, \theta_s, \tilde{\theta_{c,t}})$: $\{\tilde{\mathbf{M}_{\mathbf{c,h}}}, \mathbf{M}_s, \tilde{\mathbf{M}_{\mathbf{c,t}}}\}$ such that $\tilde{\mathbf{M}}$ simulates the behavior of $\mathbf{M}$. After training $\tilde{\mathbf{M}}$, the adversarial server is able to obtain a representation $\tilde{\mathbf{M}_{\mathbf{c,h}}}$ such that $\tilde{\mathbf{M}_{\mathbf{c,h}}}(x) \sim \mathbf{M}_{c,h}(x)$. As the

next step, with the help of a decoder, $\tilde{\mathbf{M}}_{\mathbf{c,h}}^{-\mathbf{1}} \sim \mathbf{M}_{c,h}^{-1}$, to reconstruct the raw image from intermediate representation, it is able to reconstruct the raw input from $\mathbf{M}_{c,h}(x)$.

C. Assumptions of other related works

In this section, we provide an overview of various attack models and the assumptions adopted in other works related to collaborative inference (CI) under privacy-preserving machine learning (PPML). Since different works potentially use different collaboration strategies between the client and the server, we will use the generic notation, where $\mathbf{M}_c$ is held by the client, and $\mathbf{M}_s$ is held by the server. Generally, the attacks from the server will fall into three categories:

Membership Inference Attacks that try to predict if certain attributes, including but not limited to individual samples, distributions, or certain properties, are a member of the private training set used to train $\mathbf{M}(x, \theta)$. If successful, the privacy of the training dataset will be compromised. We refer readers to the survey by [21] and [22] for more details.

Model Inversion Attacks that try to recover a particular input during inference when its raw form is not shared by the client. For example, in an image classification task, the client may want to split $\mathbf{M}$ such that it only shares latent features computed locally to the server. However, upon successful model inversion attacks, the server will be able to generate the raw image for classification tasks based on the latent features. It is important to note that, in this paper, we adopt the same definition of model inversion attacks as of [4]. This term also refers to attacks that reconstruct the private training dataset in other works. We will focus on reconstructing private raw input for the rest of this paper.

Model Extraction Attacks that try to steal the parameters and even hyper-parameters of $\mathbf{M}$. This type of attack compromises the intellectual property of the private model and is often employed as sub-routines for model inversion attacks when the server lacks direct access to the private model's parameters.

Different works also make different assumptions about the capability of the server. First, it is widely accepted that the server has sufficiently yet reasonably large computing power and resources, as its role is often providing ML service. Regarding the auxiliary information on $\mathbf{M}$, they generally fall into three levels:

White Box assumes that the server has full access to architecture details of $\mathbf{M}$ such as the structure and parameters [23]. Different definitions also add different auxiliary available information such as training dataset [23], corrupted raw input [24], or a different dataset [25]. This setting is often associated with attacks that try to reconstruct private training datasets [25, 24, 26].

Black Box assumes that server does not have any information on both $\mathbf{M}$ and the training dataset. However, it is allowed to send unlimited queries to the client to get $\mathbf{M}_c(x)$ [27, 28].

Query-Free restricts the server from querying $\mathbf{M}_c$. While such an assumption greatly limits the reconstruction ability of the adversarial party, there are no limitations on auxiliary information available to the server besides the actual weights of $\mathbf{M}_c$. [4, 29] have both shown that $\mathbf{M}_c$ is still vulnerable to leaking private information of its input when the server has information on the model architecture and training dataset. Our work uses this setting.

III. *Ensembler* ARCHITECTURE

While it is possible to protect sensitive data by increasing the depth of the client network, such depth is often impractical for edge devices due to the computational demands involved. In this section, we present *Ensembler*, a framework that augments the privacy of intermediate information sent by the client without requiring extra computation efforts of the client during inference. *Ensembler* is highly extensible, and it is compatible with existing works that apply noises and perturbation during both DNN training and inference. We will go over the inference pipeline of *Ensembler* in Section III-A, the training stage of this new framework in Section III-C, an intuitive explanation of why *Ensembler* works in Section III-B, and finally the time complexity analysis in Section III-D.

A. Inference Pipeline

As illustrated in Figure 2, *Ensembler* leverages model ensemble on the server to generate a regularized secret $\mathbf{M}_{c,h}$ that is hard to be reconstructed by the adversarial server. It comprises three parts: standard client layers, N different server nets, and a Selector. During the CI pipeline, the client computes the addition of $\mathbf{M}_{c,h}(x)$ and a predefined noise, and transmits the intermediate output to the server. The server then feeds the intermediate output through each of the $\mathbf{M}_s^i$ and reports the output of each $\mathbf{M}_s^i$ to the client. The client then employs a user-defined private selector to perform a selection of the feedback from the server, which activates the results of P out of N nets and combines them. As a final step, it computes the last few layers ($\mathbf{M}_{c,t}(x)$) to classify the input image. We will introduce these separately in this section.

1) Client Layers: During collaborative inference, the client runs a part of the DNN. Under the proposed framework, the client is responsible for running the first h layers $\mathbf{M}_{c,h}$ and the last t layers $\mathbf{M}_{c,t}$. These layers are the same as the client part of a typical collaborative inference framework. $\mathbf{M}_{c,h}$ takes the raw input (often an image) and outputs the intermediate result, whereas $\mathbf{M}_{c,t}$ takes the output from the server as input and outputs the likelihood of each class.

2) Server Nets: On the server side, the network consists of N copies of DNN, with each $M_s^i \in M_s$ corresponding to what the server would normally process in a typical CI pipeline. That is, each $M^i : \{M_{c,h}, M_s^i, M_{c,t}\}$ is a standard pipeline for the inference task. Upon receiving $\mathbf{M}_{c,h}(x) + N(0, \sigma)$, which is the intermediate features generated by the client, the server shall feed this input into each of M_s^i. It outputs N representations of hidden features used for classification and sends all of them back to the client. We denote those outputted feature maps as $M_s(x') = \{M_s^i(x')\}$.

3) Selector and $\mathbf{M}_{c,t}$: To increase the difficulty of the server reconstructing the model and recovering the raw input, a user-defined private selector is applied to the outputs returned

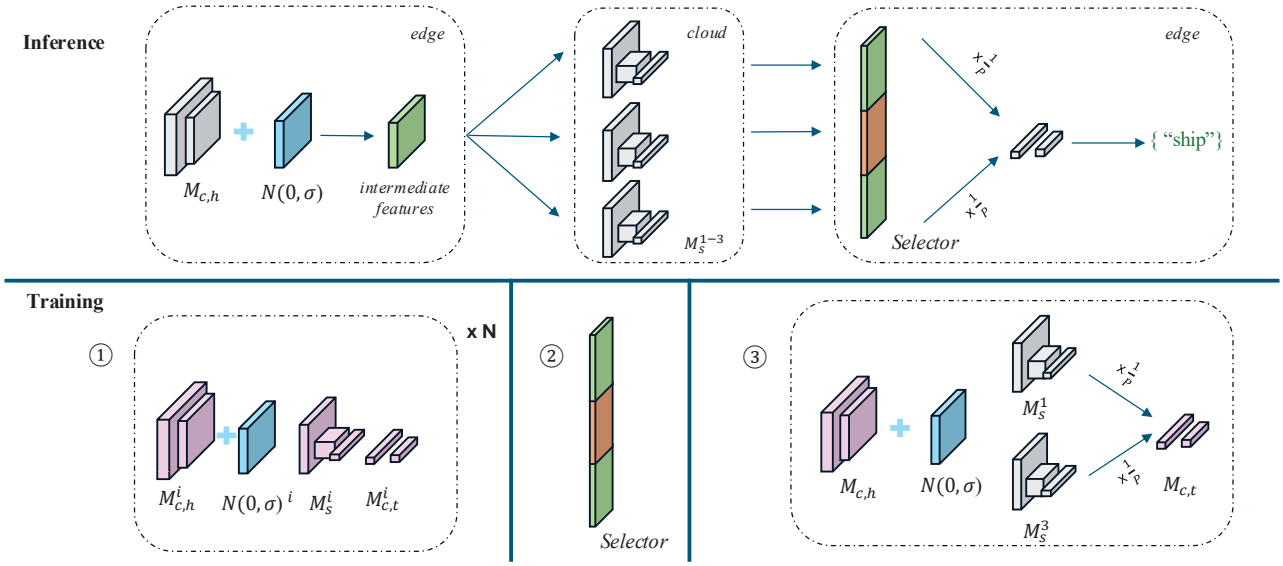

Fig. 2. Illustration of the proposed architecture, *Ensembler*, during inference and training. Unlike traditional CI pipelines, during inference, *Ensembler* deploys N neural networks on the server and uses a private selector to activate P of the N nets, making the reconstruction of the client network infeasible. During training, *Ensembler* follows a three-stage training procedure, and the purple elements are trainable parameters of each stage.

by the server before the client runs $\mathbf{M}_{c,t}$. The selector is a secret activation function, activating a subset of $M_s(x')$. We denote this subset of activated feature maps as $M_s(x')_p$, and there are in total P activated feature maps. Then, the Selector is defined by Eq. 1, where S_i is the activation from the Selector, and $\odot$ is the element-wise multiplication. For simplicity, we consider $S_i = 1/P$. In other words, the client will normalize P of the N feature maps returned by the adversarial server and concatenate them as the input features to $\mathbf{M}_{c,t}$ while keeping those selections private to the server.

$$Sel[M_s(x)] = Concat[S_i \odot f \quad \forall f \in M_s(x')_p] \tag{1}$$

B. Intuition behind Ensembler

In this section, we provide an intuitive explanation of *why* the proposed architecture can defend the client's private information against MIA through a simulated MIA performed by the adversarial server. As defined by the threat model in Section II-B, the server has access to the training dataset, model architecture, and M_s. To perform a MIA, it will construct $\tilde{\mathbf{M}}_{\mathbf{c,h}}$ and $\tilde{\mathbf{M}}_{\mathbf{c,t}}$. Now, let's further assume that each of $M_s \in \{M_s^i\}$ has different weights (how to achieve this will be shown in the next subsection). With brute-forcing all combinations being exponential and unpractical, and since the adversarial server does not know the user-defined selector, there remain two possible MIA constructions. The server could either construct the shadow network with a random subset of $\{M_s^i\}$, or it could use the entire $\{M_s^i\}$. We will show that both methods result in $\tilde{\mathbf{M}}_{\mathbf{c,h}}(x) \not\sim \mathbf{M}_{c,h}(x)$. Without loss of generality, for the first approach, the server is assumed to construct $\tilde{\mathbf{M}}_{\mathbf{c,h}}$ from a single M_s^i that is a subset of the networks selected by the Selector.

Proposition 1: Reconstructing input from single neural network $\mathbf{M}_s^i$ results in $\tilde{\mathbf{M}}_{c,h}(x) \not\sim \mathbf{M}_{c,h}(x)$.

Let's consider the most extreme case, where the Selector selects $\mathbf{M}_s^1$ and $\mathbf{M}_s^2$, and the adversarial server is constructing its shadow network with $\mathbf{M}_s^1$. Since $\mathbf{M}_{c,h}$ is trained with both networks, the gradient of weights of $\mathbf{M}_{c,h}$ is calculated as (roughly) $\eta(\nabla_x \mathbf{M}_s^1 + \nabla_x \mathbf{M}_s^2)$ during backpropogation. After minimization, as long as $\nabla_x \mathbf{M}_s^2$ is not zero, the weights of $\mathbf{M}_{c,h}$ will be affected by both $\mathbf{M}_s^1$ and $\mathbf{M}_s^2$ (we will show how to let the gradient not be zero through loss regularization in the next section). Since $\mathbf{M}_s^1$ and $\mathbf{M}_s^2$ have different weights, their gradient will point to different directions. A shadow network $\tilde{\mathbf{M}}_{c,h}$ trained on only $\mathbf{M}_s^1$ will represent different weights compared to $\mathbf{M}_{c,h}$, and thus the decoder based on $\tilde{\mathbf{M}}_{c,h}$ will also reconstruct incorrect client's secret input.

Proposition 2: Reconstructing input from the entire set $\{\mathbf{M}_s\}$ results in $\tilde{\mathbf{M}}_{c,h}(x) \not\sim \mathbf{M}_{c,h}(x)$.

A similar conclusion from the analysis in the first case may be derived. Let's still use the simple example of $\mathbf{M}_s^1$ and $\mathbf{M}_s^2$. This time, the Selector selects only $\mathbf{M}_s^1$, but the server decides to train on both $\mathbf{M}_s^1$ and $\mathbf{M}_s^2$. It is not hard to see that the weights of $\mathbf{M}_{c,h}$ and $\tilde{\mathbf{M}}_{c,h}$ are just swapped with each other, and now, the decoder is still based on incorrect weights and still leads to an incorrect reconstruction of $\mathbf{M}_{c,h}(x)$.

C. Training Stages

As mentioned above, the key idea behind *Ensembler* is to use N **different** networks with a private Selector to obfuscate MIA. To achieve the N different networks and make sure $M_{c,h}$ is properly trained with all of the selected subsets, the proposed architecture uses a three-staged training pipeline, as shown in the bottom half of Fig. III.

Stage 1: First, *Ensembler* obtains N different networks by injecting N different noises after each of the network's $M_{c,h}^i$ and training each of the networks. Since randomly initialized noises are quasi-orthogonal to each other and each network

needs to adjust its weights to reverse the effects of the added noise on the intermediate feature map, the resulting weights of $M^i_{c,h}$ will be different from each other. Formally, the first stage optimizes Eq. 2, where $N(0,\sigma)^i$ is a fixed Gaussian noise added to the intermediate output. We choose Gaussian noise because of simplicity in implementation, and we argue that any method leading to distinctive $M_{c,h}$ will be sufficient.

$$L^i_\theta = -\sum_j y_j * log\ M^i_{c,t}(M^i_s[M^i_{c,h}(x) + N(0,\sigma)^i])_j \quad (2)$$

Stage 2: After the first training stage, N different DNNs are obtained. The client secretly selects P out of the N networks as the activation of the Selector.

Stage 3: With the Selector defined, the client is now able to aggregate P networks together to form the "ensembled" inference pipeline. At the last stage of the training process, P server networks together form the body of the final network, and their weights are frozen. The client re-trains its private network $M_{c,h}$ and $M_{c,t}$, with a newly defined Gaussian noise added to the output features of $M_{c,h}$. This Gaussian noise follows the same definition as the Gaussian noise in Stage 1's training. Formally, this stage's training loss follows Eq. 3 by adding a high penalty to the model when the gradient descends only to the direction of some single server net M^i_s. It is worth noting that this loss has two terms. The first part is a standard cross-entropy loss used to train a classification network, and the second part is a regularization term to enforce M to learn a joint $M_{c,h}$ and $M_{c,t}$ representation from all of the P server networks. In the equation, CS is the cosine similarity, and λ is a hyperparameter to control the regularization strength. The idea behind such a regularization is that if $M_{c,h}$ only learns from one single network, then its weights will be very similar to one of the previous $M^i_{c,h}$. Thus, we regularize it to be as quasi-orthogonal to all of the previous $M^i_{c,h}$.

$$\begin{aligned} L_\theta &= \sum_i^{i\in P} CE + Regularization, \quad where \\ CE &= -\sum_j [y_j * log M_{c,t}(Sel[M^i_s[M_{c,h}(x) + N(0,\sigma)]])_j] \\ Regularization &= \lambda \max_i [CS(M_{c,h}(x), M^i_{c,h}(x))] \end{aligned} \quad (3)$$

D. Time Complexity of Ensembler

From the previous subsections, it is clear that the inference time complexity of the proposed framework on the client is the same as the standard non-private inference pipeline. On the server, it is N times the individual network on a single-core GPU, and there is negligible extra communication cost between the client and the server. However, it is noteworthy to emphasize that since each M^i_s is independent of each other, the proposed framework is friendly to parallel execution and even multiparty (multi-server) inference. Under those settings, the theoretical time complexity of $O(N)$ would be replaced with lower practical time costs.

Regarding the MIA's time complexity, following the analysis in Section III-B, it is not hard to see that the expected MIA time of a single server is $O(2^N)$. Since an arbitrary reconstruction on some subset of the network will lead to a reasonable shadow network $\tilde{\mathbf{M}}_{\mathbf{c,h}}$, the server has no way of telling whether its reconstruction is an actual representation of the client's network. Thus, to ensure optimal reconstruction, it must use brute force and try all possibilities. In addition, under multiparty inference scenarios, without access to a subset of the activated networks, the adversarial server will not be able to perform the desired reconstruction.

IV. Experiments and Evaluations

A. Implementation details

During the experiment, we consider the most strict setting, where h=1 and t=1 on a ResNet-18 [31] architecture for three image classification tasks, CIFAR-10 [32], CIFAR-100 [32], and a subset of CelebA-HQ [33]. That is, the client only holds the first convolutional layer as well as the last fully connected layer, which is also the minimum requirement for our framework. For CIFAR-10, the intermediate output's feature size is [64x16x16], for CIFAR-100, we remove the MaxPooling layer and the intermediate output's feature size is [64x32x32], and for CelebA, the intermediate output's feature size is [64x64x64]. We consider the ensembled network to contain 10 neural networks (N=10), each being a ResNet-18. The selector secretly selects $\{4,3,5\}$ out of the 10 nets (P=$\{4,3,5\}$), respectively. The adversarial server is aware of the architecture and the training dataset. It constructs a shadow network $\tilde{\mathbf{M}}_{c,h}$ consisting of three convolutional layers with 64 channels each, with the first one simulating the unknown $\mathbf{M}_{c,h}$, and the other two simulating the Gaussian noise added to the intermediate output. It also has $\tilde{\mathbf{M}}_{c,t}$ with the same shape as $\mathbf{M}_{c,t}$. An adaptive shadow network learns from all 10 server nets with an additional activation layer that is identical to the selector. For any noises added to the intermediate outputs during the training and inference stage, we consider a fixed Gaussian noise $\mathbf{g} \sim N(0, 0.1)$.

B. Experiment Setup

We employ two key metrics: Structural Similarity (SSIM) and Peak Signal Noise Ratio (PSNR). Higher SSIM and PSNR values indicate better reconstruction quality and thus worse defense. In addition, we report the changes in classification accuracy (ΔAcc) after adding the defense mechanism. As our proposed architecture operates in parallel with existing perturbation methods, we mainly compare our method with its single network counterpart (Single) [30], where only one $M^i : \{M_{c,h}, M^i_s, M_{c,t}\}$ is used. In the ablation study, we provide a deeper analysis using CIFAR-10, and we compare the following methods against *Ensembler*: no protection (None), training the noise injected to Single (Shredder [6]), adding dropout layer in the single network or ensembled network, but without the first stage training (DR-single and DR-10) [34]. For the proposed architecture, we evaluate the performance of both reconstruction attacks discussed in Section III-B. For reconstruction with a single server net, we report the best reconstruction, or worst defense, in terms of SSIM (Ours -

TABLE I

DEFENSE QUALITY OF *Ensembler* AND SINGLE [30] ACROSS DATASETS. FOR SSIM AND PSNR, LOWER VALUES INDICATE BETTER DEFENSE QUALITY. WE REPORT ON THE TWO RECONSTRUCTION ATTACKS DISCUSSED IN SECTION III-B. FOR RECONSTRUCTING WITH A SINGLE NETWORK, WE REPORT THE STRONGEST RECONSTRUCTION ATTACK (LEAST DEFENSE QUALITY) OUT OF N NETWORKS.

	CIFAR-10			CIFAR-100			CelebA-HQ		
Name	ΔAcc	SSIM ↓	PSNR ↓	ΔAcc	SSIM ↓	PSNR ↓	ΔAcc	SSIM ↓	PSNR ↓
Single	2.15%	0.39	7.53	-0.97%	0.46	8.52	-1.24%	0.27	14.31
Ours - Adaptive	-2.13%	0.06	5.98	0.31%	0.09	4.77	2.39%	0.09	13.37
Ours - SSIM	-2.13%	0.29	4.87	0.31%	0.26	5.07	2.39%	0.18	12.06
Ours - PSNR	-2.13%	0.22	5.53	0.31%	0.26	5.07	2.39%	0.18	12.06

TABLE II

DIFFERENT DEFENSE MECHANISMS WITH CIFAR-10. THE LAST THREE ARE THE PROPOSED FRAMEWORK. THE UNDERSCORED NUMBER REPRESENTS THE BEST DEFENSE FROM OTHER EXISTING METHODS.

Name	Δ Acc	SSIM ↓	PSNR ↓
None	0.00%	0.49	9.86
Shredder	-2.92%	<u>0.29</u>	6.70
Single	2.15%	0.39	7.53
DR-single	2.70%	0.35	<u>6.67</u>
DR-10 - SSIM	1.42%	0.37	7.35
DR-10 - PSNR	1.42%	0.32	7.96
Ours - Adaptive	-2.13%	0.06	5.98
Ours - SSIM	-2.13%	0.29	4.87
Ours - PSNR	-2.13%	0.22	5.53

SSIM) and PSNR (Ours - PSNR) among the N networks. For the reconstruction using all networks, we denote it as (Ours - Adaptive). We run the experiments on an A6000 GPU server using Python and PyTorch. For Section 4, we used a mixture of A6000 and T4 GPU. In addition, we report the real-world time delay of the proposed method compared with its single counterpart and a recent encryption-based method [35]. We evaluate the inference time on a Raspberry Pi communicating with the A6000 server over a wired network.

C. Comparison of Results

We provide the quantitative evaluations of *Ensembler* compared to its non-ensembled counterpart (Single [30]) in Table I. It could be seen that the proposed framework significantly decreases the reconstruction quality of the adversarial party. *Ensembler* incurs a 2.13% drop in classification accuracy compared to the model without any protection, which is acceptable compared to its advantage in protecting the privacy of the client's raw input. It should be noted that the adaptive MIA strategy performs worse than the best reconstruction with a single network, which is expected. While Equation 3 constraints $M_{c,h}$ to learn from all server networks, it might still have one that is more "favored". Thus, a reconstruction based on that favored network yields the best results. On the other hand, a reconstruction based on all networks might not select the same one as its "favored" network, which causes the shadow network's weights to significantly deviate from $M_{c,h}$.

Moreover, we delve into a more thorough analysis of *Ensembler*'s performance on the CIFAR-10 dataset compared to other existing methods. The results are summarized in Table II. It could be observed that *Ensembler* defends the client's input on par with Shredder [6] on structural similarity, and exceeds it on peak signal-noise ratio. In addition, it should be noted that Shredder [6] and dropout defense [34] can be combined with *Ensembler* together. The additive noise $N(0, \sigma)$ in the third stage could be replaced by Shredder's trained noise, and dropout can also be added to the network's FC layer to perform further protection of the client's sensitive data.

TABLE III

TIME TAKEN (SECONDS) TO RUN A BATCH OF 128 IMAGES THROUGH DIFFERENT DEFENSE STRATEGIES.

Name	Client	Server	Communication	Total
Standard CI	0.66	0.98	2.30	3.94
Ensembler	0.66	1.02	2.45	4.13
STAMP [35]	–	–	–	309.7

D. Latency

Time required by the standard CI setting and *Ensembler* is provided in Table III. In addition, STAMP [35] is a hardware-optimized version of encryption-based private inference, and we show their reported results (LAN-GPU). For all experiments, we use the setting in STAMP to run ResNet-18 on a batch size of 128 images. *Ensembler* incurs only **0.19 seconds (4.8%)** overhead compared with running the standard CI pipeline, but with much stronger protection on the client's sensitive data. It can also be observed that the increment of time comes from two parts, with more server computing taking the minor role and more communication between the client and the server taking the major role. In the future, more attention on improving client-server communication is pivotal for a more efficient and practical collaborative inference.

V. CONCLUSION

During collaborative inference, the client's sensitive information is prone to model inversion attacks from the adversarial server, especially when the client only holds a very small portion of the network. In this paper, we present a novel collaborative inference framework, *Ensembler*, designed to significantly increase the complexity of reconstruction for adversarial parties. *Ensembler* leverages a selective model ensemble on the adversarial server and a secret Selector to defend against the server's model inversion attacks. In addition, it seamlessly aligns with existing methods that introduce diverse forms of noise to intermediate outputs, potentially yielding robust and adaptable architectures if combined with them. Lastly, *Ensembler* is a latency-friendly framework that incurs only marginal overhead during inference. Our experiments highlight the substantial deterioration in reconstruction quality for images safeguarded by *Ensembler* when compared to those without its protection.

***Abstract*—Portability poses a significant challenge for Deep Learning (DL)-based profiling Side-Channel Analysis (SCA) on AES encryption, as attackers cannot always ensure that training and target samples use the same encryption mode. To address this, we propose an Unsupervised Domain Adaptation (UDA) DL-SCA framework for achieving effective and robust cross-encryption-mode attacks. By incorporating cross-attention and UDA techniques, our framework aligns high-dimensional input samples, reducing interference from encryption mode mismatches. Evaluation across five distinct AES modes demonstrates that our method achieves robust SCA performance without requiring prior knowledge or multiple labeled datasets for analysis.**

***Index Terms*—side channel analysis, cross-attention mechanisms, unsupervised domain adaptation, deep learning.**

I. Introduction

Since Kocher's pioneering 1996 study on timing attacks [1], Side-Channel Analysis (SCA) has emerged as a critical technique for extracting sensitive information through the analysis of physical leakages [2]–[4]. One of the most powerful type of SCA, namely Profiling SCA, works by modeling leakages from similar devices to extract data from target devices [5], [6]. This approach was pioneered by Template Attacks (TA) [5], [7] and later enhanced by machine learning methods, such as Support Vector Machines (SVM) [8] and Random Forests (RF) [9]. The introduction of Deep Learning (DL) has further advanced profiling SCA. Specifically, deeper models such as Convolutional Neural Networks (CNN) and Multi-Layer Perceptrons (MLP) are capable of handling complex inputs more efficiently, allowing SCAs powered by such techniques to provide better results with regard to both the overall generalization capability and the performance in managing masked data [10]–[12].

In a DL-based SCA (henceforth DLSCA) against the AES encryption algorithm, the attacker's goal is to infer the secret key by correlating side-channel measurements from the encryption process with a leakage model (trained in the off-line reconnaissance phase with data collected from attacker-controlled devices) [4], [13]. Intuitively, this attack strategy is more likely to succeed if training samples of the leakage model is collected from the exact same hardware/software configure with the targeted devices, and we have indeed witnessed extensive DLSCA studies which only considered the scenario where both the reconnoitered devices and the targeted ones run AES in the same encryption mode [14]–[16]. Unfortunately, practical attack scenarios could be more generalized, involving target devices that are different from the reconnoitered one at hardware-level, or alternatively, operate with AES modes different from the one observed during the off-line reconnaissance.

Related Work. Attentions on the portability of DLSCA, as well as the mode-specific AES vulnerabilities, has emerged only recently. While Wang *et al.* [17] analyzed the impact of mode diversity on DLSCA, Perusheska *et al.* [18] further highlighted the effectiveness of DLSCA using plaintext-ciphertext analysis across multiple AES modes. Other recent advancements focused on the scenario of across-device DLSCAs. Das *et al.* [19] demonstrated that training on diverse hardware in X-DeepSCA analysis enhances cross-device performance. Golde *et al.* [20] applied preprocessing methods, including dynamic time warping and Principal Component Analysis (PCA), with a MLP to mitigate cross-device discrepancies. Bhasin *et al.* [21] addressed portability challenges with a Multi-Device Model (MDM) that leverages three devices for training, validation, and attack. Cao *et al.* employed adversarial learning [22] and domain adaptation [23] to counteract device-based performance degradation, while Yu *et al.* [24] introduced meta-transfer techniques to address leakage inconsistencies in DLSCA across different device types. Nevertheless, researches on DLSCA that generalizes across multiple AES encryption modes remain limited. This gap underscores the need to study the possibility of building robust leakage models adaptable to diverse AES configurations, which could be the last piece of the puzzle on the completeness of DLSCA.

Contributions. Motivated by the current state-of-the-arts, we propose CA-SCA (Cross-Attention Side-Channel Analysis), a novel approach aiming to address the challenges in launching DLSCA against AES algorithms with the presence of mode variations. At the model design level, CA-SCA integrates cross-attention mechanisms with unsupervised domain adaptation (UDA) in order to have different sets of side-channel samples (which are potentially of different distributions) aligned at high-dimensional space to subsequently enable interactive training. To the best of our knowledge, while cross-attention has been widely used in multimodal [25] and

reinforcement learning [26] tasks [27], its application for AES mode adaptation in the SCA community remains unexplored. Thus our effort could be the first to make such an attempt.

In summary, the main contributions of this work are:

- We propose CA-SCA (Cross-Attention Side-Channel Analysis), a novel SCA approach that leverages cross-attention mechanisms and unsupervised domain adaptation to mitigate interference from mismatching of encryption modes, while requiring no specific preprocessing, fine-tuning, labeled attack traces or multiple analysis datasets.
- We evaluated CA-SCA on a software implementation of AES-128 across five encryption modes (ECB, CBC, CTR, CFB, and OFB) using the STM32F3 chip. The results demonstrate that CA-SCA reliably recovers keys across different encryption modes within 500 attack traces, outperforming current state-of-the-art methods[1].
- We present a comprehensive comparison of existing theoretical and experimental results on portable attacks using CA-SCA. Experimental results indicate that X-Deep and MDM may fail when encryption mode differences are substantial. In contrast, CA-SCA, using only a single mode as the analysis dataset, enables previously infeasible attacks.

The paper is organized as follows: Section II provides background knowledge and introduces the evaluation metrics. Section III outlines the proposed methodology. Section IV describes the experimental setup and presents the attack results, while Section V analyzes the impact of two key parameters on CA-SCA. Finally, Section VI concludes the paper and suggests future research directions.

II. Background

A. DLSCA

DLSCA differs from TA [5] for not requiring extensive prior knowledge. Instead, deep learning models automatically learn the relationship between physical leakages (traces) and labels, classifying traces through a neural network that maps them to labels based on the leakage patterns of sensitive operations.

During training, the neural network learns a classification function $\mathcal{F}_\theta$ that maps input traces $\mathbf{T}_i$ to score vectors $\vec{p} = \mathcal{F}_\theta(\mathbf{T}_i)$, where S is the number of possible classes. The network parameters θ are updated via backpropagation and an optimizer to minimize the batch loss:

$$\theta_{\text{epoch}} = \theta_{\text{epoch-1}} - \alpha \nabla_\theta L_{\text{batch}}, \tag{1}$$

where α is the learning rate. In the attack phase, the trained model classifies each attack trace and generates score vectors for key guessing. For AES in specific, in the first and last rounds of the en-/decryption, inference of the the neural network can be performed byte-by-byte (8 bits, yielding 256 possible values). This makes DLSCA particularly effective in attacks this cryptographic primitive.

[1]https://github.com/hfl110529/CA-SCA

B. Unsupervised Domain Adaptation

Unsupervised Domain Adaptation (UDA) [28] is a key technique in deep learning for improving model performance in unfamiliar domains, particularly when labeled data is scarce. The core idea is to leverage unlabeled data, enabling the model to learn general features across domains or modes, thereby enhancing robustness and adaptability to unseen data.

A common UDA method is Maximum Mean Discrepancy (MMD) [23], [29], which measures feature distribution differences between the source (X_s) and target (X_t) domains as:

$$\text{MMD}(X_s, X_t) = \left\| \mathbb{E}_{X_s}[\phi(X_s)] - \mathbb{E}_{X_t}[\phi(X_t)] \right\|^2, \tag{2}$$

where $\phi(\cdot)$ maps inputs to a high-dimensional space. By minimizing the combined loss function:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{classification}} + \lambda \cdot \mathcal{L}_{\text{MMD}}(X_s, X_t), \tag{3}$$

we jointly optimize the classification loss ($\mathcal{L}_{\text{classification}}$) and domain alignment loss, enhancing the model's generalization in the target domain. Here, λ is a weighting parameter that balances the MMD loss and classification loss.

C. Evaluation metric

Guessing Entropy (GE) [30] is a common security metric in SCA. Given N_{attack} traces in the attack phase, the attacker estimates a key guessing vector $\mathbf{k}_{\text{guess}} = [k_1, k_2, \ldots, k_{|\mathcal{K}|}]$, where $|\mathcal{K}|$ denotes the size of the keyspace, arranged in decreasing order of likelihood. When the rank of the true key k^* reaches zero in $\mathbf{k}_{\text{guess}}$, the number of traces used is referred to as $\bar{N}_{\text{GE}}$.

III. Methodology

Recall that CA-SCA is designed based on the combination of cross-attention mechanisms and UDA to enhance network portability. The core idea is to enhance the network's generalization across different data domains by leveraging attention mechanisms to emphasize relevant features, while domain adaptation techniques align analysis and target data in a high-dimensional space. In Subsection III-A outlines the threat model for the proposed approach, Subsection III-B discusses the rationale behind the attention mechanism, and Subsection III-C details the implementation of CA-SCA.

A. Threat Model

We consider a standard profiling side-channel setting focused on power and electromagnetic (EM) SCAs to recover secret keys from encryption algorithms. This threat model is widely recognized and realistic, as numerous certification laboratories evaluate security-critical products under similar conditions daily. Power and EM side-channels are commonly exploited to compromise modern communication devices [31] and have also been used for program flow tracking [32].

In the profiling phase, we assume the attacker has access to a cloned device running a cryptographic algorithm, though its encryption mode may differ from that of the target device. Typically deployed on an embedded platform, this cloned device can be queried with known or chosen parameters (e.g.,

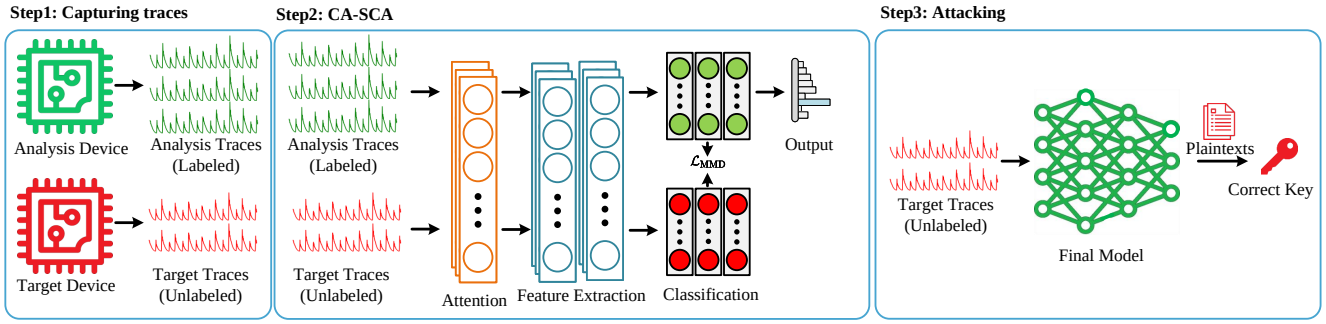

Fig. 1: Overall architecture of CA-SCA.

key, plaintext), allowing the attacker to record the resulting physical leakage (e.g., power or EM). Additionally, the attacker can acquire a limited amount of unlabeled leakage data from the target encryption mode, which is incorporated during model training to facilitate domain adaptation and address distributional differences between encryption modes.

In the attack phase, the attacker applies the trained leakage model and combines it with side-channel leakage traces from the target device to recover the encryption key. The domain adaptation technique allows the model to adapt to different encryption modes, enabling effective SCA even without labeled data from the target mode during training.

B. Attention Layer

Given an input sequence $X = [x_0, \ldots, x_{n-1}] \in \mathbb{R}^{n \times d}$, the attention layer computes an output sequence $\hat{V} = [\hat{v}_0, \ldots, \hat{v}_{n-1}] \in \mathbb{R}^{n \times d_v}$ as follows:

$$\hat{v}_i = \sum_{j=0}^{n-1} \text{softmax}\left(\frac{q_i^T k_j}{\sqrt{d}}\right) v_j = \sum_{j=0}^{n-1} \frac{\exp\left(\frac{q_i^T k_j}{\sqrt{d}}\right)}{\sum_{l=0}^{n-1} \exp\left(\frac{q_i^T k_l}{\sqrt{d}}\right)} v_j, \tag{4}$$

where

$$q_i = W_q x_i, \quad k_i = W_k x_i, \quad v_i = W_v x_i,$$

for $i = 0, \ldots, n-1$, with $W_q, W_k \in \mathbb{R}^{d_k \times d}$ and $W_v \in \mathbb{R}^{d_v \times d}$. The final output of the attention layer is given by:

$$\hat{Y} = \hat{V} W_o^T + X,$$

where $W_o \in \mathbb{R}^{d \times d_v}$ is the projection matrix.

Multi-Head Attention: A single attention operation using parameters W_q, W_k, W_v is referred to as an attention head. In practice, multiple attention heads are employed in parallel, forming an H-head attention layer as follows:

$$\begin{aligned} \hat{V}^{(i)} &= f_A(X; W_q^{(i)}, W_k^{(i)}, W_v^{(i)}), \quad i = 0, \ldots, H-1, \\ \hat{V} &= \text{concat}(\hat{V}^{(0)}, \ldots, \hat{V}^{(H-1)}), \\ \hat{Y} &= \hat{V} W_o^T + X, \end{aligned} \tag{5}$$

where concat denotes row-wise concatenation of the output matrices. This enables multi-head attention to capture information from different subspaces.

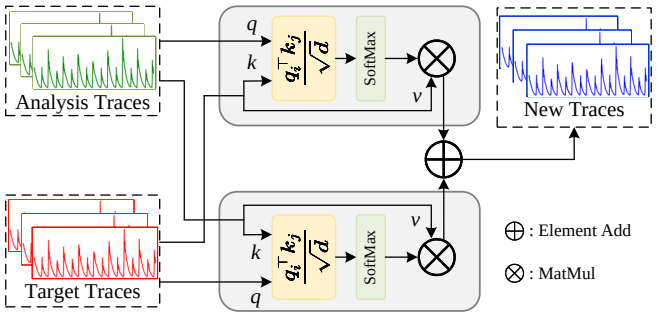

Fig. 2: Flowchart of the cross-attention mechanism.

Algorithm 1 CA-SCA Optimization Procedure

Input: Labeled analysis dataset $X_s = \{(x_i^s, y_i^s)\}_{i=1}^{n_s}$, Unlabeled target dataset $X_t = \{x_i^t\}_{i=1}^{n_t}$
Output: Optimized CNN model M_{best}
Split X_s into training set $X_{s,\text{train}}$ and validation set $X_{s,\text{val}}$
Initialize CNN model M with attention layer, feature extraction layer, and classifier parameters
Set initial best validation loss $val_loss_{\text{best}} \leftarrow \infty$
while not M.convergence **do**
    Forward pass on $X_{s,\text{train}}$ and X_t using M
    Compute total loss: $\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{classification}} + \lambda \cdot \mathcal{L}_{\text{MMD}}$
    Update M parameters via backpropagation to minimize $\mathcal{L}_{\text{total}}$
    Evaluate $val_loss = \text{Evaluate}(M, X_{s,\text{val}}, X_t)$
    if $val_loss < val_loss_{\text{best}}$ **then**
        $val_loss_{\text{best}} \leftarrow val_loss$
        $M_{\text{best}} \leftarrow M$
    end if
end while
return M_{best}

C. Tailoring CA-SCA for SCA

To implement UDA with an attention layer, we modified the model architecture to simultaneously optimize both classification loss and MMD loss (as shown in Fig. 1). This architecture enhances feature representation of both analysis and target data through an interactive attention mechanism, facilitating effective generalized learning.

The training process begins with a classic CNN stage, where

the parameters θ of the classifier f_θ are initialized, and the model parameters are optimized by minimizing the cross-entropy loss $\mathcal{L}_{\text{classification}}$ on the analysis dataset:

$$\mathcal{L}_{\text{classification}}(f_\theta) = \sum_{x_s^i, y_s^i \in X s} l(f_\theta(x), y). \tag{6}$$

Next, the target data undergoes feature extraction and, together with the analysis data, is fed into the attention layer. The attention layer computes a correlation matrix between the data, guiding the network to focus on key features, as shown in Fig. 2.

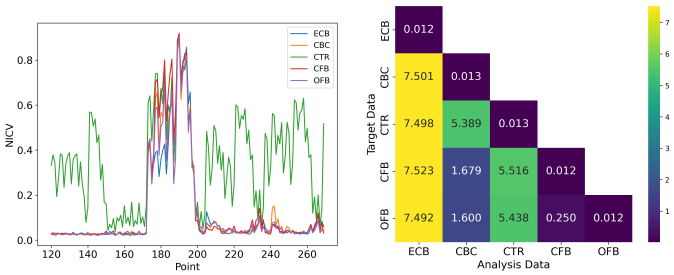
Throughout the training process (Algorithm 1), the total loss function $\mathcal{L}_{\text{total}}$ combines classification and MMD losses: the classification loss is calculated using labeled analysis data, while the MMD loss is based on features from both analysis and target data. Both losses jointly update all trainable model parameters, promoting effective generalization to the target data:

$$\theta' \leftarrow \theta - \alpha \frac{\partial \mathcal{L}_{\text{total}}}{\partial \theta}, \tag{7}$$

where α is the learning rate.

IV. Experiments

A. Dataset



AES supports multiple encryption modes—ECB, CBC, CTR, CFB, and OFB—each influencing data processing and security differently. Although based on the same core algorithm, operational differences result in varying resistance to SCA, highlighting the need for cross-mode evaluation in comprehensive security analysis.

To evaluate generalization across modes, traces were collected from the CW308T-STM32F3 target board for each AES mode. Following the methodology in [33], Points of Interest (POIs) from the final encryption round were selected due to their favorable trace characteristics. Each dataset comprises 25,000 traces with 500 sampling points, and specific leakage models capturing key encryption operations are summarized in Table I.

To further analyze mode differences, we applied Normalized Inter-Class Variance (NICV [34]) to detect physical leakage variations. As shown in Fig. 3(a), leakage quality and timing vary across modes (e.g., CTR mode shows a time shift). Maximum Mean Discrepancy (MMD) was also used to quantify numerical differences, as shown in Fig. 3(b). Diagonal values indicate same-mode comparisons with minimal MMD values, while cross-mode comparisons yield higher values. Notably, CFB and OFB exhibit smaller MMD values due to structural similarities, while larger values highlight greater challenges in achieving generalization across different modes.

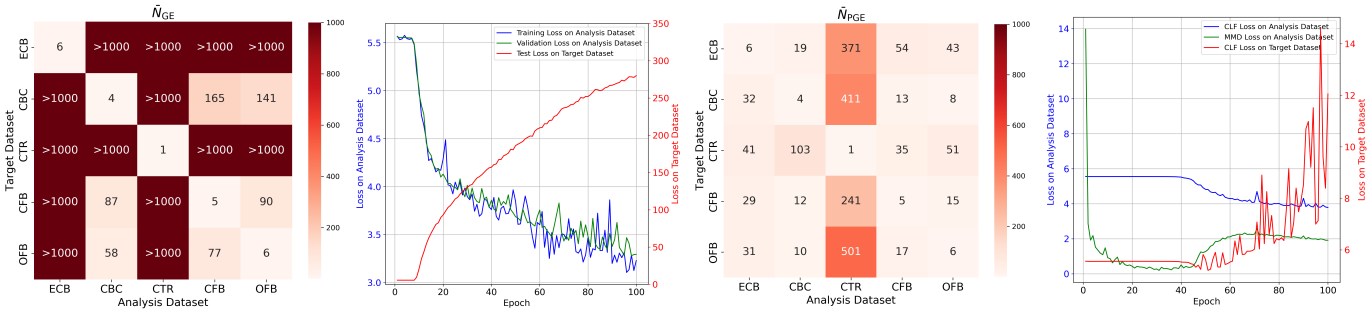
B. Setups

In the profiling phase, 20,000 traces are used, with 80% allocated for training and 20% for validation, while 500 unlabeled attack traces from the target dataset are reserved for model constraints. During the attack phase, 5,000 attack traces are used for evaluation. The metric $\bar{N}_{\text{GE}}$ is defined as the number of attack traces required for GE to reach rank 0. To estimate $\bar{N}_{\text{GE}}$, 1,000 attack traces are randomly selected, tested 200 times, and the average result is reported.

(a) Normalized Inter-Class Variance. (b) Maximum Mean Discrepancy.

Fig. 3: Analysis of AES mode variations using NICV and MMD metrics.

TABLE I: Leakage modeling for various encryption modes, where p_t denotes the plaintext, c_t denotes the ciphertext, SBox^{-1} represents the inverse SBox operation, InvSR denotes the inverse shift rows operation, and $k^*_{R^{10}}$ denotes the expanded key for round 10. All models utilize the ID leakage model.



Leakage model	Encryption mode
$\text{InvSR}(c_t) \oplus (\text{SBox}^{-1}[c_t \oplus k^*_{R^{10}}])$	ECB
$\text{InvSR}(c_t) \oplus (\text{SBox}^{-1}[c_t \oplus k^*_{R^{10}}])$	CBC
$\text{InvSR}(c_t) \oplus ((\text{SBox}^{-1}[(c_t \oplus p_t) \oplus k^*_{R^{10}}]))$	CFB
$\text{InvSR}(c_t \oplus p_t) \oplus ((\text{SBox}^{-1}[(c_t \oplus p_t) \oplus k^*_{R^{10}}]))$	OFB
$\text{InvSR}(c_t \oplus p_t) \oplus ((\text{SBox}^{-1}[(c_t \oplus p_t) \oplus k^*_{R^{10}}]))$	CTR

Our focus is on assessing CA-SCA performance across different AES modes rather than fine-tuning network architecture. Accordingly, we use a simple CNN architecture with three convolutional layers and three fully connected layers. The attention layer has 8 heads with an embedding dimension of 64. The convolutional layers have filter sizes of 16, 32, and 64, and kernel sizes of 1, 50, and 3, respectively. Each fully connected layer consists of 20 neurons. *SELU* is used as the activation function for the input and hidden layers, and *softmax* for the output layer. We set the batch size to 100, epochs to 100, and the hyperparameter λ to 0.02, using the *Adam* optimizer with a learning rate of 0.001.

All experiments are conducted with PyTorch 1.8.0 and Python 3.8.0 on hardware with an Intel® Xeon® Platinum 8358P CPU @ 2.60 GHz and an NVIDIA GeForce GTX 4090 24GB GPU.

C. Results

To facilitate comparative analysis, we first evaluated the performance of DL-PA [10] across different AES modes. The attack results are illustrated in Fig. 4(a), where the x-axis represents the analysis dataset and the y-axis represents the target dataset. The CNN model is trained on the x-axis dataset and attempts to recover the key for the target dataset. As shown, the same mode (along the diagonal) can recover the

Fig. 4: Analysis results across different AES modes.

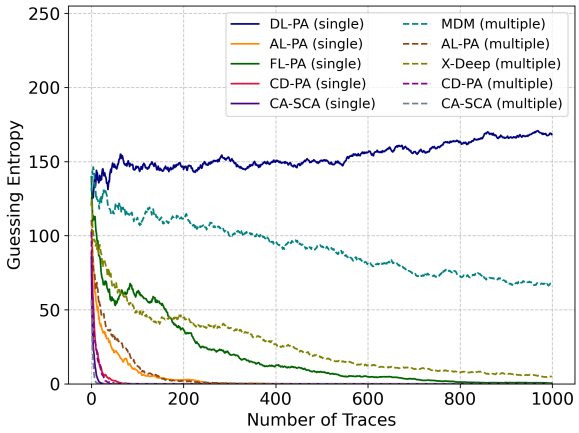

Fig. 5: Comparison with other methods. For the single-analysis dataset, training was performed on the ECB dataset and testing was performed on the OFB dataset. For multi-analysis datasets, training was performed on the ECB and CTR datasets and testing on the OFB dataset.

correct key within 10 attack traces. However, variations in AES modes may lead to reduced DL-PA performance or even failure. For instance, when the model is trained on analysis data in ECB mode, it fails to recover the key for the target mode, even after 1,000 attack traces.

To better characterize DL-PA's performance across AES modes, we present the learning curves for ECB and CBC modes in Fig. 4(b). Both training and validation losses decrease over time and stabilize around 3.2, while the testing loss on the target dataset continues to increase. This suggests that the discrepancy between target and analysis datasets is too large, leading to model failure through misclassification. In DL contexts, this is typically attributed to overfitting. However, in practical SCA, overfitting is difficult to detect without access to labeled attack traces, which prevents calculating test losses.

Fig. 4(c) summarizes CA-SCA's performance across AES modes, showcasing improved results in all cases, with some attacks nearly matching the performance achieved in identical mode scenarios. Notably, when CTR mode is used as the analysis dataset, its data-independent nature results in more pronounced leakage features. While the CNN model effectively learns these features, it struggles to generalize to other AES modes. The learning curve of CA-SCA for the ECB-CBC task, shown in Fig. 4(d), reveals that during the initial 40 epochs, the MMD loss decreases while the classification loss remains stable. Subsequently, the training loss decreases and stabilizes, but the testing loss initially decreases before rising again. This behavior suggests that the model first aligns the analysis and target datasets in high-dimensional space through attention mechanisms and MMD loss before proceeding with classification. Despite substantial differences between the datasets leading to overfitting on the analysis dataset, the intermediate model continues to perform effectively on the target data. Furthermore, as illustrated in Fig. 4(d), the results surpass those in Fig. 4(b), highlighting CA-SCA's exceptional capability to handle data variations and improve generalization across different modes.

We then compare CA-SCA with other state-of-the-art techniques. MDM [21] and X-Deep [19] are widely used for addressing portability issues, with model robustness generally increasing with the number of analytical datasets. However, MDM and X-Deep have limitations when there are substantial differences between target and analysis datasets. For example, as shown in Fig. 3(a) and Fig. 3(b), CBC, CFB, and OFB datasets are relatively similar, but differ more significantly from other datasets. To test this, we trained the model on ECB and CTR datasets and evaluated it on the OFB dataset. In Fig. 5, both MDM and X-Deep fail to recover the correct key for the target dataset. Unlike methods like AP-PA [22], FL-PA [35], and CD-PA [23], CA-SCA requires no fine-tuning or extensive prior knowledge for SCA parameter tuning. Table II provides a detailed performance comparison of the tested methods. In summary, CA-SCA requires no specific tuning knowledge, does not rely on multiple analysis datasets, and outperforms current state-of-the-art methods in certain cases.

V. Discussions

A. Impact of Parameter λ

The parameter λ in Equation 3 is critical in Unsupervised Domain Adaptation (UDA). If λ is set too small, the network focuses primarily on optimizing $\mathcal{L}_{\text{classification}}$, reducing the

influence of $\mathcal{L}_{\text{MMD}}$ on the learning process. Conversely, setting λ too large may excessively impact the learning process, potentially leading to classification failure. To assess the sensitivity of λ, we illustrate its effect on $\bar{N}_{\text{GE}}$ in Fig. 6.

Experimental results indicate that setting λ too small (e.g., $\lambda = 10^{-5}$) or too large (e.g., $\lambda = 10$) fails to enhance attack performance, consistent with our analysis that $\lambda = 10^{-3}$ is an effective choice. While various values of λ improve performance, a practical strategy is to start with smaller values, particularly in scenarios with low signal-to-noise ratios, as this encourages the network to focus on challenging classification tasks. If the reduction in $\mathcal{L}_{\text{MMD}}$ is insufficient or progresses too slowly, λ can be incrementally increased to accelerate the UDA process.

B. Impact of the Number of Attention Heads

In prior experiments, we observed that setting the number of attention heads, denoted by H, to the default value of 8 provided strong performance. To evaluate CA-SCA's sensitivity to different H values, we tested the ECB-CBC task with varying H while keeping other hyperparameters constant. For each H value, three independent networks were trained, and the $\bar{N}_{\text{GE}}$ results are summarized in Table III.

As shown in Table III, CA-SCA demonstrates notable instability for smaller H values (e.g., 2 and 4). Specifically,

TABLE III: CA-SCA attack results for different values of H on the ECB-CBC task, with T_1, T_2, and T_3 representing the $\bar{N}_{\text{GE}}$ results from three independent tests.

H	ECB-CBC		
	T_1	T_2	T_3
2	984	$>1K$	580
4	282	133	184
8	37	30	29
16	41	33	47
32	47	52	44

CA-SCA required more than 580 and 133 attack traces, respectively, to reach a $\bar{N}_{\text{GE}}$ of 0, whereas $H = 8$ achieved this with fewer than 40 attack traces across all trials. This instability for smaller H values is likely due to limited information flow to distant sample points. In contrast, CA-SCA performs well with larger H values, such as 8 and 16, though performance slightly declines at $H = 32$, possibly due to overfitting caused by the increased parameter count in the attention layer. These findings suggest an optimal range for H in CA-SCA, with values between 8 and 16 consistently delivering robust and reliable performance across the tests.

VI. Conclusions and Future Work

In this paper, we introduce CA-SCA, a novel approach to address portability challenges across different AES modes. CA-SCA leverages cross-attention mechanisms and UDA to align input samples within a high-dimensional feature space, effectively reducing interference from encryption mode mismatches. Notably, CA-SCA does not require specific fine-tuning or multiple analysis datasets. Our evaluation on five distinct AES mode datasets shows that, while traditional SCA methods often struggle with substantial mode differences, CA-SCA enables previously infeasible attacks and outperforms state-of-the-art techniques.

In future work, we aim to further explore the impact of cross-attention mechanisms and UDA on SCA. Additionally, we plan to assess CA-SCA's performance across various hardware platforms to advance portability research within the SCA community.

AttenPIM: Accelerating LLM Attention with Dual-mode GEMV in Processing-in-Memory

Liyan Chen†, Dongxu Lyu†, Zhenyu Li, Jianfei Jiang, Qin Wang, Zhigang Mao, Naifeng Jing*
Department of Micro/Nano Electronics, Shanghai Jiao Tong University, Shanghai, China
{liyan.chen, sjtuj}@sjtu.edu.cn

***Abstract*—Large Language Models (LLMs) have demonstrated unprecedented generative performance across a wide range of applications. While recent heterogeneous architectures attempt to address the memory-bound bottleneck from attention computations by processing-in-memory (PIM) offloading, they overlook two critical characteristics of attention GEMVs that distinguish them from traditional PIM scenarios: (1) dynamic matrix dimensions that scale with token length, and (2) distinct GEMV patterns between score computation ($Q \times K_t$) and context computation ($S \times V$). Existing PIM designs, employing either uniform or transposed computing modes, suffer from inefficiencies in newly generated element preparation or distinct GEMV execution. To address these limitations, we propose AttenPIM, a software-hardware co-design for efficient PIM-based attention acceleration. For bank-level execution, we propose dual-mode computing modes tailored for score and context computations with PIM-oriented data layouts and execution flows for KV storage, supported by a low-cost configurable per-bank PIM unit (PU). For system-level execution, we leverage token-level and head-level concurrency to ensure workload balance and maximize bank PU parallelism. Furthermore, dynamic allocation and kernel fusion methods are proposed to further minimize memory overhead. Experimental results demonstrate that AttenPIM achieves $1.13\times$–$5.26\times$ speedup and reduces energy consumption by 17%–49% compared to two state-of-the-art PIM baselines.**

I. Introduction

Large Language Models (LLMs) have been widely deployed across diverse applications [1], such as language understanding, content generation, and decision support. LLM inference demands immense amounts of compute and memory resources. While machine learning accelerators (e.g., GPU and TPU, referred to as xPU) demonstrate high performance on compute-bound layers, they struggle with memory-bound layers due to limited memory bandwidth and resulting underutilization [2]–[4]. For instance, with a batch size of 16 and a token length of $2K$, the memory-bound multi-head attention (hereafter attention) layers of GPT-3 13B consume more than 50% of the total time on A100 GPUs [2]. This proportion increases dramatically with larger batch sizes or longer sequence lengths, severely limiting the inference performance [4].

The attention layer comprises three operations: score, softmax, and context, with score and context computations being the most time-consuming matrix-vector multiplication (GEMV) computations. Recent studies [5]–[8] offload attention operations to processing-in-memory (PIM) designs, which have demonstrated significant performance improvements in GEMV computation [9], [10]. By integrating PIM units (PUs) within memory devices, PIM can achieve higher aggregated bandwidth and computational parallelism [11]–[14].

However, attention GEMVs in LLMs exhibit distinct characteristics that differentiate them from conventional PIM applications with static weight data and uniform execution flow [9], [10]. First, the dimensions of attention GEMV matrices dynamically expand with increasing token length, requiring additional matrix data preparation for each new token. Second, attention score and context computations, with transposed matrix dimensions, perform multiply-accumulate (MAC) operations along different dimensions during execution.

Existing PIM works fail to consider these characteristics with the PIM computing paradigm simultaneously, thus leading to performance degradation. NeuPIMs [6], built based on Newton [9], partitions both matrices column-wise while broadcasting vector data for parallel execution. However, the newly generated matrix elements cannot fully utilize DRAM burst transfer (16 bits out of 256/512 bits), incurring $50\times$ preparation time with masked accesses [7]. While AttAcc [5] proposes a multi-level partition method for two matrices in a transposed manner, it requires PUs at multiple memory levels for partial result accumulation. Additionally, the inter-PU communication would congest memory buses (particularly TSVs), leading to 15%–58% performance degradation.

We identify that it is crucial to simultaneously address both attention GEMV characteristics and PIM computing paradigm design. To achieve this goal, we propose AttenPIM, a software-hardware co-design for efficient PIM-based attention acceleration. Our contributions are as follows:

- For bank-level execution, we propose dual computing modes for score and context computations with PIM-oriented data layouts and execution flow, supported by a low-cost configurable per-bank PIM unit (PU).
- For system-level execution, we leverage token-level and head-level concurrency to ensure workload balance and maximize bank PU parallelism. Furthermore, we introduce dynamic allocation and kernel fusion methods to reduce memory space waste and memory accesses.
- We implement our design on TSMC 28nm technology and extensively evaluate it on real-world LLM datasets. AttenPIM achieves a $1.13\times$–$5.26\times$ speedup and reduces energy consumption by 17%–49% compared to two state-of-the-art PIM baselines.

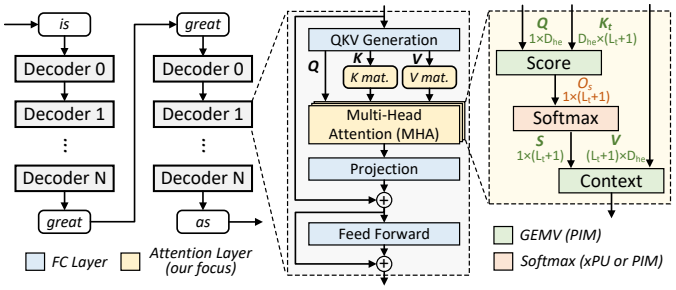

Fig. 1. Model architecture and inference (Gen stages) in LLMs.

II. Background and Motivation

A. LLM Model

LLM models are built from the Transformer decoder [15], as illustrated in Fig. 1. Each decoder consists of fully-connected layers (QKV Generation, FFN), attention layers (MHA). The inference process consists of an initial Sum stage followed by recurring Gen stages. The Sum stage computes the initial KV cache (matrices) from the input prompt and generates the first token while each Gen stage updates KV matrices by concatenating and generates a new token auto-regressively.

The MHA layer consists of multiple independent heads, each performing two types of GEMVs: score computation ($Q{\times}K_t$) and context computation ($S{\times}V$), and a softmax operation. Given head embedding dimension D_{he} and current sequence length L_t, the score computation involves a $1{\times}D_{he}$ vector Q and a $D_{he}{\times}(L_t{+}1)$ matrix K_t, while the context computation involves a $1{\times}(L_t{+}1)$ vector S and a $(L_t{+}1){\times}D_{he}$ matrix V. The MHA layer with low compute-memory ratio is underutilized in xPU. For instance, with GPT-3 13B under a batch size of 16 and token length of $2K$, it can consume more than 50% of the total time on A100 GPUs [4].

B. HBM-based PIM for Attention

An HBM device [16] integrates multiple DRAM dies with a buffer die through TSVs, as shown in Fig. 2(a). Each DRAM die comprises independent (pseudo) channels, with each channel subdivided into multiple bank groups (BGs) consisting of four banks. HBM-based PIM, which incorporates PUs at various memory hierarchies (die, BG, bank), offers promising solutions for GEMV through high aggregated bandwidth.

Recent studies have explored offloading attention GEMVs to HBM-based PIM for acceleration [5], [6]. NeuPIMs [6] and works [7], [8], depicted in Fig. 2(b), partitions both matrices K_t and V column-wise. They leverage a global shared buffer to broadcast vector data while confining GEMV execution within bank PUs. AttAcc [5], as shown in Fig. 2(c), partitions matrix K_t token-wise across BGs, with each matrix tile further subdivided embedding-wise within each BG, and leverages a transposed layout for matrix V. Partial results of $Q{\times}K_t$ in bank PUs are accumulated in BG PUs, while partial results of $S{\times}V$ are accumulated in die PU.

Considering that softmax operation execution time is typically masked through head-level pipelining [5], [6], this paper primarily concentrates on attention GEMVs. Notably,

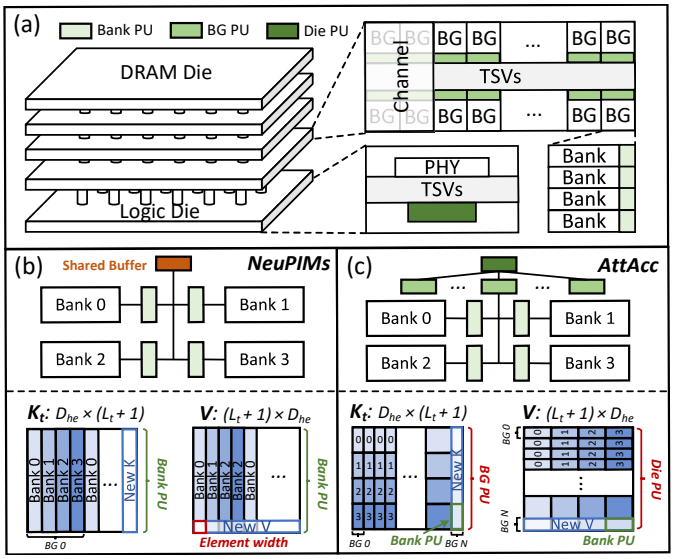

Fig. 2. (a) HBM-PIM. (b) NeuPIMs architecture. (c) AttAcc architecture.

AttenPIM design can also extend to PIM designs based on other memory devices, such as GDDR [10], DIMM [17].

C. Motivation

Attention GEMVs in LLMs exhibit unique characteristics that distinguish them from conventional PIM applications [9], [10]. First, attention matrices expand with token length, introducing an additional matrix preparation phase. Second, attention GEMVs encompass score and context computations with transposed matrix layouts, which perform MAC operations along different dimensions during execution. The efficiency of both phases is fundamentally determined by matrix data layout. While existing PIM designs adopt either uniform or transposed partitioning strategies to distribute matrices K and V, these one-size-fits-all approaches demonstrate inefficiencies in either the preparation or computation phase.

NeuPIMs distributes newly generated V head elements across different banks, where the element width (e.g., 16 bits) underutilizes burst transfer capabilities (e.g., 256/512 bits). The masked accesses for V preparation consume about $50{\times}$ more time compared with preparation for matrix K_t, accounting for 12%-77% of total execution time across various token lengths. AttAcc introduces contention on shared memory buses between PUs. Specifically, TSV bandwidth emerges as a bottleneck for context computation ($S{\times}V$), resulting in 15%-58% performance degradation. Additionally, the requirement for diverse vector data across bank PUs necessitates distributed input buffers in each bank PU. These performance penalties accumulate during token generation, substantially impacting end-to-end inference performance.

Motivated by these observations, we identify that there is an urgent need for specialized data layouts and compatible execution flows tailored separately for PIM-based attention score computation ($Q{\times}K_t$) and context computation ($S{\times}V$), which can maintain burst transfer efficiency and eliminate inter-PU communication overhead.

III. AttenPIM Architecture

AttenPIM implements a multi-level acceleration strategy for LLM attention, spanning from bank-level optimizations to system-level enhancements. At the bank level, we introduce dual computing modes for score and context computations with PIM-oriented data layouts and execution flows. We confine GEMV execution within bank PUs while leveraging broadcast mechanisms to eliminate distributed buffers. At the system level, we exploit token-level parallelism and head-level parallelism to ensure workload balance, complemented by kernel fusion and dynamic allocation methods to minimize memory accesses and memory waste. Given the independent nature of attention head computations, we use a single head as a representative example, unless stated otherwise.

A. Computing Mode: Score

Building upon the demonstrated efficiency of NeuPIMs in score computation ($Q \times K_t$) with bank PUs, we follow their proposed data layout and execution flow. We present a brief overview using a two-bank configuration as an illustrative example, while not claiming this as our innovation.

1) Data Layout: As illustrated in Fig. 3(a), when a new K_t column is generated, all head elements are mapped to a designated bank and stored continuously within a bank row. In this case, score computation ($Q \times K_t$) can be performed within bank PU with high DRAM operation efficiency during both the storage and execution stage.

2) Execution Flow: Inner-product is leveraged for score computation ($Q \times K_t$). As depicted in Fig. 3(c), head elements from two tokens are positioned in identical row and column locations across different banks to enable parallel read operations. In each phase with burst-width transfer, bank PUs retrieve head elements from DRAM arrays (❶), while the shared buffer broadcasts corresponding vector data of Q to all bank PUs (❷). These elements undergo multiplication and accumulation to generate a partial output element (❸). The output elements from different phases are accumulated to generate the final result (❹).

B. Computing Mode: Context

AttenPIM introduces a specialized data layout for V matrix storage and implements a compatible execution flow for context computation ($S \times V$).

1) Data Layout: We identify burst length as the minimum storage granularity that maintains DRAM operation efficiency, which we leverage for partitioning each newly generated vector V. Consider the burst transfer length of N_{bl} and model element precision of N_{pre}. As shown in Fig. 3(b), a token head is divided into N_{BB} burst blocks, where $N_{BB} = D_{he}/N_{bl}$. Each burst block consists of N_{bl}/N_{pre} elements. The mapping of these burst blocks follows two key principles: (1) burst blocks with identical indices across different tokens reside in the same bank (e.g., BB_1 of all tokens are stored continuously in bank 1), and (2) data alignment in identical rows and columns is maintained to enable parallel read operations between banks.

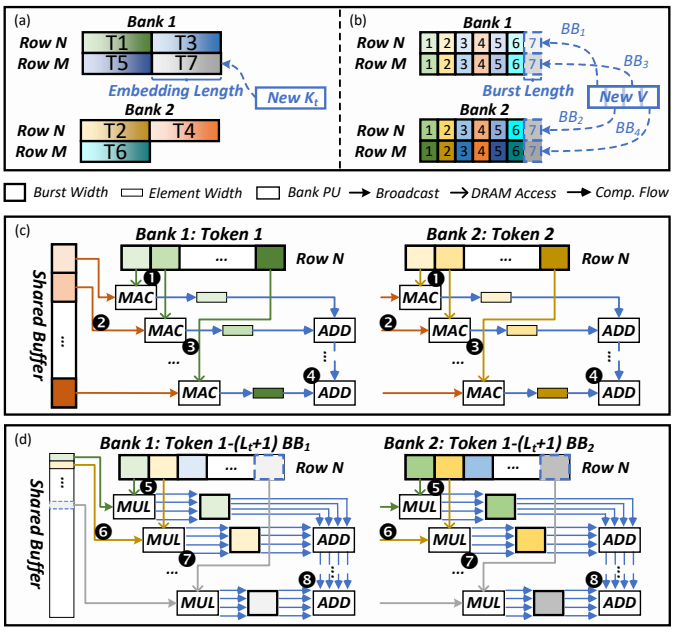

Fig. 3. (a) Data layout for K matrix. (b) Data layout for V matrix. (c) Execution flow for score. (d) Execution flow for context.

2) Execution Flow: The data layout ensures that elements requiring multiplication and addition operations are localized within the same bank. Based on it, we propose to perform context computation ($S \times V$) using an outer product approach. As depicted in Fig. 3(d), burst blocks BB_1 and BB_2 of N_t token are allocated to bank 1 and bank 2, respectively. During each phase, bank PUs read a burst block of a token from DRAM arrays (❺), while the shared buffer only needs to broadcast a single element of vector S to bank PUs (❻). This element is shared and multiplied with each head element of the burst block instead of MAC, generating N_{bl}/N_{pre} partial outputs (❼). These partial results undergo element-wise accumulation across phases to generate the final results (❽).

C. Hardware Support: Configurable PU

To efficiently support dual-mode GEMV operations, we propose a cost-effective configurable PIM unit at the bank level, complemented by a global shared buffer for data broadcasting. To match the burst transfer bandwidth, each PU incorporates N_{bl}/N_{pre} multipliers and adders, along with multiple buffers for pipelined execution.

1) Inner product: The inner product computation follows an adder tree architecture, as illustrated in Fig. 4(a). Using a configuration with four multipliers, four adders, and a result buffer as an example: during each phase, the multipliers receive and execute burst-length inputs of N_{bl}/N_{pre} elements from both the shared buffer and DRAM row buffer. The adder tree performs accumulation of outputs from multipliers and accumulation of partial outputs between phases. Consequently, $D_{he} \times N_{pre}/N_{bl}$ phases are needed to complete one head GEMV. The host can either read the result buffer for softmax operation (kernel fusion detailed in Section III-E2) or write it back to banks for subsequent computations.

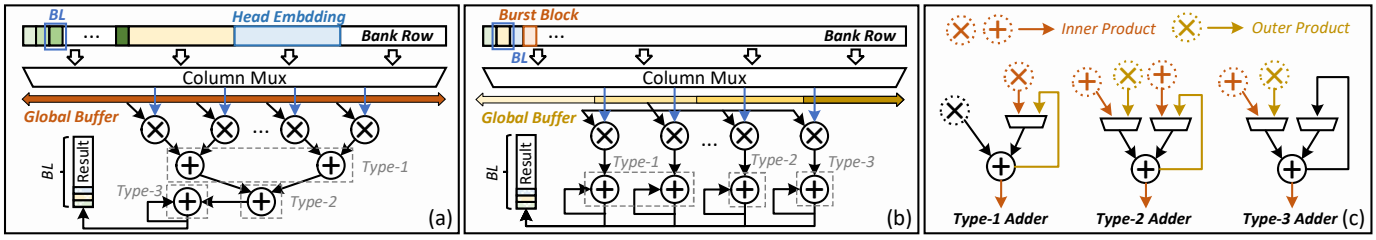

Fig. 4. (a) Inner product mode for score. (b) Outer product mode for context. (c) Three types of adders. Buffers for pipeline are not shown.

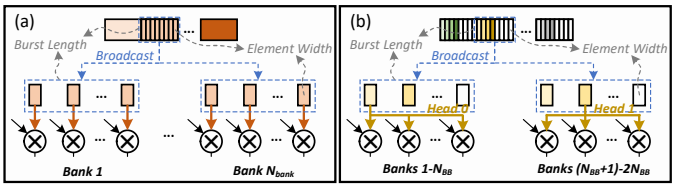

Fig. 5. (a) Broadcast in score execution. (b) Broadcast in context execution.

2) Outer product: The outer product implementation employs a self-accumulation approach, where outputs accumulate within individual multiplier-adder sets without inter-set data transfer. As shown in Fig. 4(b), in each phase, a single input element from the shared buffer is shared by all multipliers to be multiplied with data from DRAM row buffer. Each set's adder combines the new multiplier output with the previously accumulated sum. In this case, N_{bl}/D_{he} outputs are generated concurrently through self-accumulating. L_t+1 phases are needed to generate final results.

3) Configurable Path: The Bank PU implements three types of adders to support both inner and outer product operations, as depicted in Fig. 4(c). First, the type-1 adder combines input from a multiplier with either another multiplier's output (inner product) or its own previous output (outer product). Second, the type-2 adder processes inputs from two other adders (inner product) or combines a multiplier output with its own previous output (outer product). Third, the type-3 adder adds its previous output with another adder's output (inner product) or a multiplier's output (outer product). The mode configuration is performed only once for each head of the entire batch to amortize overhead.

D. Workload Balance

1) Score $Q\times K_t$: AttenPIM adopts the mapping strategy in NeuPIMs, assigning each head of K matrix to one channel and each token to one bank. In contrast, AttAcc maps a head across the entire HBM device and allocates each token to a BG for cross-level accumulation. Since the number of BGs in an HBM device significantly exceeds the number of banks in a channel, NeuPIMs and AttenPIM achieve better workload balance for requests with relatively short token lengths.

2) Context $S\times V$: The context execution of one head cannot exploit all-bank parallelism, thus leading to potential workload imbalance. Specifically, the number of burst block N_{BB} is typically smaller than the available channel banks N_{bank} (e.g., N_{BB}=8 in GPT-3 while N_{bank}>16 in a HBM device). To address this limitation, we implement concurrent context computation for multiple heads instead of single-head execution across all banks.

For head selection, we prioritize different heads from a single request over heads from different requests for two key reasons: (1) Requests with varying token lengths require different numbers of phases for context completion, potentially causing new workload imbalance. (2) Data arrangement in banks may differ across requests, preventing effective parallel read operations. Conversely, heads within the same request maintain consistent phase length and data layout. Consequently, we perform context execution for N_{bank}/N_{BB} heads in a channel at the same time.

Unlike score computation ($Q\times K_t$) where all bank PUs share the same input vector Q, context matrices V of different heads multiply with different input vectors S, challenging the broadcast mechanism. However, in our computing mode for context, only one element is required in the execution phase of N_{BB} bank PUs (one head), allowing the remaining bits of the shared buffer to be leveraged for other heads. As illustrated in Fig. 5(a), for score computation, the elements broadcast by the shared buffer are leveraged in all banks, multiplied with corresponding matrix data. In contrast, as shown in Fig. 5(b), different elements from the shared buffer are leveraged in context computations of different heads. Consequently, the shared buses can provide vector S elements to N_{bl}/N_{pre} heads' context computations concurrently, with each head utilizing N_{BB} banks, thereby ensuring optimal all-bank parallelism and workload balance.

E. Memory Optimization

1) Dynamic Allocation: Recent research has introduced dynamic KV allocation strategies (e.g., allocating memory space for several tokens when needed) to decrease memory waste from static allocation (e.g., allocating space for maximum token lengths at a time). While these strategies effectively increase batch size, they cannot be directly implemented in PIM designs due to PIM's requirement for precise data layout across columns, rows, and banks.

In AttenPIM, for score computation ($Q\times K_t$), to ensure all-bank parallelism, the same row and same columns of all banks in the channel should be allocated when existing memory space is exhausted. For context computation ($S\times V$), N_{BB} banks are employed per token head. Similarly, we allocate the same entire row of these banks as needed.

TABLE I
DYNAMIC ALLOCATION METHOD COMPARISON

	K Cache	V Cache
NeuPIMs	$N_{bank} \times N_{row}/D_{he}$	N_{row}/N_{pre}
AttAcc	$N_{ch} \times N_{bank} \times N_{row}/D_{he}$	$N_{ch} \times N_{bank} \times N_{row}/D_{he}$
AttenPIM	$N_{bank} \times N_{row}/D_{he}$	N_{row}/N_{bl}

Table I compares the number of tokens per dynamic allocation (parameters in Section IV). For K Cache allocation, NeuPIMs and AttenPIM allocate the same entire row (size of N_{row}) of all banks when needed, with an allocation size of $N_{bank} \times N_{row}/D_{he}$ tokens. Since AttAcc maps heads across the entire HBM device, it requires $N_{ch}\times$ memory space. For V Cache allocation, NeuPIMs allocates V cache of N_{row}/N_{pre} tokens at a time, which significantly wastes memory space. AttAcc leverages a transposed data layout of K Cache with the same allocation size. AttenPIM allocates entire row of D_{he}/N_{bl} banks, whith total allocation size is N_{row}/N_{bl}.

2) Kernel Fusion: NeuPIMs and AttAcc overlap softmax execution time between heads by executing GEMV operations in the PUs while performing softmax operations in softmax unit (SU, either in xPU or PIM) for different heads. To achieve this, NeuPIMs introduces double row buffers in each bank to enable concurrent access from PU and SU, while AttAcc implements direct data transfer from PU buffer to SU without interrupting PU execution. AttenPIM adopts AttAcc's approach for kernel fusion, achieving enhanced benefits due to its context operations within bank PUs, which reserves all TSV bandwidth for softmax operation transfers.

IV. EVALUATION

A. Experiment Setup

1) Baselines: We compare AttenPIM with two state-of-the-art PIM architectures: NeuPIMs [6] and AttAcc [5]. While these baselines provide comprehensive xPU-PIM heterogeneous acceleration for LLMs, AttenPIM specifically targets attention GEMV operations, which constitute the primary performance bottleneck. We leverage HBM as the memory device, with configurations detailed in Table II. To ensure a fair comparison, we maintain consistent hardware parameters across all implementations, including channel count, bank group count, bank count, and so on.

2) LLM Workloads: Our evaluation employs four variants of GPT-3 [18], the Large Language Model developed by OpenAI, as detailed in Table III. Since various LLM variants (including other architectures such as Llama [19]) differ primarily in their number of heads while maintaining consistent head dimensions, the attention performance metrics (e.g., execution time, energy consumption) scale approximately linearly with the number of heads. Consequently, we normalize the results relative to the baseline and present the averaged measurements.

For comprehensive performance assessment, we utilize four diverse real-world LLM inference datasets: Alpaca [20], ShareGPT [21], MultiNews [22], and LCC [22]. Alpaca dataset is an instruction dataset generated using OpenAI's text-davinci-003 engine, characterized by compact token lengths of less than 100 tokens on average. ShareGPT dataset is a set of conversations scraped from the real-world user logs of ChatGPT, with a maximum token length of $2K$ and average of about $0.5K$. Both MultiNews and LCC are from LongBench [22] with average token length of more than $2K$ and $4K$, respectively, which are specialized in long-context processing.

* Precision: $N_{pre} = 2$ (16-bit floating point); Head Embedding: $D_{he} = N_e/N_h = 128$.

3) Simulation: We develop an in-house simulator by modifying DRAMSim3 [23] to evaluate the performance of AttenPIM. We also implement the data layout and execution flow of NeuPIMs and AttAcc in this simulator for comparative analysis. Following NeuPIMs' methodology, we randomly pick sequence lengths from each dataset for simulation. This way, we can warm up the inference batch so that the batch is filled with requests having various sequence lengths.

For energy consumption, we distinguish memory access at die level (with TSVs) and bank-level (without TSVs), referring to energy consumption reported in previous work [24]. For hardware validation, we implement a prototype of AttenPIM PU with RTL and evaluate it with Synopsys Design Compiler under 28nm CMOS technology.

B. Performance of AttenPIM

We evaluate AttenPIM's execution time against two baseline architectures, with results normalized to NeuPIMs for each dataset, as illustrated in Fig. 6. The total execution time comprises four distinct components: K preparation, V preparation, score computation ($Q\times K_t$), and context computation ($S\times V$).

First, AttenPIM demonstrates superior performance across all LLM datasets, achieving speedups of $1.20\times$–$5.26\times$ over NeuPIMs and $1.13\times$–$3.91\times$ over AttAcc. Compared to NeuPIMs, AttenPIM takes DRAM operation efficiency into consideration, significantly decreasing the time for V preparation. Compared to AttAcc, AttenPIM constrain all computations within bank PU, eliminating TSV bandwidth constraints.

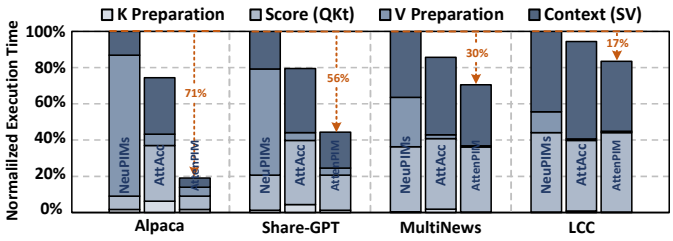

Fig. 6. Normalized performance comparison.

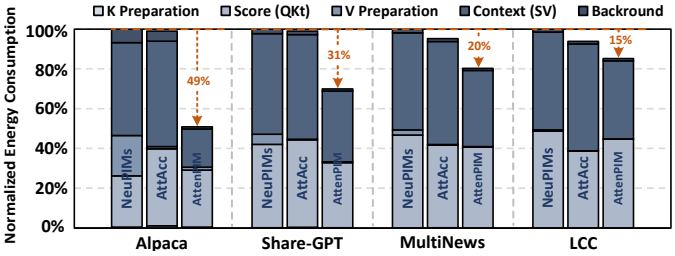

Fig. 7. Normalized energy consumption comparison.

Second, AttenPIM exhibits robust performance across varying token lengths. AttAcc shows worse performance with short token lengths than with long ones due to workload imbalance. NeuPIMs and AttenPIM partition heads to channels instead of HBM devices, whose bank number is usually smaller than token lengths, which results in less workload imbalance with short token lengths.

Third, the performance advantages of AttenPIM show a correlation with dataset token lengths. For individual token attention operations, the relative performance gain decreases as the number of previously generated tokens increases, primarily due to GEMV execution's growing dominance in total execution time. However, since long token sequences are generated incrementally from shorter sequences, AttenPIM's time reductions accumulate at each step, contributing to overall end-to-end inference efficiency.

C. Energy of AttenPIM

We compare the memory access energy consumption of AttenPIM and two baseline architectures. As illustrated in Fig. 6, results are normalized to the highest-consuming baseline for each dataset. The energy analysis is decomposed into five components: K preparation, V preparation, Score $Q \times K_t$, Context $S \times V$, and background (of entire execution).

First, AttenPIM demonstrates significant energy efficiency improvements, achieving reductions of 14.8%–48.1% and 14.4%–49.2% over NeuPIMs and AttAcc, respectively. The primary energy savings stem from optimized DRAM operations during V cache preparation (over NeuPIMs) and reduced memory accesses on TSVs (over AttAcc). Second, the energy efficiency advantages of AttenPIM also show a correlation with dataset token lengths. The energy waste of masked reads in NeuPIMs and TSV transfers in AttAcc are significant with short token lengths. For long token lengths, the energy for score and context would dominate the overall consumption.

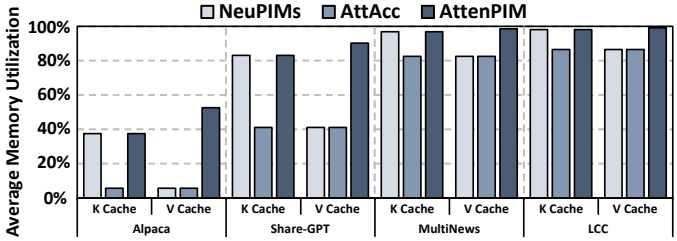

Fig. 8. Memory utilization of allocation method comparison.

TABLE IV
AREA AND POWER OVERHEAD

	NeuPIMs	AttAcc	AttenPIM	HBM
Area (mm^2)	0.79	1.58	0.86	>100 (DRAM process)
Power (W)	0.24	0.26	0.29	116 (Device Budget)

D. Memory Allocation Efficiency

We compare the memory utilization of allocation methods of AttenPIM and two baselines, as shown in Fig. 8. For K cache allocation, both NeuPIMs and AttenPIM demonstrate superior memory utilization compared to AttAcc across all evaluated datasets. This improved efficiency can be attributed to their optimized head distribution strategies. For V cache allocation, AttenPIM achieves the highest memory utilization through the burst block distributed data layout, which achieves memory utilization exceeding 90% as token length increases.

E. Overhead of AttenPIM

We implement bank PU of AttenPIM and two baseline designs in RTL and evaluate them using Synopsys Design Compiler. Based on NeuPIMs' configuration of banks per DRAM die, the result of 64 PUs is shown in Table IV. The evaluation shows that AttenPIM introduces negligible area and power overhead compared to NeuPIM, while achieving a 47% area reduction compared to AttAcc through the elimination of a large input buffer. When considering the scaling of PU area to the third-generation 10nm class (1z-nm) DRAM process, although the area density would be $10\times$ lower than the equivalent logic process, the overhead remains acceptable given the HBM specifications of more than $100mm^2$ DRAM dies and $116W$ power budget.

V. CONCLUSION

In this paper, we propose AttenPIM, a software-hardware co-design for efficient PIM-based attention acceleration. We propose PIM-oriented data layouts for KV storage and dual-mode computing paradigms tailored for score and context computations, which are supported by a configurable PIM unit design. In addition, we exploit token-level and head-level parallelism to optimize workload balance, while kernel fusion and dynamic allocation methods are proposed to further minimize memory overhead. Experimental results demonstrate that AttenPIM achieves $1.13\times$–$5.26\times$ speedup and reduces energy consumption by 17%–49% compared to two state-of-the-art PIM baselines.

***Abstract*—Edge intelligent workstations load (store) massive empirical data from (to) remote cloud storage due to limited local storage. However, current remote storage access frameworks are complex. They use expensive computing resources to manipulate multiple concurrent request queues in modern high-speed storage devices for saturating performance. Complex software stacks and limited CPUs on edge intelligent workstations hinder saturating concurrent request queues, thus resulting in up to 75% performance degradation for remote storage. We propose Leopard, a hardware pass-through remote storage access framework with queue concurrency, which provides lossless remote storage access for edge intelligence. Leopard proposes a custom NVMe controller using SmartNIC's FPGA core to emulate it as an NVMe device, which eliminates complex remote storage stacks for edge workstations. Operations for remote storage access are implemented as hardware circuits inside the controller to eliminate CPU cycles. Parallelized and pipelined workflows are proposed for hardware circuits to accelerate remote storage access operations. Our evaluation presents that Leopard exhibits 1.09×∼6.04× lower remote storage access latency than SOTA solutions for realistic workloads in edge intelligent workstations.**

***Index Terms*—edge intelligent workstations, remote storage, hardware pass-through, queue concurrency, parallelized and pipelined workflows.**

I. Introduction

In recent years, more and more edge intelligent workstations [11], [43] have been deployed on the data generation side to perform edge intelligence. They reserve limited computing (CPUs or GPUs) and storage resources to implement edge intelligent applications using edge data and massive empirical data. The large volume of empirical data is persistently stored in remote cloud storage servers (remote storage) [42] and needs to be loaded/stored via remote storage access on demand. Remote storage access is implemented using a software stack known as the remote storage access framework.

There are several remote storage access frameworks have been proposed, such as famous and widely used iSCSI [1] and NVMe Over Fabric (*NVMe-oF*) [28]. iSCSI is a single-queue framework for traditional hard disk drives (HDDs) [7]. It introduces unacceptable performance degradation and CPU overheads for modern multi-queue non-volatile memory express [30] solid state drives (NVMe SSDs) [13]–[16] due to its inefficient single-queue design. Specifically, iSCSI reduces the application-level throughput of NVMe SSDs by >20% [10]. Furthermore, it needs to consume 14 CPU cores for saturating a single modern multi-queue NVMe SSD [12]. *NVMe-oF* is a remote storage framework with a multi-queue design. It mitigates the performance degradation for remote access by leveraging multiple physical request queues in modern NVMe SSDs. *NVMe-oF* can be categorized into NVMe-over-TCP [31] (*nvof-tcp*) and NVMe-over-RDMA [29] (*nvof-rdma*) according to the transport layer. *nvof-tcp* is constructed based on TCP [8] network protocol. *nvof-rdma* is constructed based on remote memory direct access (RDMA) [34] protocol and RDMA network card (RNIC) [23]. However, they are implemented as complex software stacks deployed on both Initiator and Target Hosts[1]. Multiple CPU cores are used to manipulate multiple physical request queues in SSDs to saturate performance. Experiments in Section III show that *nvof-tcp* reduces remote access performance of NVMe SSDs to about 1/4 of local access when using a 100Gbps network card (NIC). And *nvof-rdma* has a performance degradation of about 10%∼20% compared to local access [10].

Previous works [12], [26] have investigated the aforementioned disadvantages for traditional remote storage access frameworks. For example, an offloading method [26] is proposed to mitigate these disadvantages. Specifically, RNIC on the Target Host directly accesses NVMe SSDs in a peer-to-peer (P2P) manner, thereby slimming down the software stack on the Target Host. However, these works are proposed for cloud scenarios with sufficient CPU resources. Besides, they overlook multiple physical request queues in modern network devices, which can be used to improve concurrency for remote storage access. Figure 2 presents that these solutions still cannot avoid performance degradation for remote storage access in edge intelligent workstations when using modern high-performance NVMe SSDs. Therefore, we argue that existing remote storage access frameworks cannot fully leverage the queue concurrency in modern network devices and NVMe SSDs to implement high-performance remote storage access for edge intelligent workstations. The reasons are as follows: (i) The remote storage initiator (edge intelligent workstation) needs a complex software stack that integrates storage and network. (ii) The limited CPU resources in edge intelligent workstations cannot saturate multiple concurrent request queues in modern network devices and NVMe SSDs. (iii) The CPU still participates in remote storage access operations.

To this end, we propose Leopard, a hardware pass-through remote storage access framework using Field Programmable Gate Array (FPGA) [39]-based smart network cards (SmartNICs) [35]. It fully utilizes the queue concurrency in modern high-speed network devices and NVMe SSDs to implement lossless remote storage access for edge workstations. SmartNICs can independently perform tasks and optimize performance with low cost and low power consumption, such as [5], [20]–[22], [41]. The network functions in modern emerging SmartNICs also allow us to focus on investigating remote storage access workflows comprehensively without overly focusing on the network. First, Leopard customizes a native NVMe driver-compatible NVMe controller using SmartNIC's FPGA core to eliminate complex software stacks for Initiator Host. The Initiator Host only needs to submit remote storage requests without implementing remote-related operations. Second, Leopard constructs several FPGA-based accelerators that utilize multiple request queues in network devices and NVMe SSDs to accelerate remote storage access operations. Fi-

This work was funded by the National Key Research & Development Program of China (No. 2022YFB4502002), NSFC (No. 62402317 & 62032008), STCSM (No.24ZR1435500), and supported by the project from Wuxi Institute of Advanced Technology, a grant from State Key Laboratory of Avionics Integration and Aviation System-of-Systems Synthesis, and the Fund of Kunpeng&Ascend Center of Excellence, Shanghai Jiao Tong University. [1]In this paper, we refer to edge workstations that perform edge computing and initiate remote storage requests as the Initiator Host, and remote cloud storage servers that manage persistent storage devices as the Target Host.

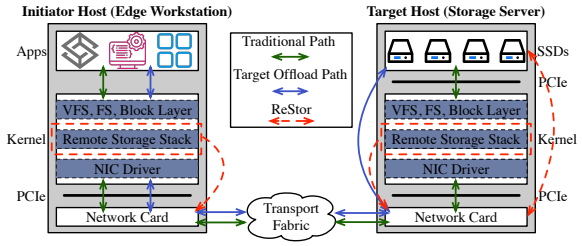

Fig. 1: Request/data path for remote storage access frameworks.

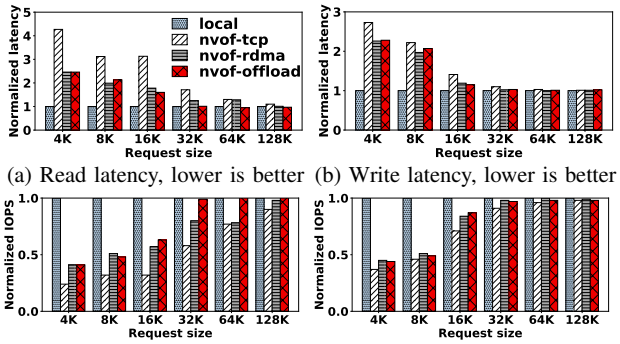
nally, Leopard accesses NVMe SSDs on remote cloud storage servers via SmartNIC's onboard peripheral component interconnect express (PCIe) slots. Leopard eliminates software stacks for Initiator Host and Target Host and provides queue-granularity remote storage access acceleration, thus optimizing remote storage access performance for edge workstations. The following are the main contributions:



1) We propose Leopard, a hardware pass-through remote storage access framework based on SmartNICs. It enables remote storage performance close to local access for edge intelligent workstations with limited CPU resources.
2) We propose several hardware accelerators for remote storage access, which construct queue-granularity parallelized and pipelined workflows to fully exploit multiple request queues in network devices and NVMe SSDs. They accelerate request and data processing for remote storage access.
3) We implement a Leopard prototype and evaluate remote access latency and throughput using micro-benchmarks and realistic workloads. Experiments for realistic workloads exhibit that the remote read/write latency of Leopard is consistent with local access, which is 1.09×∼6.04× better than SOTA solutions.

II. Preliminaries and Related Work

A. Preliminaries

Edge Workstation. Edge workstations [11], [17], [43] are deployed in several fields to implement edge intelligence. They are implemented in remote sensing [33], healthcare [9], [24], manufacturing [4], and agriculture [36], [38] scenarios to collect geospatial, image, and sensor data. They also perform edge intelligent applications using empirical data and collected data. However, edge workstations typically reserve limited computing (CPUs/GPUs) and storage resources required by applications. The large amount of empirical data is persistently stored in remote cloud storage servers. Edge workstations read/write empirical data from/to remote cloud storage servers via remote storage access (frameworks). Therefore, remote storage access in this scenario affects the performance of applications.

Remote Storage Access. Figure 1 depicts the breakdown of remote storage access paths for traditional and target offloading [26] frameworks. Remote storage requests are initiated by applications on the Initiator Host and transmitted to NVMe SSDs on the Target Host. Remote access paths of traditional frameworks (*nvof-tcp* and *nvof-rdma*) are the longest. Specifically, storage requests initiated by applications (Apps) need to go through software stacks (file system, block layer, remote storage stack, and driver) and NIC on the Initiator Host, as well as NIC and software stacks on the Target Host. The target offloading framework utilizes RNIC to manipulate (P2P) NVMe SSDs, eliminating software stacks and PCIe overheads on the Target Host. However, remote storage access operations still consume edge workstation's CPUs due to software stacks present on the Initiator Host. Besides, existing frameworks utilize multiple CPU cores to operate multiple physical request queues in NVMe SSDs, thereby maximizing SSDs' performance. Unfortunately, CPU resources in edge intelligent workstations are limited. Therefore, complex software stack hierarchy and CPU dependency prevent traditional and target offloading frameworks from implementing efficient

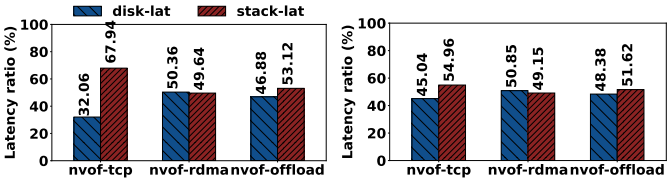
remote storage access for edge intelligent workstations. Next, we provide an overview of existing remote storage access frameworks.

B. Related Work



Traditional Remote Storage Frameworks. iSCSI [1] is a traditional remote storage access framework designed for low-speed HDDs. It is unable to provide low-latency and high-throughput remote storage access as the development of modern network and storage devices. *NVMe-oF* [28] was proposed in 2014 and scaled to Ethernet, Fiber, and InfiniBand [32] in 2016. *NVMe-oF*'s multi-queue design achieves better latency and throughput performance for remote storage access compared to iSCSI. *nvof-tcp* and *nvof-rdma* are two classic *NVMe-oF* protocols. *nvof-tcp* introduces significant performance overhead compared to local access since the network layer adopts the TCP protocol, which is implemented by CPU software. *nvof-rdma* is proposed to mitigate the performance degradation for remote storage access using RDMA protocol and RNIC. However, the remote access performance of *nvof-rdma* in edge intelligent workstations is still 10%∼20% worse than local access.

Remote Storage Framework Optimization. Several solutions [12], [19], [26] for optimizing existing remote storage access frameworks have been proposed. For example, *i10* [12] is proposed to optimize the performance of *nvof-tcp*. Its performance is similar to *nvof-rdma*. Highly optimized pipelines between CPU cores and remote storage access stacks are proposed to optimize bottlenecks at the boundary of the network stack and NVMe storage stack. Besides, NVME-OF TARGET OFFLOAD [26] is proposed to use RNIC's P2P ability for directly accessing NVMe SSDs, thus eliminating software stacks and PCIe overheads on the Target Host. ReFlex [19] designs and implements user-space storage and network frameworks to access remote Flash storage efficiently. However, the deployment and migration of user-space frameworks are complicated. They not only do not support POSIX interfaces but also are user-aware. Besides, these frameworks are designed for cloud scenarios with sufficient CPU resources. Their remote access performance is still worse than local access for edge workstations with limited CPUs.

III. Performance Characteristics

We conduct experiments to investigate performance bottlenecks and optimization opportunities for existing remote storage access frameworks in edge intelligent workstations. The software/hardware configuration of experiments is introduced in Section V. Intel SSD DC P4600 (P4600) [16] is used as the target disk.

Latency. Figures 2a and 2b present the remote read/write latency of existing remote storage access frameworks. Flexible I/O (FIO) [3] workloads with different request sizes (4KB∼128KB) are used to collect evaluation data. The thread count and request depth of workloads are 1 and 4, and the I/O engine is libaio. *local* indicates

(a) Read latency breakdown (b) Write latency breakdown

Fig. 3: Remote read/write latency breakdown for *nvof-tcp*, *nvof-rdma*, and *nvof-offload*.

TABLE I: The size of data in a single storage request for applications in edge intelligent workstations.

Data Type	Data Size	Data Type	Data Size
Sensor data [40]	<10KB	Log file	<100KB
Device status	<10KB	Image [18]	<100KB
Calculation result	<10KB	Configuration file	<100KB

accessing local SSDs, and *nvof-offload* indicates the target offloading framework proposed in [26]. Latency values are normalized to *local*. We make an observation from Figure 2a that the remote access constructed by existing remote storage access frameworks has higher read/write latency than *local*. Specifically, the remote read latency of *nvof-tcp* is 1.1×∼4.2× higher than the local read when the request size is <128KB. The remote read latency is still 1.63× and 1.52× higher than the local read on average, even using *nvof-rdma* and *nvof-offload* frameworks. Similarly, the remote write latency (Figure 2b) of *nvof-tcp*, *nvof-rdma*, and *nvof-offload* is higher than the local write when the request size is <32KB. **Therefore, existing remote storage access frameworks cannot provide low-latency remote storage access for edge intelligent workstations.**

Throughput. The number of I/O requests processed per second (IOPS) is the metric for storage throughput. FIO workloads in latency experiments are used to collect the remote read/write throughput for *nvof-tcp*, *nvof-rdma*, and *nvof-offload* frameworks. The remote read/write throughput exhibits a similar trend to the remote read/write latency, as shown in Figures 2c and 2d. The remote read/write IOPS of *nvof-tcp*, *nvof-rdma*, and *nvof-offload* frameworks is reduced to 1/4 and 1/3 of the local access when the request size is <128KB/32KB. **The throughput observation reveals that existing remote storage access frameworks in edge intelligent workstations cannot exploit the high throughput of modern high-speed NVMe SSDs.**

It is worth noting that the latency and throughput penalties introduced by existing frameworks decrease with increased read/write size. The insight is that NVMe SSDs handle small-size read/write faster than software remote storage access stacks, resulting in remote access stacks being the bottleneck for small-size remote read/write. On the contrary, SSDs require more time to handle large-size read/write, which leads to the overhead of remote access stacks being negligible as the read/write size increases. Therefore, existing remote storage access frameworks are more suitable for large-size read/write scenarios in edge intelligent workstations. However, **the small-size read/write is a common I/O characteristic for practical applications in edge intelligent workstations**, as shown in Table I.

Latency Breakdown. We breakdown the read/write latency of 8KB FIO workload for *nvof-tcp*, *nvof-rdma*, and *nvof-offload* frameworks to investigate the performance bottleneck. As shown in Figure 3, *disk-lat* represents the read/write latency of the SSD, and *stack-lat* represents the latency of remote storage access stacks. It is evident that *stack-lat* accounts for >49% of remote read/write latency in *nvof-tcp*, *nvof-rdma*, and *nvof-offload* frameworks, which results in SSD having higher remote read/write latency than local access. Next, optimization methods and insights in Leopard for mitigating these overheads are discussed.

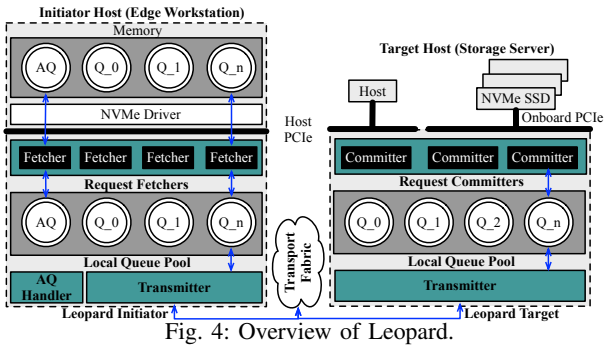


Fig. 4: Overview of Leopard.

IV. Leopard Design

A. Leopard Overview

We propose a hardware pass-through framework called Leopard. It consists of two SmartNICs, as shown in Figure 4. We customize them as Leopard Initiator and Leopard Target and connect them to Initiator Host and Target Host via PCIe. **Request Fetchers**, **Local Queue Pool**, **Admin Queue Handler (AQ Handler)**, **Transmitter**, and **Request Committers** are five novel accelerators. The processing of NVMe storage requests, including remote storage, is characterized by high density and high concurrency, as stated in the NVMe (Over Fabric) specification [28], [30]. FPGA is more suitable for concurrent tasks than traditional processors (such as x86 and ARM [2] CPUs). It also reserves the flexibility to customize hardware interfaces, including PCIe. Therefore, Leopard adopts FPGA-based SmartNICs instead of ARM-based SmartNICs [27].

Request Fetchers & Request Committers. Request Fetchers are implemented in Leopard Initiator. They parallelly fetch storage requests from Initiator Host memory using the direct memory access (DMA) engine of PCIe. It aims to minimize the fetching latency for remote storage requests as much as possible. Similarly, Request Committers are implemented in Leopard Target. They parallelly submit storage requests to NVMe SSDs using SmartNIC's onboard PCIe DMA engine. It aims to minimize the latency of remote storage requests reaching NVMe SSDs. The philosophy behind these accelerators is the potential parallelism between multiple NVMe request queues and multiple PCIe DMA channels. Specifically, multiple PCIe DMA channels in SmartNICs are used to parallelly fetch remote storage requests from multiple NVMe request queues in Initiator Host memory. They are also used to parallelly submit requests to multiple NVMe request queues in SSDs.

Local Queue Pool. Local Queue Pool is allocated in Leopard Initiator and Leopard Target to cache remote storage requests, aiming to construct multiple independent (queue-granularity) request processing pipelines. The Local Queue Pool in Leopard Initiator caches remote storage requests fetched from Initiator Host memory. And the Local Queue Pool in Leopard Target caches remote storage requests received from the Transmitter (Transport Fabric, Network). It consists of multiple isolated first-in-first-out (FIFO) buffers, corresponding to multiple NVMe request queues (Q_0∼Q_n) that Leopard Initiator exposes to Initiator Host. Leopard Initiator follows NVMe specification [30], thus each exposed NVMe request queue consists of a submission queue (SQ) and a completion queue (CQ), called SQ/CQ pair. Every two FIFOs are firmly bound to an SQ/CQ pair. One FIFO is used to cache pending requests submitted by the Initiator Host to SQ. Another FIFO is used to cache completion requests submitted by NVMe SSDs to CQ. The FIFO width is set to 512 bits for achieving compatibility with NVMe storage requests. The depth of FIFO is set to 1024 (1K) to construct request processing pipelines at queue granularity. Note that FIFOs are implemented using FPGA's on-chip memory that supports independent read/write. It aims to leverage parallelism in NVMe request queues and PCIe DMA channels.

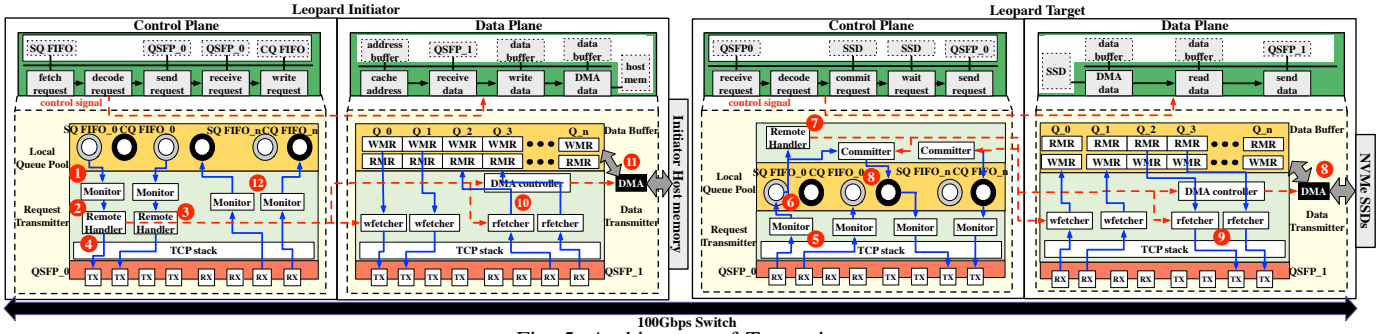

Fig. 5: Architecture of Transmitter.

AQ Handler. Initiator Host needs a dedicated software stack to implement remote storage access using existing frameworks. The software stack in edge workstations introduces performance overheads and CPU costs, as discussed in Sections III and II-A. AQ Handler disguises Leopard Initiator as a standard NVMe device compatible with the native NVMe driver, which eliminates remote storage access stacks for Initiator Host. In other words, AQ Handler is a customized NVMe controller. It allows Initiator Host's CPUs to simply submit remote storage requests to Leopard Initiator (via the native NVMe driver) for remote access without additional operations. The remote-access-related workflow is implemented by Leopard Initiator and Target. AQ Handler uses a workflow that follows the NVMe specification [30] to process NVMe admin requests submitted by the Initiator Host. NVMe admin requests are mainly used to manage and identify Leopard Initiator, such as creating and deleting NVMe request queues (Q_0∼Q_n). Therefore, admin requests submitted to the admin queue (AQ) are only cached to the corresponding FIFO in Leopard Initiator's Local Queue Pool, then processed by AQ Handler without being transmitted to Leopard Target.

Transmitter. Transmitter is the core accelerator for Leopard, which implements efficient hardware pass-through remote storage access. It not only accelerates storage and network stacks but also better utilizes multiple request queues in network devices and NVMe SSDs compared to existing solutions. Transmitter constructs a hardware pass-through queue-granularity parallelized and pipelined remote storage request processing flow between Leopard Initiator and Leopard Target, which eliminates CPU involvement. It mitigates software stacks and CPU overheads introduced by current remote storage access frameworks for Initiator and Target Hosts. Remote Handler and Monitor are its two hardware components. Remote Handler is used to implement the control plane for remote storage access (including remote storage requests and data). Monitor is used to poll FIFOs in Local Queue Pool or network receivers to fetch remote storage requests as fast as possible, thereby reducing latency. Next, we will discuss the detailed design for Request Fetchers, Request Committers, and Transmitter, which are closely related to remote storage access performance.

B. Design Details

Request Fetchers & Committers. The same number of Fetchers and Committers as NVMe request queues are implemented in Request Fetchers and Committers (Figure 4) to achieve queue-granularity fetching and submitting for remote storage requests. They exploit the parallelism of PCIe DMA channels in SmartNICs and NVMe request queues in SSDs by proposing independent hardware units (instead of multiple CPU cores). Fetcher and Committer consist of one Monitor and one DMA Controller, which are used to implement control and data planes for fetching and submitting remote storage requests.

Fetcher's workflow is as follows. **S1:** Monitor monitors the SQ of NVMe request queues in Initiator Host memory. It also monitors corresponding CQ FIFO in the Local Queue Pool of Leopard Initiator. **S2:** As soon as the Monitor detects a new remote storage (completion) request in SQ (CQ FIFO), it sends address information and control signal to the DMA Controller. **S3:** DMA Controller then manipulates PCIe DMA to copy remote storage requests from Initiator Host memory to corresponding SQ FIFO located in the Local Queue Pool of Leopard Initiator. Completion requests are copied from CQ FIFO to CQ of the corresponding NVMe request queue located in the Initiator Host memory.

The workflow of Committer is similar to Fetcher. The difference is that it implements queue-granularity NVMe request interaction with NVMe SSDs via onboard PCIe DMA in Leopard Target. It eliminates software stacks, as well as PCIe and CPU overheads for remote storage access in Target Host. We equip each SQ/CQ pair with a Fetcher and a Committer to fully utilize the parallelism between NVMe request queues. The independent Fetcher and Committer are also adopted within each SQ/CQ pair to achieve parallelized transmission for the SQ/CQ pair's internal requests.

Transmitter. Software stacks and limited CPU resources are the bottleneck for small-size remote read/write in edge workstations, as discussed in Sections III and II-A. Transmitter is proposed to further mitigate software stacks and CPU overheads for Initiator Host and Target Host. It implements hardware pass-through processing for remote storage requests and data to replace software remote storage access stacks. It also leverages parallelism among multiple NVMe request queues, multiple network channels, and multiple PCIe DMA channels to construct parallelized and pipelined workflows. Figure 5 depicts the architecture of Transmitter, which proposes a highly parallelized and pipelined processing flow. It is divided into a control plane and a data plane. Four full-duplex network (QSFP_0) channels are used in the control plane to transmit remote storage requests parallelly. Another four full-duplex network (QSFP_1) channels are used in the data plane to transmit data triggered by requests.

We use remote read to demonstrate the Transmitter's workflow. ①**:** In Leopard Initiator, independent Monitors poll corresponding SQ FIFO in the Local Queue Pool and notify the Remote Handler in the control plane if the SQ FIFO is not empty. ②**:** The Remote Handler fetches remote storage requests from the non-empty SQ FIFO. Note that multiple Remote Handlers are deployed to implement queue-granularity acceleration. ③**:** Remote Handler decodes the request's opcode field (OPC, byte 0). If OPC is the read operation, the Remote Handler decodes the target address and size of the data from the request. They are buffered into the corresponding DMA address buffer (in the DMA controller) in the data plane. The corresponding rfetcher in the data plane is also notified to poll the data receiving channel in QSFP_1. ④**:** Then, requests are sent to Leopard Target via the hardware TCP stack and dedicated channel in QSFP_0. Leopard adopts TCP for compatibility with most edge scenarios.

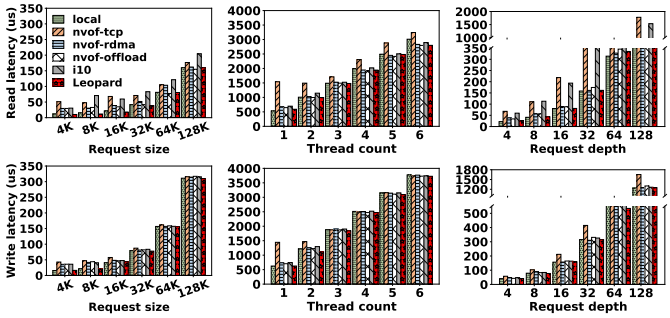
Leopard Target further processes remote storage requests. Specifically, ⑤**:** The multiple Monitors in Leopard Target's control plane poll four receiving channels in QSFP_0. ⑥**:** Monitors dispatch received requests to corresponding SQ FIFO in the Local Queue Pool. ⑦**:** The

TABLE II: Configuration of Initiator and Target Hosts.

Initiator Host (Edge Workstation)	AMD Ryzen 5 5600X 6-Core processor Mellanox ConnectX-5 [23] Western Digital (WD) HDD, 1TB DDR4 2666MHz, 16GB FPGA-based SmartNIC [35]
Target Host (Remote Cloud Storage Server)	Intel(R) Xeon(R) CPU E5-2680 processor Mellanox ConnectX-5 Western Digital (WD) HDD, 4TB DDR4 3200MHz, 64GB Intel SSD DC P4600 (P4600) [16], 2TB FPGA-based SmartNIC

TABLE III: Hardware cost & power of Leopard Initiator & Target.

	LUT	LUTRAM	FF	BRAM	Power (W)
Initiator	173719	10703	248981	536	16.67
	33.23%	6.64%	23.82%	54.47%	
Target	110721	10111	190547	386	14.19
	21.18%	6.27%	18.23%	39.23%	



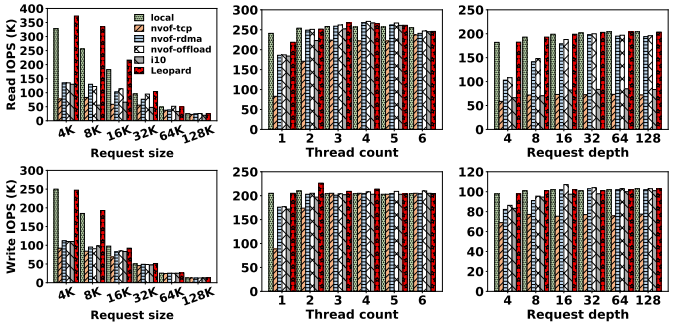
Remote Handler in Leopard Target's control plane fetches requests from SQ FIFO and parses OPC and data address fields. If OPC is the read operation, the Remote Handler utilizes the source address and size of the data to inform the DMA controller in Leopard Target's data plane. Besides, the Committer is also notified to submit requests to the corresponding request queue in SSD via onboard PCIe and wait for SSD's completion request. ⑧**:** The data will be read by DMA (manipulated by the DMA controller) from SSD to the memory region (RMR) of the corresponding SQ FIFO in the data buffer. The SSD's completion request is written to CQ FIFO by Committer and transmitted to Leopard Initiator by Monitor via QSFP_0. ⑨**:** Hardware TCP stack in Leopard Target's data plane encapsulates data in RMR into TCP packets and sends them to Leopard Initiator via the dedicated channel in QSFP_1.

Leopard Initiator then processes data. ⑩**:** The refetcher in Leopard Initiator receives data from the receiving channel in QSFP_1 and writes it to the corresponding RMR in the data buffer. ⑪**:** The data in RMR will be transferred by DMA to the target address (cached in Step ③) in Initiator Host memory. ⑫**:** Finally, the Monitor in the Leopard Initiator's control plane receives the completion request from the Leopard Target and writes it to the corresponding CQ FIFO in the Leopard Initiator's Local Queue Pool. Note that the data buffer is constructed using FIFO for correctness, which allows data to be processed in order of request submission.

The workflow for remote write is similar to remote read, but the data transmission direction is from Initiator Host memory to SSDs. We propose optimizing steps ①∼⑫ using queue-granularity parallelized and pipelined workflows, thereby accelerating the remote-access-related processing for storage requests and data.

V. Evaluation

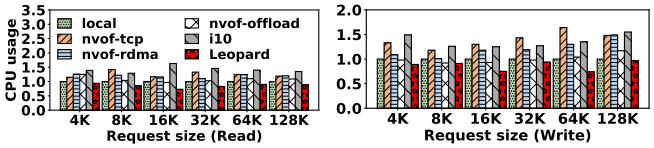
Hardware Setup. Two FPGA-based SmartNICs [35], one edge workstation (Initiator Host), and one cloud storage server (Target Host) are used to construct the testbed, as listed in Table II. The FPGA-based SmartNIC contains one Xilinx xczu19eg-ffvc1760-2-e FPGA core and several communication interfaces, such as PCIe and QSFP [25] (100Gbps). We implement the Leopard prototype on FPGA (Frequency 250 MHz) using Verilog. Two FPGA-based SmartNICs are implemented as Leopard Initiator and Leopard Target, respectively. They connect to the Initiator Host and Target Host via PCIe. PCIe is configured as Gen3×8 in our implementation. Leopard is also compatible with high version PCIe (Gen4 or Gen5). Besides, Target Host is equipped with a 2TB Intel SSD DC P4600 (P4600) to test remote access performance for Leopard and baselines. The Initiator Host and Target Host are connected to a 100Gbps switch via Mellanox ConnectX-5 (RDMA NIC), and P4600 is connected to the Target Host via rack PCIe for testing baselines. The Initiator Host and Target Host are connected to the 100Gbps switch via Leopard, and P4600 is directly connected to Leopard Target via onboard PCIe for testing Leopard.



(a) Request size (b) Thread count (c) Request depth

Fig. 6: Remote read and write latency comparison using FIO workloads, lower is better.

Software Setup & Baselines & Metrics. Ubuntu 20.04.4 LTS operating system with Linux kernel 5.10.73 is installed on the Initiator Host and Target Host. FIO (version 3.31) [3], RocksDB [37], and YCSB [6] are installed to generate evaluation workloads. All workloads are running on Initiator Host. We adopt the following baselines: 1) ***local***: This is local access performance obtained by directly accessing local P4600 on the Initiator Host. 2) ***nvof-tcp*** [31]: Software remote storage access framework using TCP. 3) ***nvof-rdma*** [29]: Software remote storage access framework using RDMA. 4) ***i10*** [12]: Software optimized *nvof-tcp*. 5) ***nvof-offload*** [26]: *nvof-rdma* with target offload. We adopt remote read/write latency, throughput, and CPU cost to evaluate performance.



Hardware Cost & Power. The hardware cost and power consumption of Leopard are directly proportional to the number of parallel request queues (workflows). However, edge intelligent workstations typically adopt devices with low cost and low energy to minimize the total cost of ownership (TCO). Fortunately, we find that excessive queues (workflows) in Leopard result in unacceptable channel arbitration overhead due to limited channels in SmartNIC's PCIe DMA and network interfaces. The arbitration overhead will compromise remote storage access performance. Leopard adopts 32 queues (workflows), which is less than the request queues within modern NVMe SSDs, but evaluation shows that it is sufficient to saturate modern SSDs. If faster SSDs are used in the future, Leopard's design can scale at queue granularity using sufficient FPGA resources to maximize SSDs' remote access performance. Leopard Initiator and Target only consume 29.54%/21.23% of FPGA resources on average (Table III), which is approximately $174.65/$125.66 in hardware cost. The power consumption of Leopard Initiator and Leopard Target is 16.67 watts (W) and 14.19W, which is lower than implementing remote storage access using CPUs (>100W).

Latency and Throughput. We use remote read/write latency and throughput metrics to compare Leopard with baselines. FIO is installed on the Initiator Host. It generates sequential read/write workloads with different request sizes (4KB∼128KB), different thread counts (1∼6), and different request depths (4∼128) to access SSD on the Target Host via Leopard and baseline frameworks. The I/O engine (ioengine parameter in FIO) is set to libaio. Existing remote storage access frameworks are unfriendly to small-size requests in edge workstations, as discussed in Section III. Therefore, the small-size workloads are adopted in experiments with different request sizes to present Leopard's improvements for edge workstations. Figure 6 presents the remote read/write latency. It is obvious that only Leopard enables remote read/write latency to be consistent with

(a) Request size (b) Thread count (c) Request depth

Fig. 7: Remote read and write throughput comparison using FIO workloads, higher is better.

(a) Remote read, lower is better (b) Remote write, lower is better

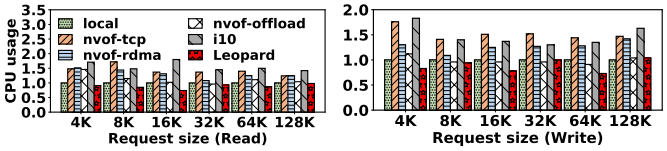


Fig. 8: CPU cost for remote read/write, normalized to ***local***.

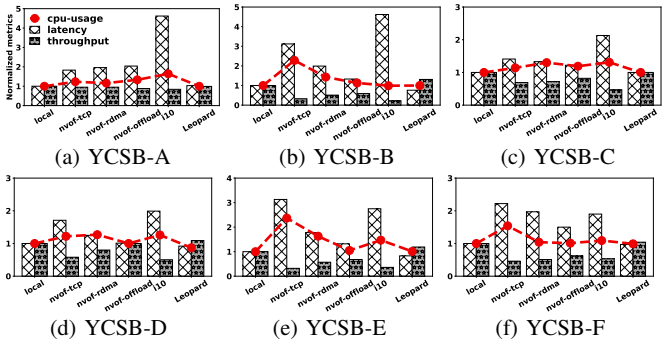
local read/write (***local***). Compared to baselines (***nvof-tcp***,***nvof-rdma***, ***nvof-offload***, and ***i10***), Leopard's remote read (write) latency for workloads with different parameters (request size, thread count, and request depth) is reduced by 2.59×, 1.75×, 1.66×, and 2.61× (1.49×, 1.34×, 1.36×, and 1.34×) on average. Leopard's remote read/write throughput is also better than baselines, achieving the same throughput as local read/write. The remote read (write) throughput of Leopard is 2.55×, 1.73×, 1.63×, and 2.60× (1.51×, 1.35×, 1.38×, and 1.36×) higher than baselines on average, as shown in Figure 7.

Leopard is more suitable for scenarios with small request sizes, according to Figures 6a and 7a. The response of SSD is fast in this scenario, causing existing complex remote storage access frameworks to become a bottleneck, as discussed in Section III. However, the small-size request is a typical remote storage access type for real applications in edge workstations (Table I). Leopard optimizes this bottleneck by (1) Customizing a highly parallelized and pipelined hardware pass-through workflow for fast remote storage access. (2) Integrating remote access tasks into FPGA-based SmartNIC to mitigate software layers and PCIe and CPU overheads for remote storage access. Therefore, Leopard is more suitable for edge workstations.



CPU Cost. Existing frameworks use multiple CPU cores to maximize the remote access performance for SSDs, as discussed in Section II-A. This not only introduces latency overhead but also incurs additional CPU cycles for edge intelligent workstations with limited CPU resources. We measure CPU usage in Initiator and Target Hosts for Leopard and baselines using FIO workloads with different request sizes (4KB∼128KB). The queue depth and thread count are 16 and 8. The I/O engine is set to libaio. Figure 8 presents the experimental results, which are normalized to ***local*** values for intuitive comparison. The CPU usage of Leopard is close to local access. Compared to baselines (***nvof-tcp***,***nvof-rdma***, ***nvof-offload***, **and** ***i10***), Leopard's CPU usage for remote read (write) is reduced by 2.90×, 1.58×, 1.33×, and 2.22× (2.22×, 1.76×, 1.41×, and 1.83×).

Figure 9 also presents the CPU usage in kernel space for Leopard and baselines. Leopard's read (write) CPU usage in kernel space is 1.64×, 1.50×, 1.28×, and 1.80× (1.74×, 1.45×, 1.13×, and 1.69×) lower than baselines. The advantage of CPU cycles for Leopard comes from two factors. (1) Leopard Initiator is compatible with the native NVMe driver. It allows Initiator Host's CPUs to simply submit remote storage requests to Leopard Initiator for remote access without additional operations. Leopard Initiator enables edge workstations to access SSDs on remote cloud storage servers as if they were accessing

(a) Remote read (b) Remote write

Fig. 9: CPU cost in kernel space for remote frameworks, normalized to ***local***, lower is better.

(a) YCSB-A (b) YCSB-B (c) YCSB-C

(d) YCSB-D (e) YCSB-E (f) YCSB-F

Fig. 10: Remote read/write comparison using YCSB workloads, all experimental values are normalized to ***local***.

local SSDs. (2) The processing flow (including storage and network) for remote read/write is handled by Leopard Initiator and Leopard Target without CPU intervention. Therefore, Leopard is more suitable for edge intelligent workstations with limited CPUs.

Realistic Workloads. The latency, throughput, and CPU usage (cpu-usage) of remote storage access for Leopard and baselines are collected using realistic workloads to evaluate the benefits of Leopard in real-world scenarios. The YCSB [6] workloads based on RocksDB [37] are used to collect evaluation metrics. YCSB is a widely used evaluation tool for storage systems. It can generate standard and customized realistic workloads. Figure 10 collects the remote access latency, throughput, and CPU usage for Leopard and baselines using standard YCSB-A∼YCSB-F workloads. YCSB-A∼YCSB-F are six different realistic workloads. They have different request types (read-only, write-only, mixed, read-modify-write, etc), different request sizes, different read/write ratios, different thread counts, and different request depths. All experimental values are normalized to ***local*** for intuitive comparison. As shown in Figures 10a∼10f, Leopard provides a remarkable optimization in remote storage access latency and CPU usage for YCSB-A∼YCSB-F, achieving an optimization of 1.09×∼6.04× and 1.03×∼2.34× compared to existing remote storage access frameworks. It also exhibits a 1.04×∼6.02× improvement for throughput. More importantly, Leopard provides the same latency, throughput, and CPU usage for remote storage access and local storage access. This experiment presents that Leopard effectively maintains remote storage access performance consistent with local access for realistic workloads in edge intelligent workstations.

VI. Conclusion

We present Leopard, an efficient hardware pass-through remote storage access framework based on SmartNIC for edge intelligent workstations. The end-to-end remote storage access workflow is formulated as multiple accelerators in SmartNIC's FPGA core. The AQ Handler helps Leopard adopt the native NVMe driver, thus eliminating the dedicated software stack. Request Fetchers, Request Committers, Local Queue Pool, and Transmitter construct a hardware pass-through remote storage access workflow using pipeline architecture. In the workflow, the concurrency of request queues, DMA channels, and network interfaces is fully utilized for fast remote access. The evaluation presents that Leopard provides lossless remote storage access for edge intelligence in edge intelligent workstations.

***Abstract*—Long-context inference has become a central focus in recent self-regressive Transformer research. However, challenges still remain in performing decode stage due to the memory bandwidth bottleneck of attention mechanisms and the substantial memory overhead associated with KV cache. Although attention sparsity has been proposed as a potential solution, conventional sparsity methods that rely on heuristic algorithms often suffer from accuracy degradation when applied to ultra-long sequences.**

To break through the dilemma between accuracy-performance and bandwidth-capacity, this work proposes DIAS, a distance-based irregular attention sparsity approach with processing-in-memory (PIM) architecture. DIAS employs approximate top-K attention (AKAttention) scores through graph-based search to improve inference efficiency while maintaining accuracy. Furthermore, a scalable tree-like PIM (TreePIM) architecture is introduced to achieve both memory capacity and bandwidth improvement by isolating enormous memory access for KV cache into the PIM units. Evaluations on various configurations of DIAS for Longbench with Llama3-405B models with 1M sequence length show up to 75 times speedup compared with the state-of-the-art LLM accelerator, with accuracy drop of less than 1%.

I. Introduction

Large Language Models (LLMs) built on the attention-based Transformer architecture [1] have demonstrated remarkable potential and achieved significant advancements across computer vision (CV) [2], natural language processing (NLP) [3], and automatic control [4]. Especially, emerging applications, such as long-term agency, retrieval-augmented generation (RAG) [6], and multimodal processing [7], underscores the growing demand for long-context LLM inference, with sequence length requirements increasing from approximately 1K to beyond 10M.

However, it is challenging to deploy Transformer-based LLM in long-context scenarios in terms of memory bandwidth and capacity. As shown in Figure 1 (a), GB-level KV cache has to be totally loaded to generate the next token, which results in serious memory bandwidth and memory capacity bottleneck. What's worse, the memory bandwidth and capacity is a dilemma in physic. Existing scale-out scheme for expansion is severely constrained due to inter-chip communication. which incurs significant performance degradation.

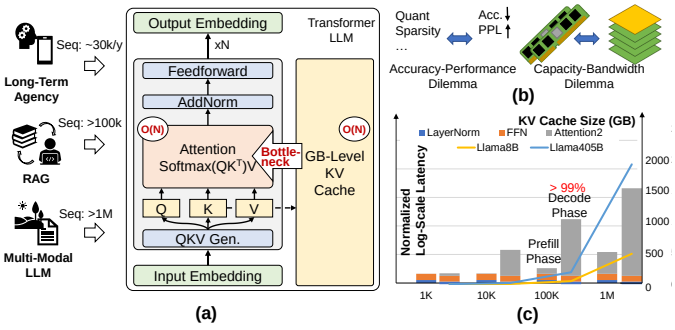

Fig. 1: The long-context LLM inference challenges illustration of (a) memory bandwidth bottleneck due to KV cache, (b) accuracy-performance and capacity-bandwidth dilemma, and (c) the latency breakdown and memory capacity trends.

Fortunately, various solutions for the long-context LLM inference have been proposed, including quantization [8] [9], speculative decoding [10] [11], alternative attention mechanism [12] [13], and attention sparsity [14] [15]. Quantization, while compatible with other techniques, inevitably leads to accuracy degradation, as shown in Figure 1 (b), and can result in significant fine-tuned knowledge loss in industrial LLMs. Furthermore, speculative decoding can accelerate inference by utilizing the multiple consecutive inference results of a small model. But this approach highly depends on the capacity of small models and could increase the decoding energy cost and delay. Alternative model architectures, such as Mamba [33] and TTT [34], have been proposed as potential replacements for Transformers. However, these emerging structures introduce significant information loss in long-text scenarios due to single hidden state compression. Thus far, sparsity exploitation remains the most promising and effective approach for addressing the memory-bond in long-context inference.

Numerous works have attempted to leverage the sparsity in attention computation shown in Figure 2. Recent work ToPick [14] could early eliminate the K cache retrieving by calculating the probability of attention score. However, the compression rates is still limited due to the pruning method. What's more, heuristic sparse methods like Window Attention [15], Stream LLM [16], H_2O [17] are proposed to discard part of KV cache based on different importance prediction strategy. For instance,

* : Both authors contributed equally to this research.

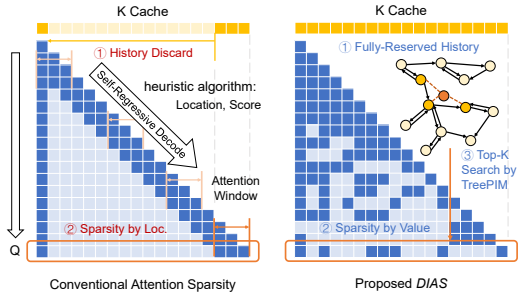

Fig. 2: Illustration of the bottlenecks of conventional attention sparsity [15] [16] and the innovations of proposed DIAS.

Window Attention only utilizes local context windows, which completely loss the history information. Other methods, such as infLLM [18], attempt to offload KV cache from GPU memory to CPU memory by selecting representative keys for different groups and retrive KV cache with look up table . Although these methods claim efficiency, there remains significant accuracy drop in ultra-long-context scenarios.

To tackle the aforementioned problems, we proposed DIAS, a distance-based irregular attention sparsity for long-sequence P/D separated transformer acceleration. As a software-hardware co-design solution, DIAS focuses on the bottleneck in decode phase of self-regressive LLM to break through the accuracy-performance and bandwidth-capacity dilemma. The innovations includes: (1) a spatially structured and dynamic updated representation of KV cache, (2) an effective attention sparsity computing method based on approximate top-K value to achieve performance improvement with accuracy maintaining, and (3) TreePIM architecture based on switches to achieve high bandwidth with large capacity. Notably, this work is compatible with recent researches on attention modifications, such as decoder-decoder model [20], razor attention [21], making DIAS applicable widely. Additionally, this method could be further researched and utilized in ultra-long-context scenarios to tackle attention noise problems and the bottleneck of model pretraining length, both of which have emerged as central challenges in the field of LLM algorithms

The major contributions of this paper are as follows:

- A distance-based irregular attention sparsity algorithm AKAttention in attention computing with almost no accuracy drop to address the memory bandwidth bottleneck due to KV cache retrieve.
- An effective hardware architecture TreePIM is presented for balancing the gap between memory bandwidth and capacity by processing-in-memory to address the dilemma between memory capacity and bandwidth.
- Rich experiment results shows that the proposed DIAS achieves about x25.3-171 speedup and x1.7-5.0 energy efficiency compared with conventional works.

II. Background

A. Attention Mechanism

The key contribution of Transformer [1] is the self-attention mechanism, which enables the model to capture long-range dependencies between elements in a sequence, thereby enhancing its ability to model complex patterns.

As is shown in Figure 1, in a typical Transformer layer, each input token undergoes a series of transformations through multiple sub-layers, the most important of which is the multi-head self-attention mechanism. For a given input sequence of tokens, represented as embedding $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n]$, self-attention model computes as follows:

$$O = softmax(\frac{XW_Q \cdot (K_{Cache}, XW_K)}{\sqrt{d_k}}) \cdot (V_{Cache}, XW_V)$$

It could be found that attention computing is a typically memory-intensive application. The memory access and computation complexity grows linearly with sequence length, which results in serious performance bottlenecks.

B. ANNS Algorithms

Approximate nearest neighbor search (ANNS) algorithms are essential for accelerating large-scale search tasks by efficiently identifying approximate neighbors in high-dimensional spaces. These methods are particularly valuable in applications like similarity search and are widely used in large-scale machine learning systems, such as recommendation system[li2019approximate].

ANNS algorithms have been extensively researched, with each approach offering distinct advantages suited to different scenarios. Well-established methods such as KD-Tree [23], Product Quantization (PQ) [24], and Inverted File (IVF) [25] are widely used for efficient nearest neighbor search. Graph-based methods, however, are considered state-of-the-art for ANNS due to their high efficiency and accuracy. Hierarchical Navigable Small World (HNSW) graphs [26], for example, is one of the most effective and widely used graph-based ANNS methods. More recently, CAGRA [27] has emerged as an advancement over HNSW. CAGRA is designed to leverage the parallel processing capabilities of GPUs, achieving substantial improvements in speed and scalability compared to traditional CPU-based approaches.

C. Processing-in-Memory (PIM) Architectures

Processing-in-Memory (PIM) architectures have become a key solution for reducing data movement in data-intensive tasks. In Transformer models, PIM approaches like ReTransformer [28] use ReRAM-based memory to speed up attention calculations, while TransPIM [30] combines PIM with High Bandwidth Memory (HBM) for faster processing. More recently, AttAcc [36] and NeuPIMS [37] have delved into architecture design and in-memory parallelism. Furthermore, SpecPIM [38] leverages a PIM architecture to speed up speculative decoding in language models.

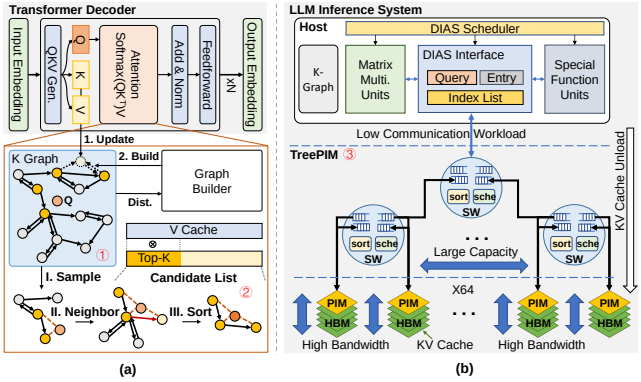

Fig. 3: Proposed DIAS: (a) irregular attention sparsity based on top-K score search algorithm, and (b) TreePIM architecture for graph-based sparsity attention acceleration.

For Approximate Nearest Neighbor Search (ANNS), PIM architectures like NDSearch [29] and Pyramid [31] leverage near-data processing to optimize graph traversal, introducing different designs in dataflow, hierarchy and memory management methods. These PIM designs are critical for scaling Transformer models and ANNS tasks in large applications, providing high throughput and reduced energy costs.

III. Proposed Work

A. Overall Architecture DIAS

The overall architecture is depicted as Figure 3. The P/D separation technique is adopted in this work to focus on the decode phase of self-regressive LLM. This work proposed (1) graph-structure dynamic-updated K Cache, (2) irregular attention sparsity based on top-K attention score search, and (3) tree-like PIM architecture for isolating the high data communication into the separated PIM units to achieve both large memory capacity and high bandwidth.

Firstly, a K-graph is built based on K Cache during the prefill stage on the host device. While the large KV cache is unloaded to the PIM device. At the costly decode stage, new query, key, and value vectors are computed on host by matrix multiply unit (MMU). Then, DIAS scheduler would iteratively generate and dispatch query batches based on the K-graph. Switch units (SW) are organized as a binary tree to support scalable capability and will route query batches to corresponding PIM units. The PIM units effectively compute the inner production benefited with high parallelism and DRAM bandwidth, while inner product results will be gathered to Host by SWs and sorted with parallel bitonic sort algorithm. After several iterations, Top-K attention score of $softmax(QK^T)$ will be calculated. and finally be scattered to the PIM unit to complete the sparse attention computation with V Cache.

Moreover, graph update is also performed at the same time. Graph update is performed on host and KV vectors are uniformly assigned to PIM units to keep TreePIM balance and highly utilized. Both operations are time-overlapped and hidden from the attention computation part.

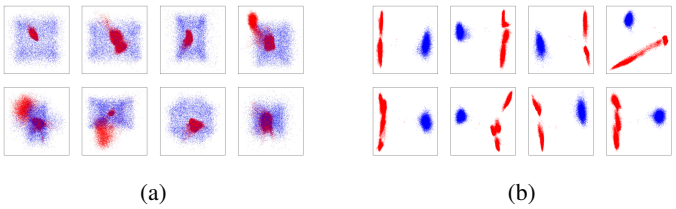

Fig. 4: Illustration of distribution on (a) separated dims, and (b) PCA with red refer to query and blue refer to key.

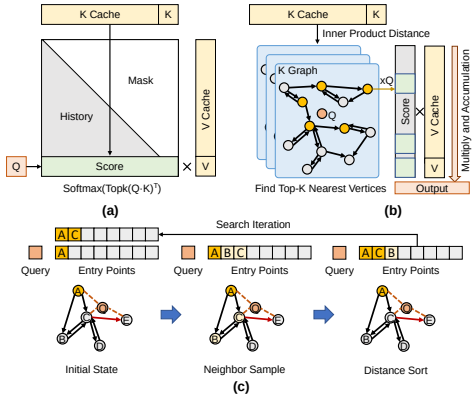

Fig. 5: Distance-based sparsity attention computing (a) principle, (b) illustration of the method, and (c) workflow.

The proposed DIAS achieves an $O(1)$ complexity and constant memory access when generating a token in Transformer-based LLMs. In contrast, conventional solutions generate one token in the conventional Attention layer with a complexity of $O(L)$ and increasing memory access, making the total complexity of generation $O(L^2)$, where L represents the sequence length.

B. AKAttention Algorithm

1) Theoretical Analysis: Figure 8 visualizes Llama3.1 as a sample of query, and key distributions. It shows disperse key vectors and centralized query vectors, which motivates the sparsity attention by ignoring the unrelated key cache. In contrast to conventional given keys pruning methods, this work proposes a graph-based technique to search the top-K related key cache for each query. Considering the attention score $S = softmax(QK^T)$, the relativity between query and key cache could be represented as the inner product distance.

As shown in Figure 5(b), with the transitivity of inner product, a graph built by key cache (K-Graph) could be constructed with inner product distance to represent the relativity between tokens and perform efficient attention computation with graph based ANNS algorithm integrated in work flow.

2) Initialization: The K-graphs of AKAttention is initialized in the prefill stage. Redundant edges in K-graph is pruned motivated by CAGRA [27] using detourable route counts, making each vertices with a fixed out-degree to fully utilize the parallelism. The entry points are set to recent visited or

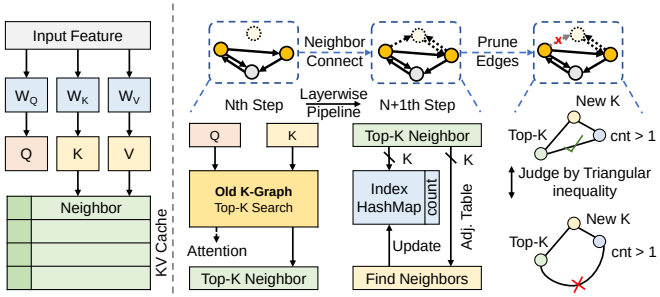

Fig. 6: Dynamic K-Graph update method in the proposed AKAttention.

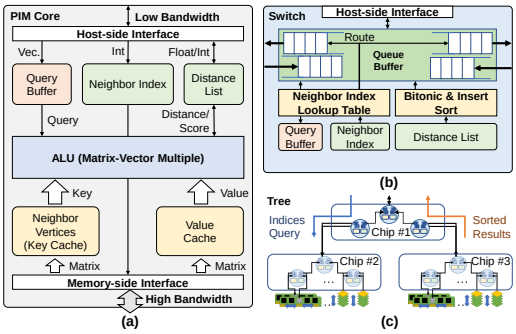

Fig. 7: Circuits design of (a) processing-in-memory unit for effectively sparsity attention computing, and (b) switch unit for (c) dynamic scalable capability.

updated vertices cached on host, while generated KV cache are uniformly offload to TreePIM as interleave or random mode.

3) AKAttention Workflow: Figure 5(c) shows how AKAttention finds the top-K attention scores after the new key, value, and query generation:

At the first step of iteration. AKAttention computes the inner product between the entry points of K cache and the new query. The results will be sorted and the top-K largest keys will be reserved. At the second step of iteration, the neighbors of the reserved keys in the K-graph is sampled from key graph as the new entry points.

After reaching the maximum number of iterations, AKAttention will compute the attention scores by softmax the inner production results and multiply with the corresponding value cache to generate the final attention computing results.

Notably, the smallest value in top-K queue is cached in the host to prune useless candidates and their inner product result.

4) K-Graph Dynamic Update: The dynamic update method for K-graph is illustrated as Figure 6.

During the decode phase, the new key in K-graph is firstly connected to top-K neighbors, which is searched together with the new query in the AKAttention. Then detourable routes are counted using the same criteria in proxy graph initialization and edges with the most detourable routes are pruned. With index hash map, this process is performed $O(1)$ complexity, which could be fully parallel among different layers.

The detourable criteria used in AKAttention is: $(e_{X\to Z}, e_{Z\to Y})$is a detourable route if $\max(w_{X\to Z}, w_{Z\to Y}) < w_{X\to Y}$

C. TreePIM Architecture

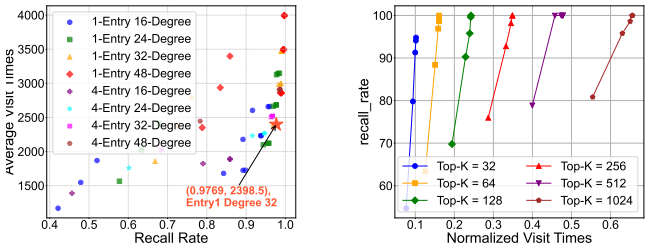
1) TreePIM Structure: The proposed AKAttention provides an approach to maximum utilizing the sparsity in attention computing. Furthermore, an processing-in-memory architecture TreePIM is proposed to cope with the dilemma between the memory bandwidth and memory capacity.

As depicted in Figure 7, TreePIM is a tree-like scalable PIM architecture utilizing the relatively small communication cost of sending indices and inner production results in AKAttention to achieve ultra high memory bandwidth with scalable large memory capacity in AKAttention computation. TreePIM is composed by PIM devices and switches while switches connect in a tree-like mode while the PIM devices are organized as leaves.

The low-cost indices and inner production results is passed through the switch tree, where the high-bandwidth key-query inner production are performed parallel in PIM devices, boosting the total memory bandwidth in the system level.

Also, TreePIM is internally flexible with tree-like topology, meeting the large variation of memory budget in different inference scenarios ranging from 8B Model 10k tokens to 405B Model with 10M tokens.

2) PIM Unit: The PIM unit used in this work shows as Figure 7(a). As only inner product and weighted sum are involved in PIM computation, the proposed PIM unit is relatively simple, resulting in small area and energy overhead.



When the PIM unit receives query vectors and entry point indices, query vectors are cached in the query buffer and reused in the following top-K search iterations. PIM utilizes high bandwidth communication to read the KV cache vectors from memory and compute inner production, then send the lightweight result back through switches.

3) Switch: The switch unit shows as Figure 7(b), consisting of lookup tables and sort units. When a switch unit receives packages from its father node, it redirects the package to left or right according to the lookup tables. The package will be passed to both left and right if the lookup tables miss. The lookup table is dynamically updated using the return results from its left son and right son.

The sort part works when results are returned from left son and right son. In switch, high parallelism sort is performed utilizing the bitonic sort algorithm. Insert sort is performed if a switch is connected to PIM unit to make a bitonic sequence.

4) Workload Balance: To deal with different scenarios, '-S', '-L', '-LL' memory manage modes are proposed.

S mode is designed for relatively small KV cache. In the S mode, graph structure and location of each key are stored on host. In this scenario, each package is assigned with a certain target dram and switch could transfer based on it. And sampling is conducted on host which alleviate the communication cost between switch.

(a) (b)

Fig. 8: (a)Top-K search average retrieved vertices and corresponding recall rate on different numbers of search entry and graph degrees (b) Analysis of recall rate on different iteration times and top-K setup.

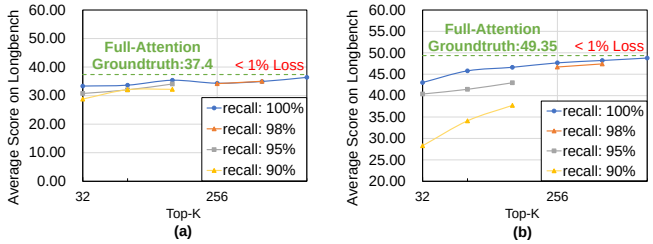


Fig. 9: Performance variation with top-K and recall rate of Longbench on (a) Mistral-7B, and (b) Llama3.1-8B.

L mode is designed for larger KV cache size. In L mode graph structure is stored in TreePIM, and retrieved each time with indices and inner product results. Only the neighbor lists of updated top-K vertices and top-K vertices for new generated key vector are stored on host, which will be used for sampling and update in next layer computation respectively.

In LL mode, location table of each key are also abandoned to alleviate memory cost. Lookup table is used to instruct transfer process in switch and candidate broadcast could lead to more transfer cost.

Notably, KV pairs are uniformly assigned to the DRAM devices in TreePIM with interleave or random method. This mechanism ensures load balancing and system efficiency.

IV. Experiment

A. Experiment Setup

1) Software setup: PyTorch is used as the Transformer-based LLM framework for the tasks inference of the proposed DIAS architecture on 8 NVIDIA A100. The proposed AKAttention is adopted as the attention sparsity mechanism. The LLM structure used in experiments is the widely used Llama3.1 and Mistral. All models are well pretrained large model. To evaluate the advantages of AKAttention in long-context scenario, the Longbench [32] is selected as benchmark, which includes 21 datasets in different scenarios. The datasets contains prompts with average length approximate to 10K, and maximum length up to 40k, which is fairly evaluated

TABLE I: System-Level Performance Comparison

	DIAS (This Work)	Vanilla	Window Attention	ToPick DAC'24
Config	4 * 16 32GB HBM	HBM-PIM		16GB HBM2
Model&Seq Len	Llama3.1-405B&1M			
Acc. Drop	<1%	Full	>30%	Negligible
Throughput (Token/min)	461.5	2.705	45.801	6.21
Energy Eff. (Token/kJ)	1.7	0.42	4.1	1.68
Speedup	**171.7**	1	16.9	2.3

the accuracy impact of different attention sparsity methods in varied long-sequence LLM application scenarios.

2) Hardware setup: The performance of PIM units and switch units in TreePIM architecture are based on DC simulations in a 28nm CMOS process. The memory and peripheral latency and energy consumption are obtained from commercial memory and bus standard, DDR, HBM, and PCIE. In the system-level experiment, two configurations of DIAS are used for Llama3.1-8B decoding from 100k tokens scenario and Llama3.1-405B decoding from 1M tokens scenario. In 100k-8B model scenario, DIAS decodes with top-1K tokens utilizing 8-PIM-units 3-level TreePIM managed in S mode. For the other scenario, DIAS decodes using top-3K tokens with 4 channel of 16-PIM-units 4-level TreePIM managed in L mode.

3) Baseline setup: In the system evaluation, vanilla is assigned with conventional attention mechanism and typical loop-reduced-based scale-out architecture. TreePIM-Only performs conventional attention mechanism in TreePIM architecture, and AKAttention-Only performs AKAttention with conventional architecture. DIAS denotes the proposed design combined with AKAttention and TreePIM. The software evaluation compares the accuracy on the proposed AKAttention of 128-top-K and 1k-top-K with previous attention sparsity methods: Streaming LLM [16], InfLLM [18], Infinite [35], H2O [17]. The system-level performance is compared with vanilla, slide window attention [35], and SOTA LLM accelerating architecture ToPick [14] utilizing retrive pruning.

B. Experiment results

1) Top-K retrieving analysis: Figure 8a shows the relationships between average number of retrieved vertices in searching and the corresponding recall rate in AKAttention of different configurations. It could be found that there is a significant increase in recall rate as out-degree of the K-graph grows, which is useful for improving the inference accuracy with attention sparsity. However, the average retrieved vertices, which represents the overhead of AKAttention also increased. On the other hand, 1 entry for 1 top-K out performs 4 entry in both recall rate and efficiency. Considering the trade-off between performance and accuracy, this work suggests the use of 1-Entry 32-Degree to achieve the best system-level throughput with negligible accuracy drop.

Further, analysis on the selection of top-K is discussed in Figure 8b. It shows that the proposed AKAttention in DIAS could achieve over 99% recall rate on most of the top-k based

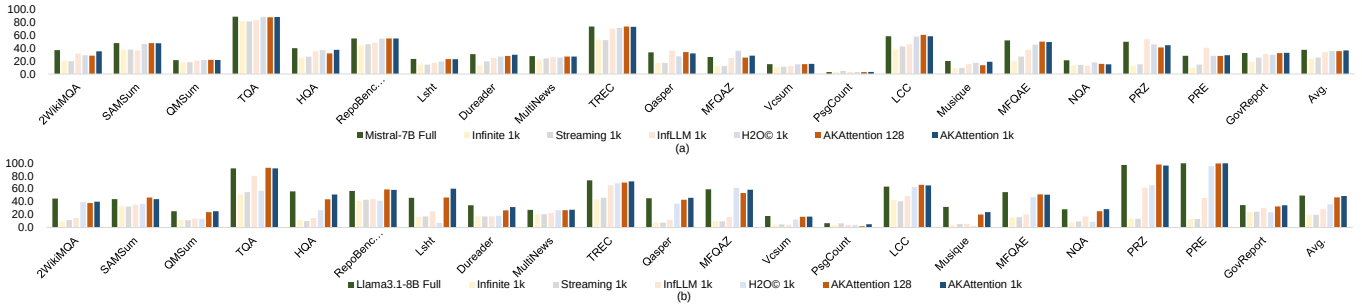

Fig. 10: Accuracy comparison between the proposed DIAS and conventional sparsity methods on Longbench with (a) Mistral-7B, and (b) Llama3.1-8B.

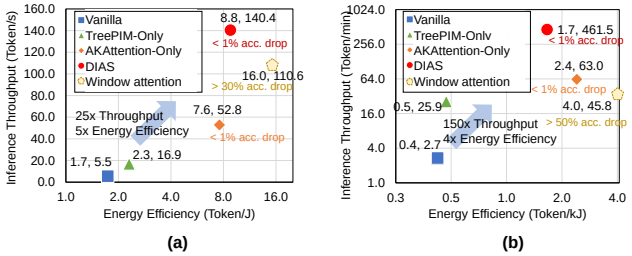

Fig. 11: System-level inference throughput and energy efficiency simulation results with (a) 100k seq len on Llama3.1-8B, and (b) 1M seq len on Llama3.1-405B.

on the previous configuration. In this work, the selection of top-K is a configurable parameter that depends mainly on the accuracy and performance needs of the tasks. As shown in Figure 9, an accuracy drop less than 1% could be achieved on both Mistral-7B and Llama3.1-7B, with a proper top-K.

2) End-to-end accuracy evaluation: Figure 10 shows the accuracy comparison between the proposed AKAttention in DIAS and the conventional sparsity methods on the long-context dataset Longbench. As shown in the figure, the proposed AKAttention achieves less than 1% accuracy drop or even better on most tasks in Longbench even with the top-128 setup configuration, which is much smaller than the other methods that could lose more than 30% of accuracy.

3) System-level performance comparison: Table. I shows the performance comparison with conventional architecture and the prior SOTA ToPick [14]. Despite extreme energy efficiency of Window Attention, its accuracy degradation in long-sequence scenarios is lethal. ToPick achieves about 2x efficiency improvement by employing prediction in K cache retrieving. However, the improvement is still limited due to the constraint of the possibility calculation.

Fig.11 visualize the performance comparison between various scheme. In 1M tokens Llama3.1-405B scenario, DIAS achieves about 170x speedup and 1.7x energy efficiency improvement. While in 100k tokens Llama3.1-8B scenario, DIAS achieves 25x speedup and 5x energy efficiency improvement. Compared with window attention algorithm of over 30% accuracy loss, the proposed DIAS effectively utilizes the sparsity in attention with less than 1% accuracy degradation. DIAS shows great potential on long-context LLM inference and could be compatible to many other techniques.

V. Overhead Discussion

Although this work achieves an extremely high throughput improvement using a Top-K based irregular sparse attention mechanism, a large number of inter-switch transfers become a new bottleneck. inter-switch transfers k cache indices with a relatively small amount of data. However, the bandwidth of switch units remains a bottleneck under the scalability constraint due to the low dimension of each header in the current large model architecture, which is only 128. There are several potential mitigation schemes for this problem, including expanding hidden size of each head, index list compression and packetized fetching of multiple headers. These will be further investigated in the future work.

VI. Conclusion

In this paper, a scalable, high-throughput PIM architecture DIAS for long-context LLM inference is proposed to deal with the memory bandwidth bottleneck in attention computing. DIAS utilizes approximate near neighbor search (ANNS) to find the top-K relative key cache with the given query, which greatly alleviates the memory bandwidth challenges. On the one hand, AKAttention only needs to fetch a small portion of the key cache, reducing the total communication volume. On the other hand, TreePIM isolates the high-bandwidth key retrieving into the PIM region with scalabilty. The communication inter-chip is reduced by hundreds times compared with conventional loop-reduced scale-out architecture. The system-level evaluation shows that the proposed DIAS achieves up to 75 times speedup compared with the SOTA LLM accelerator, with less than 1% accuracy degradation.

***Abstract*—This paper presents a novel covert timing channel (CTC) that enables a malicious entity to exfiltrate data from a benign cloud FPGA user without requiring dedicated outgoing messages from the cloud FPGA, minimizing the detection risk by both the victim and the cloud service provider. The proposed CTC exploits the handshake signals of the Advanced eXtensible Interface (AXI) protocol and inter-packet delay of the Internet to establish the CTC from a cloud Field-Programmable Gate Array (FPGA) to an off-cloud computer. This paper analyzes the bit-error rate (BER) of the AXI-based CTC under varying conditions and demonstrates its effectiveness in truly enabling remote power analysis attacks on cloud services, such as Amazon Web Services Elastic Compute Cloud (AWS EC2). The proposed CTC achieves a BER as low as 0.01988%.**

***Index Terms*—Covert Timing Channels, Cloud FPGA, AXI Protocol, Remote Power Analysis Attacks.**

I. Introduction

Field-Programmable Gate Arrays (FPGAs) are increasingly deployed in cloud environments, vitalizing the importance of investigating remotely deployable hardware-level security threats. Cloud FPGA services, such as Amazon Web Services Elastic Compute Cloud (AWS EC2) F1 instances, provide users with FPGA resources in a virtual environment, restricting direct user interaction with peripherals for consistency and security. In AWS EC2 F1 instances, the Advanced eXtensible Interface (AXI) protocol [1] manages communication between the AWS-provided shell [2], which controls peripherals, and the user-generated custom logic circuit.

This paper introduces, for the first time, a covert timing channel (CTC) [3] that enables data exfiltration from a cloud FPGA user, without requiring dedicated outgoing messages from the cloud FPGA. The proposed CTC is composed of two phases. In the initial phase, the CTC leverages the handshake signals of the AXI protocol to covertly transfer data from a cloud FPGA to an off-FPGA resource. In the second phase, it exploits inter-packet delays over the Internet to continue the covert transfer from the cloud resource to an off-cloud computer, creating a CTC from the cloud FPGA to the off-cloud computer. To demonstrate the threat posed by the proposed CTC, power consumption data gathered from a cryptographic circuit deployed on a cloud FPGA are exfiltrated to an off-cloud computer, where it is analyzed to extract the secret key of the cryptographic circuit. Moreover, this paper evaluates the efficacy of the CTC by analyzing the bit-error rate (BER) of the proposed CTC under varying design and operational conditions. Hence, the CTC presented in this paper poses a significant security risk to benign cloud FPGA users, exhorting users to take preventive measures.

Paper Contributions:

- Presents the first covert communication channel to exfiltrate data from a cloud FPGA without requiring explicit outgoing messages from the FPGA.
- Demonstrates the possibility of exploiting the handshake signals of the AXI protocol to establish a CTC on an FPGA.
- Signifies the importance of CTC to fully realize a remote power analysis (RPA) attack [4], emphasizing the implications for cloud FPGAs and their users.
- With substantial experimentation, analyzes the effectiveness of the CTC with respect to BER under design and operating condition changes.

Paper Organization: The rest of this paper is organized as follows. Section II provides key background knowledge for understanding this paper, while Section III discusses related works from the literature. The assumed threat model is detailed in Section IV. Section V presents a performance and effectiveness evaluation of the proposed CTC while the subsequent Section VI presents the design of signal processing techniques associated with the CTC. Section VII concludes this paper.

II. Background

Architecture of AWS EC2 F1 Instances: AWS EC2 F1 instances allow the deployment of FPGA-based hardware accelerators on cloud FPGAs. Each AWS EC2 F1 instance includes virtual central processing units (vCPUs) running a general-purpose operating system and FPGA cards implementing user-defined custom hardware accelerators. Configuring an FPGA on an AWS EC2 F1 instance requires loading an Amazon FPGA Image (AFI) onto the FPGA. First, the users are required to compile the custom logic circuit to an intermediate design checkpoint (DCP), and then submit the DCP to AWS to perform design rule checks (DRCs). A DCP that passes all the DRCs, conducted by AWS, is transformed into an AFI by wrapping the custom logic circuit of the DCP with an AWS-designed shell [2]. The shell implements the interfaces for FPGA external peripherals, PCIe, DRAM, and interrupts [2]. User interactions with PCIe and DRAM are to be conducted through the shell interfaces, which are implemented using the AXI protocol [2].

AXI Protocol: AXI protocol is an on-chip interconnect specification [1] that utilizes five unidirectional channels, namely Write Address (AW), Write Data (W), Write Response (B), Read Address (AR) and Read Data (R). Each AXI channel uses a pair of handshake signals to indicate the readiness of the endpoints for a data exchange. The source asserts the VALID signal when it has loaded valid data onto the AXI connection. The READY signal is asserted by the destination when the destination is ready to accept incoming data. In this manner, the handshake allows both endpoints to control the rate of data exchange on an AXI channel and thereby control the rate of data exchange on the AXI connection.

In the AXI protocol, a transfer refers to a sequence of signals that perform a data exchange with a single handshake. A transaction refers to a sequence of transfers that begins with an address transfer, followed by one or more data transfers. In a write transaction, a response transfer follows all the data transfers.

Correlation Power Analysis (CPA): CPA is a statistical method to analyze power measurements to extract the secret key of a cryptographic module [5]. In CPA, the attacker partitions the secret

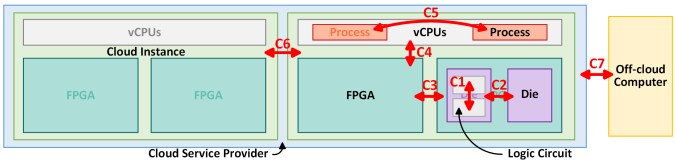

Fig. 1. Covert Communication Channels in Cloud Context

key into bytes, models the power consumption for each byte guess and calculates correlation between observed and modeled power consumption for each one of the byte guesses [6]. With sufficient observations, the correlation factor of the correct guess stands out, revealing the secret key.

Low-Density Parity-Check (LDPC) Codes: LDPC is a scheme of error-correcting codes designed to recover errors caused by transmission over noisy channels [7]. An LDPC code is defined by a parity-check matrix, typically generated randomly under certain constraints. When decoding using an LDPC code, the parity-check matrix is used to iteratively refine an initial guess of the error-correct output for a predefined number of times.

III. Related Work

The schematic in Fig. 1 depicts various covert communication channels implementable in a cloud service hosting FPGAs. The bidirectional arrow labeled C1, in Fig. 1, represents a covert communication channel between two disjoint logic circuits on an FPGA die within a cloud FPGA. A covert communication channel between two dies, also known as Super Logic Regions (SLRs), within an FPGA is represented by the bidirectional arrow labeled C2, in Fig. 1. Similarly, the bidirectional arrows labeled C3, C5 and C6, in Fig. 1, correspondingly illustrate covert communication channels between two FPGAs within a cloud instance, two vCPUs within a cloud instance and two cloud instances within a cloud service.

The covert communication channels represented by C4 and C7, in Fig. 1, are fundamentally different from the other covert communication channels due to the asymmetry of the endpoints. The upward C4 covert communication channel, as illustrated in Fig. 1, requires a transmitter on the FPGA and a receiver on vCPUs, while the downward covert communication channel requires the reversed endpoint configuration. Thus, a covert communication channel that is designed to infiltrate data to a cloud FPGA fails to exfiltrate data from a cloud FPGA. In C7, the leftward covert communication channel has the transmitter implemented on an off-cloud computer and the receiver implemented within the cloud service provider. Conversely, the rightward C7 covert communication channel features a transmitter within the cloud service provider and a receiver on an off-cloud computer.

Giechaskiel et al. [8] demonstrated a covert communication channel exploiting crosstalk between adjacent long wires in an FPGA. A malicious entity capable of routing a long wire next to a lengthy piece of wire belonging to an unsuspecting victim residing on an FPGA could exfiltrate data from the victim by using crosstalk-induced signal propagation delay variations [8]. This methodology [8] enables covert communication between two logically isolated circuits deployed on an FPGA. Gnad et al. [9] presented a voltage-based covert communication channel that exploits the power delivery network (PDN) of the FPGA. In this method [9], the malicious user deploys power wasters to modulate data into voltage fluctuations that occur on an FPGA and capture the voltage fluctuations using a logically isolated circuit. Both of the above methods [8], [9] illustrate implementations of the C1-labeled covert communication channel in Fig. 1.

Using voltage fluctuations that traverse the PDN of an FPGA, Giechaskiel et al. [10] established a covert communication channel between the SLRs of an FPGA. The authors [10] demonstrated the deployment of the covert communication channel in Amazon and Huawei cloud computing services, achieving a minimum bandwidth of 4.6 Mbps and an accuracy over 97.6%. Covert communication channels with similar capabilities are represented by C2 in Fig. 1.

Giechaskiel et al. [11] further demonstrated a methodology to exploit a shared power supply unit to construct a covert communication channel capable of infiltrating data into a cloud FPGA from a central processing unit (CPU), a graphics processing unit (GPU) or another FPGA. The authors [11] modulated the data as voltage fluctuations induced by power-wasting techniques, and demonstrated that induced voltage fluctuations are observable from an FPGA sharing the power supply unit with the component inducing voltage fluctuations. As per Fig. 1, the FPGA to FPGA covert communication channel [11] fits category C3, the transmitter being a power waster circuit constructed on an FPGA and the receiver being a voltage sensing circuit constructed on another FPGA. The CPU to FPGA covert communication channel [11] implements the C4 covert communication channel in the downward direction, as shown in Fig. 1, where CPUs adjust the load, thereby the instantaneous power, to transmit information while voltage sensing circuits on FPGAs measure the voltage fluctuations to receive covertly transmitted information.

Over several decades, using response time as a covert communication channel has been investigated by researchers. In 1987, Girling [12] demonstrated the use of inter-packet delay of a local area network (LAN) to establish a covert communication channel; a concept later applied in software-defined networks (SDNs) [13] and the Internet [14]. Lee et al. [14] demonstrated a covert communication channel spanning several thousand miles over the Internet, achieving 81 kbps bandwidth and less than 10% BER using a Software-defined Network Interface Card (SoNIC) [15]. In FPGA-equipped cloud instances, a SoNIC can be constructed within the FPGA, which can be exploited as proposed by Lee et al. [14] to implement C7 in Fig. 1. Ristenpart et al. [16] and Pessl et al. [17] have proposed techniques that implement the covert communication channel labeled C6, in Fig. 1. Ristenpart et al. [16] exploited the behavior of caches, while Pessl et al. [17] exploited the addressing mechanism used in Dynamic Random Access Memory (DRAM) to exfiltrate data from one cloud instance to another cloud instance that reside on the same physical computer. Alagappan et al. [18] developed a covert communication channel between CPU processes, represented by C5 in Fig. 1, utilizing power governors of a CPU to covertly modulate data into the CPU operating frequency, achieving up to 20 bps.

In the literature, covert communication channels that implement the upward, as illustrated in Fig. 1, covert communication channel C4 (FPGA to vCPU) are scarce and often tied to specific attack scenarios. Purnal et al. [19] exploited the behavior of CPU caches to construct an FPGA to the CPU covert communication channel. This method [19] uses a malicious process, running on the CPU, to prime the caches by loading specific symbols, which the FPGA then selectively overwrites based on the information to be exfiltrated. Finally, the malicious process measures the read times, revealing the symbols overwritten by the FPGA. The authors [19] achieved a 264 kbps bandwidth with a 1. 43% BER and also claimed that their proposition is less detectable to runtime analysis as the FPGA design belonging to the malicious user can rapidly overwrite symbols written by the malicious process, without affecting the runtime of a process.

Despite the covert communication channel by Purnal et al. [19]

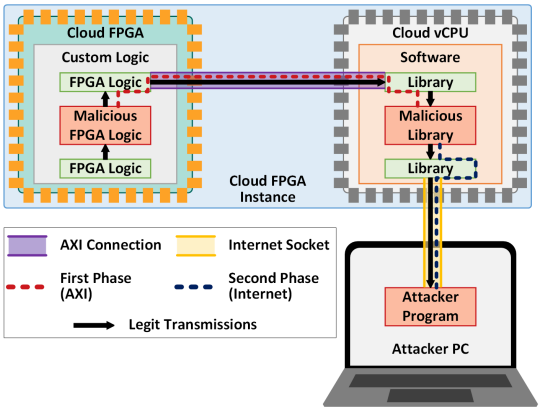

Fig. 2. Threat Model

is capable of staying undercover within the software domain, it lacks effective concealment on the hardware. The authors [19] in their threat model, assume a malicious user controls at least one CPU core and a secondary device such as an FPGA, dispatching operations to both software and hardware while sharing memory between them. In cloud FPGA instances, where AXI interfaces are limited, overt transmission over AXI poses the risk of exposing the covert communication channel to the cloud service provider or other users of the cloud FPGA instance. The covert communication channel from FPGA to CPU proposed by Weissman et al. [20] also relies on cache exploitation and data transfers between the FPGA and the memory, making the covert communication channel similarly vulnerable to detection.

Establishing effective FPGA to vCPU and cloud to off-cloud covert communication channels is pivotal for malicious entities residing on cloud FPGAs, to exfiltrate data from the cloud FPGA to an off-cloud resource. The existing literature lacks effective covert communication channels for establishing the FPGA to vCPU connection in the context of cloud FPGAs, with existing techniques [19], [20] exhibiting notably specific attack scenarios. Furthermore, the literature lacks effectiveness assessment of covert timing channels (CTCs) over the Internet, in the context of cloud. This paper, for the first time, proposes a CTC effective for exfiltrating data from a cloud FPGA to an off-cloud computer. In the first phase, the proposed CTC exploits the VALID and READY handshake signals of the AXI protocol to covertly transmit data from the FPGA to the vCPUs of a cloud FPGA instance. In the second phase, the proposed CTC exploits the inter-packet delay over the Internet to covertly transmit data from the cloud to an off-cloud computer.

IV. Threat Model

The threat model in this paper focuses on a cloud FPGA instance, such as an AWS EC2 F1 instance, targeted by an attacker residing external to the cloud service. As depicted in Fig. 2, the cloud FPGA instance hosts a system with a malicious hardware-software suite injected by the attacker. The malicious hardware-software suite consists of a logic circuit (labeled Malicious FPGA Logic) integrated into the custom logic of an unsuspecting victim, and a software library (labeled Malicious Library) invoked by the software process executing on cloud vCPUs. The malicious hardware-software suite aims to covertly transfer data from the cloud FPGA to the cloud vCPUs and thereafter to the off-cloud personal computer (PC) controlled by the attacker, by implementing the upward C4 covert communication channel of Fig. 1 and the rightward C7 covert communication channel of Fig. 1, respectively.

Complex FPGA logic circuits often use third-party intellectual property (IP) cores like encryption engines, audio/visual pipelines and arithmetic units [21]. With cloud FPGA instances offering powerful vCPUs, users can offload vCPU-efficient tasks onto vCPUs, paving the way for third-party hardware-software IPs to become prevalent in the near future. To infiltrate the infrastructure of an unsuspecting victim, the malicious hardware-software suite disguises itself as a useful hardware-software IP by providing services verified through test vectors. The functionality of the Malicious FPGA Logic and the Malicious Library is verified individually by supplying test vectors and comparing the outputs with the expected algorithmic output. The Malicious FPGA Logic does not necessarily have a direct connection to the Malicious Library, blocking the opportunity for output manipulation. However, the Malicious FPGA Logic can alter the time it takes to validate the data transferred between the FPGA and vCPU sides in the cloud FPGA instance.

In comparison to existing work, this paper assumes a holistic and realistic attack scenario with broader applicability to cloud FPGAs. An attacker with access to a small logic area on the cloud FPGA and a minimal portion of runtime on vCPUs can deploy both phases of the proposed CTC, without requiring the ability to share memory between software and hardware. Prior works [19], [20] typically assumed that the malicious user could dispatch operations to both software and hardware while sharing memory between them. *Furthermore, note that the attacker does not need to be an endpoint of Internet communication to intercept inter-packet delay.* It is sufficient for the attacker to merely eavesdrop on an ongoing Internet traffic.

V. Performance Evaluation

A. Experiment Setup

The experiment setup implements the threat model in an AWS EC2 F1 instance to evaluate the performance of the proposed CTC. The AWS EC2 F1 instance featured eight vCPUs derived from an Intel Xeon E5-2686 v4 multiprocessor and an AMD Xilinx UltraScale+ XCVU9P-FLGB2104-2-I FPGA. To mimic FPGA logic of the victim, a simple echo server was implemented on the FPGA and the AXI Connection, as shown in Fig. 2, was used to receive and echo back messages between the FPGA and the vCPU. In addition, the transmitter of the first phase of the CTC was placed at the FPGA side interface of the AXI Connection (to be specific, R channel of the AXI Connection). The FPGA logic circuit was synthesized and implemented using Xilinx Vivado v2021.2, available through the FPGA Developer AWS Machine Image (AMI) at the time of the experiment. *Please note that the FPGA logic was clocked at 125 MHz.*

The vCPU side of the AWS EC2 F1 instance implemented a software service to route User Datagram Protocol (UDP) network clients to the echo server, mimicking the software belonging to the victim. Moreover, the receiver for the first phase and the transmitter for the second phase of the CTC too were implemented on the vCPUs. The receiver of the first phase of the CTC utilized the RDTSCP instruction (Read Time Stamp Counter and Processor ID) [22] to capture precise time stamps from the Time Stamp Counter (TSC) of the processor [23]. Modern Intel 64 and IA-32 processors, including vCPUs in AWS EC2 F1 instances, feature an advanced Invariant TSC [23] which continues to increment regardless of the state of the processor (sleep or active) and remains invariant to the core executing the RDTSCP instruction [23]. Inspired by [12], the transmitter for the second phase of the CTC performed the covert transmission by selectively delaying the transmission of UDP packets echoed back from the server. The attacker PC analyzed the inter-packet delay to recover the covertly transmitted information.

TABLE I
COVERT TIMING CHANNEL PERFORMANCE – RPA ATTACK EFFICACY

Power Trace Set	Bit Errors (out of 204.8M bits)	Power Traces to Recover Key	Increase in Power Traces to Recover Key (vs. Reference)
Reference	*Not Applicable*	17,100	*Not Applicable*
After CTC first phase	46,592	18,600	9%
After CTC second phase	1,302,835	21,300	24%

To demonstrate the effectiveness of the proposed CTC in RPA attacks, the exact set of power consumption traces from the RPA attack specific Power to Pulse Width Modulation Sensor (PPWM), published as artifacts [5], was used. PPWM is an area-efficient on-chip sensor that produces a single bit output per measurement of power consumption [5]. This characteristic enables attackers to effectively utilize a lower-bandwidth channel, such as the proposed CTC, to discreetly transfer power consumption data from a cryptographic engine deployed on a cloud FPGA to an off-cloud PC, where key inference can be performed using Correlation Power Analysis (CPA). *Please note the power consumption traces correspond to an unprotected 128-bit Advanced Encryption Standard (AES) circuit.*

In this experiment, the set of power consumption traces was transmitted via the first phase (AXI) and the second phase (Internet) of the CTC. After each phase, the output was collected at the receiver end and subjected to CPA for key inference. A CPA was also conducted on the original set of power consumption traces as reference.

In the first phase of the CTC, a logic `1` was covertly transmitted by delaying the VALID signal of the AXI Connection by 2 clock cycles, while a logic `0` was transmitted without inducing a delay. In the second phase of the CTC, a logic `1` was transmitted by delaying a UDP packet by 2 ms, with no added delay for the transmission of a logic `0`. Synchronization between transmitter and receiver is essential for accurate demodulation [24]. However, as UDP is a best-effort service without packet delivery guarantees [25], packet loss can disrupt synchronization, hindering the demodulation of subsequent transmissions. To address the aforesaid issue, the transmitter introduced a 100 ms delay after every 2,000$^{\text{th}}$ unit of data, defined as a *block*. A *block* contains data bits along with a set of parity bits and reference bits to aid in demodulating and decoding the data bits. The receiver advanced the computation to the start of a *block* upon observing the increased delay. Missing observations were padded with zeros. Data in 2,000 *blocks* equated to 100 power consumption traces from PPWM and the frequency of inserting the 100 ms delay was experimentally determined. In this paper, a streaming protocol, feeding continuous data, is assumed above the *block* level of the protocol stack. However, the streaming protocol can be replaced by a packet-based protocol [26], [27], if required.

B. Results

Table I summarizes the key experiment result of this paper. The first column of Table I identifies the power consumption trace sets used for CPA. The next column presents the number of bit errors observed in the power consumption traces, which in total spanned 204.8 million bits. The subsequent column displays the number of power consumption traces needed to successfully recover the secret key of the targeted cryptographic engine. The last column quantifies, as a percentage, the increase in the number of power consumption traces required for complete key recovery relative to the reference trace set.

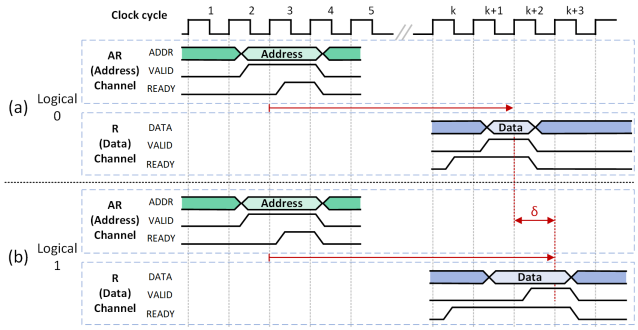

Fig. 3. AXI Read Transaction - Timing Diagrams

In this experiment, the reference trace set needed 17,100 power consumption traces to fully recover the cryptographic key. After transmission through the first phase of the CTC, this number increased by 9% to 18,600. Subsequently, the final output after the second phase of the CTC required 21,300 power consumption traces, marking a 24% increase compared to the reference. Overall, this experiment demonstrated the possibility of using the proposed CTC together with a PPWM sensor to perform an RPA attack that does not require physical access to measure or retrieve power consumption traces from a cloud FPGA to an off-cloud PC. *Please note that BERs of first phase and second phase of the CTC were* 0.02275% *and* 0.6134%*, respectively.*

VI. THE PROPOSED COVERT TIMING CHANNEL – DESIGN PARAMETERS

A. Overview of Design Parameters

This section evaluates the impact of key design parameters on the first phase of the CTC. The authors expect similar effects to be observed in the second phase of the CTC. The transmitter of the first phase of the CTC is implemented as a logic circuit on the FPGA that can manipulate the timing of the VALID signal of the AXI Connection and the receiver of the CTC is a software component integrated within the compute pipeline on vCPUs, which gauges the time consumed by a read transaction. The transmission medium of the CTC is the time consumption of transactions performed through the AXI Connection.

When read transactions occur through the AXI Connection, the transmitter of the CTC bit-by-bit injects the *block* into the transmission medium, the time consumption of read transactions, by delaying the VALID signal of the R channel by an arbitrary number of clock cycles. In the bit modulation scheme for the CTC, a logic `0` is transmitted by inducing no delay in the VALID signal. Conversely, a logic `1` is transmitted by delaying the VALID signal by δ clock cycles. Upon completing the read transaction, the receiver residing on the vCPU side measures the elapsed time and uses the elapsed time measurements of the modulated reference bits to demodulate the data bits and the parity bits. Afterwards, the covertly transmitted data bits are decoded using the intrinsic information from the received data bits and the extrinsic information from the received parity bits. *Note that the number of delay clock cycles,* δ*, is chosen arbitrarily by the attacker at the design time of the CTC.*

The timing diagrams (a) and (b) in Fig. 3 correspondingly show the behavior of the signals on the AR and R channels of the AXI Connection for covertly transmitting a logic `0` and a logic `1`. The timing diagrams in Fig. 3 assume $\delta = 1$ and a read transaction

35: **return** E

consumes k clock cycles. It should be emphasized that the value of k can vary across read transactions.

The receiver of the CTC serves two main functions: (1), demodulating the received signal and (2), decoding the received information. In the demodulation step, the receiver measures the time taken to perform each of the read transactions over the AXI Connection and remaps the expected value of a transmission of logic `1` and the expected value of a transmission of logic `0` to the real numbers -1 and 1, respectively. The remapping is chosen to simplify the subsequent decoding step and is influenced by binary phase-shift keying (BPSK) modulation [28]. In BPSK, a digital signal is modulated into an analog carrier signal by shifting the phase into one of the two (hence, binary) phase offsets.

1) Decoding at the Receiver: The algorithm shown in Algorithm 1 is used for decoding a *block* and it is derived from the min-sum algorithm used in the LDPC code schemes [29]. Min-sum algorithm produces a minimal set of simple operations for decoding a BPSK transmission over an additive white Gaussian noise (AWGN) channel and the inherent resource efficiency of the algorithm is essential to preserve the stealthiness of the CTC. The parity check matrix used in experiments is defined in Equation 1 and is referred to as H, in Algorithm 1.

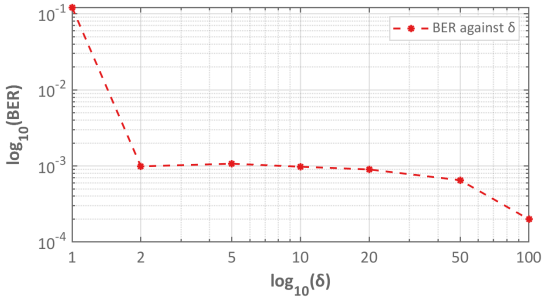

Fig. 4. Variation in Bit-Error Rate – δ

Algorithm 1 is structured as a function named DECODE, which takes an array, $[D_1, D_2, D_3, \ldots, D_n]$, as input. At the start of the DECODE function, m, E and L are initialized to the number of rows in the parity check matrix, the input array and an $m \times n$ matrix of zeros, respectively. Then, each element $L[j, i]$ of matrix L is set to D_i, the input array element at the index corresponding to the column index of $L[j, i]$, if $H[i, j]$ equals 1 (lines 5 - 8). The subsequent section of the DECODE function iteratively improves the beliefs stored in array E, aiming to recover the originally transmitted bits. Based on preliminary experiments, the iterative process (lines 10 - 34) required eight rounds for the optimal result.

$$H = \begin{bmatrix} 1&0&1&0&0&0&0&0&0&0&0&0&0&0&0&0 \\ 0&1&0&1&0&0&0&0&0&0&0&0&0&0&0&0 \\ 1&1&0&0&1&0&0&0&0&0&0&0&0&0&0&0 \\ 1&0&0&1&0&1&0&0&0&0&0&0&0&0&0&0 \\ 0&1&1&0&0&0&1&0&0&0&0&0&0&0&0&0 \\ 0&0&1&1&0&0&0&1&0&0&0&0&0&0&0&0 \\ 1&0&0&0&0&1&0&0&1&0&0&0&0&0&0&0 \\ 0&1&0&0&1&0&0&0&0&1&0&0&0&0&0&0 \\ 1&0&0&0&0&0&1&0&0&0&1&0&0&0&0&0 \\ 0&1&0&0&0&0&0&1&0&0&0&1&0&0&0&0 \\ 0&0&1&0&1&0&0&0&0&0&0&0&1&0&0&0 \\ 0&0&0&1&0&1&0&0&0&0&0&0&0&1&0&0 \\ 0&0&1&0&0&0&0&1&0&0&0&0&0&0&1&0 \\ 0&0&0&1&0&0&1&0&0&0&0&0&0&0&0&1 \end{bmatrix} \quad (1)$$

The iterative process transforms the matrix L by replacing each of its rows with a replacement row (row_r) computed using the values of the row being replaced. Firstly, the algorithm finds the minimal value (min_1) among the elements of row that have a 1 stored in the identical position of H (lines 13 - 16). Simultaneously, pos is updated with the position of min_1 (line 16). Next, a second minimal value (min_2) is found among the elements of row, excluding the element in position pos, that have a 1 stored in the identical position of H (lines 18 - 20). Then, the product of the signs of all elements of row that have 1 stored in the identical position of H is computed (lines 22 - 24) and stored in $sign$. The last step in constructing row_r, populates an array of zeros of length n with $min_2 \times (sign \times sgn(row[k]))$ if $k = pos$ and $min_1 \times (sign \times sgn(row[k]))$ otherwise, provided that the identical position of H is 1. After constructing row_r, row of L is replaced by row_r and the computation moves to the next row until all rows are transformed. Then, the array E is updated by adding the column sum of L to E (line 33). As the final step of the iterative process, L is updated by subtracting L from a matrix that is generated by replicating E, m number of times to match the height of L. The final output of Algorithm 1 is the values stored in E after the eighth round.

After executing Algorithm 1, the error-corrected data bits received can be inferred by observing the sign of the corresponding elements of E. If the sign of the element is negative, the bit is inferred as a logic `1` and if the sign of the element is positive or zero, the bit is inferred as a logic `0`. In this manner, bits that are covertly transmitted by the transmitter are inferred at the receiver, establishing

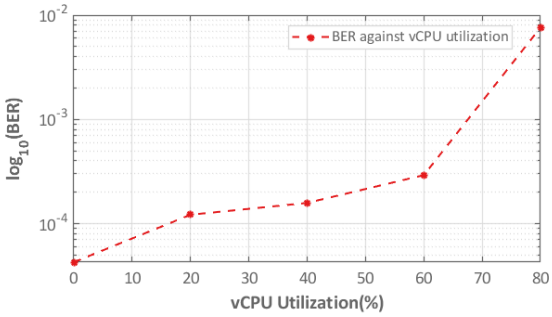

Fig. 5. Variation in Bit-Error Rate – vCPU Utilization

a CTC between the FPGA side and the vCPU side of a cloud FPGA instance. The experiments in this paper were based on $n = 16$ and *blocks* containing 2 data bits.

B. Impact of δ on Bit-Error Rate

To evaluate the dependence of the BER of the CTC on δ, the number of delay clock cycles induced on the VALID signal to covertly transmit a logic `1`, multiple experiments were carried out by varying δ between 1 and 100. The result of this experiment is shown in Fig. 4, with δ on the x-axis and BER on the y-axis, both presented on the base-10 logarithmic scale ($\log_{10}$). The graph in Fig. 4 shows that the CTC is effective for all δ values tested in the experiment. Notably, the BER decreases sharply when δ increases from 1 to 2 and an overall downward trend continues, reaching a minimum BER of 0.01988% at $\delta = 100$. The decrease in BER, as δ increases, can be attributed to improved distinguishability between covertly transmitted logic `1`s from covertly transmitted logic `0`s and the sharp decline in BER from $\delta = 1$ to $\delta = 2$ can be hypothesized as a consequence of exceeding the ambient noise level of the AWS EC2 F1 instance.

In this experiment, changing the value of δ impacted the time taken to complete a read transaction. However, the interval between consecutive read transactions depended on the frequency of echo requests from the client side, regulated by the scheduling of processes on the vCPUs and therefore unaffected by the value of δ. It is important to highlight that the bandwidth of the CTC is influenced by both the intra-read and inter-read transaction delays. When changing δ from 1 to 100, no discernible pattern was observed in the overall time required to execute each experiment, indicating the prominence of the uncertainty associated with the inter-read transaction delay.

C. Impact of vCPU Utilization on Bit-Error Rate

This experiment examined the impact of the vCPU utilization on BER by placing an artificial CPU-intensive workload on the vCPU side of the cloud FPGA instance. Using the `taskset` command, the workload was assigned to the same vCPU as the receiver of the CTC, while CPU utilization of the workload was managed with the `cpulimit` utility. δ was set to 10 for this experiment.

As depicted in Fig. 5, with vCPU utilization on the x-axis and BER (in the $\log_{10}$ scale) on the y-axis, BER shows an upward trend with increasing vCPU utilization. This observation aligns with expectation, as the receiver of the CTC is unable to precisely capture the timestamp when the artificial workload is scheduled on the vCPU. Consequently, inaccuracies in the recorded time intervals lead to decoding errors and demodulation errors, causing higher BER. vCPU utilization becomes relevant to the BER only when the artificial workload interrupts an ongoing read transaction. *Note that, scheduling the artificial workload between two read transactions does not lead to bit errors and as seen from Subsection VI-B, the inter-read transaction delay was prominent, reducing the likelihood of the artificial workload interrupting an ongoing read transaction.* Therefore, in contrast to approaches that rely on modulating covert information via inter-read transaction delay, the proposed technique, which encodes covert information by modulating the duration required to complete a read transaction, offers enhanced reliability for the attacker.

TABLE II
VARIATION IN BIT-ERROR RATE – MODULATION TECHNIQUE

δ	BER		Relative Improvement as Percentage
	Proposed Scheme (LDPC-based)	Repetition Code	
1	12.140%	22.510%	185%
2	0.099%	0.144%	146%
5	0.048%	0.066%	138%
10	0.098%	0.116%	119%
20	0.090%	0.191%	213%
50	0.065%	0.158%	243%
100	0.020%	0.147%	739%

D. Impact of Modulation Technique on Bit-Error Rate

In order to assess the effectiveness of the LDPC-based error correction scheme used in the decoding algorithm, an experiment was carried out by augmenting Algorithm 1 to implement a decoder based on repetition code. The structure of a *block* was also changed, to facilitate the repetition code and the error corrected two data bits of the *block*, d_1 and d_2, were calculated according to Equation 2 and Equation 3, respectively. The experiment was repeated for different values of δ in the range of 1 to 100.

$$d_1 = \begin{cases} 0, & \text{if } \frac{(d_{11}+d_{12}+d_{13}+d_{14}+d_{15}+d_{16}+d_{17}+d_{18})}{8} > 0 \\ 1, & \text{otherwise} \end{cases} \quad (2)$$

$$d_2 = \begin{cases} 0, & \text{if } \frac{(d_{21}+d_{22}+d_{23}+d_{24}+d_{25}+d_{26}+d_{27}+d_{28})}{8} > 0 \\ 1, & \text{otherwise} \end{cases} \quad (3)$$

Table II presents the results of the experiments evaluating LDPC-based and repetition code schemes for the CTC. The first column of Table II represents the values of δ used in the experiment. The second and third columns show the BER obtained from the experiment using the proposed LDPC-based scheme and repetition code, respectively. The fourth column shows the improvement in BER as a percentage, calculated by dividing the repetition code BER by the LDPC-based BER. The results in this section show that the proposed LDPC-based scheme outperformed the repetition code, even though it is composed of a minimal set of simple operations. In the pair of experiments where $\delta = 100$, the BER improvement of the proposed LDPC-based scheme is over seven folds compared to the repetition code. Hence, these results portray the ability of the proposed LDPC-based scheme to effectively decode *blocks* while maintaining the stealthiness of the CTC.

VII. CONCLUSION

This paper introduced, for the first time, a CTC that provides an attacker with the capability to covertly transfer data from a cloud FPGA to an off-FPGA resource. Using experiments, this paper demonstrated the application of the CTC in exfiltrating power consumption traces from an on-chip sensor on a cloud FPGA to an off-cloud attacker PC for performing RPA attack. Further, an analysis on the BER of the proposed CTC under various operating conditions was also presented. The findings emphasize the need for increased vigilance and security measures from both cloud FPGA providers and users to protect logic circuit designs deployed on cloud FPGAs.

***Abstract*—Write amplification (WA) from migrating valid pages during garbage collection (GC) degrades SSD performance and lifespan. Although stream management based on high-level software semantics reduces WA, existing solutions require host modifications, hindering their adoption. We introduce StreamCSD, an SSD-autonomous stream management approach using in-storage content learning, eliminating host-side changes. Leveraging compression ratios from embedded compressors in computational storage drives (CSDs), StreamCSD employs a streaming K-means algorithm to cost-efficiently cluster data into streams. Evaluations show that StreamCSD reduces WA from 1.7 to 1.06 under multimodal generative AI workloads, matching state-of-the-art methods with minimal impact on bandwidth. StreamCSD operates without host modifications, promoting broader adoption of multi-stream SSDs.**

I. Introduction

SSDs in data centers typically serve multiple workloads, such as databases, virtual machines, and file storage. These workloads produce writes, updates, and deletions, each with distinct patterns and timing. Consequently, the lifetime of the data is inconsistent. A standard block-interface SSD cannot distinguish between pages from different write streams due to a lack of semantic information. As a result, pages within a flash erase block have varying lifetimes, leading to the migration of many valid pages during garbage collection (GC) [21], [22] and causing write amplification (WA), which degrades SSD performance and requires over-provisioned flash resources for mitigation, which are major sources of the *block interface tax* [9].

Effectively mitigating WA involves storing pages with similar lifetimes in the same physical stream or block group within SSDs. However, accurately predicting page lifetime is a challenge due to workload variability and dynamics [19], [23]. In practice, instead of relying directly on lifetime, existing approaches utilize programmer hints through new IO interfaces [9], [10] and stream IDs based on data types [17] and program contexts [19], which are semantically or empirically linked to data lifetimes [28], to manage streams.

Open-Channel [10] and Zoned Namespace (ZNS) [9] revamp the block interface, empowering the host with direct control over the placement of data in flash blocks. However, they are incompatible with systems and applications designed for block interfaces. In contrast, multi-stream SSDs [17], [19], [25] and Flexible Data Placement (FDP) [27] enhance the existing block interface by allowing the host to use software semantics to establish distinct write streams. This enables SSDs to judiciously place data with the same stream ID across separate flash blocks. However, these solutions require extensions to the host-SSD communication protocol. This necessitates modifications to NVMe drivers or applications to include stream or placement identifiers, presenting a barrier to adopting these stream management schemes.

The interface changes or host dependencies result in significant limitations to existing schemes. As a supplier of data center SSDs, more than 95% of our SSD shipments consist of traditional block-interface SSDs. Given the still prevailing use of block-interface SSDs, we raise a critical and fundamental question: Can we retain block interfaces while eliminating host dependencies to devise a fully SSD-autonomous, cost-efficient stream management mechanism for reducing GC-induced WA?

We introduce *Learned Streaming*, an SSD-autonomous stream management approach that leverages content as a novel semantic dimension to eliminate host dependency. However, learned streaming requires data feature extraction, which presents challenges in terms of *universality* and *efficiency*. For instance, traditional content clustering algorithms, such as TF-IDF [8], are limited to text formats (e.g., txt, JSON) and suffer from slow execution speeds, making them unsuitable for latency-sensitive SSD stream management.

We propose *StreamCSD* to address the above challenges. By using Shannon entropy (ENT) or compression ratio (CR) as features, *StreamCSD* can differentiate a wide range of streams with varying lifetimes. By leveraging the computational storage drive (CSD) [32] architecture and piggybacking page feature extraction on SSD hardware compressors (emerging SSDs tend to integrate hardware compressors to reduce storage cost and prolong lifetime) [11], [29], [31], *StreamCSD* introduces negligible overhead. Furthermore, for SSDs without built-in compressors, the overhead can be mitigated by implementing a Shannon entropy accelerator. Following feature extraction, *StreamCSD* employs a lightweight *streaming K-means* algorithm for feature clustering and stream assignment. *Learned Streaming* based on the page compression ratio also faces the challenge from two aspects. First, pages sharing the same compression ratio might have different lifetimes. Second, pages with different compression ratios may have similar lifetimes. These limitations compromise the goal of separating data with different lifetimes. We further propose GC-guided page-to-stream remapping (§IV-C) and secondary lifetime-assisted stream mapping (§IV-D) to complement *Learned Streaming*.

We implement *StreamCSD* with the *Learned Streaming* mechanism on both the FEMU emulator [20] and a PCIe 5.0 ×4-lane SSD with a built-in hardware compressor. Experimental results show that *StreamCSD* reduces WA by 63.4% and improves IO performance by 74% compared to baseline, matching or surpassing state-of-the-art methods including *PCStream* [19] and MiDAS [23]. Under multimodal generative AI workloads, StreamCSD lowers the WA from 1.7 to 1.06 while having a negligible effect on write bandwidth.

II. Background and Related Work

The block interface tax [9], [10] arises from the mismatch between the block interface and flash memory's characteristics. To bridge this gap, numerous mechanisms have been proposed. Open-channel [10], [24] and ZNS [9], [15] interfaces expose different levels of flash memory management to the host. The multi-stream [17] and FDP [27], [34] allow hosts to deliver hints of data placement to SSDs.

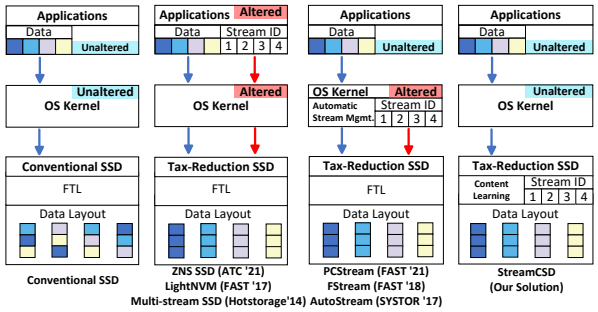

Fig. 1: SSD block interface tax reduction mechanisms. StreamCSD targets a host-transparent multi-stream SSD with a block interface.

Previous works have exploited various software hints through the multi-stream interface, such as multi-level semantics of LSM-tree [17], data types in file systems [25], and program contexts at the application layer [19]. LBA-based clustering methods classify page hotness by analyzing historical LBA write patterns, including recency, frequency, sequentiality and so on.

Figure 1 illustrates the host dependencies of existing mechanisms. Open-channel [10] and ZNS [9] interfaces require significant modifications to the application and OS kernel. The open-channel interface exposes raw NAND details, forcing the host to manage tasks like data mapping, garbage collection, and wear leveling. ZNS requires the host to manage sequential writes, zone resets, and garbage collection while the SSD firmware handles wear leveling. Similarly, Multi-stream [17] and FDP [27] require the application and OS kernel to assign stream or placement IDs, demanding application-specific knowledge to abstract different write streams. Although techniques like PCStream [19], FStream [25], and AutoStream [39] can autonomously extract application streams, they still necessitate OS kernel modifications. LBA-based clustering can be integrated directly into SSDs, independent of the host. However, these methods often require extensive statistics, such as LBA update intervals and block GC survival counts, or even develop complex models [23], [39] for clustering. These methods consume non-trivial amounts of valuable CPU and memory resources in SSDs, and rely on LBA access locality, making them unsuitable for frequently changing IO patterns and log-structured systems (e.g., RocksDB and F2FS) [19].

III. Motivation: Content-based Stream Management

A. Opportunities and Challenges

Content-based clustering, a robust unsupervised learning technique, is extensively employed in recommendation systems and big data analysis to group objects like documents [33], images [12], and videos [7] based on similarity or relevance. Techniques such as the *K-means* algorithm exploit term frequency-inverse document frequency (TF-IDF) vectors for clustering documents [8]. Inspired by these methods, we investigate the application of content learning within SSDs to enhance data placement and reduce write amplification.

However, implementing content-based clustering for intra-SSD stream management faces significant challenges. Current algorithms, designed for specific types of data such as documents and images, cannot be universally applied across the varied data handled by SSDs. Furthermore, the computational overhead of these clustering methods, particularly the high-dimensional processing and vectorization in TF-IDF, imposes a substantial CPU burden, demonstrated by a latency of 0.24 seconds for clustering 64 pages (or 4ms per page). This can severely impact SSD performance. Therefore, a universal and efficient content-based clustering algorithm is essential to effectively differentiate data streams without overwhelming the SSD resources.

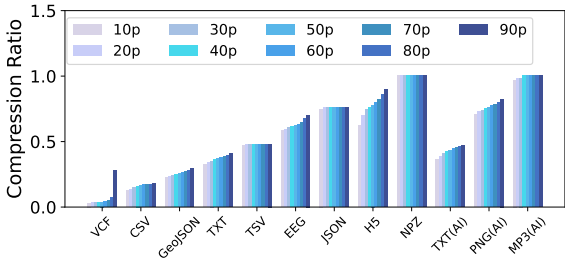

Fig. 2: Percentile distribution of 4KB page compression ratio in real datasets. '10p, 20p' refers to the 10th, 20th percentile CR and etc. These datasets are also employed to fill the microbenchmark as described in Table I and will be published.

B. Compression Ratio: A Good Multi-Stream Indicator?

Compression ratio feature. Typically, different types of data content are often managed independently, resulting in distinct write streams. For instance, file systems and databases typically separate user data, system metadata, and recovery logs into different streams. Similarly, multimodal generative AI applications produce a variety of content types—such as text, images, audio, and video—each stored in separate streams based on its unique structural characteristics. These structural differences, or content patterns, play a critical role in determining data compressibility. Compression algorithms exploit these patterns to minimize data size by replacing repeated sequences with pointers (e.g., LZ [41]), using shorter codes for frequent symbols and longer ones for rare symbols (e.g., entropy coders [16]). Therefore, the compression ratio is potentially a valuable indicator of the internal pattern and structure of data content.

Compression ratio and stream ID. To demonstrate whether compression ratio or entropy is a good indicator for distinguishing streams, we analyze 9 domain-various datasets from a public repository [1] and 3 AI-generated datasets [3]. Each dataset corresponds to a write stream and is split into 4KB pages, which are compressed to quantify percentile distributions of compression ratios. As depicted in Figure 2, the CRs of pages within each stream converge closely, with a mean deviation of only 0.02, which indicates *compressibility locality*. A similar observation is made in a recent work [36]. We also observe that the CRs or entropy values of pages diverge across different write streams. As Figure 3 illustrates, 9 of the 12 datasets exhibit significant distinction in either compression ratio or entropy value, highlighting a strong correlation between compression ratio and entropy. From the above results, we can see both the compression ratio and entropy are universal and representative features effective enough for content-based data page clustering.

Compression ratio and data lifetime. As shown in Figure 4, entropy strongly correlates with data lifetime in many important scenarios, and this also applies to the compression ratio. RocksDB's Write-Ahead Logs (WALs) exhibit lower entropy values or compression ratios and shorter lifetimes compared to Sorted String Tables (SSTables) [19]. WALs avoid compression to minimize latency [5], while SSTables use Snappy compression to reduce storage usage. Similar patterns are seen in Cassandra's flushing and compaction SSTables [2]. The redo and DB files in MySQL are difficult to distinguish based on entropy. However, for the overall data, those with lower entropy values tend to have shorter lifetimes, while data with higher entropy values tend to have longer lifetimes. In GCC compilation, intermediate files like preprocessed and assembly files have different entropy and compression ratios compared to long-lived object files. The correlation between file extensions and compression ratios has also been proven effective for stream separation [17], [25].

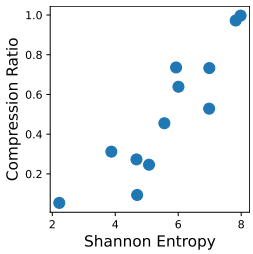

Fig. 3: Compression ratios and Shannon entropy.

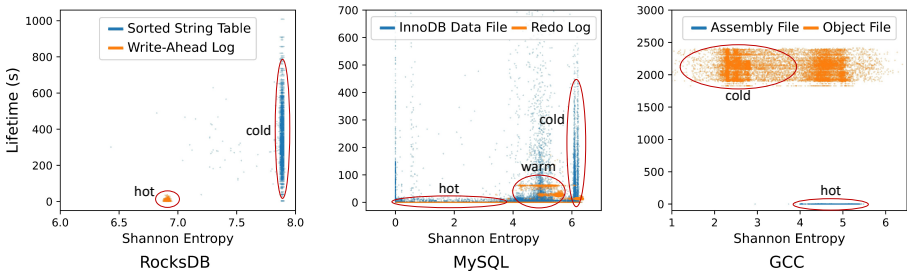

Fig. 4: Correlation between Shannon entropy and data lifetime in representative databases and Linux kernel source code compiling applications.

IV. Design of StreamCSD

A. Overview

To alleviate the block interface tax, we propose a computational SSD, called *StreamCSD*, which employs a *learned streaming* mechanism. It bears the following design goals:

- **G1: Host-transparent in-storage multi-streaming.** StreamCSD presents a standard block device and infers stream ID based on page content for automatic multi-streaming to reduce GC overhead. No application-specific expertise and host software modifications are required.
- **G2: Real-time multi-streaming.** StreamCSD can perform real-time identification of write streams among incoming data pages on the write IO path, eliminating the need to track and analyze historical access patterns of LBAs.
- **G3: Comparable efficacy to existing approaches.** StreamCSD should be comparable to or even outperform host-guided multi-stream approaches and LBA-based clustering approaches in representative application scenarios.
- **G4: Free from side effects.** StreamCSD should be lightweight with insignificant overheads. Even when the workload is unfriendly for StreamCSD, the performance and WA should not degrade.

Figure 5 presents the design overview of StreamCSD, which integrates a content learning accelerator for real-time page feature extraction. The *Shannon entropy* or *compression ratio* can be used as the learned feature, which is consumed by the streaming K-means algorithm to separate incoming data pages into different learned streams (§IV-B). The basic workflow of StreamCSD is as follows. ❶ The host NVMe write request is transmitted into the SSD via the PCIe interface. ❷ The NVMe controller inside the SSD parses the request. ❸ Each data page is transferred into the data cache of the content learning accelerator via a high-speed bus for content learning and feature extraction. These feature values are processed through clustering to obtain the corresponding stream ID (LearnedID). ❹ The data pages along with their stream IDs are written into the SSD write buffer. ❺ The FTL flushes data pages with different stream IDs to the corresponding physical blocks or reclaim units.

However, pages originating from different applications, with varying lifetimes but similar compression ratios, may be clustered into the same stream. StreamCSD employs a *GC-guided stream remapping* mechanism (§IV-C) to overcome this issue. Moreover, multi-stream SSDs support a limited number of physical streams, typically 4 to 16 [9], [19], [39], but high-concurrent application scenarios can generate more learned streams than available physical streams. To resolve this mismatch, we propose a *secondary lifetime-assisted stream mapping* mechanism that efficiently merges learned streams to fit the available physical streams (§IV-D).

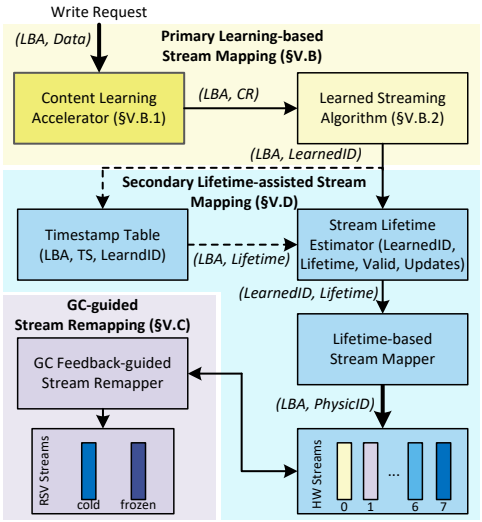

Fig. 5: The design overview of StreamCSD. Note, the secondary lifetime-assisted stream mapping mechanism is conditional. When it is not activated, learned IDs directly map to physical stream IDs.

B. Primary Page Content Learning-based Stream Mapping

Compression ratio and Shannon entropy, as universal data-characterizing features, yield similar classification accuracy. However, relying on the SSD controller's ARM cores for compression or Shannon entropy calculation can create performance bottlenecks in the write IO path. To address this, we propose using hardware acceleration and a learned streaming algorithm within the SSD as an effective solution.

1) Content Learning Accelerator: Accurately determining the stream for each page is critical for host-transparent multi-stream SSD. Efficiency is crucial in designing the feature extraction algorithm to avoid a significant impact on SSD write performance.

Piggyback feature extraction on compressors. Some SSDs have integrated hardware compressors [29], [31] for storage savings. In these instances, *StreamCSD* can utilize the SSD's internal compressor to extract page features, thereby eliminating the need for an additional content-learning accelerator. Consequently, *StreamCSD* leverages the page compression ratio as a primary metric in identifying page stream ID, without incurring extra computational costs.

Shannon entropy accelerator. In SSDs without built-in compressors, implementing a Shannon entropy accelerator for feature extraction is recommended, as it is significantly simpler than a compression engine [6], [18]. The hardware engine for entropy computation efficiently analyzes symbol (byte) frequency in input data. It consists of a data buffer for input storage, a counter array to monitor symbol frequencies, a probability calculator, a logarithm unit

utilizing an approximation technique, and an accumulator to handle the multiplication of probabilities and logarithms. In our simulation on a *Vivado XCVU19P FSVA3824* FPGA, the entropy module is remarkably compact, taking up less than 1% of the area relative to embedded processor cores. The computation for a 4KB page is accomplished in 1024 cycles, corresponding to 1μs at a 1GHz core frequency. Notably, a 6.25% sampling of 256 bytes achieves 98% entropy accuracy with a calculation time of only 0.05μs, ensuring minimal impact on SSD performance.

2) Learned Streaming Algorithm: **Streaming K-means clustering.** For real-time efficiency in SSD multi-stream identification, we employ a streaming K-means algorithm [30] to cluster learned streams. Unlike traditional K-means, which processes data in batches, streaming K-means continuously updates clusters and assigns stream IDs as new data arrives. The algorithm begins by specifying the number of clusters (K) and initializing centroids to maximize the minimum distance between them [14]. As new pages arrive, the algorithm calculates distances based on accelerator-generated features, assigns stream IDs to each page, and updates centroids when the predefined batch size is reached.

Wait-free clustering for single-page. Page features and stream IDs are cached until a predefined threshold triggers a batch update to the K-means centroids. Notably, our customized K-means algorithm assigns stream IDs on a per-page basis, eliminating clustering wait time. This separation of model updates from stream ID assignments ensures immediate stream ID retrieval, which is crucial for continuous data influx. As a result, tasks such as FTL address translation and backend data flushing can proceed without delay. Combining hardware-accelerated features of compression ratio or entropy, this approach ensures immediate page flushing to NAND flash with readily available stream IDs.

C. GC-guided Stream Remapping

Learning-based stream mapping is effective for streams with consistent lifetimes, such as WAL or SSTables. However, non-uniform workload distributions (e.g., *Zipfian*, *latest*) [13], and limitations of unsupervised clustering could result in the mixing of hot and cold data. To handle this problem, StreamCSD employs GC-guided remapping to reduce lifetime variance within each physical stream. GC-guided remapping reallocates outlier pages to dedicated streams based on their hotness.

Identification of outlier pages in a stream. Intra-SSD multi-stream management enables StreamCSD to detect page hotness by utilizing GC statistics. The typical GC process involves: 1) selecting a victim block; 2) migrating valid pages from the victim block to a new block; and 3) erasing the victim block. To identify outlier pages, StreamCSD tracks the migration count of each valid page. If a page undergoes excessive migrations, indicating its longevity and outlier status, it should be moved to a more appropriate stream. Empirical evaluation shows that 4 bits per migration count are sufficient, requiring only 128MB for a 1TB SSD.

Remapping state transition. StreamCSD designates two streams (*cold* and *frozen*) for outlier pages (refer to Figure 6). Pages are initially assigned to normal streams based on their stream IDs. If a page is migrated during GC, its *migration count* is incremented. When the count exceeds the *T1* threshold, the page is remapped to the cold stream. Cold stream pages are either returned to the original stream (with the *migration count* set to 0) or moved to the frozen stream. Pages in the frozen stream may move to the cold stream, setting their *migration count to T1*. The default *T1* and *T2* values are 1 and 2, based on empirical testing across various workloads.

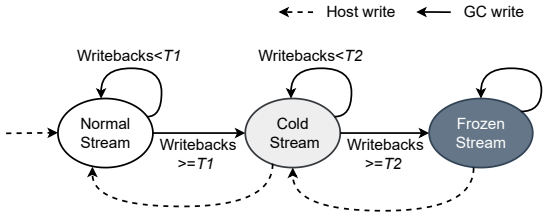

Fig. 6: The remapping state transition. *T1* and *T2* are configurable writeback thresholds.

D. Secondary Lifetime-assisted Stream Mapping

In multi-application environments, the number of learned streams generated by the primary stream mapping may exceed the available physical SSD streams [39], [40]. We propose secondary lifetime-assisted stream mapping to tackle this issue. The main idea is to merge learned streams into the same physical stream based on their lifetime estimates.

***Learned stream* lifetime.** The learned stream's lifetime is estimated from its pages' lifetimes. However, tracking each page's lifetime requires significant memory, especially for high-capacity SSDs. To balance accuracy and memory consumption, we track lifetime at the chunk level. A chunk contains 256 consecutive pages, which share a timestamp table entry containing *chunk ID*, *learned stream ID*, and *timestamp*. If pages within a chunk belong to different learned streams, the chunk will have multiple entries, each corresponding to a different learned stream. Upon page updates or deletions, the timestamp table entry is adjusted, and new entries are created if none exist. Each update computes the chunk's lifetime by subtracting the *timestamp* from the current time, which is then used to update the learned stream's lifetime. By averaging the chunk lifetimes, we estimate the learned stream's lifetime.

Stream mapping mechanism. We designed a mapping mechanism to align learned streams with physical streams. Learned streams with similar lifetimes are grouped into the same physical stream, reducing intra-stream lifetime variance. A stream mapping table records the learned-to-physical mapping and other fields. Due to space limitations, we omit details.

V. Evaluation

A. Experimental Setup

We implemented StreamCSD on FEMU [20], a widely used NVMe SSD emulator for full-system research [35], [37]. StreamCSD is configured similarly to [35], with 32GB storage capacity, 8 channels, 8 planes per channel, 512 blocks per plane, 256 pages per block, and a 4KB page size. The Greedy policy [26], [38] is adopted as the default for GC victim selection. We also developed a real system prototype based on a PCIe 5.0 7.68TB CSD with a hardware compressor to further validate the functionality and efficiency of StreamCSD. We primarily use the FEMU emulator for comprehensive evaluation. The

TABLE I: Microbenchmark and representative real-world applications that are employed for evaluation.

Benchmark	Description
Microbench (with public datasets)	Eight threads read data from real-world datasets and append to files with various data lifetimes.
RocksDB (DbBench)	LSM-tree based key-value store known for handling a large amount of sequential writes.
MySQL (TPC-C)	Relational database known for handling a large number of random writes.
SQLite (TPC-C)	Widely used embedded relational database with a lot of random writes.

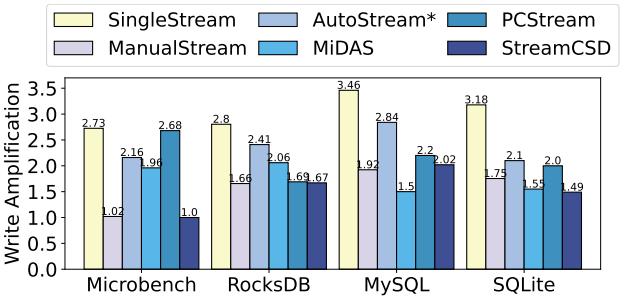

Fig. 7: Write amplification factor (WAF) (lower is better).

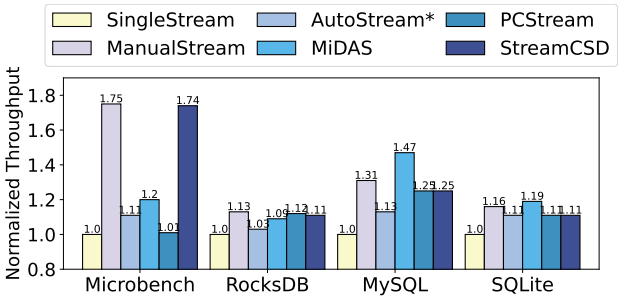

Fig. 8: SSD performance (higher is better).

hardware platform is used to evaluate AI workload performance and the actual overhead of learned stream management.

Benchmarks. We benchmark StreamCSD using a synthetic benchmark and three representative real-world applications listed in Table I. Microbench is designed with 8 threads, each sequentially writing datasets with varying entropy and lifetime. RocksDB performs random writes of 64 million key-value pairs, flushing WAL every 4 KB and compressing SSTables with the ZSTD algorithm. MySQL and SQLite are evaluated with TPC-C workloads, using 60 and 170 warehouses, respectively. The total data written exceeds the SSD capacity: 280GB for RocksDB and 120GB each for MySQL and SQLite, all hosted on the Ext4 file system.

Counterparts. We dedicated significant efforts to port state-of-the-art multi-streaming schemes listed in Table II. Particularly, AutoStream [39] leverages historical IO patterns for LBA-based stream identification. PCStream [19] identifies streams by using program context. MiDAS [23] segregates data by age and dynamically adjusts groups. To ensure fairness, write amplification and throughput metrics are evaluated under consistent resource conditions and configurations.

B. WAF and Performance Evaluation

WAF. We begin the evaluation by comparing the Write Amplification Factor (WAF) improvements under Microbench, as shown in Figure 7. Significant WAF reductions are observed for ManualStream and StreamCSD, both achieving around 63.4% reduction compared to SingleStream. MiDAS and AutoStream* also show reductions of 28.2% and 20.9%, respectively. However, PCStream shows negligible improvement, as Microbench generates IO requests using multiple threads that share the same task handler, resulting in insufficient program context to distinguish datasets with different lifetimes.

For RocksDB, StreamCSD and ManualStream both demonstrate the highest WAF reductions of approximately 40%, compared to PCStream (39.6%), MiDAS (22.5%) and AutoStream* (13.9%). For MySQL, MiDAS achieves the highest WAF reduction of 56.64%, followed by ManualStream (44.5%), StreamCSD (41.6%), PCStream (36.4%), and AutoStream* (17.9%). MiDAS identifies hot data based on update intervals but struggles with out-of-place updates, as valid pages may be directly discarded. This limits MiDAS' efficiency in RocksDB, where out-of-place updates are more prevalent. However, it works effectively for MySQL, which has many in-place updates. In contrast, StreamCSD addresses this limitation by learning data content, enabling more accurate stream identification upon the first write. In SQLite, StreamCSD significantly outperforms ManualStream. Although ManualStream uses separate lifetime hints for rollback journals, WALs, and database files, it fails to distinguish between hot and cold data within a single database file. In contrast, StreamCSD employs GC-guided remapping, enabling more effective differentiation of intra-file hot and cold data.

Performance. There is a strong correlation between WAF and performance. A lower WAF means lower GC overhead. As illustrated in Figure 8, StreamCSD significantly outperforms SingleStream in various applications, delivering performance improvements of 74%, 11%, 25%, and 11% for Microbench, RocksDB, MySQL, and SQLite, respectively. Compared to MiDAS, StreamCSD provides higher throughput for Microbench and RocksDB with extensive out-of-place updates, whereas MiDAS performs better for MySQL and SQLite with numerous in-place updates.

C. In-depth Analysis

Effect of primary learning-based stream mapping. We use RocksDB as a case study. As shown in Figure 7, we see that both StreamCSD and PCStream achieve near-optimal WAF reduction. To investigate further, we analyze the underlying mechanisms. RocksDB generates several types of files, including the Write-Ahead Log, level 0 SSTables (L0), and level 1 to n SSTables (L1–Ln). ManualStream assigns unique labels to these file types, allowing SSDs to manage them with dedicated Stream IDs for optimal performance. Similarly, PCStream identifies these streams by deriving program context from function call stacks, effectively differentiating WAL, L0, and L1–Ln. StreamCSD achieves a similar categorization by perceiving upper-level compression strategies: no compression for WAL, lightweight compression for L0, and standard compression for L1–Ln.

Effect of GC-guided stream remapping. We compare the WAF results with GC-guided remapping enabled and disabled across different workloads. Figure 9 shows that for MySQL and SQLite, where database files inherently mix hot and cold data, remapping reduces WAF by 22.9% and 21.2%, respectively. For RocksDB, remapping achieves a moderate WAF reduction of 5.6%, addressing SSTable level identification challenges. In contrast, for Microbench, remapping has minimal impact as data lifetimes within each learned stream have already converged. Futhermore, as shown in Figure 10, we analyze the remapping mechanism's sensitivity to threshold *T1*

TABLE II: Description of various multi-streaming schemes and a regular SSD as the baseline.

Scheme	Description
SingleStream (Regular SSD)	Mix pages from all streams causing serious write amplification. (**Baseline**)
ManualStream [17]	Multi-stream, programmer manually tag stream identification. (**Programmer-dependent**)
AutoStream*	LBA-based multi-streaming. A ported FEMU implementation of AutoStream [39]. (**Historical IO pattern-dependent**)
MiDAS [23] (State-of-the-art)	Self-adjusting data grouping, segregating data blocks by age. (**Historical IO pattern-dependent**)
PCStream [19] (State-of-the-art)	Multi-stream, program context-based stream identification. (**Host-dependent**)
StreamCSD (**Our solution**)	Multi-stream, content learning-based stream identification. (**Host-transparent**)

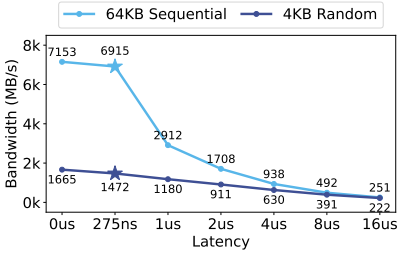

Fig. 14: Impact of stream management overhead on SSD write performance.

for RocksDB, MySQL and SQLite, respectively, with *T2* always set to *T1* + 1. Varying the threshold clearly influences WAF. Smaller thresholds lead to significant WAF reduction. At a *T1* threshold of 1, almost all workloads achieve the minimum WAF, which supports our default threshold settings.

Effect of secondary lifetime-assisted stream mapping. In a physical stream-limited scenario with 4 physical streams and 8 learned streams, we compare two merging strategies: one based on stream lifetime and the other on uniform division, where learned streams are evenly divided by IDs and mapped to physical streams. Figure 11 shows that, for Microbench and RocksDB, lifetime-assisted merging reduces WAF by 19.8% and 20.3%, respectively, highlighting the necessity of secondary mapping. However, this strategy does not improve other applications. For MySQL and SQLite, the relatively large page lifetime variance within learning streams limit the effectiveness of the lifetime-assisted strategy. It is worth noting that secondary mapping does not introduce significant side effects.

D. Hardware StreamCSD for Generative AI Workloads

We notice that the compression ratio-based stream management is very effective in emerging generative AI multimodality applications. We evaluate the StreamCSD hardware prototype using data from *OpenAI* [3] and *Runway* [4]. We emulate multimodality applications generating and concurrently flushing *ChatGPT* txt, *DALL-E* png, *OpenAI TTS* mp3, and *Gen-2* mp4 data into a 7.68TB SSD. Without prior large-scale file lifetime knowledge, we assign the lifetime of these data streams in a 1:2:4:8 ratio. The SSD's built-in compressor is used to obtain the data compression ratio; therefore, the cost of feature extraction is negligible. As shown in Figure 12, the WAF of SingleStream increases with the growth in generative AI file writes, while StreamCSD's WAF remains almost unchanged. Figure 13 demonstrates the variation in GC migration ratio during the *Write-16T* test. GC process resulted in an additional 10.68 TB of data being written to SingleStream, with an average 38% migration ratio, leading to a WAF of 1.7. However, StreamCSD significantly reduces GC-written data. It categorizes the four types of AI files based on their compression ratios and directs them to distinct streams. With an average 4% migration ratio, StreamCSD notably reduces WAF compared to SingleStream.

E. Impact of Learned Streaming on StreamCSD Performance

We evaluate the impact of learning-based stream management on write performance with the real PCIe 5.0 hardware SSD prototype. Learning-based stream mapping involves two components: a content-learning module for feature extraction and a clustering module for stream ID determination. We focus on the clustering module's impact, as the overhead of feature extraction is negligible due to the SSD's compression accelerator. Our customized streaming K-means algorithm takes *275ns* to assign a stream ID, resulting in a moderate performance impact—3.3% decrease for coarse-grain sequential writes and 11.6% for fine-grain random writes, as shown in Figure 14. These findings highlight the importance of lightweight feature extraction, efficient clustering algorithms, and hardware acceleration in intra-SSD stream management design.

VI. Conclusion

Traditionally, reducing SSD write amplification and enhancing performance have depended on changes to interfaces or host-assisted stream ID labeling. However, in the age of AI and computational storage, it is crucial to advance SSD intelligence toward device-autonomous stream management for WA reduction. StreamCSD addresses this need by utilizing unsupervised content learning to eliminate dependency on the host. It autonomously assigns stream IDs to IO requests through content clustering. StreamCSD has been implemented and validated on both the FEMU emulator and a production-grade SSD hardware prototype equipped with a data compression accelerator, showcasing the feasibility and effectiveness of autonomous multi-stream SSDs. Although the current use of compression ratio as the feature representation poses limitations, preventing the complete elimination of the block interface tax, StreamCSD still significantly reduces this tax. Overall, StreamCSD exemplifies the transformative role of AI in storage technology, with significant implications for the future of SSD design.

***Abstract*—The parameterizable and synthesizable RISC-V processors enable the automatic generation of customized CPU cores through EDA tools. However, current methods often explore the extensive design space with significant model errors while neglecting design constraints, which are critical for practical implementations. To address these limitations, we propose a Self-Review Bayesian Optimization method (SRBO). This method integrates a teacher-student paradigm within a local Bayesian optimization framework to reduce model errors and enhance exploration efficiency. Additionally, it employs deep ensembles for effective constraint handling. Experimental results demonstrate that our approach outperforms state-of-the-art methods within a limited time budget, significantly enhancing exploration efficiency.**

I. Introduction

As RISC-V processor agile design emerges and diverse application demands increase, CPU customization has become increasingly popular. Open-source frameworks, such as Chipyard [1], automatically generate Register-Transfer Level (RTL) files based on user-defined design configurations written in Chisel [2]. With the support of HAMMER framework [3] and Electronic Design Automation (EDA) tools, the entire Very Large Scale Integration (VLSI) flow, which is from Chisel to GDSII, can be automated. Designers can easily modify their designs by adjusting various design parameters, including microarchitecture parameters and EDA tool options, to achieve improved Performance, Power, and Area (PPA) outcomes. Consequently, traditional challenges of CPU design can be redefined as design parameter optimization or Design Space Exploration (DSE) problems.

However, conflicts often arise among various Quality of Results (QoRs) metrics. For instance, better performance often necessitates greater power consumption or increased area. Traditional optimization methods employ weighted approaches to balance PPAs, converting the problem into a Single-Objective Optimization (SOO) framework. Nonetheless, with the advent of hierarchical design methodologies, module specifications may need adjustment in response to upper-level design requirements. In a SOO scenario, any changes in weights assigned to QoR metrics render the problem fundamentally different, necessitating re-optimization. On the other hand, conducting design verification for each adjustment incurs significant time costs, often requiring several weeks to complete the entire VLSI flow. Consequently, Multi-Objective Optimization (MOO) methods have been introduced into the DSE problems. MOO results in a set of Pareto solutions, each representing an optimal design that reflects a trade-off among different QoRs. When design requirements change, designers can select a design from the Pareto set according to their demands, eliminating the need for re-optimization. This significantly reduces the repeated optimizations and enhances design efficiency.

Traditional MOO methods, such as NSGA-II [4] and MOEA/D [5], are based on evolutionary algorithms. However, they require a substantial number of simulation points, which is not suitable for DSE problems that necessitate time-consuming simulation. In contrast, Bayesian optimization (BO) is a model-based optimization method that can yield effective results with relatively few actual simulation points. BOOM-Explorer [6], [7] and GRL-DSE [8] utilize BO in conjunction with features of RISC-V microarchitecture to facilitate effective exploration of the microarchitecture design space. However, these methods necessitate the evaluation of entire design space using surrogate models to identify the next data point for simulation, even when only a subset of design points requires simulation. Therefore, they consider only a limited number of microarchitecture design parameters and neglect the EDA tool parameters, which also significantly influence the design process. In contrast, REMOTune [9] and ROI-HIT [10] employ local BO [11], [12] and dimension reduction techniques [13], [14], effectively handling the high-dimensional DSE problem including the parameters of both microarchitecture and EDA tools. However, they ignore the constraint handling. In practical design scenarios, although a design yields excellent PPA results after logical synthesis, it cannot work if it violates timing constraints. Consequently, it is essential to incorporate constraints into the DSE process.

In addition, the number of parameters within the design space, encompassing both microarchitecture parameters and EDA tools (such as logic synthesis tools), can exceed 50, with the scale potentially reaching 10^{30}. Simultaneously, completing the processes of RTL generation, RTL simulation, and logic synthesis for a specific design parameter configuration

†Equal contribution
*Corresponding authors: {zhaori_bi, xzeng}@fudan.edu.cn

can take from 1 to 6 hours. Consequently, DSE methods can only model this vast design space based on a very limited dataset, inevitably introducing errors. Furthermore, if simulation resources are wasted on an inappropriate candidate point, it incurs significant time costs that substantially impact the effectiveness of exploration. Therefore, we propose a Self-Review Bayesian Optimization (SRBO) method for constrained high-dimensional DSE. It integrates a teacher-student paradigm within a local BO framework to reduce model errors and employs deep ensembles for effective constraint handling. Our contributions are summarized as follows:

- We propose a local Bayesian optimization based on teacher-student paradigm. To address the challenges of inaccurate modeling and low exploration efficiency within a vast design space, we concentrate on the current optimal local region and employ variable selection to identify key design parameters. Subsequently, we utilize Gaussian Process Regression (GPR) models as "students" and employ Multi-Layer Perceptron (MLP) models as "teachers" to mitigate model misdirection, thereby enhancing optimization efficiency.
- We propose a constraint classifier based on deep ensemble. To assess whether candidate design points satisfy the design constraints, we employ multiple MLPs for classification. It reduces the need for actual simulation of infeasible design points, thereby further enhancing optimization efficiency.
- The experimental results demonstrate that SRBO outperforms the state-of-the-art methods, achieving $1.93\times \sim 41.47\times$ hypervolume increment within the same time budget.

The remainder of this paper is structured as follows: Section II introduces the problem formulation. Section III details the SRBO algorithm. Section IV presents experimental results and compares performances of our proposed algorithm with state-of-the-art algorithms. Section V concludes this article.

II. Problem Formulation

The DSE problem can be formulated as a constrained MOO problem, as shown in (1).

$$\begin{aligned} \text{minimize} \quad & f_1(\boldsymbol{x}), \cdots, f_M(\boldsymbol{x}), \\ \text{s.t.} \quad & g(\boldsymbol{x}) \geq C, \end{aligned} \tag{1}$$

where $\boldsymbol{x}$ is design parameters and $f_i(\cdot)$ represents PPAs. $g(\cdot)$ denotes constraints, such as setup and hold time requirements.

To assess the quality of MOO, the concept of *domination* is introduced. For arbitrary data points $\boldsymbol{a}$ and $\boldsymbol{b}$, $\boldsymbol{a} \prec \boldsymbol{b}$ ($\boldsymbol{a}$ *dominates* $\boldsymbol{b}$) if

$$\begin{aligned} & \forall i \in \{1, \cdots, M\} \quad f_i(\boldsymbol{a}) \leq f_i(\boldsymbol{b}) \\ \text{and} \quad & \exists i \in \{1, \cdots, M\} \quad f_i(\boldsymbol{a}) < f_i(\boldsymbol{b}). \end{aligned} \tag{2}$$

The MOO yields a Pareto Set PS and the corresponding performance space is referred to as Pareto front PF.

$$\begin{aligned} & PS = \{\boldsymbol{x} \in X_C \mid \nexists\, \boldsymbol{x'} \in X_C : \boldsymbol{f}(\boldsymbol{x'}) \prec \boldsymbol{f}(\boldsymbol{x})\}, \\ & PF = \{\boldsymbol{f}(\boldsymbol{x}) \mid \boldsymbol{x} \in PS\}, \; X_C = \{\boldsymbol{x} \in X \mid g(\boldsymbol{x}) \geq C\}. \end{aligned} \tag{3}$$

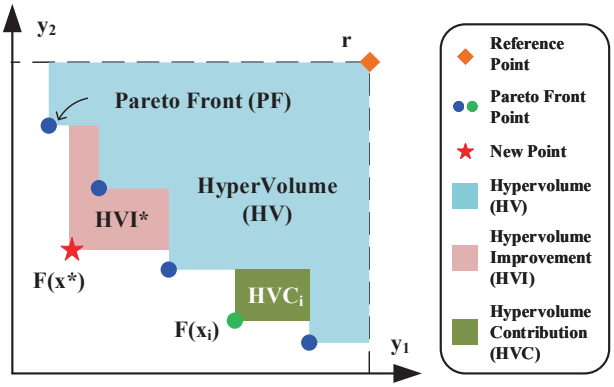

Fig. 1. The illustration of HyperVolume (HV), HyperVolume Improvement (HVI), and HyperVolume Contribution (HVC). A larger HV means a better PF.

In MOO, HyperVolume (HV) is a common performance indicator to assess the quality of the PF. As Fig. 1 shows, given a reference point $\boldsymbol{r}$ and a finite PF, the HV is the M-dimensional Lebesgue measure $\mathcal{M}$ of the space dominated by PF, as defined in (4).

$$\mathrm{HV}(PF, \boldsymbol{r}) = \mathcal{M}(\bigcup_{j=1}^{|PF|} [\boldsymbol{r}, \boldsymbol{y}_j]), \tag{4}$$

where $[\boldsymbol{r}, \boldsymbol{y}_j]$ denotes the hyper-rectangle bounded by $\boldsymbol{r}$ and $\boldsymbol{y}_j$. A larger HV value indicates a better PF, which means a better MOO result.

To compare the points in the PS, HyperVolume Contribution (HVC) is defined as (5). Similarly, to select the best candidate point, HyperVolume Improvement (HVI) of a candidate point $\boldsymbol{x}^*$ is defined as (6). As shown in Fig. 1, the green area is the HVC of $\boldsymbol{x}_i$, and the red area is the HVI of $\boldsymbol{x}^*$.

$$\mathrm{HVC}(\boldsymbol{x}_i | PF, \boldsymbol{r}) = \mathrm{HV}(PF, \boldsymbol{r}) - \mathrm{HV}(PF \setminus \boldsymbol{f}(\boldsymbol{x}_i), \boldsymbol{r}), \tag{5}$$

$$\mathrm{HVI}(\boldsymbol{x}^* | PF, \boldsymbol{r}) = \mathrm{HV}(PF \cup \boldsymbol{f}(\boldsymbol{x}^*), \boldsymbol{r}) - \mathrm{HV}(PF, \boldsymbol{r}). \tag{6}$$

III. Self-Review Bayesian Optimization

A. Overview of SRBO Framework

Our proposed SRBO framework is shown in Fig. 2. The SRBO method is built upon a local BO framework. It identifies key design parameters through a variable selection technique and explores designs near the current optimal design point with the highest HVC. The surrogate models leverage a teacher-student paradigm, where MLP models serve as the teachers and GPR models act as the students. This interaction reduces model error and yields more accurate prediction points. Additionally, SRBO employs a constraint classifier based on deep ensembles to model constraints, allowing it to assess the feasibility of candidate design points and filter out potentially invalid ones. Subsequently, the local BO computes the HVIs of the feasible candidate points based on the predicted values from the surrogate models, and the point with the largest HVI is selected for simulation. The results from the simulation will be incorporated into the explored dataset, thereby updating each model.

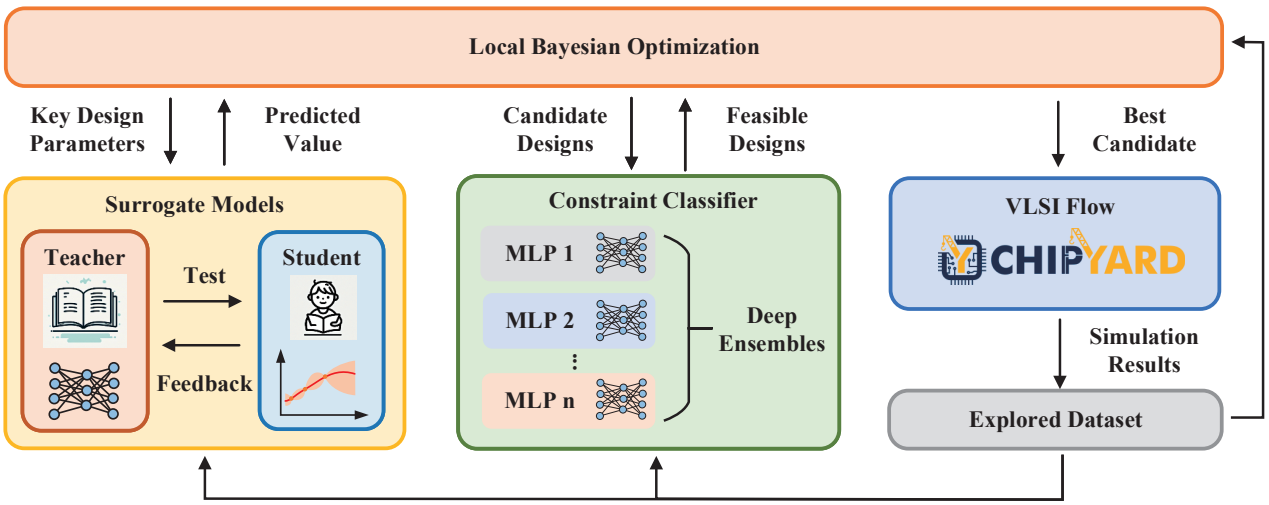

Fig. 2. An illustration of our proposed SRBO method. It utilizes a local BO framework to identify the key design variables and explore designs near the current optimal design point. The surrogate models based on the teacher-student paradigm model the PPAs in the key design space and provide the predicted value after self-review. Simultaneously, the constraint classifier based on deep ensemble assesses the constraints, filtering all candidate designs generated by the local BO to obtain the predicted feasible design points. The local BO ranks the candidates according to the predicted values provided by the surrogate models, selects the optimal candidate for simulation, and incorporates the results from the simulation into the explored dataset, updating each model with this new design point.

B. Teacher-Student Paradigm

The design space for high-dimensional DSE problems is extensive. For instance, the design space encompassing the parameters of the RISC-V BOOM microarchitecture and the Genus logical synthesis tool consists of 53 design variables with a range of 10^{30}. Consequently, modeling such a large design space using a limited number of sampled points inevitably introduces errors. These model errors may misguide the exploration process. Therefore, we employ a Teacher-Student Paradigm (TSP) to enhance model accuracy through self-review, improving overall exploration efficiency.

Traditional BO models the design space using a GPR model, which provides the mean and variance of predictions. Although the acquisition function can be employed to balance these mean and variance estimates, selecting an appropriate acquisition function and setting the hyperparameters often require sophisticated techniques, as the optimal choices can vary across different cases. This variability diminishes the robustness and generalization of BO.

TSP incorporates a teacher model and a student model. In our SRBO, the MLP model acts as the teacher $T(\cdot;\boldsymbol{\theta}_T)$, and the GPR model serves as the student $S(\cdot;\boldsymbol{\theta}_S)$. In addition to training with the dataset, the MLP incorporates the error between the predictions of the GPR model and the true outcomes into its loss function. By leveraging the GPR model's strong expressiveness while mitigating its misleading uncertainties, the MLP achieves more accurate predictions through a process of self-review, eliminating the need for experienced tricks.

As the Fig. 3 shows, firstly, the teacher (the MLP model) predicts the values of the candidate points (the red stars) based on the explored points D (the blue points).

$$\hat{\boldsymbol{y}}_{cand}(\boldsymbol{\theta}_T) = T(\boldsymbol{X}_{cand};\boldsymbol{\theta}_T), \tag{7}$$

where $\boldsymbol{X}_{cand}$ denote the candidate points.

Then, the teacher provides the candidate points and a selection of the explored points to the student for modeling.

$$\boldsymbol{\theta}_S^*(\boldsymbol{\theta}_T) = \arg\min_{\boldsymbol{\theta}_s} L_S(D_{test}(\boldsymbol{\theta}_T);\boldsymbol{\theta}_S), \tag{8}$$

$$D_{test}(\boldsymbol{\theta}_T) = \{\boldsymbol{X}_{cand} \cup \boldsymbol{X}_{valid}, \hat{\boldsymbol{y}}_{cand}(\boldsymbol{\theta}_T) \cup \boldsymbol{y}_{valid}\}, \tag{9}$$

where $\{\boldsymbol{X}_{valid}, \boldsymbol{y}_{valid}\}$ are extracted from the explored dataset D. L_S represent the loss function of the student. The student evaluates the explored points and returns the error between the predicted values and the actual values to the teacher.

$$L_{test}(D;\boldsymbol{\theta}_S^*(\boldsymbol{\theta}_T)) = MSE(\boldsymbol{\mu}_{\boldsymbol{\theta}_S^*(\boldsymbol{\theta}_T)}(\boldsymbol{X}), \boldsymbol{y}). \tag{10}$$

After that, the teacher is retrained in accordance with the loss function of the teacher L_T and the loss function L_{test} derived from the student's feedback to develop a more accurate model.

$$\boldsymbol{\theta}_T^* = \arg\min_{\boldsymbol{\theta}_T} L_T(D;\boldsymbol{\theta}_T) + \lambda L_{test}(D;\boldsymbol{\theta}_S^*(\boldsymbol{\theta}_T)). \tag{11}$$

In this work, our teacher model is set up as follows:

$$\begin{aligned} T(\boldsymbol{x};\boldsymbol{\theta}_T) : &Input\ \boldsymbol{x} \rightarrow Linear(n,256) \rightarrow ReLU \\ &\rightarrow Linear(256,64) \rightarrow ReLU \\ &\rightarrow Linear(64,32) \rightarrow ReLU \\ &\rightarrow Linear(32,1) \rightarrow Output\ y \end{aligned} \tag{12}$$

Acknowledging the potential for misleading pseudo-label predictions by the teacher, the student is evaluated against the existing ground truth labeled data, and its performance is consequently communicated back to the teacher. Upon the completion of the teacher-student interaction, the teacher, refined through regularization, produces reliable pseudo-labels for training the GPR model, thereby enhancing its data querying capability, even with limited labeled training data.

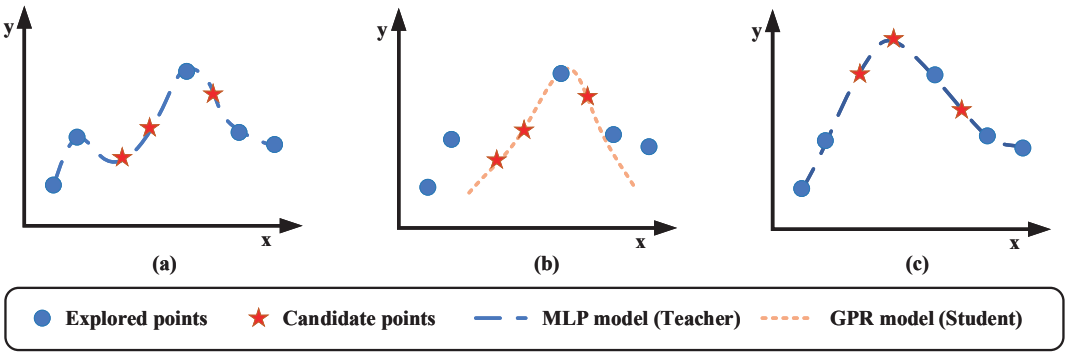

Fig. 3. An illustration of the Teacher-Student Paradigm (TSP). The blue points represent explored points, while the red stars denote candidate points. In the TSP of SRBO, the MLP model acts as the teacher, and the GPR model serves as the student. (a) Initially, the teacher predicts the values of the candidate points based on the explored points. (b) Subsequently, the teacher provides the candidate points and a selection of the explored points to the student for modeling. The student evaluates these explored points and returns the error between the predicted values and the actual values to the teacher, which is utilized as a loss function. (c) The teacher is then retrained in accordance with the loss function derived from the student's feedback to develop a more accurate model.

C. Constraint Classifier based on Deep Ensembles

In RISC-V processor design, it is crucial to adhere to the specified design constraints. For instance, if the timing constraints are not satisfied, even a design with optimal PPAs may result in functional errors, rendering it infeasible. Existing DSE methods often overlook constraint handling and typically only investigate design spaces that comply with these constraints. However, in the vast, high-dimensional DSE, there may exist design points that do not satisfy timing constraints, necessitating effective constraint management.

A common approach for handling constraints is to penalize design points that deviate from the required constraints. However, in digital IC design, a lack of adherence to constraints like timing can result in substantial changes across the entire design. At times, fine-tuning parameters may fail to yield a design that meets these constraints, rendering the distance from the constraint requirements ineffective as a guide for exploration direction.

To address these challenges, we propose using deep ensembles to transform the satisfaction of design constraints into classification problems. This involves utilizing multiple MLPs as classifiers and aggregating their predicted outputs to derive final results.

Deep Ensembles (DE) consists of a collection of neural networks, commonly MLPs, and are employed to model epistemic uncertainty. By training multiple independent MLPs and harnessing their diversity, DE improves accuracy and enhances uncertainty estimation. Each MLP in the ensemble is trained on the same dataset but initialized with different random weights. During inference, predictions from the ensemble are derived by averaging or combining the outputs of the individual models.

In the SRBO, we independently train N identical MLPs on all explored points D to model the probability of each design being either feasible or infeasible. The output of each MLP is a probability value between 0 and 1 for a given design point $\boldsymbol{x}$. Our constraint classifier computes the mean of the predicted values, utilizing the trained weights θ_i^* from each model.

$$C(\boldsymbol{x}) = \frac{1}{N}\sum_{i}^{N} M_{\theta_i^*}(\boldsymbol{x}). \tag{13}$$

In this work, we propose that if $C(\boldsymbol{x}) > 0.5$, $\boldsymbol{x}$ is considered a feasible design candidate for subsequent optimization. We utilized 5 MLPs to construct the DE, where each MLP comprises 2 hidden layers, each containing 64 neurons.

D. Local Bayesian Optimization

In addition to the vast design space associated with high-dimensional DSE problems, the time required for design simulation and verification is substantial. For instance, generating RTL files, performing RTL simulation, and executing logic synthesis for a single RISC-V BOOM design can take between 1 and 6 hours. Consequently, achieving a global optimum within a limited time budget is impractical. In this context, identifying a better solution is often more valuable than pursuing the absolute best. Therefore, our approach prioritizes the exploration of current optimal design points in the vicinity and emphasizes key design parameters, which significantly reduces the problem's dimensionality and enhances optimization efficiency.

Like ROI-HIT [10], we apply a sensitivity matrix S [15] to measure the importance of variables.

$$S = \{s_{ij} \mid i = 1, \cdots, n,\ j = 1, \cdots, M\}, \tag{14}$$

$$\begin{aligned} s_{ij} &= \frac{Var[E(y_j|x_i)]}{Var(y_j)} \approx \frac{\sum_{l=1}^{r_i} |A_i^l|[(\bar{y}_j)_i^l - \bar{y}_j]^2}{\sum_{\boldsymbol{x}\in X}[y_j(\boldsymbol{x}) - \bar{y}_j]^2}, \\ \bar{y}_j &= \frac{1}{|X|}\sum_{\boldsymbol{x}\in X} y_j(\boldsymbol{x}), \quad (\bar{y}_j)_i^l = \frac{1}{|A_i^l|}\sum_{\boldsymbol{x}\in A_i^l} y_j(\boldsymbol{x}), \end{aligned} \tag{15}$$

where X represents the dataset, r_i represents the number of value which x_i can be and A_i^l represents the set of points for which the variable x_i is set to its l-th value.

Given that the current optimal point in our work satisfies the constraints, we posit that the key design parameters should exhibit sensitivity to PPAs while remaining insensitive to the

constraints. Consequently, we assign equal weights to PPAs and assign negative values to the weights of the constraints. The key design variables are obtained as follows.

$$V_i = \sum_{j=1}^{m} (w_j \cdot s_{ij}) + C_p\sqrt{1/n_i}, \tag{16}$$

$$var_{key} = \{var_i \mid V_i \geq p \cdot V_{max}\}, \tag{17}$$

where n_i is the number that the i-th variable has been selected as the key variable, and C_p and p are hyper-parameters. In this work, $C_p = 0.01$ and $p = 0.5$.

We select the explored point with the highest HVC, which can be calculated using (5), as the optimal design. The design space is then restricted to the vicinity of this current optimum. For non-key variables, the values remain consistent with the current optimum, while for the key variables, only the values within the neighboring interval are considered as candidate points. Surrogate models and constraint classifier are trained exclusively for the key variables. Candidate points are firstly filtered from infeasible points using the constraint classifier. Subsequently, surrogate models are employed to predict their PPAs, followed by the calculation of HVI using (6). The design exhibiting the maximum HVI will be simulated.

IV. Experimental Results

A. Experimental Setup

We explore the design space for a RISC-V BOOM [16], [17] core and a Rocket [18] core, both configured as RV64GC. The PPA results are evaluated using System-on-Chip (SoC) designs in all experiments, each equipped with either the BOOM core or the Rocket core as its processor. The peripheral modules of these SoCs consist of standard components provided by the Chipyard framework. A 7nm ASAP7 Process Design Kit (PDK) [19] is utilized within the VLSI flow. Since ASAP7-based designs are not manufacturable, this paper focuses solely on the front-end design for the experiments. The design parameters are shown in TABLE I.

Firstly, the RTL design is generated by Chipyard framework. Then, an open-source simulator Verilator [20] simulates the design to obtain Cycle Per Instruction (CPI). 13 benchmarks are selected to evaluate the performance of the design: *dhrystone, median, mm, mt-matmul, mt-vvadd, multiply, qsort, rsort, spmv, towers, vvadd, fir2dim*, and *whetstone*. The average CPI of benchmarks is taken as the performance metric. Finally, Cadence Genus Synthesis Solution 19.10 is used as the logic synthesis tool to report the timing violations and estimate power and area metrics. The power metric is the total power. The clock frequency is set as 500MHz. Design points that fail to meet the timing constraints are categorized as failure points and are excluded from the resulting statistics.

We compare SRBO with 4 state-of-the-art methods: (1) BOOM-Explorer [6], a BO-based method for microarchitecture DSE, (2) GRL-DSE [8], another BO method for microarchitecture DSE, (3) REMOTune [9], a local BO method for high-dimensional DSE that by the trust regions and random embedding, (4) ROI-HIT [10], a recent local BO method for high-dimensional DSE that combines the ROIs and variable selection. To verify the effectiveness of TSP and DE, we implement two versions of SRBO: (1) SRBO w/o TSP, a SRBO method without TSP, (2) SRBO, the full version of SRBO.

All algorithms are implemented in Python. All algorithms are initialized with the same set of 100 designs. The experiments are executed within a maximum time budget of one day (86400 seconds). The HV indicator serves as a benchmark

metric for evaluating the quality of the solutions generated by the algorithms. For HV computation, the reference point is defined as the maximum observed values of CPI, power, and area within the initial dataset. The experiments are conducted five times, and the average results are subsequently reported.

B. RISC-V BOOM Design Space Exploration

The optimization results are shown in TABLE II and Fig. 4. In the table, Δ *HV* denote the increase in HV compared to the HV of the initial dataset, while *# Fail.* and *# Sim.* represent the number of failure points and simulation points, respectively. Compared with the state-of-the-art methods, SRBO obtains the largest Δ HV and achieves 41.47× and 3.04× HV increment over REMOTune and ROI-HIT.

BOOM-Explorer and GRL-DSE are well-suited for microarchitecture design space exploration (DSE) problems with relatively few design variables. However, for high-dimensional DSE problems characterized by extensive design spaces, both BOOM-Explorer and GRL-DSE exhibit less increase in HV. The introduction of the local BO method significantly enhances the performance of ROI-HIT, SRBO w/o TSP, and SRBO during the early stages of optimization. Additionally, the implementation of a constraint classifier allows SRBO w/o TSP and SRBO to achieve a lower failure rate. Although the BOOM-Explorer has the zero failure rate, it has little HV increase, so its failure rate has little significance. Furthermore, thanks to the teacher-student paradigm, the accuracy of the SRBO model continually improves, enabling it to escape from local optima in the ROI-HIT method.

C. Rocket Design Space Exploration

The optimization results are shown in TABLE III and Fig. 5. Compared with the state-of-the-art methods, SRBO obtains the largest Δ HV and achieves 6.79× and 1.94× HV increment over REMOTune and ROI-HIT.

The optimization results for Rocket are generally consistent with those of RISC-V BOOM. However, Rocket is relatively easier to optimize within the specified constraints, allowing other unconstrained methods to also achieve favorable optimization results. As illustrated in the Fig. 5, both SRBO and ROI-HIT became trapped in the same local optimum region. But, due to the self-review model, SRBO successfully escapes from this region.

V. CONCLUSION

In this paper, we propose a self-review Bayesian optimization method for constrained high-dimensional DSE. To address the challenges posed by the vast design space and time-consuming simulations, SRBO integrates a teacher-student paradigm within a local BO framework to reduce model errors and enhance the exploration efficiency. Given the importance of design constraints in digital IC designs, SRBO utilizes deep ensembles for effective constraint handling. Experimental results demonstrate that our approach outperforms state-of-the-art methods within a limited time budget. Our proposed SRBO method is a general framework that we anticipate will be applicable to other high-dimensional, expensive optimization problems with constraints in the future.

***Abstract*—Sparsity is widely prevalent in real-world applications, yet existing compiler optimizations and code generation techniques for sparse computations remain underdeveloped. Sparse matrix-matrix multiplication (SpMM) is a representative operator in sparse computations, whose performance is often limited by the design of sparse formats and the extent of hardware architecture optimization. Most existing solutions achieve high-performance SpMM through two approaches: (1) meticulously designed kernels and specialized sparse formats, which require extensive manual effort, or (2) tensor compilers that support code generation, though these typically offer limited support for sparse patterns, making it challenging to adapt to complex sparsity patterns in practical applications. This paper presents SpMMTC, an input-aware sparse tensor compiler. Given a sparse matrix as input, SpMMTC analyzes its non-zero distribution and generates a vectorized kernel optimized for SpMM on the specific matrix. We evaluated SpMMTC on various workloads. It achieves speedups of 1.21x to 2.97x over state-of-the-art methods such as TACO, TVM, and ASpT on different multi-core processors. It also provides a speedup of up to 1.52x for sparse MobileNetV1 inference on the edge device.**

I. Introduction

Sparsity is prevalent in deep learning applications, such as image classification [1], natural language processing [2], and object detection [3]. As DNN models grow, pruning weights becomes essential to reduce storage and computation, especially on resource-constrained devices [4]. Unstructured sparsity, a common pruning method, removes weights with minimal impact on accuracy, resulting in matrices with many zeros. Likewise, graph neural networks [5] often feature sparse adjacency matrices. Sparse matrix-matrix multiplication (SpMM) is a fundamental operator in sparse computation, multiplying a sparse matrix A with a dense matrix X to produce a dense matrix Y. SpMM is widely applied in areas like PageRank [6], recommender systems [7], and graph clustering [8].

The performance of SpMM is primarily influenced by two factors: 1) ***sparse pattern*** and 2) ***hardware architecture***. The sparse pattern impacts memory access during computation, as the indices pointing to the dense matrix are non-contiguous, leading to a low data reuse ratio. The hardware architecture affects SpMM performance by enabling the development of high-performance parallel execution strategies that fully leverage the hardware's capabilities. Existing solutions for high-performance SpMM predominantly rely on runtime libraries. These libraries requires a carefully designed SpMM kernel and typically reorders the sparse matrices to improve data reuse before the kernel is executed. However, this often introduces cumbersome reordering algorithms and similarity measurements between rows or columns of the matrices [9]. Additionally, previous works, such as TC-GNN [10], aim to exploit dense blocks in sparse matrices to better utilize the tensor core units in NVIDIA GPUs, but this approach inevitably leads to unnecessary computations on zero elements, known as *redundant FLOPs* [11]. To achieve a high-performance SpMM kernel without extensive manual effort, tensor algebra compilers, such as TACO [12] and TVM [13], [14], have been proposed to automatically generate SpMM kernels. However, these compilers rarely analyze the sparse pattern of matrices, and TVM-style compilers often rely on long-term auto-tuning processes.

Therefore, to take both the sparse pattern and hardware architecture into consideration, we propose SpMMTC, an input-aware sparse tensor compiler for SpMM on multi-core CPUs. It takes the sparse matrix A and dimensions of dense matrix X as input, analyzes the non-zeroed distribution of A, then determines the optimal tile sizes along the direction of the rows of A and the columns of X based on the analysis results and backend architecture. Since the number of non-zeros in each row of A varies, the tiles of A may have unequal dimensions, which differs from the tiling techniques used in GEMM optimization [15]. SpMMTC generates high-performance kernels for these tiles that leverage SIMD units without redundant FLOPs. To accommodate the vectorized kernels, SpMMTC also generates transformation code to reorganize the data layout of the tiles. The generated code is assembled into several functions that are compiled into a library and invoked at runtime as needed.

In summary, our contributions in this paper can be concluded as the following:

- We propose SpMMTC, a sparse tensor compiler designed to automatically generate high-performance SpMM kernels tailored to specific sparse patterns, dimensions, and hardware architectures.
- SpMMTC analyzes the non-zero distribution of sparse matrices, optimizes memory access, and generates high-performance SpMM kernels with vectorized execution.
- We conducted experiments to evaluate SpMMTC on SpMM across various workloads on multi-core proces-

✉Corresponding Author

sors. The experimental results show SpMMTC achieves speedups of 1.21x to 2.97x over state-of-the-art baselines such as TACO, TVM, and ASpT on Intel and ARM multi-core processors. SpMMTC also provides a speedup of up to 1.52x for sparse MobileNetV1 inference on the widely-used edge device.

II. Background and Motivation

SpMM is formulated as $Y = AX$, where A is sparse matrix with dimension $M \times K$, X is a dense matrix with dimension $K \times N$, and their calculation results are stored in dense matrix Y with dimension $M \times N$. The sparse A is usually stored in compressed sparse format like CSR and CSC. Algorithm 1 illustrates SpMM computation using the CSR format. A key challenge in SpMM is the indirect memory access in the dense matrix X (Line 4). Because the column indices of matrix A are non-contiguous, multiple rows of X are skipped as the iteration over the K-dimension progresses, leading to poor cache locality.

Algorithm 1 SpMM (Sparse Matrix Matrix Multiplication)

Input: CSR $A[M][K]$, float $X[K][N]$
Output: float $Y[M][N]$
1: **for** $i = 0$ **to** $A.num_rows - 1$ **do**
2: **for** $k = A.\text{ptr}[i]$ **to** $A.\text{ptr}[i+1] - 1$ **do**
3: **for** $j = 0$ **to** $N - 1$ **do**
4: $Y[i][j] += A.\text{values}[k] * X[A.\text{col_idx}[k]][j]$

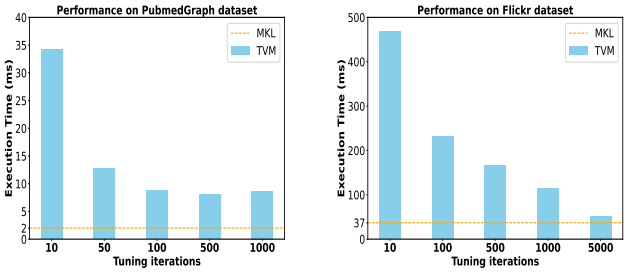

Fig. 1: Performance comparison between MKL and TVM for single-precision SpMM on x86 architecture

Recently, tensor algebra compilers such as TACO and TVM have been introduced to automatically generate high-performance kernels. These compilers generally adhere to the philosophy of separating the computation from the scheduling [16]. They provide a Domain-Specific Language (DSL) [17]–[19] that allows developers to independently define both the computation and the scheduling primitives of operations such as parallelizing, reordering, and unrolling for-loops. Moreover, TVM provides the auto-tuning ability to generate optimized, high-performance kernels. We compare the MKL [20] with TVM, using different tuning iterations, on the PubmedGraph and Flickr datasets[1] for SpMM on x86 architecture. The results are shown in Figure 1. As the number of iterations increases, the performance of TVM improves, but it remains lower than MKL; additionally, the tuning process is time-consuming (e.g., tuning 5,000 iterations on the Flickr dataset takes over 10 hours). While compiler-based methods free developers from dealing with intricate hardware architecture and complex kernel designs, they struggle to analyze sparse patterns, which hinders further optimization of SpMM kernels.

[1]available at https://networkrepository.com

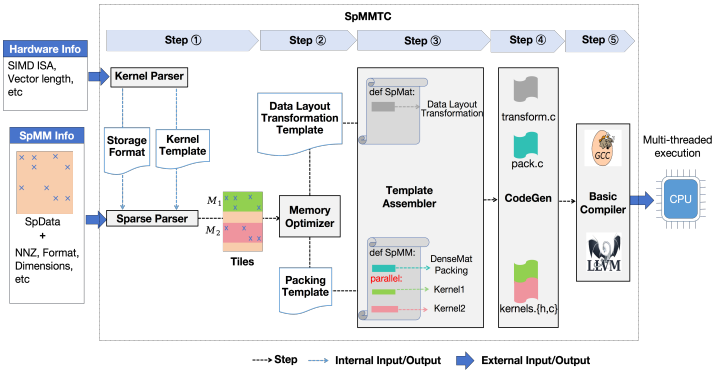

Fig. 2: Overview of SpMMTC. SpMMTC takes SpMM information, including the sparse matrix, storage format, dimensions of the two involved matrices, and other details as input, then optimizes and generates code tailored for the specific SpMM.

Motivated from the above analysis, we design SpMMTC, an input-aware sparse tensor compiler to generate SpMM kernels and its overview is shown in Figure 2. SpMMTC follows five steps to generate SpMM kernels: 1) It takes SpMM and hardware information as input, analyzes the sparse patterns, and determines the storage format, kernel template, and sparse tiles for the computation; 2) It optimizes memory access for sparse and dense matrices and outlines the corresponding templates; 3) It assembles these separate templates into functions; 4) It generates C/C++ source code to instantiate the templates and implement these functions; and 5) All the code is compiled and executed on multi-core CPUs.

III. SpMMTC Design

In this section, we detail SpMMTC, which is composed of the Kernel Parser, Sparse Parser, Memory Optimizer, Template Assembler, and CodeGen modules.

A. Kernel Parser

Kernel Parser determines how computations are performed on SIMD units and sketches out the sparse kernel template. Inspired by BLIS [15], the template uses an outer-product approach as shown in Figure 3. The advantages of outer product include a high computation-to-memory ratio (CMR) [21] and the elimination of redundant FLOPs.

1) Storage Format: The template utilized by Kernel Parser operates on tiles in A and X. To maintain the outer-product computation, it is essential to organize the sparse tiles of A in column-major order using three arrays: **tiles**, **indices**, and **data**, which are consistent with CSR or CSC formats. Each tile occupies a few entries in **tiles** that **tiles**$[i][0]$ represent the offset in **indices** and **data**, **tiles**$[i][1]$ indicates the starting row of the i-th tile. The indices of non-zero elements of this

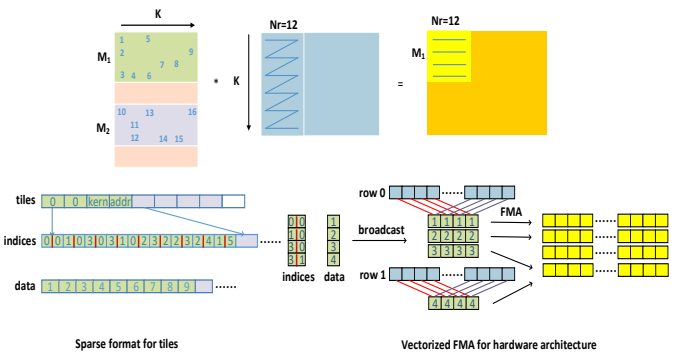

Fig. 3: Sparse kernel template. The numbers in the matrix represent non-zero elements. The black grids represent vector registers and we assume each vector register holds 4 elements. The sparse matrix is organized by three arrays: **tiles**, **indices** and **data**.

tile store from **indices**[**tiles**$[i][0]$] to **indices**[**tiles**$[i+1][0]$], and **tiles**$[i][2:]$ stores the address of the kernel for this tile. Slightly different from CSR, each entry in **indices** is divided into two parts bitwise. The higher part stores the row index of the non-zero element within the tile, while the lower part stores its column index, facilitating the retrieval of the vector register used to store computation results. In our experiments, the type of **indices** is **int32_t** for single precision data and **int64_t** for double precision data, with the upper 5 bits used for the row index and the remaining lower bits for the column index. **data** stores the value of each non-zero element in the tile and corresponds to the entries in **indices**.

```
// template parameters
const int Mi = 4, N = 64, Nr = 12, d = 4, si = 2;
int j;
for (j = 0; j <= (N - Nr); j += Nr) {
int32x4_t loc;
float32x4_t sp, bd0, bd1;
// Following registers are determined by Mi and Nr
float32x4x3_t ds0, ds1, res0, res1, res2, res3;
int col_prev = -1;
for (int t = tiles[i][0]; t < tiles[i + 1][0]; t += d) {
    sp = load(&data[t]), loc = vload(&indices[t]);
    for (int m = 0; m < d; m += si) {
        int idx0 = loc[m] >> 27;
        int c0 = loc[m] & 0x7ffffff;
        bd0 = broadcast(sp[m]);
        if (c0 > col_prev) ds0 = vload(&Xpack[c0][j:j+Nr]);
        switch (idx0) case 0: res0 = vFMA(res0, bd0, ds0);
        // omit other cases: 1, 2, 3
        // next FMA
        int idx1 = loc[m + 1] >> 27;
        int c1 = loc[m + 1] & 0x7ffffff;
        bd1 = broadcast(sp[m + 1]);
        if (c1 > c0) ds1 = vload(&Xpack[c1][j:j+Nr]);
        else ds1 = ds0;
        switch (idx1) case 0: res0 = vFMA(res0, bd1, ds1);
        // omit other cases: 1, 2, 3
        ds0 = ds1, col_prev = c1;  // next iteration
    }}
// write back to output
int r = tiles[i][1];
vstore(&Y[r + 0][j], res0); vstore(&Y[r + 1][j], res1);
vstore(&Y[r + 2][j], res2); vstore(&Y[r + 3][j], res3); }
// handling the boundary of remaining 4 = (N - j)
...
```

Listing 1: An instantiation of kernel template on **FP32** precision with an unrolled vectorized FMA

2) Kernel Template: Kernel Parser can determine the SIMD ISA and vector register length of the backend CPU architecture in advance. To implement high-performance sparse kernel, Kernel Parser outlines kernel template that utilizes SIMD instructions. For convenience, we assume d represents the number of elements each vector register can hold, the size of the i-th tile in A is (M_i, K), and the tile size in X is (K, N_r). Since the non-zeros of each tile are stored contiguously, every d non-zeros can be loaded into a vector register with a single load instruction. The computation involves multiplication of two tiles, requiring one vector register to store the broadcast values and N_r/d vector registers to store a row of the dense tile, with results maintained in $M_i \times N_r/d$ vector registers. N_r/d vectorized FMA operations are then performed on these three types of vector registers. Moreover, the corresponding indices are loaded into a vector register to determine which row of the dense tile to load and where to store the results in the vector registers. To maximize instruction-level parallelism, the template unrolls the for-loop associated with FMA operations by a factor of s_i, as shown in Listing 1.

3) Optimization Goal: The sparse kernel for the i-th tile is derived from kernel template by CodeGen module and is determined by the parameters M_i, N_r, d and s_i. Taking Listing 1 as an example, we assume the iteration over non-zeros of the i-th tile goes through T times (Line 10), the CMR can be calculated as follows:

$$\begin{aligned} \text{CMR} &= \frac{\sum_{t=1}^{T} N_r \cdot d}{\sum_{t=1}^{T} [1 + 1 + N_r \cdot c(t)/d]} \\ &= \frac{d^2}{2d/N_r + \sum_{t=1}^{T} c(t)/T} \end{aligned} \tag{1}$$

where $c(t)$ represents at the t-th iteration, the number of distinct column indices in vector register loaded from **indices** array (Line 11), which determines the frequency of memory accesses to the rows of the dense tile (Lines 16 and 23). Additionally, since the number of vector registers is limited in each core, the vector registers used in our sparse kernel must satisfy the following constraints:

$$\begin{cases} 1 + 1 + s_i + \frac{N_r}{d} s_i + \frac{M_i N_r}{d} \leq \#\text{vec_reg} \\ s_i \geq 1, d \ \% \ s_i == 0, N_r \ \% \ d == 0 \end{cases} \tag{2}$$

where "1+1" indicates vector registers to store elements in **indices** and **data**, and the number of vector registers to store broadcasting values and dense tiles is multiplied by s_i due to the unrolling of for-loop (Lines 6 and 8). The optimization goal of sparse kernel is to maximize CMR while also maximizing s_i, subject to the constraints in (2). From equation (1), larger N_r and smaller $\sum_{t=1}^{T} c(t)/T$ contribute to greater CMR. In our experiments, we set $N_r = 16$ and 12 on x86 and ARM processors, respectively. The value of $\sum_{t=1}^{T} c(t)/T$ is related to the sparse tile size M_i and will be discussed later. After determining M_i and N_r, the maximum s_i is calculated as follows:

$$\begin{cases} s_i \leq (\#\text{vec_reg} - 2 - \frac{M_i N_r}{d})/(1 + \frac{N_r}{d}) \\ s_i \geq 1, d \ \% \ s_i == 0 \end{cases} \tag{3}$$

Algorithm 2 Tile selection

        }
    }
}
```

Listing 2: An instantiation of data layout transformation template

B. Sparse Parser

Since kernel template is based on tiles from sparse matrix, Sparse Parser aims to select the sparse tiles so that the i-th tile, with shape (M_i, K), minimizes $\sum_{t=1}^{T} c(t)/T$ in equation (1) to achieve optimized CMR.

To address this, Sparse Parser first calculates the number of non-zeros in each row (e.g., **ptr**[i+1]-**ptr**[i] in CSR format), then adopts a greedy strategy to choose tiles, as shown in Algorithm 2. The algorithm takes sparse storage format like CSR as input and returns the number of tiles N_t along with their row ranges $\{(S_1, E_1),...(S_{N_t}, E_{N_t})\}$, where (S_i, E_i) indicate the range of the i-th tile. Intuitively, a tile composed of rows with more non-zero elements is likely to reduce the number of distinct columns in the vector register and increase the number of for-loop iterations, resulting in a smaller $\sum_{t=1}^{T} c(t)/T$. Thus, the algorithm begins with the available row that has the maximum number of non-zeros when identifying a new tile (Lines 6∼8). The algorithm tentatively expands the current tile by adding its last row or next row, then simulates the procedure of sparse kernel on the expanded tile to calculate $\sum_{t=1}^{T} c(t)/T$. The algorithm records the best result and expands the tile accordingly. If the calculations from the tentatively expanded tile are less than the recorded best result, or if expanding by one row would violate the constraint in (2), the shape and row range of the current tile are determined, and the algorithm proceeds to find the next tile.

C. Memory Optimizer

1) Data Layout Transformation: Conventionally, sparse matrices are stored in CSR or CSC formats. To adapt the storage format to our sparse kernel, Memory Optimizer outlines a template for data layout transformation, which is later instantiated by the CodeGen module. Listing 2 illustrates the instantiation of transformation template from CSR format shown in Figure 3. Variables such as **NNZ, Nt, t_info** are template parameters populated at CodeGen stage. **t_info**[i][0] and **t_info**[i][1] store the row range of the i-th sparse tile, while **t_info**[i][2:] stores address of the specific sparse kernel to be invoked during the computation of the sparse tile. Memory optimizer employs min heap to ensure the non-zeros in the tile are organized in column-major reorder.

2) Dense Matrix Packing: The above descriptions focus on the optimization of the sparse matrix, but optimizing the data layout of the dense matrix is also important. Memory Optimizer also outlines a template for packing dense matrix into tiles with shape (K, N_r). The benefit of packing is to improve the locality of dense tiles in sparse kernel. The template packs dense matrix as shown in Figure 4. Specifically, each thread is responsible for packing one row. Since both the dense matrix and tiles are typically stored in row-major order, this row packing effectively leverages cache locality.

D. Template Assembler

So far, there are three types of templates proposed by SpMMTC. Since these templates are separate, Template Assembler assembles them into two types of functions: sparse matrix definition (**SpMat**) and **SpMM** kernel, as shown in Figure 2. The specific code for these functions is generated by the CodeGen module. The **SpMat** function internally utilizes the

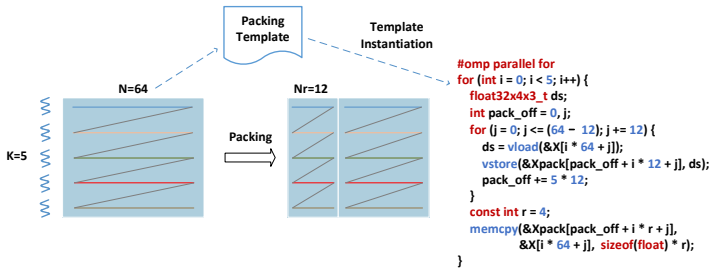

Fig. 4: Packing of a dense matrix and instantiation of a template with dimensions 5 × 64 and **FP32** precision. Each thread is responsible for packing one row.

data layout transformation code to convert the original sparse format (e.g., CSR, CSC) into the structures **tiles**, **indices**, and **data**, as previously described, and returns a handler specifying these structures. Users must call this function before executing the **SpMM**. When invoking the **SpMM** function, users provide the handler and the dense matrix as inputs. The function first packs the dense matrix and then calls the appropriate sparse kernel based on the current tile being processed.

E. Code Generation

The CodeGen module generates code to implement the **SpMat** and **SpMM** functions defined by the Template Assembler. For dense matrix packing, the code can be directly generated based on the dimensions of the dense matrix and the packing template. For sparse matrices, the sizes of each tile are determined using Algorithm 2, where the size of the i-th tile with a row range (S_i, E_i) is calculated as $M_i = E_i - S_i$. CodeGen then generates transformation code using the data layout transformation template proposed by the Memory Optimizer, as shown in Listing 2. Furthermore, based on the constraint in (3), SpMMTC selects the maximum unroll factor s_i to generate code with kernel template. The generated code consists of C/C++ source files, and the corresponding functions are compiled into a dynamic library, enabling users to invoke them at runtime.

IV. EXPERIMENT

A. Setup

We evaluate SpMMTC on x86 and ARM multi-core architectures: Intel Xeon Gold 5120, Kunpeng 920 (KP920) and Raspberry Pi 4 (RPi 4). In our experiments, the two servers are equipped with 56 and 64 cores, respectively, each with 256 GB of RAM, while the embedded device has 4 cores and 4 GB of RAM. We implement SpMMTC in C/C++, and the generated code is compiled using GCC with the `-O3` optimization flag.

B. Benchmarks

We conduct SpMM evaluations on two workloads: (I) sparse matrices in scientific computation and (II) sparse matrices in deep learning. For SpMM in scientific computation, we select datasets as shown in Table I, and for SpMM in deep learning, we use sparse matrices of ResNet50 model with magnitude pruning and random pruning [22] provided by deep learning

matrix collection (DLMC) [23]. The following state-of-the-art libraries or compilers are used as baselines: 1) MKL, a linear algebra library optimized for x86 architectures by Intel; 2) ASpT [9], a high-performance sparse computation library that enhances data reuse by reordering rows; 3) TACO, a tensor compiler for linear algebra; 4) TVM, a tensor compiler with auto-tuning capabilities; and 5) XNNPack [24], a deep learning library providing SpMM interface.

C. Performance Analysis

1) Workload I: We evaluate these methods on SpMM using both FP32 and FP64 precisions, setting the columns of dense matrices (N) to 512. The experiments are performed in a multi-thread environment (56 threads on Intel and 64 threads on KP920) and their results are shown in Figure 5. ASpT demonstrates superiority over other baselines by reordering rows of sparse matrices before execution, thereby improving data reuse. Among the two tensor compilers, TVM outperforms TACO in most datasets due to its auto-tuning capability for generated kernels. On the Intel server, SpMMTC achieves up to 419.52 GFLOPs (FP32) and 200.78 GFLOPs (FP64), surpassing the baselines with an average speedup of 2.46x over MKL, 1.30x over ASpT, 3.11x over TACO, and 2.97x over TVM. On the ARM server, where XNNPack is used instead of MKL, SpMMTC achieves up to 299.65 GFLOPs (FP32) and 177.79 GFLOPs (FP64), outperforming all baselines with an average speedup of 1.99x over XNNPack, 1.48x over ASpT, 2.08x over TACO, and 1.95x over TVM, similar to its performance on the x86 architecture. Additionally, SpMMTC selects each optimal tile in at most 28 iterations on x86 architectures and 8 iterations on ARM architectures (Lines 10∼21 in Algorithm 2), making it more efficient than other tensor compilers' auto-tuning process.

2) Workload II: Unlike scientific computation, matrix dimensions in deep learning are smaller. We also evaluate SpMMTC performance under this scenario on Intel and KP920 servers using FP32 precision. Figure 6 shows the evaluation results on the sparse matrices of ResNet50. The model is pruned under varying sparsity levels with magnitude pruning and random pruning, comprising a total of 540 matrices.

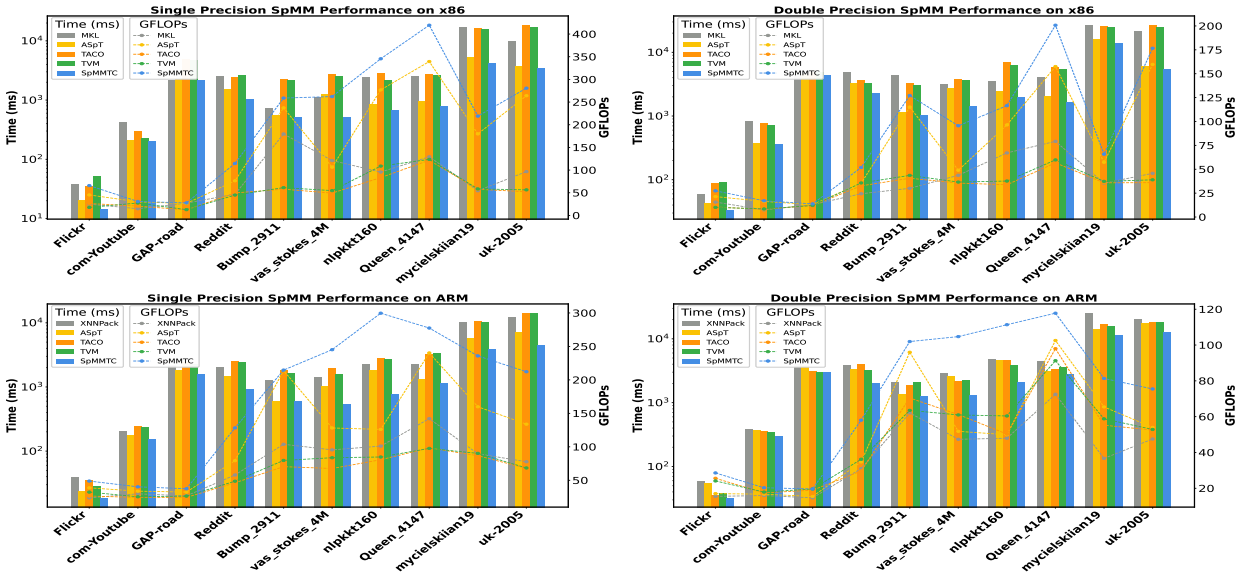

Fig. 5: SpMM performance of *Workload I* on x86 (Top) and ARM architectures (Bottom).

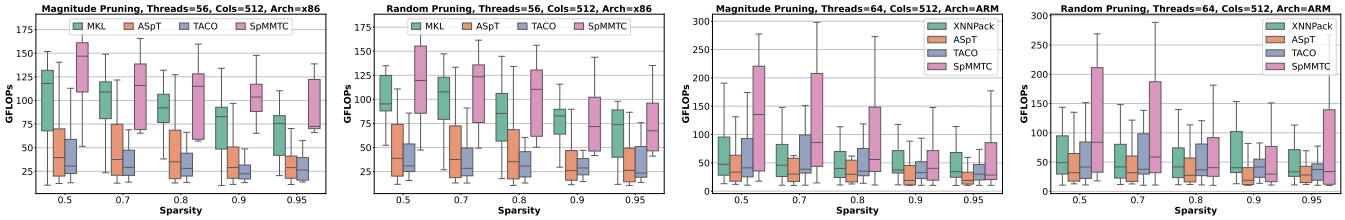

Fig. 6: SpMM performance of pruned ResNet50 on x86 and ARM architectures.

These matrices come from sparse filters, where convolution operations can be converted into matrix multiplications with im2col operation. The evaluations are conducted in a multi-thread environment, with the columns of the dense matrix set to 512 as well. The experimental results show that the throughput of these methods is affected by sparsity. As sparsity increases, their throughput decreases accordingly. In *Workload I*, ASpT demonstrates advantages over other baselines, but it is less efficient for deep learning computation workloads. SpMMTC outperforms all baselines on both architectures, achieving an average speedup of 1.21x over MKL, 1.84x over ASpT, 1.39x over XNNPack, and 2.28x over TACO.

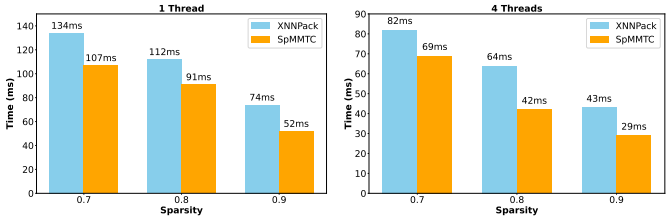

Fig. 7: End-to-end inference time of pruned MobleNetV1 on RPi 4 device.

3) MobileNetV1 on edge: MobileNetV1 is a well-known DL model widely used in image classification and object detection on mobile or edge devices. Optimizing the model's performance can help improve user experience and battery energy consumption. To evaluate SpMMTC performance on MobileNetV1, we replace sparse convolution operations with im2col operations using our SpMM and evaluate end-to-end inference under different sparsity levels on the RPi 4 device. We compare SpMMTC with XNNPack, and the results are shown in Figure 7. SpMMTC achieves a speedup of up to 1.52x over XNNPack under sparsity levels ranging from 0.7 to 0.9.

V. Conclusion

In this paper, we propose SpMMTC, a sparse tensor compiler designed to automatically optimize and generate SpMM code. SpMMTC takes a sparse matrix and the dimensions involved in SpMM as inputs, analyzes the sparse patterns of the matrix, and generates high-performance kernels specialized for SpMM with identical dimensions and sparse matrix, leveraging vectorized acceleration on multi-core architectures. In our experiments, SpMMTC outperforms state-of-the-art methods, including MKL, ASpT, TACO, and TVM.

jack25946705@gmail.com, ylli@cs.nycu.edu.tw

ABSTRACT

As technology nodes continue to shrink, Complementary FET (CFET) structures, which stack PMOS and NMOS together, have emerged as a promising candidate for next-generation technology. Due to the reduction in routing tracks, the insertion of dummy polys to increase routing resources and the use of M2 during the synthesis of CFET standard cells have become more inevitable. These two factors make block-level routing significantly more challenging. To address this, we introduce the methods to utilize the backside (BS) routing resources at the CFET standard cell synthesis stage and efficiently handle CFET transistor folding. To the best of our knowledge, this is the first work to consider BS routing resources at the cell synthesis stage and efficiently address transistor folding in the CFET stacked structure. In the transistor folding and placement stages, we utilize Euler paths to estimate the lower bound of contacted poly pitch (CPP) and apply dynamic programming (DP) to calculate the frontside minimum required tracks (FMRT) of BS-resource-aware placements. The subsequent satisfiability modulo theories (SMT) approach determines which tracks the devices occupy and completes cell routing. Experimental results show that compared to previous work [11], we achieve reductions of 1%, 45%, and 19% in #CPP, #M2 tracks, and runtime, respectively.

1. INTRODUCTION

Due to the scaling of semiconductor technology, device structures like FinFET face limitations due to the separation between two types of devices. Therefore, CFET structures, which stack both device types together, have become a mainstream approach for the next generation technology. However, the reduced number of available routing tracks and complex design rules impose significant challenges on both cell-level and block-level routing in the frontside (FS) back end of line (BEOL). Backside power delivery networks (BS PDN) [1] have demonstrated IR-drop reduction in both 2D and 3D designs. [2] further introduces BS signal routing to enhance performance and power efficiency at the 2nm technology node. Inspired by [2], we apply BS routing resources, including nano-Through-Silicon Vias (nTSVs) and backside metals (BSMs), during the CFET cell synthesis stage to alleviate routing congestion on the FS of the chip. Fig. 1 illustrates the impact of utilizing BS resources. The signal *Y* is routed through M0 metals, nTSVs and BSMs (Fig. 1(a)) without the use of M1 and M2 wires, whereas in Fig. 1(b), two M1 wires and one M2 track are required to complete the routing. Compared to Fig. 1(b), Fig 1(a) saves two M1 wires and one M2 track.

In CFET structures, the contact allocation for the bottom device signal can be blocked by the top device signal in the same column when they differ and partially overlap in the *z*-direction, with each source, drain, or gate signal occupying a separate column. This issue becomes more severe when the top device obstructs more routing tracks, and it is evident that a larger top device blocks more tracks in a column. Transistor folding, which divides a larger transistor into multiple smaller

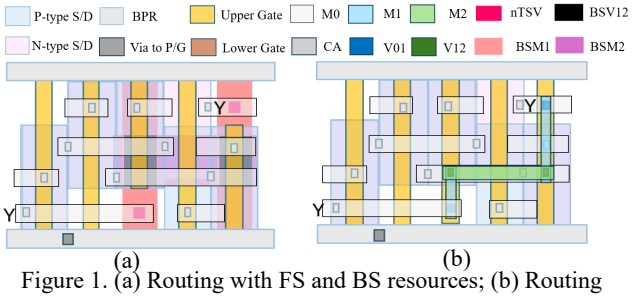

Figure 1. (a) Routing with FS and BS resources; (b) Routing with only FS resources.

Figure 2. (a) CFET folding; (b) Simple folding.

transistors (fingers), helps release more routing resources for the bottom device. However, transistor folding in CFET stacked structures is simplified, with previous works mainly focusing on planning structures. In the non-stacked structures, [3] addresses both transistor folding and placement simultaneously through search tree exploration. [4] applies ILP to determine the size of each finger and minimize cell area. [5] estimates the cell width using an Euler graph and presents search tree pruning techniques. The main difference of folding problems between in stacked and non-stacked structures is that, in stacked structures, we need to account for the space required to allocate contacts for bottom signals to access M0. Besides, measuring this space is critical, which is not a concern in non-stacked structures. Fig. 2 highlights the significance of the folding issue in CFET. In Fig. 2(a), the bottom device signal *S* is successfully routed via M0 through the diffusion contact access. However, as shown in Fig. 2(b), the contact location at the cross position for the bottom signal S fails due to being blocked by the top device, ultimately causing routing failure.

Previous works have addressed transistor placement with various approaches. For instance, [6] applies a bipartite graph and graph-based chaining processes to maximize diffusion sharing, while [7] uses DP to generate routability-aware transistor placement. For cell routing, common algorithms like maze, Boolean satisfiability (SAT), integer linear programming (ILP), mixed integer linear programming (MILP) and network flow are employed. The proposed ILP M0 planning model in [7] systematically selects M0 segments, followed by implicitly adjustable grid map maze routing to produce higher-quality cell layouts that are compliant with ASAP 7nm technology compared to the handcrafted cell library. The SAT approach in [8] generates cell layouts free of design-rule violations and minimizes undesired patterns while considering design-for-manufacturing. In [9], a spare M1 track is reserved to enhance

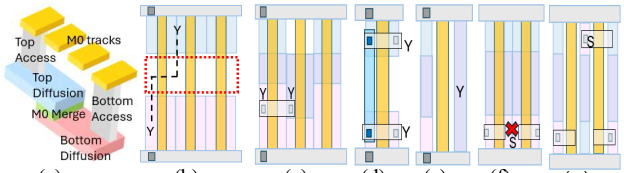

Figure 3. (a) A 3D view; (b) (c) FinFet and CFET structures; (d) With real MOS widths; (e) With simplified MOS widths; (f) Our routing model; (g) The simplified routing model

pin accessibility, and MILP is used to concurrently complete cell routing and pin allocation. In previous CFET cell library synthesis works, [10] simultaneously handles placement and routing using SMT. However, due to the high complexity of the model, generating large cells faces scalability challenges. Moreover, since placement and routing are explored simultaneously, the process may overlook placements that could lead to more efficient routing due to time constraints. The approach [11] demonstrates that traditional two-stage cell synthesis, cell placement and cell routing, can not only outperform [10] in terms of the cell area, but also additionally resolve the scalability issue. Nonetheless, these CFET works ignore transistor widths specified in SPICE netlists, which will be discussed in more detail in Section 2. Synthesized standard cell layouts must comply with SPICE netlists to ensure cell functionality and characteristics, such as performance, and power consumption.

This is the first work to introduce BS routing resources during the cell synthesis and to handle the folding issue for transistors with large width in CFET stacked structures. Our main contributions are as follows: (1) The CPP lower bound of a folding outcome is calculated using Euler paths, followed by a DP-based FMRT calculation of BS-resource-aware placements; (2) The proposed SMT formulation decides the tracks used by the devices and performs cell routing considering BS resources; and (3) Compared to previous work [11], we achieve reductions of 1%, 45%, and 19% in #CPP, #M2 tracks, and runtime, respectively.

In Section 2, we introduce the CFET cell structure and highlight the differences in the routing model between our approach and previous works. Section 3 addresses CFET folding, BS-resource-aware placement, and the SMT formulations for cell routing. Section 4 presents the experimental results and Section 5 concludes this work.

2. PRELIMINARY

2.1 CFET Stacked Structures

In CFET with buried power rails (BPRs), the middle region disappears due to stacking PMOS and NMOS together. The following two CFET routing features simplify connecting signals between two different types of devices, making it easier than in FinFET. First, a vertical wire connecting two diffusion signals, which overlap in the *z*-direction, is replaced by an M0-merge to interconnect them. Second, a Z-shaped wire can be eliminated by using a horizontal M0 wire to connect signals from both types of devices, provided their contact allocations are on the same routing track. Fig. 3(a) shows a 3D view of the M0-merge. The red dotted rectangle in Fig. 3(b) represents the middle region in FinFET structures, where the signal *Y* requires vertical wires. In contrast, Fig. 3(c) shows that no vertical wires are needed in CFET structures.

2.2 The Previous Routing Models

The previous work [11] simplifies both the routing model and MOS widths. There are at most two signals in a column. Since the two signals in a column are distinct and the bottom

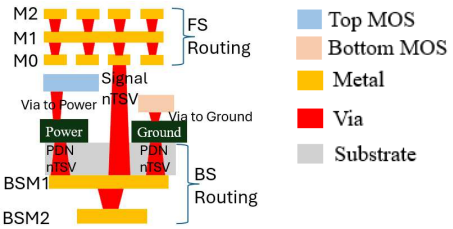

Figure 4. Layers on front and back sides.

signal requires a contact to access the upper M0 layer, contact placement for this signal is limited to either the top or bottom track to avoid the obstruction caused by the top device. However, if the top signal is VDD or VSS, and connects to power or ground rail, the bottom signal has only one available track. If the two signals in a column are identical, all tracks remain available for the bottom signal. On the contrary, the top signal can allocate the contact on any available track, regardless of whether the two signals in a column are distinct or not.

The layout style in [11] prioritizes routing simplicity over strict adherence to transistor width specifications. Transistor widths are treated as flexible and adjusted as needed to facilitate easier routing. For example, the DFFHQN cell in [11] does not follow the transistor width specification. Figs. 3(d) to 3(g) demonstrate why the cell design complying with transistor width specification is much harder than that in [11]. The layout style in Figs. 3(d) and 3(f) are ours, while those in Figs. 3(e) and 3(g) are from previous work [11]. Fig. 3(d) shows that the layout of two non-overlapping devices with small widths requires two M0 and one M1 wires to realize signal *Y*'s connection. M0-merge cannot be used in this case. In contrast, Fig. 3(e) demonstrates the flexible MOS widths allow the use of an M0-merge for routing signal *Y*. The assumption in [11] that two identical signals in the same column can always be routed with an M0-merge may fail under real MOS width specification.

In Fig. 3(f), top devices occupy the top three tracks, leaving only one bottom free track for the bottom signals, which produces a design rule violation (DRV) between signal *S* with two other M0 wires during M0 access. In Fig. 3(g), the routing model in [11] encourages signal *S* accessing the top M0 track, which results in misalignment between two diffusions in the top device; however, they should be aligned.

2.3 BS Routing Resources

BS routing resources, which are manufactured separately, are located under the substrate, while FS routing resources are on the substrate. Therefore, the metal pitch, metal width, and design rules for the BS are independent of the FS. To connect to the frontside metals (FSMs), specifically M0 in this work, BSMs utilize nTSVs that pass through the substrate. Careful placement of these nTSVs is crucial to avoid damaging any existing devices, such as poly or diffusion layers. In this work, we assume nTSVs can be placed on any track and in any column as long as there is no overlap with devices in the *z*-direction. According to our assumption, an nTSV occupies one grid on the FS and retains its size before passing through the substrate. As the number of BSM layers is configurable, there are two BSM layers in this work: backside metal 1 (BSM1) and backside metal 2 (BSM2). We assume that the BSM1 pitch is twice the CPP, and its width equals three times the M1 width. There is one BSM2 routing track, with a width three times that of M2 metal and spacing rules the same as M2. Fig. 4 shows a cross-sectional view of the layers on front and back sides.

2.4 Balanced Design-Rule-Check-Aware Remaining Pin Access (BDARPA)

The proposed BDARPA in [11] is an enhancement of remaining pin access (RPA) in [12]. BDARPA optimizes the RPA value of each IO pin evenly, while ensuring no violations occur when an M1 access point connects to an M2 wire during block-level routing. BDARPA provides a more accurate estimation of pin accessibility compared to RPA.

2.5 Graph-based Transistor Placement

In [13], there are four steps in transistor placement: clustering, pairing, chaining, and chain placement. Clustering uses common signals in PMOS and NMOS to divide the entire netlist into several sub-netlists. Pairing pairs the PMOS and NMOS with the same gate signal within the same clustering group. Chaining maximizes the number of shared diffusions using a depth-first search with a pruning technique. Finally, chain placement determines the permutation and orientation of the chains established in the previous step.

3. METHODOLOGY

The following discussion focuses on stacking P-type transistors on N-type transistors. The analysis can be extended to the configuration where N-type transistors are stacked on P-type transistors. Given a SPICE netlist, we first address CFET transistor folding and estimate the CPP lower bound of the folding results. The folding results with the lowest estimated value will proceed to the BS-resource-aware transistor placement stage. We utilize graph-based transistor placement from [13] to obtain placement results. Additionally, a diffusion column is considered undesirable if the top device's width in that column is not smaller than the number of routing tracks minus one. During the placement stage, we minimize CPP, FMRT, undesired diffusion columns, and then total wirelength. We also predict whether a column can accommodate an nTSV and calculate FMRT considering BS resources using a shortest path algorithm and DP. Finally, the SMT solver processes placement candidates, determining which tracks the devices occupy and completing cell routing.

3.1 CFET Transistor Folding

Transistor folding is the process of dividing a larger transistor into several smaller ones, called fingers. [11] briefly addresses CFET folding. Let tr_no_{M0} represent the number of M0 routing tracks. In [11], a transistor with a size greater than or equal to tr_no_{M0} is folded so that each finger has a size less than tr_no_{M0}, and the number of fingers is minimized. In our work, we not only fold transistors with sizes greater than or equal to tr_no_{M0}, but also fold top transistors with sizes greater than or equal to tr_no_{M0} minus one to explore more folding solutions. Since top devices block bottom devices, our goal is to create more room for the bottom by breaking down the top transistors. Additionally, the number of fingers in our approach ranges from $\lceil \frac{sz_{tran}}{tr_no_{M0}} \rceil$ to $\lceil \frac{sz_{tran}}{x} \rceil$ (where sz_{tran} represents the transistor size, and x is user-defined; in this work, x equals two). Each finger size is equal to or less than tr_no_{M0}.

We construct a folding table by enumerating all possible finger configurations for each transistor and estimate the CPP lower bound for each folding result. When a transistor is folded into several fingers, its signal is split into the corresponding number of signals. We then sum the number of each diffusion signal across all transistors, as only diffusion signals affect subsequent estimations. A signal is considered odd when its count is odd. For example, two P-type transistors, (*net*1, *A*, *Y*) and (*VDD*, *B*, *net*1), are both folded into three fingers. The number of diffusion signals for *net*1, *Y*, and *VDD* is six, three, and three, respectively. Using Euler graphs, the following formula to compute the number of diffusion breaks (n_{df_bk}) is obtained:

$$n_{df_bk} = \begin{cases} 0, \ if \ n_{o_sg} < 3 \\ \left\lfloor \frac{n_{o_sg}-1}{2} \right\rfloor, if \ n_{o_sg} \geq 3 \end{cases}, \quad (1)$$

where n_{o_sg} is the number of odd signals. We sum the number of fingers and diffusion breaks to estimate the CPP lower bound. P-type and N-type devices are estimated separately, and we choose the larger estimated value as the CPP for the entire cell, as the larger value obviously dominates. We proceed with transistor placement only for the folding results that have the lowest estimated value in the folding table.

It is also worth mentioning that during the pairing stage, we exclude two illegal pairing results. One occurs when the NMOS width occupies all tracks and the *VDD* signal has no room to connect down to the power rail. The other occurs when the PMOS width occupies all tracks, leaving the NMOS signal no room to connect up to M0 if necessary.

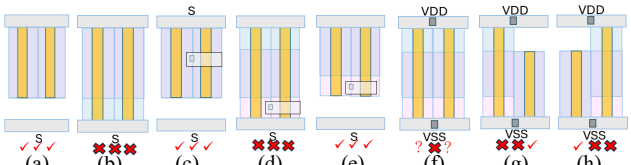

Figure 5. (a) - (e) n_{rm_trk} is 1, 0, 1, 0, and 1, respectively; (f) In case 4, n_{rm_trk} can only be used to predict the middlemost column, while the other two remain uncertain. (g) – (h) The left and right columns must be predicted by other abutting pairs. An nTSV can be placed by shifting the right (g) and left (h) devices, respectively.

3.2 BS-resource-aware MOS Placement

3.2.1 nTSV Column Prediction

After the pairing stage, we predict whether an nTSV can be placed on a column when abutting two transistor pairs. A local net refers to a net that is not *VDD*, *VSS*, or an IO signal and completes its routing without using metal, relying only on diffusion sharing.

We define the notations used in this section first. The number of remaining tracks on a column is n_{rm_trk}. wid_T and wid_B represent the larger width value of the two abutting top and bottom devices, respectively. n_{rm_trk} is calculated by subtracting the number of tracks that devices occupy on a column from the total number of M0 tracks, as placing an nTSV on devices will damage them. An n_{rm_trk} value greater than 0 implies that an nTSV can be placed on this column; otherwise, an nTSV cannot be placed.

In Fig. 5, a tick indicates that an nTSV can be placed in the column, a cross means the column cannot accommodate an nTSV, and a question mark represents uncertainty. We focus on discussing the three middle columns since the leftmost and rightmost columns must be predicted based on other abutting pairs.

Case 1: In Figs 5(a) and 5(b), the abutting bottom signal *S* is a local net. Since *S* does not need to connect up to M0, the bottom device can hide under the top device, potentially freeing up space for nTSV placement. In this case, $n_{rm_trk} = tr_no_{M0} -$

$max(wid_T, wid_B)$. In Fig. 5(b), there is no available column for placing an nTSV since n_{rm_trk} is 0.

Case 2: In Fig. 5(c), the abutting signals for top and bottom devices are the same (*S*), and the bottom *S* is not local. Even though S is not local, it also can use an M0-merge to connect to the top device, which then accesses M0. The bottom device can still hide under the top device. Here, $n_{rm_trk} = tr_no_{M0} - max(wid_T, wid_B)$.

Case 3: In Figs 5(d) and 5(e), the abutting signals for top and bottom devices differ, and the abutting bottom signal *S* is not local. Since *S* needs to allocate a contact to connect up to M0, at least one track must be reserved for contact allocation for *S*. In this case, $n_{rm_trk} = tr_no_{M0} - 1 - max(wid_T, wid_B - 1)$.

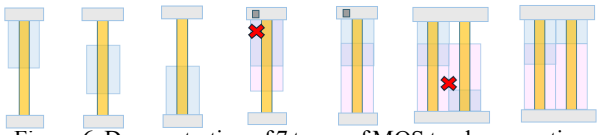
Case 4: In Figs 5(f) to 5(h), the abutting top and bottom signals are power and ground. Since both the power and ground signals need to connect to their respective power and ground rails, at least one top device and one bottom device must occupy the top and bottom tracks. n_{rm_trk} is calculated separately for both device types, with $n_{rm_trk} = tr_no_{M0} - wid_T - wid_B$.

To verify the accuracy of our nTSV column prediction, we also enumerate all possible track occupations of an MOS to check whether an nTSV can be placed on a column. We directly incorporate information about MOS track occupation in the following stages: pairing, chaining, and chain placement, which enlarges the placement solution space. Fig. 6 demonstrates the enumeration, pairing, and pairing abutment rules. In Fig. 6, a cross indicates an invalid pattern. Types 1 – 3 illustrate the partial enumeration with the top diffusion on different tracks. During pairing, the pairing pattern in Type 4 is invalid because the bottom device blocks the top device from connecting to the power rail, while Type 5 is valid. When abutting two transistor pairs, Type 6 is invalid as the top devices do not share their diffusion, while Type 7 is valid.

3.2.2 DP-based and BS-resource-aware FMRT

After the chaining and chain placement stages, we calculate the FMRT of a placement candidate (PC), considering BS resources to further reduce FMRT and ease M2 track usage in the subsequent routing stage. Fig. 7 depicts the routing results of two PCs, where Fig. 7(b) utilizes the BS resources while Fig. 7(a) cannot. Without considering BS resources, the evaluation of FMRT of two PCs are the same. However, after introducing BS resources, the FMRT in 7(b) becomes less than that in 7(a). Even though both consider BS resources, 7(b) further reduces FMRT by routing one signal using BS resources, while 7(a) cannot. Factors that impact FMRT when considering BS resources include the position of signals, and the number and position of nTSVs. We calculate the FMRT of a PC using a shortest path algorithm and DP.

For a PC, each signal has two ways to realize its shortest path. The first way uses only M0, while the second can utilize both M0 and BS resources. The shortest paths for a signal are determined in the absence of the shortest paths for other signals. All shortest paths are used in enumerating the FMRT. To identify the second shortest path, evaluating whether an nTSV can be placed on a column can help link the M0 and BS resources. Additionally, to ensure the BS resources are explored, their cost is set lower than that of the M0 resources. The path exploration space for each signal ranges from the leftmost to rightmost columns of its pins with slight expansion. The source and target for paths are set on the M0 layer.



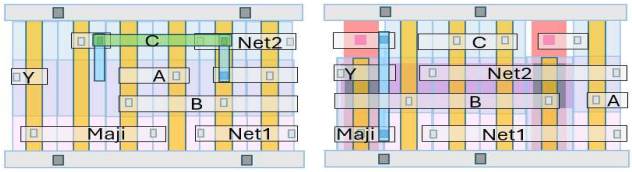


Figure 6. Demonstration of 7 types of MOS track occupations and the pairing and pair abutment rules, considering the information about MOS track occupation.

(a) (b)

Algorithm 2. FMRT_Recursive_Process

Input: a graph $\mathcal{G}_\mathcal{R}$ and a node set *M*
Output: FMRT of the given graph $\mathcal{G}_\mathcal{R}$
1. **if** $\mathcal{G}_\mathcal{R}$ is $\emptyset$
2. **return** FMRT according to *M*
3. Pick a node *n* with the least node value and #neighbors
4. Push node *n* and its neighbors into queue *q*
5. **for** each node *s* in queue *q*
6. $\mathcal{G}_\mathcal{R}' \leftarrow \mathcal{G}_\mathcal{R}$ removes node *s*, its neighbors, and their edges
7. $M' \leftarrow M$ adds node *s*
8. $dp[\mathcal{G}_\mathcal{R}] \leftarrow$min($dp[\mathcal{G}_\mathcal{R}]$, FMRT_Recursive_Process($\mathcal{G}_\mathcal{R}'$, *M'*))
9. **return** $dp[\mathcal{G}_\mathcal{R}]$

Figure 9. FMRT_Recursive_Process.

After finding the paths, we construct a resource constraint graph, $\mathcal{G}_\mathcal{R}$, for the PC. If a signal uses BS resources in its second path, the signal has its respective node in $\mathcal{G}_\mathcal{R}$. If not, no node is created. If two signals' second paths overlap in the use of BS resources, an edge is created to link their respective nodes in $\mathcal{G}_\mathcal{R}$, indicating that the signals cannot use the BS resources simultaneously. We calculate the FMRT for each node in $\mathcal{G}_\mathcal{R}$ as its node value, assuming the corresponding signal uses its second path while the other signals choose their first paths for signal connections. The FMRT calculation focuses on the leftmost to rightmost columns of the corresponding signal's pins and equals the number of signal overlaps in the y-direction on M0.

DP is then applied to $\mathcal{G}_\mathcal{R}$ to determine which signals should utilize BS resources to minimize the FMRT of the PC. Fig. 8 and Fig. 9 illustrate our algorithm. In Fig. 8, we construct $\mathcal{G}_\mathcal{R}$, and $V(\mathcal{G}_\mathcal{R})$ represents the node set of $\mathcal{G}_\mathcal{R}$. There are $2^{|V(\mathcal{G}_\mathcal{R})|}$ possible combinations of BS signal usage. Each element of the array *dp* represents the FMRT when considering only the corresponding signals in the graph. We initialize all *dp* values to a large number *S* and set *M* as an empty node set. After initialization, a recursive procedure is called to calculate the FMRT of the PC. If $\mathcal{G}_\mathcal{R}$ is

(a) (b) (c) (d) (e) (f)

TABLE 1. NOTATIONS

S^{SN}/S^{N}	The subnet/net space
$TD_{i,t}/BD_{i,t}/G_{i,t}$	The bool variable indicates whether the i^{th} top diffusion/bottom diffusion/gate occupies track t.
$\mu_v^S(c,t,l,n)/\mu_e^S(c,t,l,n)$	The bool variable indicates whether the vertex/edge in c^{th} column, t^{th} track, l layer and S space is used by net n. A horizontal edge connects the c^{th} and $(c+1)^{th}$ columns. A vertical edge connects the t^{th} and $(t+1)^{th}$ tracks. A via edge connects the l^{th} and $(l+1)^{th}$ layers. S can be either SN or N.
$deg^{SN}(v)$	The integer variable indicates the number of used edges of vertex v in the SN space.

empty, we calculate and return the FMRT for the entire placement when the corresponding signals in M use their second paths, while other signals use their first paths for connections (Fig. 9, Lines 1-2).

We select a node n in $\mathcal{G}_{\mathcal{R}}$ with the smallest node value and the fewest neighbors to reduce recursion calls (Line 3). Node n and its neighbors are pushed into a queue, and we iterate through each node in the queue to call the recursive procedure, minimizing the dp value at each iteration (Lines 4-8). Node n and its neighbors are not selected simultaneously due to the overlap in BS resources. We iterate through all nodes in the queue to explore all possible solutions. Once a node s is selected, $\mathcal{G}_{\mathcal{R}}'$ ($\mathcal{G}_{\mathcal{R}}$ with node s, its neighbors, and their edges removed) and M' (M with node s added) are passed down to the next recursive level (Lines 6-8).

3.3 SMT-based Cell Routing

There are two important tasks for our SMT algorithm: determining the track occupation of devices and managing signal connections while considering BS resources, both of which are determined simultaneously. Due to the additional consideration of transistor width, which was simplified in previous work, the proposed SMT formulation needs to accurately handle device track occupation, diffusion sharing, diffusion merge, and contact allocation. The diffusion track occupation differs between Fig. 10(a) and Fig. 10(b), which shows that device track occupation impacts signal connections on both sides. For the FS, contacts can only be allocated on devices. Therefore, in Fig. 10(a), the signal S can only access M0 on the third track, whereas in Fig. 10(b), it can access both the third and fourth tracks. For the BS, nTSVs cannot overlap with devices in the z-direction. As a result, in Fig. 10(a), there are two ticks indicating positions where an nTSV can be placed, whereas in Fig. 10(b), no such ticks are present.

Table 1 lists the notations used in the SMT formulations. When a net is a multiple-pin net, we decompose it into several two-pin nets, arranged from the leftmost to the rightmost column. Even if the top and bottom signals in a column are the same, we still use a two-pin net to represent them. The solution space for a two-pin net ranges from its leftmost to rightmost columns, with slight expansion. We connect each two-pin net in the subnet space, and the routing results in the subnet space are projected onto the net space. To expedite the process, we first define a net order, which is sorted in descending order based on the signal span length. All nets are routed using an M0 pattern in the initial iteration, and one more net is routed using multi-commodity flow (MCF) in subsequent iterations until the routing is complete. T represents the M0 routing track set, and $|T|$ is four in this work. Our optimization objectives, in lexicographic order, are to minimize the number of M2 tracks, maximize BDARPA as defined in [11], and minimize the total wirelength.

3.3.1 MOS Constraints

wid represents the number of tracks that the diffusion of a device occupies in a column, with one set of *wid* continuous variables being true for the device. We enumerate all possible track occupations for the diffusion. Eq. (2) defines the diffusion of the i^{th} top device, with its width being two. Other devices and widths are treated similarly. In Fig. 10(c), the encoded result for the top diffusion number zero/two is {true, false, false, false}/{true, true, true, false}.

$$(TD_{i,0} \wedge TD_{i,1} \wedge \sim TD_{i,2} \wedge \sim TD_{i,3}) \vee (\sim TD_{i,0} \wedge TD_{i,1} \wedge TD_{i,2} \wedge \sim TD_{i,3}) \vee (\sim TD_{i,0} \wedge \sim TD_{i,1} \wedge TD_{i,2} \wedge TD_{i,3}) \quad (2)$$

In a device, if the diffusion occupies a track, the gate will also occupy the corresponding track in its column. We represent i^{th} gate using Eq. (3). Both the top and bottom devices are considered due to the same gate signal. Track occupation for the gate is also enumerated.

$$(TD_{i,t} \rightarrow G_{i,t}) \wedge (BD_{i,t} \rightarrow G_{i,t}) \quad (3)$$

3.3.2 Connectivity Constraints

M0, M2, and BSM2 are used for horizontal routing, while M1 and BSM1 are used for vertical routing. Eq. (4) defines a horizontal edge, with vertical and via edges treated similarly.

$$\mu_e^{SN}(c,t,l,n) \rightarrow \mu_v^{SN}(c,t,l,n) \wedge \mu_v^{SN}(c+1,t,l,n) \quad (4)$$

$S^{SN(a,b)}$ represents a two-pin net connecting pins a and b in the subnet space. Using the MCF, we restrict the degree of vertices in Eq. (5) and Eq. (6) to complete the two-pin net connection. In Eq. (5), the pin may be a floating pin. V is the vertex set of $S^{SN(a,b)}$.

$$\wedge_{p=a,b}(\sum_{\{v|v\in p\}} deg^{SN(a,b)}(v) == 1) \quad (5)$$

$$\wedge_{v\in V, v\notin a, v\notin b}\left(deg^{SN(a,b)}(v) == 0 \vee deg^{SN(a,b)}(v) == 2\right) \quad (6)$$

3.3.3 Diffusion Sharing Constraints

There must be at least one track abutment between the diffusions of adjacent devices, or a two-pin net can be used to connect them. Figs. 10(c) and 10(d) illustrate these two options. Eq. (7) defines the first option for the connection between the i^{th} and $(i+1)^{th}$ top devices.

$$\vee_{t\in T} TD_{i,t} \wedge TD_{i+1,t} \quad (7)$$

3.3.4 Diffusion Merging Constraints

There must be at least one track overlap in the z-direction between the P-type and N-type diffusions (using an M0-merge to connect them), or a two-pin net can achieve connection. Figs. 10(e) and 10(f) illustrate two possible options for connecting the top and bottom signal Y. Eq. (8) defines the first option to connect the two types of diffusion between the i^{th} and $(i+1)^{th}$ devices.

$$\vee_{t\in T}\left(TD_{i,t} \vee TD_{i+1,t}\right) \wedge \left(BD_{i,t} \vee BD_{i+1,t}\right) \quad (8)$$

3.3.5 Contact Allocation Constraints

Contacts can only be allocated on devices. Additionally, when the two signals in a column differ, the contact allocation for the bottom signal will be blocked by the top signal. However, when the two signals are identical, the tracks occupied by two signals are available. Eq. (9) to Eq. (11) represent the contact allocation for the diffusion column. For the bottom diffusion, Eq. (9) and Eq. (10) represent the cases where the two signals in a column are different and identical, respectively. Eq. (11) defines for the top diffusion when the two signals in a column are different.

A top/bottom diffusion column consists of its two corresponding top/bottom devices due to diffusion sharing. i and j are the indexes of the corresponding devices for c^{th} diffusion column. The top/bottom signal in the c^{th} column is denoted as $TS(c)/BS(c)$. CA represents the contact layer.

$$\mu_v^N(c,t,CA,BS(c)) \rightarrow \sim(TD_{i,t} \vee TD_{j,t}) \wedge (BD_{i,t} \vee BD_{j,t}) \quad (9)$$

$$\mu_v^N(c,t,CA,BS(c)) \rightarrow TD_{i,t} \vee TD_{j,t} \vee BD_{i,t} \vee BD_{j,t} \quad (10)$$

$$\mu_v^N(c,t,CA,TS(c)) \rightarrow TD_{i,t} \vee TD_{j,t} \quad (11)$$

3.3.6 nTSV Constraints

An nTSV cannot overlap with devices in the z-direction. Eq. (12) applies to the diffusion, and the gate is treated similarly. $nTSV$ represents the nTSV layer. i and j are the indexes of the corresponding devices for c^{th} diffusion column.

$$\mu_v^N(c,t,nTSV,n) \rightarrow \sim(TD_{i,t} \vee TD_{j,t} \vee BD_{i,t} \vee BD_{j,t}) \quad (12)$$

4. EXPERIMENTAL RESULTS

This work is implemented in C++ and executed on a Linux platform with a 2.1 GHz twenty-core CPU and 252 GB of memory. We use the Z3 SMT solver [14] for the routing tasks. Our synthesis input is the ASAP7 SPICE netlist [15], and the cell structure is based on a 4.5T layout with buried power rails.

4.1 Cell Quality Comparison

All our cell libraries strictly adhere to the SPICE netlists. The design rules follow those in [11], with MAR/EOL/VR/PRL/SHR values set to 1/2/1/1/2. For transistor folding, F:CFET represents a library that considers the CFET stacked structure, while F:[11] represents a library that folds the way [11] does. Regarding routing resources, R:FB refers to a library that takes both FS and BS resources into account, while R:F refers to a library that only considers FS resources. For the nTSV column, N:P represents a library using the prediction method proposed in this work, while N:E represents a library that enumerates all possible device track occupations.

In Table 2, [11] successfully routes all cells. For each cell type, we count how many cells have a #CPP that is not larger than [11] (#CPP≤[11]), both #CPP and #M2 tracks that are not larger than [11] (#CPP≤[11]&#M2 T≤[11]), a #CPP that is lower than [11] (#CPP<[11]), and a #CPP that is not larger but with #M2 tracks lower than [11] (#CPP≤[11]&#M2 T<[11]). Our folding method benefits cells in the types INV BUF, AND OR, NAND NOR, AO AOI, OA OAI, and XOR XNOR. Due to our folding method, there are three/two/four cells with a lower #CPP than [11] in the first library for INV BUF/AND OR/NAND NOR. More than half (eleven out of twenty) of the OA OAI cells, and all XOR XNOR cells, have a #CPP that is not larger than [11]. BS resources benefit cells in the NAND NOR, AO AOI, OA OAI, MAJ MAJI, XOR XNOR, and DFF Latch types. Due to BS resources, in the first library, seven/ten cells have lower #CPP/#M2 tracks, two cells have lower #M2 tracks, and all cells have the same #CPP and #M2 tracks in AO AOI, MAJ MAJI, and DFF Latch types, respectively.

The reason for the larger #CPP in the OA OAI type is that [11] simplifies the routing model, and half of our OA OAI cells encounter the scenario shown in Fig. 3(f). Compared to [11], our library (F:CFET+R:FB+N:P in Table 2) contains six cells with one additional #CPP and three cells with two additional #CPP in the OA OAI type. Fig. 11 illustrates our DFFHQN layout with BS resources.

TABLE 2. LIBRARY COMPARISION AMONG [11] AND OURS.

Cell type/ #Cell	#CPP<=[11]/ #CPP<=[11]&#M2T<=[11]/ #CPP<[11]/ #CPP<=[11]&#M2 T<[11]			
	F:CFET+R: FB+N:P	F:CFET+ R:F+N:P	F:[11]+R :FB+N:P	F:[11]+R :F+N:P
INV BUF/12	12/12/3/0	12/12/3/0	12/12/0/0	12/12/0/0
AND OR/21	21/21/2/0	21/21/2/0	21/21/0/0	21/21/0/0

Sum	1309/11/67.4	1309/11/17018.2	1317/20/83.4

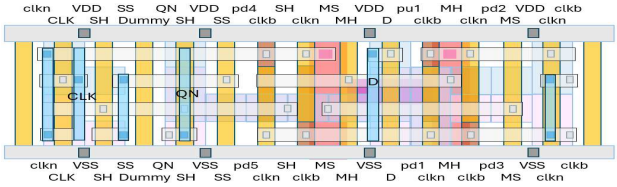

Figure 11. Our DFFHQN layout with BS resources.

4.2 NTSV Column Prediction, Cell Quality and Runtime Comparison

In Table 3, we sum the #CPP and #M2 tracks and calculate the average runtime for each cell type, with time measured in seconds. The first library predicts the nTSV columns, while the second enumerates all device track occupations to obtain the actual nTSV columns. The quality of both methods is the same, but the prediction method is 252 times faster on average than the enumeration method, reducing total runtime from 17018 seconds to 67 seconds. With total #CPP decreasing from 1317 to 1309, #M2 tracks dropping from 20 to 11, and the average runtime improving from 83.4 to 67.4 seconds, we achieve a 1%/45%/19% reduction in #CPP/#M2 tracks/runtime compared to [11]. Excluding the OA OAI type, we achieve an even greater reduction of 2% in #CPP and 68% in #M2 tracks.

5. CONCLUSIONS

To reduce the cell area and #M2 tracks, this is the first work to introduce BS resources and address stacked-structure transistor folding during the CFET cell synthesis. We fully adhere to SPICE netlists, while all previous works do not. Euler paths are utilized to estimate the CPP lower bound for folding results. In the placement stage, we calculate the FMRT with BS resources using DP. Finally, SMT decides MOS track occupation and completes cell routing. Compared to the state-of-the-art [11], we achieve superior results with reductions of 1%, 45%, and 19% in #CPP, #M2 tracks, and runtime, respectively.

***Abstract*—Processing-in-Memory (PIM) architectures offer promising solutions for efficiently handling AI applications in energy-constrained edge environments. While traditional PIM designs enhance performance and energy efficiency by reducing data movement between memory and processing units, they are limited in edge devices due to continuous power demands and the storage requirements of large neural network weights in SRAM and DRAM. Hybrid PIM architectures, incorporating non-volatile memories like MRAM and ReRAM, mitigate these limitations but struggle with a mismatch between fixed computing resources and dynamically changing inference workloads. To address these challenges, this study introduces a Heterogeneous-Hybrid PIM (*HH-PIM*) architecture, comprising high-performance MRAM-SRAM PIM modules and low-power MRAM-SRAM PIM modules. We further propose a data placement optimization algorithm that dynamically allocates data based on computational demand, maximizing energy efficiency. FPGA prototyping and power simulations with processors featuring HH-PIM and other PIM types demonstrate that the proposed HH-PIM achieves up to 60.43% average energy savings over conventional PIMs while meeting application latency requirements. These results confirm HH-PIM's suitability for adaptive, energy-efficient AI processing in edge devices.**

I. Introduction

With the advent of artificial intelligence (AI), real-world applications are rapidly expanding, fueling a trend to embed AI capabilities into IoT devices across diverse fields. However, traditional server-centric data processing, such as cloud computing, faces significant energy and latency challenges due to processing and communication overloads. Consequently, distributing AI workloads to edge devices has become a promising solution, with recent research focusing on enabling on-device AI through TinyAI models that support lightweight, local computations [1], [2].

In energy-constrained edge environments, integrating Processing-in-Memory (*PIM*) architectures has emerged as a promising approach for executing AI applications efficiently [3]–[8]. PIM enhances performance and energy efficiency in memory-intensive tasks, such as AI applications, by minimizing the overhead of data movement between processing and memory units. Early PIM designs primarily employed volatile memories like SRAM [9] and DRAM [10], but these designs faced challenges in storing large neural network weights due to the continuous power demands of volatile memory and issues such as SRAM leakage power and the periodic refresh cycles required by DRAM. To address these limitations, PIM architectures based on non-volatile memories (*NVMs*), such as MRAM [11], [12] and ReRAM [13], [14], were proposed. These designs achieve high energy efficiency in weight storage, especially when combined with power-gating techniques. However, NVMs may introduce additional read/write latency, potentially impacting overall neural network performance. Consequently, recent advances in PIM design have introduced hybrid architectures combining SRAM and NVM, known as Hybrid-PIM (*H-PIM*). These architectures use NVM to store weight data and SRAM as a buffer for input and output data, thereby enhancing both performance and energy efficiency [15]–[17].

However, H-PIM faces distinct limitations in achieving optimal energy efficiency during dynamic scenarios where inference loads fluctuate in real time on edge devices. For instance, an edge device running a YOLO model for real-time object detection experiences substantial variations in processing demand depending on the number of objects detected per video frame. Operating at a fixed performance level across all time intervals—typically set for peak computational load—inevitably leads to inefficient energy consumption. To address this, we observe that the mismatch between fixed computing resources and dynamically changing workloads has long been a challenge in traditional CPU-centric architectures. Established solutions, such as Dynamic Voltage and Frequency Scaling (*DVFS*) [18]–[21] and heterogeneous multi-processor architectures with high-performance and low-power cores [22]–[24], have been extensively researched for this purpose. Our focus centers on heterogeneous architectures, as DVFS continues to face significant challenges in edge devices due to added design complexities, such as DC-DC converters and real-time power monitoring. In contrast, heterogeneous architectures, exemplified by ARM's big.LITTLE architecture [25], are widely implemented in commercial processors, effectively improving energy efficiency by adapting to dynamic computational loads. Building on this insight, we propose configuring PIM modules, which integrate memory and Processing Elements (*PEs*) for independent computation, into high-performance and low-power configurations. This approach allows PIM architectures to dynamically balance performance and energy consumption throughout the application runtime.

To further elaborate this idea, we introduce Heterogeneous-Hybrid PIM (*HH-PIM*), an architecture designed to dynamically optimize performance and energy efficiency for AI applications on edge devices. HH-PIM integrates two distinct PIM modules: a High-Performance (*HP*) PIM module and a Low-Power (*LP*) PIM module. Each module's memory consists of a hybrid configuration of MRAM and SRAM banks, resulting in four types of memory: *HP-MRAM*, *HP-SRAM*, *LP-MRAM*, and *LP-SRAM*. Unlike conventional hybrid PIM architectures—where NVM is primarily allocated for weight storage and SRAM is reserved as an input-output buffer—HH-PIM adopts an adaptive approach. During periods of high computational demand, HH-PIM actively utilizes SRAM for weight storage as well, maximizing responsiveness to fluctuating inference loads. Additionally, to capitalize on HH-PIM's architecture, we propose an optimal data distribution algorithm that minimizes energy consumption by dynamically adjusting data allocation across the four memory types. This combinatorial optimization algorithm allocates weight data across HP-MRAM, HP-SRAM, LP-MRAM, and LP-SRAM to reduce energy use while balancing workload between HP-PIM and LP-PIM. With this design, HH-PIM efficiently adapts to the changing computational demands of AI applications, achieving significant energy savings without compromising performance.

To verify the functionality and evaluate the effectiveness of our proposed technique, we modeled the memory and PEs and performed an RTL-level design of the entire PIM processor, incorporating the HH-PIM architecture. We then conducted FPGA prototyping to confirm correct operation and measure performance of the developed PIM

processor, while power measurements were obtained through synthesis using 45nm process technology and memory model simulations. Through various benchmark scenarios, we experimentally validated the energy-saving potential of the proposed HH-PIM architecture and data distribution algorithm. Results showed that our approach maximizes energy efficiency while satisfying the latency requirements of AI applications in edge computing environments. Specifically, the developed PIM processor demonstrated superior adaptability to real-time inference load variations compared to conventional PIM-based processors, achieving up to 60.43% average energy savings across different benchmark scenarios relative to the baseline processor. These outcomes validate the suitability of the HH-PIM architecture for maximizing efficiency in edge processors running AI applications.

II. HH-PIM Architecture for AI Edge Processors

Fig. 1 illustrates the proposed HH-PIM architecture, designed as a solution to dynamically maximize energy efficiency in response to changes in inference workload, while meeting the performance demands of AI applications on edge devices. Basically, HH-PIM adopts the general structure of near-memory computing architectures, as suggested in previous research [10], [26]. It comprises multiple PIM modules, each with PEs and memory banks, a controller that manages these modules, and an interface for external communication. Operating based on dedicated PIM instructions, commands received from the processor core are sequentially stored in the *PIM Instruction Queue*. Unlike conventional PIM architectures, where a single controller manages all PIM modules based on PIM instructions, HH-PIM incorporates two distinct controllers: *HP-PIM Controller* and *LP-PIM Controller*, as shown in the figure. This dual-controller setup is designed specifically to support HH-PIM's unique heterogeneous architecture, which consists of two types of clusters: HP-PIM module cluster operating at high performance with higher power consumption, and LP-PIM module cluster operating at low power with reduced performance. The HP-PIM and LP-PIM Controllers are responsible for controlling and synchronizing their respective module types.

Another notable feature of HH-PIM is its hybrid memory architecture, where the PIM module's memory consists of MRAM and SRAM with distinct characteristics and read/write latencies. The previous H-PIM architectures leverage the data characteristics of neural networks by storing large weight data in NVM to enhance energy efficiency, while using SRAM or DRAM for input/output data to improve computational performance by providing low-latency access. HH-PIM builds upon this approach, exploiting the performance and energy efficiency benefits of hybrid memory. However, to overcome the limitations of fixed memory allocation based solely on data characteristics, HH-PIM adds flexibility. When computational demand spikes and maximum PIM computing power is required, HH-PIM allows weight data to be stored in SRAM, thus enabling stable operation even in cases where traditional H-PIM architectures cannot meet the maximum latency requirements of certain applications. To realize this capability, the PIM module is designed to support variable operand counts retrieved from MRAM and SRAM during computation. Each PIM module's internal interface is controlled by the controller, which dynamically adjusts the load process based on data storage status. This design ensures synchronization of differing memory read cycles and access speeds between MRAM and SRAM in the LOAD state, guaranteeing reliable operation.

This heterogeneous and hybrid architecture of HH-PIM enables flexible adaptation to real-time variations in inference workloads for AI applications. When computational demand is high, the HP-PIM module and SRAM can be actively utilized to boost processor performance. Conversely, in low-demand scenarios, computations can be maximally allocated to the LP-PIM module to meet application latency requirements and maximize energy efficiency. To implement this strategy effectively, it is essential to design the PIM Controllers with precision, as they play a crucial role by synchronizing components that operate at different speeds and minimizing data movement overhead between PIM operations.

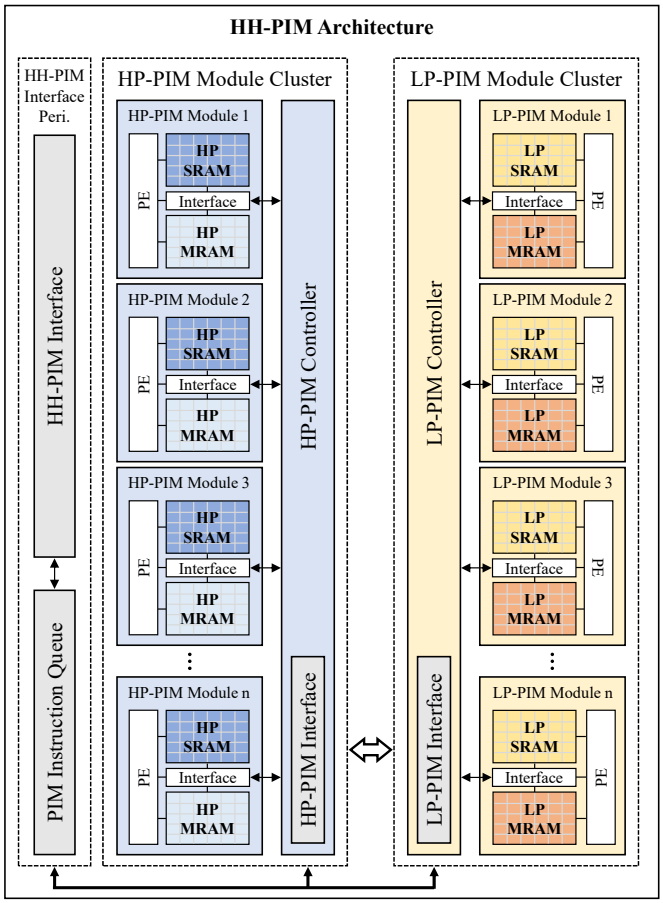

Fig. 1: Block diagram of the proposed HH-PIM architecture.

The architecture of HP-PIM and LP-PIM Controllers is fundamentally identical. Fig. 2 shows the architecture block diagram of the HP-PIM Controller, which consists of a *State Machine*, *Instruction Decoder*, *Command Encoder*, *Data Allocator*, and *Interface Logic*. The controller operates through the basic PIM instruction cycle, which includes the FETCH-DECODE-LOAD-EXECUTE-STORE phases, managed internally by the State Machine. The Instruction Decoder decodes the fetched instruction into components such as the instruction type (*Category*), specific operation or data movement details to be executed by the PIM module (*Instruction Field*), and the target module for the operation (*Module Select Signal*). The Command Encoder then generates command signals for each PIM module based on the decoded instruction details.

To minimize overhead from frequent data movement between HP-PIM and LP-PIM modules, as well as between MRAM and SRAM within each PIM module—resulting from the dynamic energy optimization of the HH-PIM architecture—the controller design of HH-PIM incorporates a Data Allocator and separates the Interface Logic as seen in Fig. 2. The Data Allocator manages data placement to minimize external data movement during PIM operations for various computations, such as convolution and Multiply-Accumulate (MAC) operations within AI applications. Additionally, the Interface Logic is divided into a CMD Interface Logic for delivering commands to the PIM modules and a MEM Interface Logic for data movement between PIM modules. When operand data is appropriately positioned in each PIM module's memory, computations can proceed efficiently through the CMD Interface Logic alone. Furthermore, the bandwidth of the MEM Interface Logic is scaled according to the number of PIM

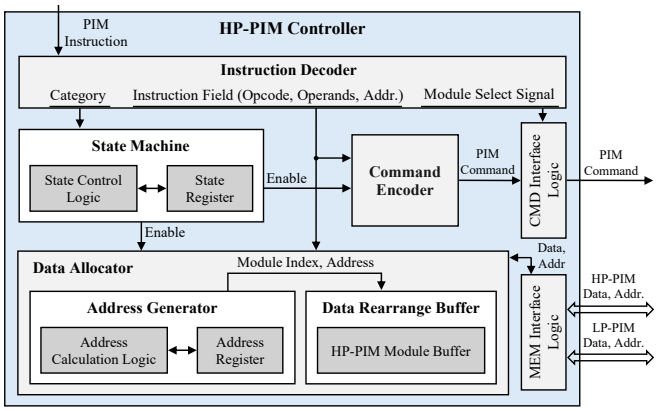

Fig. 2: Block diagram of the HP-PIM Controller architecture.

modules within each cluster, enabling parallel data transfers across clusters from multiple PIM modules simultaneously.

The controller's operation sequence for data movement between PIM modules is as follows. First, when a data placement instruction from the core prompts data transfer between HP-PIM and LP-PIM modules, the controller decodes the instruction and provides the relevant operation and address information to the Data Allocator. Based on the provided addresses, the Data Allocator accesses the memory in each PIM module via the MEM Interface Logic and stores the data to be transferred in the *Data Rearrange Buffer*. The Data Rearrange Buffer retains the data until the destination PIM module in the opposite cluster is ready for data writing, preventing data conflicts caused by the speed discrepancy between HP-PIM and LP-PIM modules. Next, the *Address Generator* within the Data Allocator generates the destination PIM module index and memory bank addresses in the opposite cluster to facilitate data movement. The generated addresses are then provided to the Data Rearrange Buffer, enabling it to place the buffered data into the memory banks of the designated PIM modules.

In summary, the PIM controllers in HH-PIM are meticulously designed to support data transfers between HP-PIM and LP-PIM modules and to effectively manage operations within each PIM module. This design maintains operational consistency and prevents data conflicts, supporting the HH-PIM architecture in achieving its design goals of real-time performance and energy efficiency optimization.

III. Dynamic Data Placement Strategy for Optimizing Energy Efficiency in HH-PIM

Optimal data placement in the HH-PIM architecture is essential for achieving maximum energy efficiency while ensuring smooth application execution without latency. In HH-PIM, each layer of a neural network is distributed across HP-PIM and LP-PIM modules for parallel computation, with the final output obtained by aggregating results from each module. When high performance is prioritized, it is critical to minimize idle times where the HP-PIM module completes its tasks quickly but must wait for the slower LP-PIM module. To achieve low output latency, a balanced distribution of data between HP-PIM and LP-PIM modules, as well as an optimal utilization ratio of MRAM and SRAM—each with different read/write latencies—must be carefully managed.

On the other hand, energy efficiency can be prioritized when AI applications do not always require the lowest possible inference latency. In such cases, HH-PIM can operate below peak performance by allocating more data to the energy-efficient LP-PIM module and increasing the usage of MRAM, thus improving overall energy efficiency while maintaining acceptable application latency. Based on this approach, we propose a dynamic data placement strategy that periodically adjusts the distribution of weight data during runtime. This strategy optimizes energy efficiency by shifting computational loads according to real-time demands, focusing on maximizing energy savings while meeting the minimum latency requirements of the application.

A. Problem Definition

In the proposed weight data placement strategy, data redistribution occurs every predefined interval T, referred to as the *time slice*. We define a set of PIM operations generated by a single inference process in an AI application as a *task*. These tasks, generated by inference, are stored in a task buffer, and HH-PIM sequentially processes the tasks stored from the previous *time slice* within the current *time slice*. This approach ensures that the operational latency of HH-PIM does not exceed $2T$, thereby maintaining the inference latency required by AI applications. In this framework, the number of tasks stored in the task buffer determines the minimum time $t_{constraint}$ needed for each task to be processed within the *time slice* without delay. Specifically, each task's processing time t_{task} must not exceed $t_{constraint}$ to guarantee that all tasks are completed within the allotted *time slice*, ensuring the system adheres to the required maximum latency.

The proposed method aims to achieve the most energy-efficient data distribution for each task within the time constraint $t_{constraint}$. The HH-PIM architecture includes four distinct storage spaces: HP-MRAM, HP-SRAM, LP-MRAM, and LP-SRAM, each with different power consumption and latency characteristics. Consequently, we are faced with a discrete combinatorial optimization problem of determining the optimal placement of each weight data in order to minimize energy consumption. This problem can be reduced to a well-known *knapsack problem* [27], with necessary adaptations for our specific context. Here, each storage space corresponds to an item i in the knapsack problem, and the time constraint $t_{constraint}$, task execution time t_{task}, and energy consumption per task E_{task} represent the knapsack's capacity, item weight, and item value, respectively. However, this problem is more complex than the standard knapsack problem, as it exhibits the characteristics of both an unbounded knapsack (due to the multiple selections of a particular storage space) and a multi-choice knapsack (due to the fixed total number of selected storage spaces, equivalent to the number of weight data).

The mathematical formulation of this problem is as follows:

$$\text{Minimize } E_{task} = \sum_{i=1}^{n} e_i \cdot x_i \tag{1}$$

$$\text{subject to: } \sum_{i=1}^{n} t_i \cdot x_i \le t_{constraint}, \quad \sum_{i=1}^{n} x_i = k,$$
$$x_i \in \mathbb{Z}_{\ge 0}, \quad \forall i = 1, 2, \cdots, n.$$

where n denotes the number of storage spaces, x_i represents the number of data assigned to storage space i, and k is the total number of weight data to be stored. Additionally, t_i and e_i denote the computation time per weight and the energy consumption per weight in storage space i, respectively. This fomula defines the objective function to minimize energy consumption per task, E_{task}, along with constraints on execution time and the total count of selected items.

B. Proposed Solution for Optimized Data Placement

Since this problem is inherently more complex than the standard knapsack problem, it is naturally NP-hard. To address the optimization problem defined in (1), we propose a bottom-up dynamic programming (DP) approach. This method uses a DP table to store intermediate results, avoiding redundant calculations and solving the problem incrementally. The recurrence relation is defined as follows:

$$dp[i][t][k] = \begin{cases} dp[i-1][t][k], & (t_i \cdot k > t) \\ \min\left(dp[i-1][t][k],\right. & \\ \left. dp[i][t-t_i][k-1] + e_i\right), & (t_i \cdot k \le t) \end{cases} \tag{2}$$

Algorithm 1 Finding Optimal Data Placement with DP.

1: **function** KNAPSACK_MIN_ENERGY
2: Set $dp[i][t][k] = \infty$ and $count[i][t][k] = 0$ for all i, t and k.
3: Set $dp[i][t][0] = 0$ for all i and t.
4: **for** i from 1 to $n/2$:
5: **for** k from 1 to K:
6: **for** t from 1 to T:
7: **if** $t_i \leq t$ **then**
8: Calculate the possible previous state time index $t-t_i$
9: $dp[i][t][k] = \min(dp[i-1][t][k], dp[i][t-t_i][k-1]+e_i)$
10: Update $count[i][t][k]$ based on the chosen minimum path.
11: **else**
12: $dp[i][t][k] = dp[i\text{-}1][t][k]$
13: $count[i][t][k] = count[i\text{-}1][t][k]$
14: **end if**
15: **end for**
16: **end for**
17: **end for**
18: **end function**

Algorithm 2 Finding Optimal (k_{hp}, k_{lp}).

1: **function** SET_ALLOCATION_STATE
2: **for** t from 0 to T:
3: Set $min_energy = \infty$, $k_opt_hp = 0$, $k_opt_lp = 0$
4: **for** k_{hp} from 1 to K :
5: $k_{lp} = K - k_{hp}$
6: **if** $dp_{hp}[n/2][t][k_{hp}] + dp_{lp}[n/2][t][k_{lp}] < \infty$ **then**
7: **if** $min_energy > dp_{hp}[n/2][t][k_{hp}] + dp_{lp}[n/2][t][k_{lp}]$ **then**
8: $min_energy = dp_{hp}[n/2][t][k_{hp}] + dp_{lp}[n/2][t][k_{lp}]$
9: $k_opt_lp = k_{lp}$
10: **end if**
11: **end if**
12: **if** min_energy remains ∞, **continue** to next t
13: $k_opt_hp = K - k_opt_lp$
14: Set $allocation_state[n][t]$ with current k_opt_hp and k_opt_lp
15: **end for**
16: **end for**
17: **end function**

where i, t, and k denote the current storage space being considered, the time constraint, and the number of weights, respectively. The value $dp[i][t][k]$ represents the minimum energy consumption required to store exactly k weight data across the first i storage spaces while satisfying the time constraint t. In this equation, when $t_i \cdot k > t$, storing k weights in the current storage space exceeds the time constraint. Therefore, in this case, the value from the previous storage space $dp[i-1][t][k]$ is carried forward. Conversely, if $t_i \cdot k \leq t$, the recurrence considers the minimum between $dp[i-1][t][k]$ and $dp[i][t-t_i][k-1]+e_i$, where the latter term represents the energy consumption if one additional weight is stored in the current storage space i, based on the previous results.

Meanwhile, in implementing the solution based on (2), it is essential to consider the architectural constraints of HH-PIM. HH-PIM allows for parallel execution of weight data distributed between HP-PIM and LP-PIM clusters; however, parallel processing is not feasible for weights stored across MRAM and SRAM within each module. To address this, we propose a partitioned approach where the DP algorithm is applied separately to HP-PIM and LP-PIM clusters, generating individual DP tables for each cluster. By combining these tables, we identify the optimal allocation of weights that minimizes energy consumption within the time constraint, yielding the best combination of k values, (k_{hp}, k_{lp}), where k_{hp} and k_{lp} represent the number of weights assigned to HP-PIM and LP-PIM clusters, respectively. This approach effectively accounts for both inter-cluster parallelism and intra-module serialization, optimizing energy efficiency while adhering to the operational constraints of HH-PIM.

First, Algorithm 1 presents the pseudo-code of the algorithm based on (2). Here, K denotes the total number of weight data to be stored in HH-PIM, and $count[i][t][k]$ is a variable used to trace the path to the optimal energy state. Lines 2 and 3 set the base conditions for the recurrence relation, while lines 7-13 correspond to the recurrence relation defined in (2). Notably, because Algorithm 1 is performed separately for both HP-PIM and LP-PIM, the iteration for i in line 4 only proceeds up to $n/2$.

Next, Algorithm 2 finds the optimal combination of k values that minimizes energy consumption using the results of the DP tables dp_{hp} and dp_{lp} generated for HP-PIM and LP-PIM, respectively. Here, *min_energy* denotes the minimum energy consumption, while *k_opt_hp* and *k_opt_lp* represent the number of weights assigned to HP-PIM and LP-PIM at this minimum. As a result, Algorithm 2 yields $allocation_state[n][t]$, representing the distribution state of weight data for each time constraint. In the proposed method, both Algorithm 1 and Algorithm 2 are performed only once during the application initialization phase to construct a Look-up Table (*LUT*) for the final output, *allocation_state*. This LUT allows rapid determination of the optimal weight placement state for varying $t_{constraint}$ values required at each *time slice* during application runtime. Furthermore, the calculation of $t_{constraint}$ at runtime incorporates the data movement overhead time needed for transitioning from the previous *time slice* data allocation to the new one, ensuring no inference delay arises due to data movement overhead.

TABLE I: Developed specifications for HH-PIM and other PIM architectures.

Architecture	PIM Module Configuration	Memory Types (per module)
Baseline-PIM	8 HP-PIM	128kB SRAM
Heterogeneous-PIM	4 HP-PIM + 4 LP-PIM	128kB SRAM
Hybrid-PIM	8 HP-PIM	64kB MRAM + 64kB SRAM
HH-PIM	4 HP-PIM + 4 LP-PIM	64kB MRAM + 64kB SRAM

The time complexities of Algorithm 1 and Algorithm 2 are $O(n \cdot T \cdot K)$ and $O(T \cdot K)$, respectively. Although these algorithms are executed only once during application initialization, the full *time slice* range for T and the large number of weight data K, often tens to hundreds of thousands in lightweight neural network models, may impose considerable overhead for energy optimization across all points in an edge processor. To mitigate this, we limit the resolution of optimization to ensure that the total computation time does not exceed 1% of each *time slice*, thereby avoiding excessive fine-grained calculations. The resulting optimal data distribution and improvements in energy efficiency are presented in the following section, along with detailed experimental settings.

IV. Experimental Work

A. Development and Evaluation of PIM Processors for Power and Performance Assessment

To evaluate the effectiveness of the proposed HH-PIM architecture and its data placement optimization strategy, we first implemented the HH-PIM architecture from Fig. 1 at the RTL level. The HP and LP clusters were each configured with four HP-PIM and four LP-PIM modules, with each PIM module equipped with 64kB of MRAM and SRAM. For a fair and precise comparison, we established Baseline-PIM, Heterogeneous-PIM (Hetero.-PIM), and Hybrid-PIM as comparison groups, each also implemented at the RTL level. Table I presents the specifications of each comparison group.

Subsequently, we developed processors equipped with the proposed HH-PIM and each of the comparative PIM architectures. RTL design and simulation were conducted using RISC-V eXpress (RVX) [28], [29]. The diagram on the right side of Fig. 3 illustrates the architecture of the processor equipped with HH-PIM, which is built with a single RISC-V Rocket [30] core. To facilitate efficient transmission and reception of large-scale AI application data, the HH-PIM communicates with the core through the AXI protocol, offering high bandwidth and

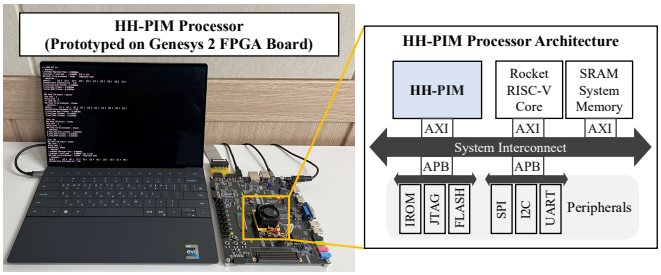

Fig. 3: Design and FPGA prototyping of the HH-PIM processor.

TABLE II: FPGA prototype resource utilization.

IPs	LUTs	FFs	BRAMs	DSPs
RISC-V Rocket Core	14,998	9,762	12	4
Peripherals	4,704	7,159	-	-
System Interconnect	5,237	7,720	-	-
HP-PIM Module	968	1,055	32	2
HP-PIM Module Controller	2,823	875	-	-
Total (HP-PIM module cluster)	6,951	5,460	128	8
LP-PIM Module	1,074	1,094	32	2
LP-PIM Module Controller	2,149	875	-	-
Total (LP-PIM module cluster)	6,680	5,616	128	8

low latency. For the system interconnect, we utilized μNoC [31], a lightweight Network-on-Chip optimized for edge devices.

Next, we performed functional verification and performance evaluation through FPGA prototyping of the developed processors. First, we modeled the operation and latency of SRAM at the RTL level, with Table III reporting the read/write latencies used in the model. These results were obtained using the NVSim simulation tool [32] at a 45nm process, with different operating voltages of 1.2V for HP-PIM and 0.8V for LP-PIM. The 0.8V operating voltage of LP-MRAM, in particular, is based on recent specifications of fabricated STT-MRAM chips [11], [33]. We then programmed the developed processors on a Genesys2 Kintex-7 FPGA board [34]. The operating clock frequency of the prototypes was set to 50 MHz, and memory latencies were scaled according to Table III. The photograph on the right side of Fig. 3 shows the prototype of the HH-PIM processor, while Table II reports the resource consumption of the prototype.

We verified the correct operation of the FPGA prototypes and measured performance metrics by running benchmark applications, expecting similar results to those observed on an SoC operating at 50 MHz [28]. For the AI benchmark applications, we used TinyML models based on CNN deep learning backbones such as EfficientNet-B0 [35], MobileNetV2 [36], and ResNet-18 [37], which are suitable for edge AI devices. We extracted the characteristics and operations of these models, calculated the proportion of PIM operations relative to the total operations, and incorporated these ratios into the benchmark applications. The *time slice* for performing the data placement algorithm in each TinyML model was set to allow up to 10 inferences per *time slice*, representing the scenario in which HH-PIM operates at maximum performance. Table IV reports the characteristics of the models incorporated into the benchmark applications. Additionally, to reflect dynamic computational load variations encountered at runtime, we configured six workload scenarios as shown in Fig. 4. These scenarios include a consistently low workload pattern (Case 1), a consistently high workload pattern (Case 2), periodic spike patterns (Case 3 and 4), a pulsing pattern with alternating high and low

TABLE III: Latency comparison of HP-PIM and LP-PIM modules.

Latency (*ns*)	STT-MRAM		SRAM		PE
	Read	Write	Read	Write	
HP-PIM (V_{dd} = 1.2*V*)	2.62	11.81	1.12	1.12	5.52
LP-PIM (V_{dd} = 0.8*V*)	2.96	14.65	1.41	1.41	10.68

TABLE IV: TinyML model specs and PIM operation ratios.

Model	# Param	# MAC	PIM Operation	–
EfficientNet-B0	95k	3.245M	85%	INT8 Quantized & Pruned
MobileNetV2	101k	2.528M	80%	
ResNet-18	256k	29.580M	75%	

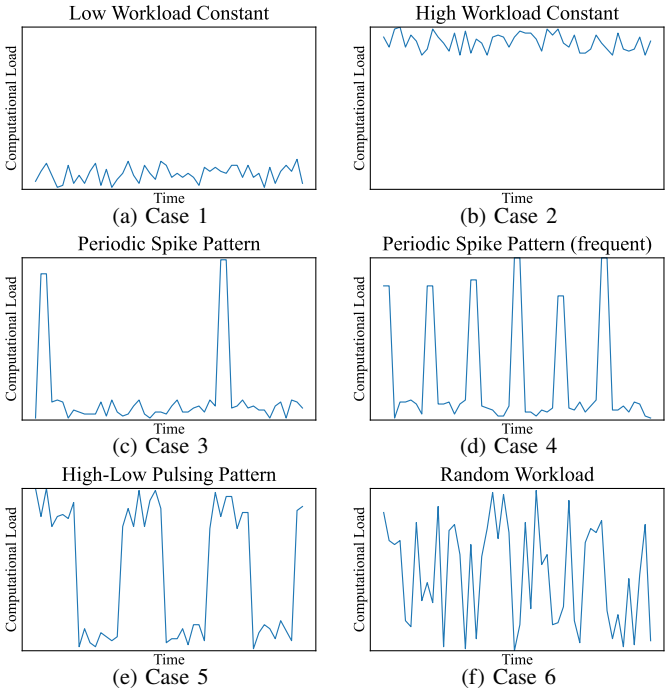

Fig. 4: Various workload scenarios of the AI benchmark app.

TABLE V: Power consumption (mW) across memory types in HP-PIM (1.2V) and LP-PIM (0.8V).

Power	STT-MRAM		SRAM		PE	
	Dynamic (Read/Write)	Static	Dynamic (Read/Write)	Static	Dynamic	Static
HP-PIM	428.48 / 133.78	2.98	508.93 / 500	23.29	0.9	0.48
LP-PIM	179.05 / 47.78	0.84	177.3 / 177.3	5.45	0.51	0.25

workloads (Case 5), and a random workload pattern (Case 6). The spike and pulse patterns simulate realistic scenarios in AI applications on edge devices, where computational demands periodically surge.

To measure the power consumption of the developed processors, we then synthesized them at a 45nm process technology. The RTL design, excluding memory, was synthesized using Synopsys Design Compiler with the 45nm Nangate PDK [38], while the memory power values were obtained through NVSim simulations at 45nm technology, as previously described. Table V details the power consumption of each memory type. These values were subsequently combined with benchmark-specific execution times, as measured from FPGA prototypes, to calculate total energy consumption. A detailed analysis of energy consumption, along with energy-saving results across various benchmark scenarios shown in Fig. 5, is discussed further in the following section.

B. Comprehensive Analysis of Energy Savings

Fig. 6 reports the results of applying the proposed data placement optimization algorithm to benchmark applications executed on HH-PIM. The x-axis represents the $t_{constraint}$ within a *time slice* (T), while the left y-axis indicates the memory utilization determined by the optimal data placement under the given $t_{constraint}$, and the right y-axis represents the corresponding energy consumption

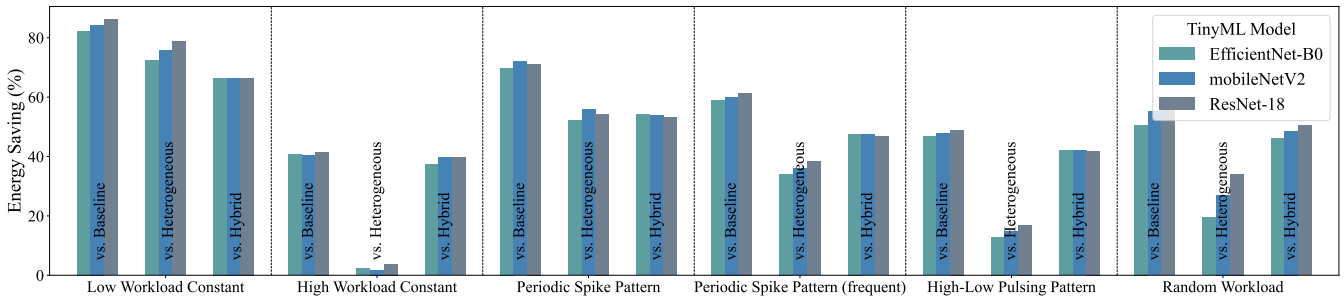

Fig. 5: Energy savings of the HH-PIM over the Baseline-, Heterogeneous-, and Hybrid-PIM across benchmark scenarios.

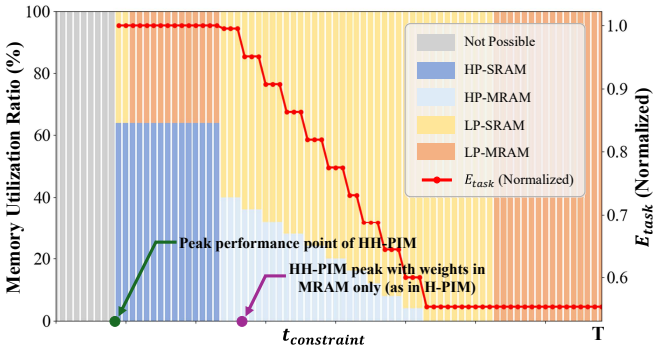

Fig. 6: Memory utilization and energy consumption across $t_{constraint}$ within *time slice* (T) based on HH-PIM's optimized data placement.

E_{task} of HH-PIM. The gray region in the graph denotes cases where $t_{constraint}$ is too small, i.e., the required performance is too high for HH-PIM to handle. The green dot marks the point where HH-PIM operates at peak performance, satisfying the application's performance requirements. At this point, HH-PIM actively utilizes SRAMs for data storage, with the total neural network data stored in a 16:9 ratio between HP-SRAM and LP-SRAM, minimizing PIM module idle times. The inference times at this point are measured as 31.06ms, 25.71ms, and 320.87ms for the EfficientNet-B0, MobileNetV2, and ResNet-18 benchmarks, respectively. As expected, energy consumption peaks at this point, and E_{task} is normalized to this value in the graph. Additionally, the purple dot indicates the peak performance point of HH-PIM when weights are stored only in MRAM (as in previous H-PIMs). At this point, the inference times for the EfficientNet-B0, MobileNetV2, and ResNet-18 benchmarks are 44.5ms, 36.84ms, and 459.74ms, respectively. This demonstrates that utilizing both SRAM and MRAM for weight storage, as proposed, outperforms the traditional method in terms of performance.

Fig. 6 demonstrates the sequential allocation of weight data across memory types as $t_{constraint}$ increases. Specifically, the distribution progresses through combinations of HP-SRAM and LP-MRAM, HP-MRAM and LP-SRAM, LP-SRAM alone, and finally LP-MRAM alone. This sequence reflects the balance between performance and energy efficiency across memory types. In the range where $t_{constraint}$ is longest, all weight data are stored exclusively in LP-MRAM, which operates at minimal power. In this configuration, other memory types are deactivated through power-gating, eliminating standby power and maximizing the processor's energy efficiency. Consequently, in this highly efficient region, HH-PIM achieves up to a 43.17% reduction in E_{task} compared to unoptimized data allocation. This significant reduction underscores the practical value of the proposed algorithm in real-world edge AI applications. Additionally, in the mid-range of $t_{constraint}$, E_{task} exhibits a quasi-linear decline with intermittent plateaus as $t_{constraint}$ increases. This pattern reflects the algorithm's capability to shift data progressively to lower-power memory while meeting inference latency constraints. These results demonstrate that the proposed solution achieves optimal energy efficiency within the constraints of application inference latency for each $t_{constraint}$, ensuring that HH-PIM can dynamically allocate data to balance energy savings and performance effectively.

TABLE VI: Energy Savings (ES) by HH-PIM for Cases 3–6.

ES (%) over	Baseline-PIM	Hetero.-PIM	H-PIM
Case 3: Periodic Spike	72.01	55.78	54.09
Case 4: Periodic Spike (frequent)	61.46	38.38	47.60
Case 5: High-Low Pulsing	48.94	16.89	42.10
Case 6: Random	59.28	34.14	50.52

Fig. 5 presents the energy savings achieved by HH-PIM compared to Baseline-PIM, Hetero.-PIM, and H-PIM (Hybrid-PIM) when executing the benchmark application across 50 *time slices* under various inference pattern scenarios from Fig. 4. The best-case scenario for HH-PIM is Case 1 (low workload constant), where the inference pattern remains low across all intervals. In this scenario, HH-PIM achieved energy savings of up to 86.23%, 78.7%, and 66.5% compared to Baseline-, Hetero.-, and H-PIM, respectively. Conversely, the worst-case scenario occurs in Case 2 (high workload constant), where the inference pattern remains consistently high. Here, HH-PIM still delivered notable energy savings of up to 41.46% and 39.69% compared to Baseline- and H-PIM, respectively. However, savings against Hetero.-PIM were limited to 3.72%, as both HH-PIM and Hetero.-PIM primarily utilize HP-SRAM and LP-SRAM in this scenario, resulting in minimal differences. Detailed energy savings for the other cases are reported in Table VI. HH-PIM achieved the highest energy savings over the baseline in ResNet-18, with up to 8.59% difference across cases. On average, HH-PIM achieved energy savings of up to 60.43%, 36.3%, and 48.58% compared to Baseline-PIM, Hetero.-PIM, and H-PIM, respectively.

V. Conclusion

In this study, we proposed the HH-PIM architecture designed to efficiently execute AI applications on edge devices. The architecture integrates HP MRAM-SRAM PIM modules and LP MRAM-SRAM PIM modules to achieve a balance between performance and energy efficiency. Additionally, we introduced a data placement optimization algorithm that dynamically allocates data based on computational demand, maximizing energy savings while maintaining application performance requirements. To validate the effectiveness of the proposed architecture and algorithm, we designed processors incorporating HH-PIM and established comparison baselines with processors equipped with Baseline-, Heterogeneous-, and Hybrid-PIM architectures. These designs were evaluated through FPGA prototyping and power simulations. By running various edge AI application benchmarks, the proposed HH-PIM demonstrated its superiority, achieving up to 60.43% average energy savings compared to conventional PIM architectures, while meeting application performance requirements.

***Abstract*—The compute-intensive nature of SPICE simulations hinders effective analog design automation. This paper introduces INSIGHT, a data-efficient, adaptive, high-fidelity, technology-agnostic universal neural simulator framework that formulates analog performance prediction as an autoregressive sequence generation task to accurately predict performance across diverse circuits. INSIGHT achieves test R^2 scores $\geq$0.95, outperforming existing neural surrogates. Cross-technology transfer learning experiments show that INSIGHT can preserve model performance with $\sim$60% less training data. Low-Rank Adaptation (LoRA) integration further reduces memory footprint by $\sim$42% and training time by $\sim$25%, maintaining high performance. Our experiments show that INSIGHT-based RL sizing framework achieves 100-1000$\times$ lower simulation costs over existing sizing methods for identical benchmarks and target specifications.**

I. Introduction

Analog circuits exhibit significant variation across and within types, each characterized by distinct performance metrics, design parameters of varying dimensions, and technologies. Consequently, this has spurred numerous optimization efforts to automate the labor-intensive analog design process. Bayesian Optimization methods [1], while known for their sample efficiency, often face scalability challenges in high-dimensional optimization for complicated analog circuit optimization tasks. On the other hand, learning-based approaches, like [2–10], require numerous real-time simulator interactions (i.e., poor sample efficiency). Given the vast and complex design space, the intricate interplay of underlying circuit physics in deep submicron technologies, and the multifaceted performance trade-offs, repeated simulations within the optimization loops become inherent for effective design space exploration for optimal circuit performance.

This heavy reliance on on-the-fly, time-consuming SPICE simulations motivates the development of cheap circuit simulator surrogates to expedite the analog optimization tasks. Traditional equation-based analog performance prediction methods [11, 12] are time-consuming, unscalable, and highly inaccurate in modern processes. Black-box ML-based performance modeling approaches employing polynomial regression [13], neural networks [14], and graph representations with neural networks [15] yield rapid inference but suboptimal prediction accuracies for complex circuits while still requiring substantial, costly simulation-based training data. [16] employs semi-supervised contrastive regression with scaling rules for synthetic data augmentation for effective analog performance prediction. While aiming for data-efficiency, this approach yields suboptimal R^2 scores with complex circuits on advanced processes across a broader range of performance metrics. Developing a *data-efficient*, *high-fidelity* circuit simulator surrogate with strong generalization capabilities and rapid fine-tuning potential remains an open challenge.

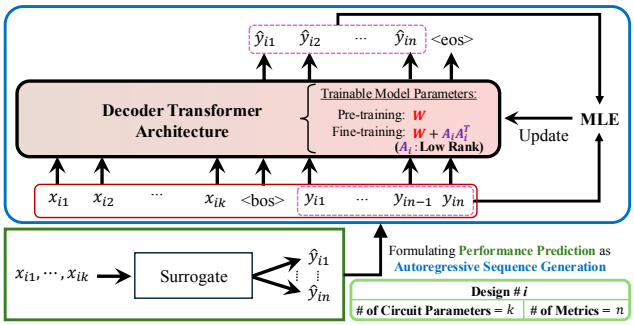

Fig. 1: INSIGHT Framework

Given the high interdependence of performance metrics inherent to analog circuits, for the first time, we propose to formulate the analog circuit performance prediction problem as *an autoregressive generation task*, i.e., predicting simulation-costly performance specification by leveraging provided design parameters and partial performance information (provided or previously-generated) in a sequential manner. The autoregressive problem setup enforces the model to automatically reason and capture the inherent interdependency in the challenging analog performance prediction task, easing the learning complexity and providing much better prediction quality than previous learning-based methods [10].

In this paper, we introduce INSIGHT, a novel, technology-agnostic, data-efficient, high-fidelity universal neural circuit simulator framework that learns to accurately predict analog performance on previously unseen parameters autoregressively, using decoder-based transformer architecture [17, 18]. Our framework's autoregressive learning facilitates accurate prediction of simulation-costly critical transient specifications leveraging performance data from less expensive simulations. INSIGHT consistently demonstrates high R^2 scores and minimal test losses across various circuits and technologies, at microsecond inference times. Furthermore, INSIGHT is highly scalable and can integrate into existing EDA optimization workflows to enhance sample efficiency. INSIGHT supports data-efficient knowledge transfer across technology nodes and

enables parameter-efficient fine-tuning on unseen nodes using Low-Rank Adaptation (LoRA) [19, 20], ensuring strong model performance and effective transfer learning.

The key contributions of this work include:

- **Novel autoregressive formulation**. We formulate analog circuit performance prediction as an autoregressive sequence modeling task, leading to our INSIGHT, a universal neural simulator framework designed around a decoder-only autoregressive Transformer architecture.
- **High data-efficiency with high prediction fidelity**: Our novel autoregressive formulation simplifies the learning complexity of the prediction task by inherently capturing the metric interdependencies and leveraging partial, less expensive metric information to boost prediction accuracy for the simulation-costly ones, thus enabling high-fidelity predictions with enhanced data efficiency.
- **A universal framework with circuit- and technology-agnostic capabilities**: The INSIGHT framework demonstrates strong generalization across unseen circuit types. Additionally, it supports efficient knowledge transfer to unseen technology nodes through parameter-efficient fine-tuning, ensuring high computational efficiency.
- We have rigorously validated INSIGHT across different circuits and technologies. Our cross-technology transfer learning experiments demonstrate INSIGHT's ability to maintain test R^2 scores $\geq$0.95 with $\sim$60% less training data than training from scratch. LoRA integration enhances computational efficiency, reducing memory footprint by $\sim$42% and training time by $\sim$25% while maintaining high model performance.
- To our knowledge, this marks the first **successful** application of a universal neural simulator framework leveraging autoregressive Transformers in analog design automation.

The source code[1] is available on GitHub.

II. Preliminaries

In this section, we briefly discuss some insights into analog circuit basics/metrics and Transformer architectures, discussing our rationale for choosing them.

A. Analog Circuit Basics and Metrics

In analog circuits, performance metrics and parameters are highly interdependent. By leveraging these interdependencies, we can build effective and data-efficient prediction models. For instance, in OPAMPs, fundamental metrics such as Quiescent Current (I_Q) and DC Gain, when combined with parameter information, can significantly enhance predictions for other key specifications, like unity-gain bandwidth (UGBW) and phase margin (PM). Similarly, integrating all static metrics provides crucial insights into the circuit's potential transient behavior. Thus, leveraging partial performance metric information can significantly enhance prediction accuracies for critical, simulation-costly specifications such as slew rate and settling time. Furthermore, given the transferable nature of circuit physics across technologies for a given topology, understanding performance interdependencies within one node provides valuable insights applicable to other nodes. These insights, combined with the adaptability and transferability of Transformer architectures, motivate the adoption of autoregressive Transformers to build a universal neural simulator framework that effectively predicts performance across technologies.

B. Transformer Architectures

Transformers constitute a powerful class of generative deep learning architectures that have revolutionized sequence modeling tasks in natural language processing and beyond [21–23]. These models stand out due to their self-attention mechanism, which effectively captures dependencies between tokens in a sequence regardless of distance. The self-attention mechanism [18] evaluates dependencies within a sequence by computing a weighted sum of value vectors. These weights highlight the most relevant token information for predicting subsequent tokens and are derived from the dot product of input vectors. Unlike traditional RNNs [24], Transformers process data in parallel, enhancing efficiency and scalability. While the original Transformer architecture [18] consists of stacked layers of encoders and decoders, decoder-only models like GPT [25] have recently demonstrated notable success in sequence data generation. Decoder-only Transformers employ solely the decoder component, composed of multi-head self-attention and position-wise feed-forward networks [26].

III. The INSIGHT Framework

In this section, we introduce our proposed universal neural simulator framework, INSIGHT, for analog performance prediction. Section III-A details INSIGHT architecture and the probabilistic rationale behind our approach. Section III-B discusses our performance metric sequencing strategy for data efficiency, while Section III-C explores INSIGHT's transfer learning capabilities.

A. INSIGHT Architecture

In INSIGHT, we are driven by a critical inquiry: Can we develop an *effective* and *efficient* surrogate model that utilizes circuit parameters and partial performance metrics information (if available) to predict remaining simulation-costly performance numbers accurately? This question is particularly pertinent as current analog front-end design automation heavily depends on time-intensive simulations like SPICE, incurring a strong demand to ease the reliance.

The problem can be formally represented as follows: For a given analog circuit topology and a B sequence of N design parameters $\{x_{i,1:N}\}_{i=1}^{B}$, where $x_{i,1:N} = (x_{i,1}, \cdots, x_{i,N})$, for example, width-to-length ratios (W/L), our goal is to predict the corresponding M performance specifications $\{y_{i,1:M}\}_{i=1}^{B}$ where $y_{i,1:M} = (y_{i,1}, \cdots, y_{i,M})$ accurately. In the context of maximum likelihood estimation (MLE), this predictive task is mathematically framed as maximizing the likelihood function $P(y_{i,1:M} \mid x_{i,1:N}; \theta)$, where θ represents the model parameters:

$$\begin{aligned}\hat{\theta} &= \arg\max_{\theta} \Pi_{i=1}^{B} P(y_{i,1:M}|x_{i,1:N};\theta) \\ &= \arg\max_{\theta} \Pi_{i=1}^{B}\Pi_{j=1}^{M} P(y_{i,j}|x_{i,1:N}, y_{i,1:j-1};\theta)\end{aligned}$$

[1] https://github.com/UTDA-group/INSIGHT-FRAMEWORK

This objective is equivalent to minimizing the Negative Log Likelihood (NLL), expressed as:

$$\text{NLL} = -\sum_{i=1}^{B}\sum_{j=1}^{M} \log P(y_{i,j} \mid x_{1:N}, y_{i,1:j-1}; \theta) \quad (1)$$

Each term, $P(y_{i,j} \mid x_{1:N}, y_{i,1:j-1}; \theta)$, quantifies the likelihood of observing the token $y_{i,j}$, given the design parameters, the previously predicted performance specifications, and the model parameters. This formulation connects to the contextual approach in autoregressive sequence generation tasks involving decoder-based Transformers like GPT [25] and motivates us to use a decoder-style Transformer model for INSIGHT. Figure 1 presents a conceptual diagram illustrating INSIGHT's autoregressive sequential inferencing of performance metrics.

The formulation of circuit performance prediction as an autoregressive sequence generation task allows us to leverage the inherent strengths of transformer architectures. Unlike fully connected layers, which require fixed input and output dimensions, transformers' adaptive capabilities automatically accommodate varying lengths, which is crucial for circuits which have varying numbers of design parameters, performance metrics, and types. While recurrent neural networks (RNNs) can handle variable-length inputs, they suffer from inefficient training due to the vanishing gradient problem and limited parallel processing capabilities. Furthermore, the self-attention mechanism in transformers captures complex interdependencies among circuit parameters and performance metrics, potentially yielding more accurate predictions than standard deep neural networks or RNNs, especially for high-dimensional, heterogeneous circuit data. INSIGHT exploits these transformer strengths, facilitating the automatic construction of tailored high-fidelity performance prediction models within a unified framework that adapts to diverse parameter lengths and performance metric lengths. Note that INSIGHT's universality stems from its adaptable framework, which can consistently accommodate diverse circuit types and topologies across technologies and not a one-model-fits-all approach.

We implement INSIGHT using a custom decoder-only transformer architecture specifically tailored for analog circuit performance prediction with real-valued inputs and outputs. Unlike traditional language models, our approach skips tokenization and directly processes continuous values [21, 27]. This streamlined design results in a compact model with ∼27.5K network parameters for a topology with 30 design variables and 20 performance metrics (total sequence length of 50). Compared to large language models (LLMs) with billions of parameters, INSIGHT's modest size enables computationally and data-efficient training from scratch, facilitating rapid training and inference. Table I presents INSIGHT's architecture details.

Remark 1: While the relationship between performance metrics, relative to design parameters and among themselves, is not inherently time-series, this formulation enables self-attention and autoregressive features to leverage their interdependencies for effective and efficient predictions.

TABLE I: INSIGHT Architecture

INSIGHT Parameter	Value
Network Architecture	Decoder-Based Transformer
Dim. of model	16
# of Heads	4
# of Decoder Layers	6
dim_feedforward	64
Activation	ReLU [28]
Learning rate	0.001 with cosine annealing scheduler [29]

B. Performance Metric Sequencing in INSIGHT

In autoregressive sequence generation, accurate prediction of one metric significantly enhances the prediction accuracy of the subsequent, emphasizing the importance of metric sequence order for effective and data-efficient predictions. We employ a greedy strategy for metric sequencing in INSIGHT.

Algorithm 1 Metric Sequencing for Data-Efficient Prediction

Require: List of performance metrics $Y = [y_1, y_2, \ldots, y_M]$
Ensure: Ordered list of metrics $P_{ordered}$
  Sort Y in ascending order based on runtime and complexity
  $P_{ordered} \leftarrow []$ ▷ Initialize as an empty list
  while $|P_{ordered}| < |Y|$ **do**
    $y^* \leftarrow \arg\max_{y_i \in Y} \text{ExpectedInformationGain}(y_i | P_{ordered})$
    $P_{ordered}$.append(y^*)
    Y.remove(y^*)
  end while
  Sequence known dependent metrics after their dependencies in $P_{ordered}$
  return $P_{ordered}$

As outlined in Algorithm 1, metrics are initially sorted based on runtime complexity. Ties are resolved by iteratively selecting metrics that provide the highest expected information gain, given the previously predicted metrics, to prioritize data efficiency. If a specification is known to be directly derived from others, it is sequenced after its dependencies to optimize both data utilization and prediction accuracy. By deferring complex metrics that demand more data and exploiting performance interdependencies, this approach leverages simpler specifications to enhance the prediction accuracy of more complex ones, ensuring effective and data-efficient sequencing. Figure 2 illustrates the performance metric sequencing for the Folded Cascode Amplifier as an example, with arrows Left → Right indicating significant contributors to the autoregressive dependencies in the prediction model.

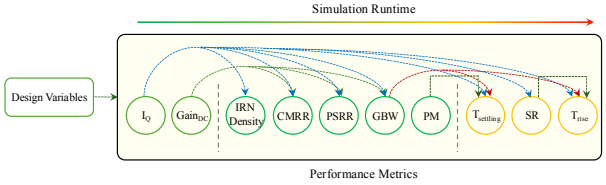

Fig. 2: Metric Sequencing in Folded Cascode Amplifier

Given a performance metric sequence order, INSIGHT utilizes self-attention to adaptively focus on the most relevant

segments of the parameter (x_1 to x_N) and generated performance output (y_1 to y_{i-1}) sequence, to accurately predict each output metric y_i. Positional encoding is used to preserve sequence order and maintain context and coherence.

Our autoregressive performance prediction formulation, integrated with the INSIGHT framework, which comprises an adaptive architecture combined with our strategy for optimizing performance sequence order, offers a data-efficient and effective analog circuit performance prediction approach.

C. Transfer Learning with INSIGHT

The fundamental circuit physics, including performance interdependencies, trade-offs, and design principles inherent to a given topology, remain largely consistent and often translate across different process technologies. INSIGHT leverages transfer learning to facilitate data-efficient knowledge transfer between processes while maintaining high prediction accuracy. This same capability further enables rapid fine-tuning to new real data within the same process and topology, allowing swift model updates—a crucial feature for effective surrogate modeling in model-based optimization frameworks.

To further enhance computational efficiency, INSIGHT incorporates Low-Rank Adaptation (LoRA) [19, 20], as detailed in Algorithm 2, to reduce the model's memory footprint and fine-tuning time by updating only a small set of rank-decomposition matrices instead of all model parameters, while maintaining high prediction performance, as shown in Fig. 3.

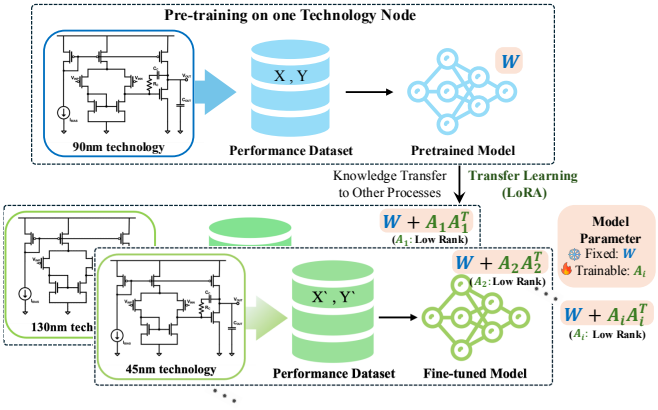

Fig. 3: LoRA-based Transfer Learning in INSIGHT

The overall wall-clock time for optimization in a model-based optimization framework can be approximated as:

$$T_{\text{optimization}} \approx t_{\text{overhead}} + K \cdot t_{\text{inference}} + N \cdot t_{\text{update}} + M \cdot t_{\text{policy-opt}} + R \cdot t_{\text{real-interaction}}, \quad (2)$$

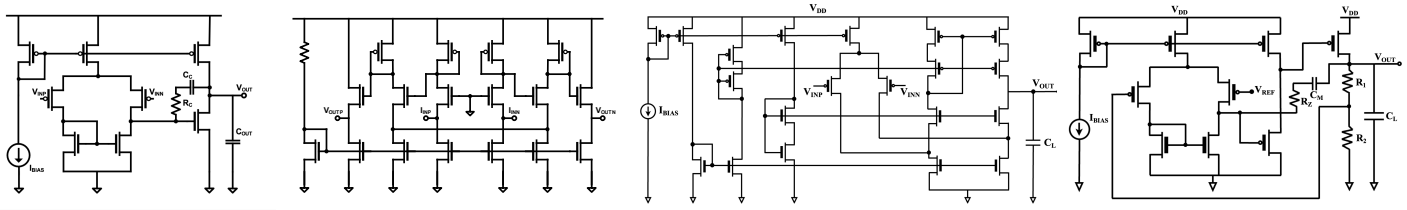
where K, N, M, and R represent the number of surrogate model inferences, model updates, policy optimization steps, and real environment interactions during the optimization, respectively, with $t_{\text{inference}}$, t_{update}, $t_{\text{policy-opt}}$, and $t_{\text{real-interaction}}$ being their corresponding time durations, and t_{overhead} the time for data processing, one-time model pre-training, and other overhead tasks. INSIGHT aims to keep the critical components of Equation 2: N, R, t_{update}, and $t_{\text{inference}}$ small using its data-efficient high prediction accuracy, effective generalization, rapid fine-tuning capabilities, and fast ML-based inference, reducing the overall optimization time and enhancing the real-time sample efficiency.

Algorithm 2 LoRA-based Transfer Learning in INSIGHT

Require: Pre-trained $model$, $train_dataset_loader$, $device$, LoRA rank r, learning rate γ, epoch E, warm start step T_0
Ensure: Fine-tuned model with updated LoRA parameters
  function APPLY_LORA_TO_MODEL(network, LoRA_rank)
    for weight W in network **do**
      $W \leftarrow W.detach() + A_W A_W^T$ for a low rank learnable vector on A_W (LoRA parameter).
    end for
    return network
  end function
  $model$=APPLY_LORA_TO_MODEL($model$, r)
  $optimizer \leftarrow$ initialize Adam optimizer with LoRA parameters, learning rate γ
  $loss_fn \leftarrow$ MSE loss function
  $num_epochs \leftarrow E$
  $scheduler \leftarrow$ CosineAnnealingWarmRestarts with T_0
  for $epoch = 1$ to num_epochs **do**
    $total_loss \leftarrow 0$
    $model.train()$
    for all $batch \in train_dataset_loader$ **do**
      compute output and loss
      backpropagate and update LoRA parameters
      aggregate loss
    end for
    update learning rate scheduler
  end for

IV. Experiments

A. Benchmark Circuits and Technologies



We trained and evaluated INSIGHT on a machine with eight NVIDIA P100 GPUs and an Intel Xeon E5-2698 V4 CPU. To demonstrate the effectiveness of INSIGHT, we compare its performance against two state-of-the-art neural surrogate approaches: Learn-by-Compare (LbC) [16] and the FC-Ensemble from CRONuS [10]. We use the following benchmark circuits:

I. 2-Stage Miller-Compensated OPAMP (NMOS Input Pair)
II. 2-Stage Miller-Compensated OPAMP (PMOS Input Pair)
III. 2-Stage TIA (Transimpedance Amplifier)
IV. 3-Stage TIA
V. Level Shifter

Additionally, we assess INSIGHT on the Folded Cascode Amplifier and Low-Dropout Regulator (LDO) using a commercial 45nm process with an extended set of performance metrics. Figure 4 provides detailed schematics for some of these circuits. Table II lists the performance metrics against which these circuits have been evaluated. We have validated our concept on 45nm, 90nm, and 130nm technologies.

B. INSIGHT Performance

1) Prediction Accuracy: An unseen test dataset of 1000 samples was held out for final evaluation. We created training sets of varying sizes; each split into an 80:20 train-validation

(a) (b) (c) (d)

Fig. 4: Schematics: (a) 2-Stage Miller-Compensated OPAMP (PMOS Input Pair), (b) 3-Stage TIA, (c) Folded Cascode Amplifier, (d) LDO

TABLE II: Performance Metrics for each circuit

Circuits	Performance Metrics									
Benchmark I Benchmark II Benchmark III Benchmark IV	I_Q (mA)	DC Gain (dB)	Input-Referred Noise Density (IRN Density) @ 1KHz ($V/\sqrt{Hz}$)		CMRR (dB)			UGBW (MHz)	Phase Margin (°)

V	**15 ± 5**	420	10,400

from scratch for varying training set sizes as described in the above setup for 90nm technology, while Figure 5(b) shows INSIGHT's performance on Folded Cascode and LDO on a commercial 45nm process. INSIGHT achieves high prediction performance ($R^2 > 0.9$) with $\leq$1500 training samples across benchmarks, highlighting its data efficiency. Table III summarizes INSIGHT's mean test performance using 2000 samples for training and validation following the setup described earlier. As shown, INSIGHT consistently achieves high test R^2 scores and low MSE losses across all benchmark circuits, outperforming our baselines [16] and [10]. Table IV highlights the effectiveness of INSIGHT's metric sequencing strategy for the Folded Cascode, showcasing improved data efficiency in limited data scenarios over the reversed order.

2) Knowledge Transfer across Technologies: For each topology, similar to the prediction accuracy evaluation setup discussed in Section IV-B1, we reserved an unseen test set of 1000 samples. INSIGHT's test performance was then evaluated on each for different training set sizes, comparing training from scratch against fine-tuning over 30 independent trials per training set size. Mean R^2 scores and standard deviations were noted. Figure 5(c) illustrates prediction performance on Benchmark II from 90nm to 130nm (to larger node), while Figure 5(d) shows results for Benchmark III from 90nm to 45nm (to smaller node). Both figures display mean R^2 scores with the corresponding 95% confidence intervals, demonstrating INSIGHT's effectiveness across technologies. Table V summarizes the training data requirements for benchmark circuits I–V transferred from 90nm to 45nm, using a mean test R^2 score of 0.9 as the minimum acceptable performance threshold. Our experiments showed a significant $\sim$60% reduction in required training data for transfers between 90nm and 45nm, and 130nm and 90nm, while preserving high prediction fidelity. Implementing LoRA allowed us to maintain high model performance while significantly reducing computational requirements. As shown in Table VI, LoRA reduced memory footprint by $\sim$42% and training time by $\sim$25% for training size of 500 while maintaining model performance above the R^2 threshold of 0.9.

3) Inference Speed: When simultaneously processing a batch of 1,000 combinations of input parameters, INSIGHT's inference time across our benchmark circuits was measured to be $115.21\mu s$ (mean) $\pm 12.01\mu s$ (std dev), compared to several minutes for the case of commercial simulators. This result was derived from 100 independent trials per circuit on our setup.

C. Analog Sizing using INSIGHT

For these experiments, INSIGHT was pre-trained from scratch on a dataset of 1,000 randomly generated samples per topology, comprising Gaussian-sampled design parameters and their corresponding SPICE-simulated performance metrics. Note that INSIGHT does not make any a priori assumption on the underlying data distribution, and using a moderate to expert dataset would likely enhance the performance of the sizing framework. PPO-based RL agents [30] with default hyperparameters were employed, a method extensively used in EDA because of its robustness and effectiveness [6, 31], and the performance compared against two established analog circuit sizing methodologies: AutoCkt [6], a PPO-based online learning-based algorithm with default hyperparameter settings, and CRONuS [10], a state-of-the-art neural surrogate-based approach. Table VII presents the performance comparison based on the number of real-time simulations (steps) required for different circuits on 45nm technology, each row representing a test case corresponding to a fixed target specification randomly selected from the same set of designer-specified performance specifications used in [10]. The INSIGHT-based framework's performance is reported as mean $\pm$ standard deviation over 30 independent trials for robust statistical analysis. Our sizing experiments show that INSIGHT effectively reduces the critical components of Equation 2 (Section III-C) for this application, achieving $\sim$ 100-1000$\times$ improvement in computation costs over existing sizing methods on identical benchmarks and test cases, demonstrating INSIGHT's efficacy.

V. Conclusion

This paper introduces INSIGHT, a novel, technology-agnostic, and data-efficient universal neural simulator framework for analog performance prediction. By formulating the prediction task as autoregressive sequence generation, INSIGHT leverages the strengths of decoder Transformer architectures and their self-attention mechanisms to capture inherent parameter-performance interdependencies. This approach allows accurate prediction of simulation-costly critical specifications leveraging less expensive (predicted or previously available) performance metrics as conditioning information, achieving high-fidelity and data-efficient predictions across diverse circuit types and technologies. The Transformer-based architecture enables adaptive handling of variable-length design parameters and performance metrics, making INSIGHT a universal framework. INSIGHT supports compute- and data-efficient knowledge transfer across processes through parameter-efficient fine-tuning using Low-Rank Adaptation (LoRA) while maintaining high model performance. Furthermore, these fast fine-tuning capabilities make INSIGHT suitable for model-based optimization frameworks where model update time is critical. Our experiments demonstrate INSIGHT's effectiveness, consistently achieving test R^2 scores ≥ 0.95 across circuits and technologies.

To our best knowledge, this work represents the first successful application of a universal neural simulator framework using autoregressive Transformers for analog design automation. Future work will focus on developing more intelligent strategies to enhance data efficiency and extend this formulation to address more complex analog design challenges.

***Abstract*—Compute-in-memory (CiM) has become a promising candidate for edge AI by reducing data movements through *in-situ* operations. However, this emerging computational paradigm also poses the vulnerability of model leakage as the weights are stored in plaintext for computing. While prior works have explored lightweight encryption methods, CiM is usually considered a separate module instead of a system component, leaving the origin of keys unclear and unprotected. Physical unclonable functions (PUFs) offer a potential origin of keys, but a comprehensive framework for securing key generation and delivery remains lacking. Besides, the complementary ciphertext storage incurs substantial costs and degrades the performance.**

This work proposes PUFiM, a robust and efficient security solution for edge computing based on ferroelectric FETs (FeFETs). For the first time, a strong PUF is synergized with CiM to enable authentication, key generation, and encrypted computations within a unified array for comprehensive protection. To achieve this synergization, a high-density hybrid storage and computation approach combining PUF and weight bits via multi-level cell (MLC) FeFETs is proposed. Besides, two PUF enhancement techniques and a novel mapping scheme are developed to improve security and efficiency further. Results show that PUFiM withstands PUF modeling attacks with up to 10M samples. Moreover, PUFiM reduces the inference accuracy by >60% under 95% key leakage and achieves >9.7× compute density and >1.2× energy efficiency improvement compared with the state-of-the-art SRAM/NVM secure CiMs.

***Keywords*—Hardware Security, Computing-in-Memory, Physical Unclonable Functions, Ferroelectric FET (FeFET)**

I. Introduction

Deep neural networks (DNNs) have shown superior performance in diverse application domains, from visual recognition to natural language processing [1]–[3]. With the increasing demand for privacy and real-time responses, DNN models are migrating from cloud to edge by deploying the trained models on edge devices for inference. However, in conventional von Neumann architectures, efficient DNN inference faces the bottleneck of substantial data movements between processing units and memories [4]. This memory wall challenge prompts the emerging computational paradigm of compute-in-memory (CiM), which aims to reduce data movements via *in-situ* operations [5], [6]. Towards the paradigm, various impressive implementations have been demonstrated, including CMOS CiMs [7], [8] and nonvolatile memory (NVM) CiMs [9]–[12].

However, in the unsupervised environment, CiMs suffer from the vulnerability of model leakage as the weights are stored in plaintext for computing. This data theft risk is exacerbated when NVMs are employed, as shown in Fig. 1(a). Therefore, weight encryption becomes crucial to protect the DNN models in NVM CiMs. Conventional approaches include software runtime encryption [13], [14] and hardware data encryption such as AES [15], [16]. Despite the wide usage of these methods, software encryption still holds an attack window during algorithm execution, while AES-based encryption is incompatible with in-memory computing. Besides, both approaches incur significant performance and energy overheads, making them less feasible for edge devices.

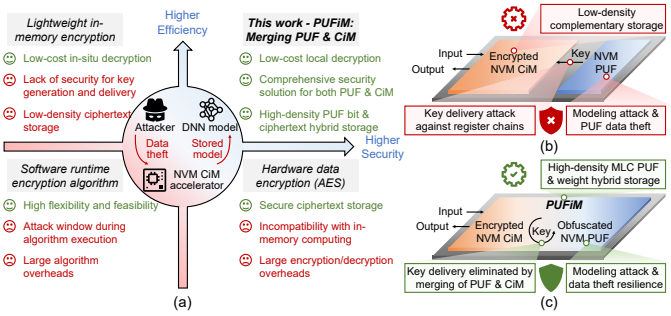

Fig. 1. Secure CiMs: (a) Comparison between encryption methods. (b) Challenges in existing designs. (c) Insights of the proposed PUFiM.

Beyond the conventional approaches, recent works have explored the use of *in-situ* XOR cipher for lightweight encryption [17]–[24]. Through the subtle combination of inputs and keys, the weight decryption can be performed simultaneously with computing, achieving ultra-low cost and secure storage. However, the security of this method is premised on the secure generation and delivery of the keys, which is underexplored in prior designs. While physical unclonable functions (PUFs), which generate unique and unpredictable responses to given challenges, can be employed for key generation [20]–[24], the attacks against PUFs [25]–[27] and key delivery via register chains [28] still pose threats to the system, as shown in Fig. 1(b). Furthermore, the commonly used complementary ciphertext storage degrades both density and efficiency.

To cope with this challenge, we highlight the necessity of viewing PUF and CiM as inseparable parts of the system and propose **PUFiM**, a robust and efficient ferroelectric FET (FeFET)-based security solution merging PUF with CiM. As shown in Fig. 1(c), the core insight is to synergize PUF with CiM in a unified array to enable local key generation, decryption and computation with comprehensive security,

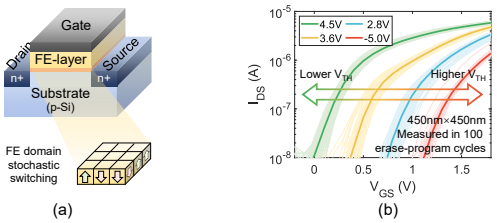

Fig. 2. FeFET: (a) Structure. (b) I_{DS}-V_{GS} curves with C2C variations [29].

where multi-level cell (MLC) FeFETs are exploited to support efficient PUF and weight hybrid storage and computation.

The highlighted contributions are summarized as follows:

- To the best of our knowledge, PUFiM is the **first** edge security solution that fuses PUF and CiM into one array for comprehensive and area-efficient protection.
- The startup value-based obfuscation and nonlinearity-enhancing post-processing are proposed to secure PUF.
- A significance-aware weight mapping scheme is proposed to improve CiM energy efficiency and security further.
- Extensive experiments are performed, and optimal configurations are explored. Results show that PUFiM reduces the inference accuracy by >60% under 95% key leakage, and achieves >9.7× compute density and >1.2× energy efficiency improvement compared with the state-of-the-art SRAM/NVM secure CiMs [18]–[21].

II. Background and Related Works

This section introduces the FeFET basics, illustrates the attack model and analyzes the bottlenecks of related works.

A. FeFET Basics

FeFET is a MOSFET with the insertion of a ferroelectric (FE) layer in the gate stack, as shown in Fig. 2(a) [29]–[31]. Reports have shown the fabrication of FeFET arrays at 28nm bulk [29] and 22nm FDSOI [31] technology node. Recent research has also reported the large-scale 3D integration of FeFETs [32] and the FeFETs with unlimited endurance [33].

The FE layer consists of multiple independent FE domains whose polarization states collectively affect the FeFET threshold voltage (V_{TH}). The multi-domain structure of the FE layer leads to two intriguing features [30] shown in Fig. 2(b): (i) By applying different write voltages (V_W) to the FeFET gate, the polarization state of the FE layer can be partially switched to achieve MLC storage; (ii) The polarization switching of a single FE domain is an abrupt and stochastic process due to the random polarization nucleation event, enabling FeFETs with significant cycle-to-cycle (C2C) variations.

Inspired by the two features, we leverage the FeFET MLC capability to achieve high-density hybrid storage and computation of the PUF and weight bits. Meanwhile, the FeFET C2C variation is exploited as the PUF entropy source by comparing the V_{TH} obtained from two write cycles of the same device.

B. Attack Model

The attacker is assumed to have access to an edge AI chip with an integrated secure CiM, which can be obtained from the market and used for inference as an authorized user. The communication channel between the manufacturer or the model vendor and the chip can be monitored. Additionally, the attacker can carry out physical attacks to probe the weights of the DNN model stored in the NVM cells and the keys stored in the register chain, as demonstrated in [28], [34]. The attacker also has complete knowledge of the hardware implementation. However, due to the advancements in technology nodes, directly probing the signals within the secure CiM array is practically infeasible [35]. Therefore, the internal signals, including those related to the computation and key operations, are assumed to be secure from such attacks.

C. Related Works

To thwart model leakage with tolerable overheads, several lightweight secure CiM designs have been explored. A common approach involves pre-storing the encrypted weights in complementary cells with dual word lines (WLs), which allows the correct WL to be selected based on the key for *in-situ* decryption. Representative works include XOR-CIM [20], Secure-RRAM [17], SRA [18] and NAND FeFET CiM [19]. However, these designs double the memory cells and incur substantial area overheads. [36] eliminates the additional cells using a novel device, though its reliability and scalability remain challenges. Moreover, the above designs consider CiM a separate module instead of a system component, neglecting key generation and delivery as the basis for CiM security.

For secure key generation, PUF is employed as security primitives, exploiting entropy sources such as manufacturing variations to produce unique challenge-response pairs (CRPs). However, the weak PUFs utilized in [20]–[22] provide insufficient CRP space for authentication, thus vulnerable to attacks on communication channels [26]. In contrast, [23], [24] implement strong PUFs based on in-memory computing but face challenges from modeling attacks [25] and NVM data theft [34]. Furthermore, the separate implementations of PUF and CiM remain prone to key delivery attacks [28] and limit the opportunity for system performance co-optimization. Therefore, PUFiM is motivated to synergize PUF with CiM in one array for comprehensive security and improved efficiency.

III. PUFiM Overview

Fig. 3(a) illustrates the complete workflow of PUFiM from PUF enrollment to edge inference. The novel merging of PUF and CiM, combined with other highlighted techniques, makes PUFiM behave as a black box for the attacker and ensures robust and efficient protection throughout the workflow:

(i) PUF enrollment with obfuscation. After the PUFiM chip is manufactured in a trusted environment, the PUF bits are generated by exploiting the FeFET C2C variations and written back into the array. Based on the random startup values from the peripherals, a subset of the PUF bits is selected and activated for CRP generation, providing obfuscation for the nonvolatile PUF bits. These startup values and CRPs are subsequently stored in the cloud as the device fingerprint.

(ii) Secure PUF authentication. Before communication, PUFiM sends challenges to the cloud and verifies between the

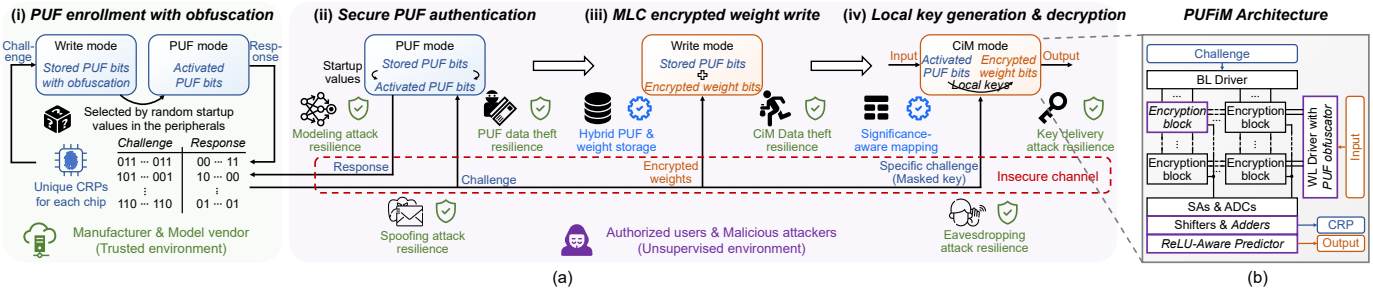

Fig. 3. Overview of PUFiM: (a) Complete workflow with security and efficiency enhancement approaches. (b) Overall architecture with blockwise structure.

received and self-generated responses for authentication. This prevents the *spoofing attack* against device identity. Besides, the proposed obfuscation and post-processing techniques provide resilience to the *PUF data theft* and *modeling attack*.

(iii) MLC encrypted weight write. Once authenticated, the model vendor encrypts the weights using the stored CRPs and offloads the encrypted weights to the edge to thwart *CiM data theft*. These weights are written to the MLC FeFETs based on the significance-aware mapping scheme and co-exist with the PUF bits, enabling high-density and secure hybrid storage.

(iv) Local key generation, decryption and computation. For edge inference, PUFiM acquires a specific challenge from the cloud and computes it with the activated PUF bits to generate local keys for each encryption block. These internal keys, distinct from the publicly accessible CRPs, are secure and can be retained until power-down. The local keys decrypt the weights in the block for computation. By merging PUF with CiM, the challenge (as a masked key) and the local keys protect PUFiM from *eavesdropping* and *key delivery attacks*.

Fig. 3(b) shows the PUFiM architecture. Challenges and DNN inputs are applied vertically and horizontally, respectively. During inference, multi-bit inputs are sequentially processed cycle by cycle, with the outputs accumulated using shifters & adders. Further summation of the outputs produces the final feature map. The encryption block with hybrid storage and computation is the core of PUFiM to enable the synergization of PUF and CiM. The startup value-based obfuscation and nonlinearity-enhancing post-processing are facilitated by the WL driver and the adders, while the significance-aware weight mapping improves efficiency via the ReLU-aware predictor.

IV. Design Details

This section details the four highlighted techniques of PUFiM, which synergizes PUF with CiM and significantly improves security, area efficiency and energy efficiency.

A. MLC Hybrid Storage and Computation

A key challenge in merging PUF and CiM lies in hybridly storing PUF and weight bits without affecting their respective computations. This becomes even more challenging with MLC, where the two bits stored in one device can cause interference, and the FeFET variations degrade the computing reliability. Therefore, PUFiM introduces a novel scheme to achieve both **high-density storage** and **reliable computation**.

Fig. 4(a) shows the proposed encoding and storage scheme. The stored bits are encoded into FeFET states with Gray code

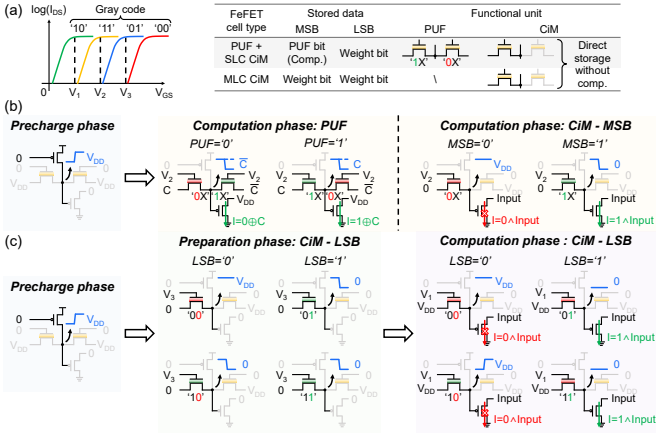

Fig. 4. MLC hybrid storage and computation: (a) Encoding and storage scheme. (b) MSB computation (PUF and CiM). (c) LSB computation (CiM).

and read out with $V_{1/2/3}$. For hybrid storage, FeFET cells are categorized into two types: (i) Some cells store weight bits in the LSB and complementary PUF bits in the MSB, with two such cells forming a PUF functional unit. (ii) Other cells store weight bits in both the MSB and the LSB. Note that all weight bits are stored directly and can be operated in one cell.

Fig. 4(b) shows the computation scheme for the MSB, which begins with a precharge phase. For PUF computation, V_2 is applied to the gates of two FeFETs with complementary PUF bits, and the challenge is input complementarily from the drains. This setup makes the PMOS on/off state consistent with the XOR result of the PUF and challenge bits. For CiM computation, the FeFETs storing '1' in the MSB discharge the internal node at V_2, activating the PMOS if the input is VDD.

Fig. 4(c) shows the computation scheme for the LSB. The preparation phase sets the FeFET gate voltage to V_3, discharging the internal nodes of all cells to GND except those storing '00'. Then V_1 is applied, and the FeFET drain is raised to VDD, which charges the '10' cells to switch off the PMOS. Consequently, only cells storing '1' in the LSB output currents.

The above method enables the hybrid storage of PUF and CiM while supporting their respective computations (XOR and AND). The FeFET variations are mitigated by converting the readout results into PMOS currents. The related evaluation of the PUFiM reliability is presented in Section V-B.

B. Local Key Generation, Decryption and Computation

Based on the proposed MLC hybrid storage and computation method, the encryption block circuit and operation mechanism are illustrated in Fig. 5 and detailed below:

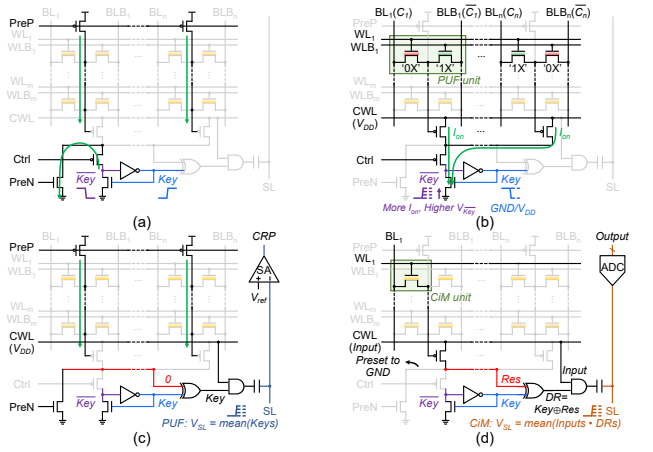

Fig. 5. Encryption block circuit and operation mechanism: (a) Precharge. (b) Local key generation. (c) PUF mode. (d) CiM mode.

(i) Precharge. The internal nodes in the FeFET array and the inverter output are precharged to VDD.

(ii) Local key generation. The challenge vector is input via BLs and BLBs to perform XOR computation with one row of PUF units. The resulting output currents are accumulated, affecting the voltage division at the inverter input. Once the voltage exceeds the inversion threshold, the inverter output (i.e., the key) switches to GND and shuts down the NMOS loop to lock the result. Otherwise, the output remains at VDD.

(iii) PUF-mode CRP generation. In PUF mode, the generated key is delivered to the capacitor connected to the SL. The capacitive coupling across encryption blocks averages the keys, and the obtained SL voltage is compared with a reference voltage by the sense amplifier (SA) to obtain the CRP. Note that this CRP requires post-processing for the final output.

(iv) CiM-mode decryption and computation. In CiM mode, one cell per block is activated to convert the weight bit into the voltage at Res, which is XORed with the generated local key for decryption. The decrypted result is subsequently ANDed with the input from the CWL for charge-domain computing.

The proposed encryption block generates and utilizes keys locally, effectively **preventing key delivery attacks**. The key generation requires only **one row of activated PUF bits** in each block without introducing heavy costs. The charge-domain computing offers energy-efficient and reliable computation, while the CMOS circuits can be shared by the FeFET array to reduce the area overheads. The block size configuration is analyzed and optimized in Section V-B.

C. PUF Obfuscation and Post-Processing

Despite the robust security of keys and weights in the PUFiM encryption block, the FeFET-based PUF remains vulnerable to probing and modeling attacks. **To thwart these threats**, obfuscation and post-processing techniques are proposed.

Fig. 6(a) illustrates the startup value-based obfuscation. Upon power-on, the bistable circuits output random startup values due to process variations, which are used to activate one of the two rows of PUF bits in a block. Therefore, the PUF bits stored in the nonvolatile FeFETs are obfuscated. However, some bistable circuits may be less robust and output unstable

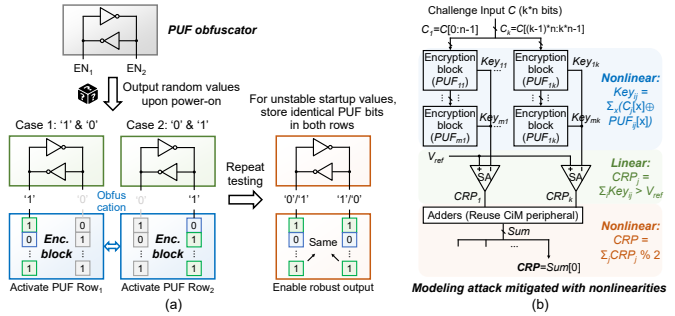

Fig. 6. PUF enhancement techniques. (a) Obfuscation. (b) Post-processing.

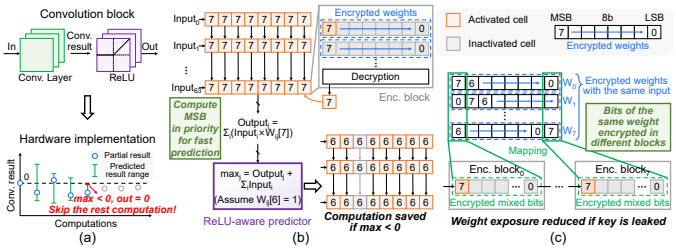

Fig. 7. Significance-aware weight mapping. (a) Insight of ReLU prediction. (b) Efficiency enhancement mapping. (c) Security enhancement mapping.

values. These circuits can be identified in advance, and the two PUF rows can be stored identically to enhance reliability at the cost of potential key leakage, as evaluated in Section V-D.

Fig. 6(b) shows the nonlinearity-enhancing post-processing with the complete CRP generation workflow. The XOR operations involved in key generation form the first nonlinear layer. Then m keys of the same column are aggregated in a linear approach. During post-processing, the adders designed for accumulating CiM outputs are **reused** to sum the results from k columns, with the LSB of the sum serving as the final CRP output. This additional nonlinearity increases the complexity of modeling the PUF without introducing additional area, and the improved resilience is shown in Section V-C.

D. Significance-Aware Weight Mapping

To further explore the potential of the PUFiM architecture based on encryption blocks, a significance-aware weight mapping scheme consisting of two sub-schemes is proposed.

Fig. 7(a) and (b) show the insight of the efficiency enhancement mapping. In convolution computation, the ReLU output would be 0 once the maximum possible value of the partial result is less than 0. As a result, the remaining computations can be skipped. Based on this observation, PUFiM maps all bits of one weight into the same encryption block and prioritizes the MSB computations in all blocks to accelerate prediction. If the predicted maximum output of any column is below 0, the corresponding blocks can be idled to save energy.

Fig. 7(c) shows the security enhancement mapping. The core idea is to shuffle the bits of the weights with the same input and map them into different encryption blocks without affecting the computations. This ensures that bits of the same weight are encrypted by different keys, significantly reducing the weight exposure caused by key leakage from any single block.

Both sub-schemes can be applied simultaneously to improve **energy efficiency and security** as shown in Section V-D.

TABLE I
PUFiM PARAMETERS

Unit	Spec	
FeFET array	Array size[1]	1024×1024 FeFETs 0.22fF/μm parasitic capacitance
	FeFET dimension[2]	Exp: 450nm×450nm Sim: 200nm×100nm
	Write voltage	-5.0V/2.2V/3.6V/4.5V, 500ns
	Read voltage	$V_1/V_2/V_3$ = 0.3V/0.95V/1.2V
	V_{TH} variation	130mV/85mV/176mV/110mV
	Capacitor	1fF MOM, σ = 0.8%, 2.74μm^2
ADCs & SAs	5-bit SAR ADC, VSA, 1 per column of blocks	

[1] The encryption block size is 8×10 based on the optimizations in Section V-B, and two rows per block store PUF bits in the MSBs.
[2] The FeFET layout in Fig. 9 is close to the fabricated ones.

V. Evaluation and Discussion

A. Experimental Setup

Hardware-level evaluation: To comprehensively capture FeFET characteristics, we utilize the experimental measurement results of 9×7 FeFET arrays fabricated at 28nm node to extract the C2C variation, MLC storage, and device non-idealities for accurate evaluation. The area, latency and energy consumption of FeFETs are simulated based on a widely used FeFET model [37] using the parameters from the fabricated FeFET arrays. 5-bit SAR ADCs and voltage SAs (VSAs) are designed, and digital peripherals are synthesized at 28nm node. The array size is set to 1024×1024 FeFETs with the parasitic capacitance considered. Table I lists the detailed information.

Software-level evaluation: Five powerful modeling attacks are performed, i.e., LR, MLP, SVM, XGBoost and CMA-ES, which have shown success against various PUF designs [25], [26], [38]. The inference accuracy is evaluated on VGG8 for CIFAR10 and ResNet18 for CIFAR100, covering different dataset scales and network complexity. We use PyTorch for quantization-aware training to obtain the model with 8-bit input and 8-bit weight. The inference process is modified to include the crypto operations and non-idealities from hardware.

Baselines: The modeling attack resilience is benchmarked with the arbiter PUF with and without 6-XOR structure [39] and the state-of-the-art FeFET PUF [23]. For secure CiM evaluation, four state-of-the-art designs based on SRAM [20], RRAM [18], STT-MRAM [21] and FeFET [19] are compared. The technology node of all baselines is scaled to 28nm using DeepScale [40] for accurate and apple-to-apple comparisons.

B. Circuit-level Evaluation and Optimization

Fig. 8 evaluates the reliability of the encryption block. As shown in Fig. 8(a), considering FeFET variations, the outputs of PUF units still exhibit tight distributions primarily induced by the CMOS variation, while the outputs of CiM units show an error rate of <2% due to the FeFET state overlap. This is attributed to the proposed MLC hybrid computation method, which converts FeFET readout results to CMOS currents. For key generation, the accumulation of output currents is sensed by the inverter-NMOS loop with <5% error rate, facilitating

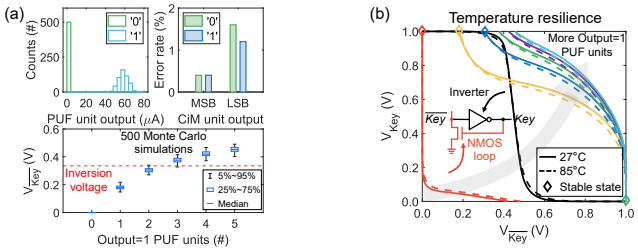

Fig. 8. Encryption block reliability: (a) Distributions and error rates of the PUF and CiM unit outputs. (b) Temperature resilience of key generation.

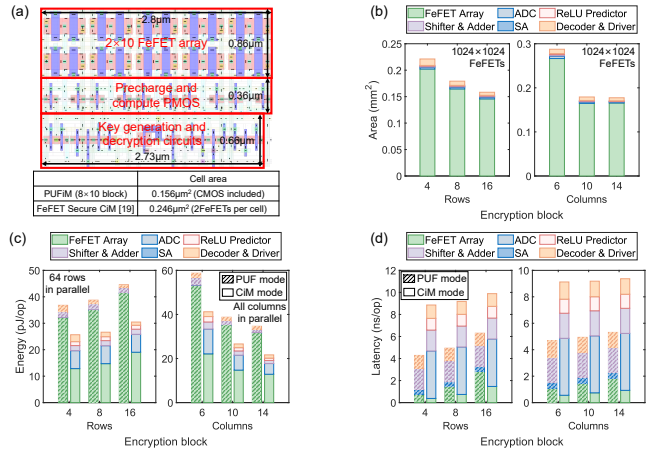

Fig. 9. Encryption block performance: (a) Layout of 2×10 block and cell area comparison with prior works [19]. (b) Area. (c) Energy. (d) Latency.

high randomness and uniqueness of the keys. Fig. 8(b) further shows the temperature resilience of the sensing circuits. Thanks to the voltage division between transistors in series, the intersection of the inverter-NMOS loop in-out curves, representing stable outputs, shifts negligibly as temperature varies from 27°C to 85°C, which indicates robust resilience.

Fig. 9(a) shows the layout of a 2×10 encryption block based on 28nm design rules. The width of the CMOS circuits perfectly matches the FeFETs, and the capacitor (2.74μm^2) can be placed on top. Consequently, PUFiM achieves 0.156μm^2 per cell with CMOS included, which is 1.6× lower than the complementary storage in [19] with the same device size.

Fig. 9(b-d) evaluate the PUFiM area, energy and latency in both PUF and CiM modes with different encryption block sizes. The FeFET array occupies most of the area as the blocks share the peripherals, and the resulting parasitic capacitance further contributes to a high energy proportion. Compared with the CiM mode, the PUF mode consumes more energy due to the power-hungry current summation required for key generation but shows less latency with the ADCs not involved.

For the impact of the encryption block size, increasing rows and columns enables the CMOS circuits to be shared by more FeFETs and reduces the area. Besides, increasing the rows within a block, while maintaining the same row parallelism, heavies the precharging burden and results in more energy and latency. While more columns have a similar effect on precharging, their impact on energy is covered by the reduction in column parallelism. With the above observations, we select **8×10** as the optimized encryption block size for PUFiM.

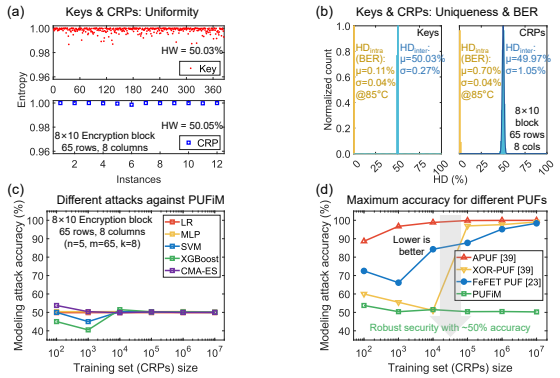

Fig. 10. PUF mode evaluation: (a) Uniformity. (b) Uniqueness and BER. (c) Modeling attack resilience of PUFiM. (d) Comparison with existing PUFs.

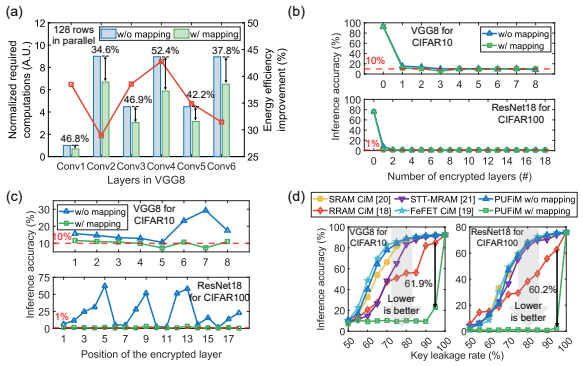

Fig. 11. CiM mode evaluation: (a) Energy efficiency improvement of the significance-aware weight mapping. (b) Encryption security performance. (c) Impact of encrypted layer position on security. (d) Key leakage resilience.

C. PUF Performance and Security Evaluation

Fig. 10(a) and (b) show the basic PUF metrics of PUFiM. Both the keys (within encryption blocks) and CRPs (after post-processing) show excellent ∼50% uniformity and uniqueness, and achieve an ultra-low <0.70% bit error rate (BER) at 85°C. This is attributed to the proposed reliable computation method and the use of FeFET C2C variations as the entropy source.

Fig. 10(c) shows the PUFiM modeling attack resilience across multiple attack models. Thanks to the nonlinearity provided by the proposed post-processing technique, PUFiM achieves a maximum accuracy of 50.26% (close to random guessing) even with a training set size of 10M, which is almost infeasible for the attacker to obtain. When applying these attacks to various PUFs, PUFiM shows significantly enhanced security compared with the vulnerable baselines.

D. CiM Performance and Security Evaluation

Fig. 11(a) shows the benefits of the proposed significance-aware mapping in VGG8. By accelerating the ReLU prediction convergence, the required computations are reduced with the related blocks idled, improving the PUFiM energy efficiency.

Fig. 11(b-d) evaluate the security performance of PUFiM inference. Encrypting a single layer drastically reduces accuracy to unusable levels, with the position of the layer affecting the accuracy drop. The proposed weight mapping scheme ensures consistently low accuracy levels close to random guessing. As shown in Fig. 11(d), thanks to the finer-grained encryption and the proposed mapping scheme, PUFiM achieves much higher security compared with the prior secure CiMs, lowering the accuracy by >60% under 95% key leakage on both models.

TABLE II
COMPARISON BETWEEN PUFIM AND SOTA SECURE CIMS

	[20]	[18]	[21]	[19]	**PUFiM**
Cell type	SRAM	RRAM	STT-MRAM	FeFET	**FeFET**
Technology	28nm	32nm	22nm	28nm	**28nm**
Bit/cell	1	1	1	2	**2**
PUF support	Weak	No	Weak	No	**Strong**[1]
Key delivery vulnerability	Yes	Yes	Yes	Yes	**No**[2]
Key leakage vulnerability[3]	74.88%	62.65%	73.88%	75.59%	**2.46%**
Storage density (Mb/mm^2)	0.05	6.85	0.73	0.61	**10.52** (>**1.5**×)
Compute density[4] ($TOPS/mm^2$)	0.004	0.046	0.044	0.011	**0.444** (>**9.7**×)
Energy efficiency[4] (TOPS/W)	2.86	0.33	12.24	8.08	**14.75** (>**1.2**×)

[1] PUFiM also achieves resilience against modeling attack and data theft on NVM PUFs.
[2] The keys are generated and used internally without the delivery via register chains.
[3] Inference accuracy of ResNet18 for CIFAR100 with 95% key leakage.
[4] Normalized to 8-bit input, 8-bit weight precision with 50% sparsity.

E. Macro-Level Comparison with SOTA Designs

Table II summarizes the macro-level comparison between PUFiM and the state-of-the-art secure CiMs [18]–[21]. **From a security perspective**, the merging of PUF and CiM eliminates the key delivery vulnerabilities, while the proposed PUF enhancement techniques and the significance-aware mapping further improve the resilience against PUF attacks and key leakage. This comprehensive security solution surpasses all the baselines in robustness for edge AI systems. **For area and energy efficiency**, thanks to the proposed MLC hybrid storage and computation, PUFiM achieves >1.5× storage density and >9.7× compute density compared with the baselines. Besides, the compact merging saves the peripherals, and the mapping scheme reduces the required computation, collectively achieving >1.2× energy efficiency improvement.

F. More Discussions

PUFiM is designed for edge inference, where infrequent weight updates mitigate FeFET endurance concerns. The reliability of MLC FeFETs can be further improved by write-and-verify [41]. Besides, resilience against chosen input attacks (i.e., collecting input-output pairs for retraining) and side-channel attacks can be improved through enhanced DNN model robustness [42] and masking techniques [43].

VI. CONCLUSION

This paper proposes PUFiM, a FeFET-based edge security solution with comprehensively robust security and significant efficiency improvement. The key highlight is the merging of PUF and CiM through MLC hybrid storage and computation, which enables highly secure local key generation and decryption. The obfuscation and post-processing techniques are proposed to enhance PUF security, and a significance-aware mapping scheme tailored for the PUFiM architecture is developed to improve CiM energy efficiency and security. Results show that PUFiM outperforms the state-of-the-art secure CiMs in security, area efficiency and energy efficiency.

EnQode: Fast Amplitude Embedding for Quantum Machine Learning Using Classical Data

Jason Han*, Nicholas S. DiBrita*, Younghyun Cho†, Hengrui Luo*, Tirthak Patel*
Rice University, Santa Clara University†*

***Abstract*—Amplitude embedding (AE) is essential in quantum machine learning (QML) for encoding classical data onto quantum circuits. However, conventional AE methods suffer from deep, variable-length circuits that introduce high output error due to extensive gate usage and variable error rates across samples, resulting in noise-driven inconsistencies that degrade model accuracy. We introduce *EnQode*, a fast AE technique based on symbolic representation that addresses these limitations by clustering dataset samples and solving for cluster mean states through a low-depth, machine-specific ansatz. Optimized to reduce physical gates and SWAP operations, *EnQode* ensures all samples face consistent, low noise levels by standardizing circuit depth and composition. With over 94% fidelity in data mapping, *EnQode* enables robust, high-performance QML on noisy intermediate-scale quantum (NISQ) devices. Our open-source solution provides a scalable and efficient alternative for integrating classical data with quantum models.**

I. Introduction

As quantum computing advances toward broader applicability, one of its key challenges is interfacing classical data with quantum algorithms [40], [34]. Quantum machine learning (QML) has shown potential in fields ranging from material discovery to the physical sciences, with amplitude embedding (AE) being the critical mechanism for encoding classical data onto quantum states [11], [12], [25]. However, current AE approaches present significant limitations for practical implementation on noisy intermediate-scale quantum (NISQ) devices. Specifically, AE circuits often have a high depth and number of gates, leading to degraded model performance on error-prone architectures, where circuit depth and gate error directly impact output interpretability [28], [29].

Current AE implementations also struggle to maintain a uniform error profile across samples, as the circuit depth and gate composition inherently depend on the data values encoded [39], [32], [8]. The variable depth across samples results in unequal noise exposure – a problem that can obscure the true performance of quantum algorithms and limit their utility in practical applications. This variability not only exacerbates decoherence issues on quantum hardware but also introduces sample-specific noise, complicating the interpretability and fidelity of downstream QML tasks. *In such settings, the depth and structure of AE circuits need to be managed delicately to balance efficiency with noise resilience [7], [33], [20], underscoring the demand for a new data embedding approach.*

To address these issues, we introduce *EnQode*, a novel amplitude embedding framework designed to achieve low error and high efficiency through approximate embedding. Rather than attempting exact amplitude representation for each sample, *EnQode* leverages a cluster-based approach to approximate AE with high fidelity. Our method begins by grouping data samples using the k-means clustering algorithm, enabling us to identify representative states for each cluster that capture the main characteristics of the data distribution. For each cluster, we then train a low-depth, machine-optimized ansatz tailored to the quantum hardware of choice.

An important aspect of *EnQode* is its generalizability across different QML applications with symbolic representation of circuit parameters. Once trained, the cluster-based ansatz allows for the rapid generation of an AE circuit for new data samples by mapping them to their respective clusters and applying transfer learning. This enables *EnQode* to yield AE circuits with over 94% fidelity while maintaining a standardized depth across samples. By reducing the number of two-qubit gates and maintaining a consistent depth across all AE circuits, *EnQode* not only enhances fidelity but also ensures uniform error profiles across data samples.

Our evaluation shows that *EnQode* achieves significant improvements in efficiency and consistency over the Baseline approach across multiple metrics. *EnQode* reduces the circuit depth by 45% and the two-qubit gate count by 35%, with zero variability across samples due to its fixed ansatz design. In noisy IBM quantum hardware simulation settings, *EnQode* demonstrates a state fidelity improvement of 13% over the Baseline, highlighting its robustness to hardware noise. Furthermore, *EnQode* reduces the compilation time per sample by 36%, with an added offline overhead of only 1.4 seconds per dataset and class, making it both time-efficient and practical for real-time quantum machine learning applications.

II. Relevant Background

A. Qubits, Quantum Gates, and Hardware Noise

Qubits are the fundamental units of quantum computation, with each qubit in a superposition state $\alpha|0\rangle + \beta|1\rangle$, where $\alpha, \beta \in \mathbb{C}$ and $|\alpha|^2+|\beta|^2 = 1$. Quantum gates operate on qubits to modify their states, implementing unitary transformations in the form of matrix operations. A unitary operator on n qubits $U \in \mathrm{U}(2^n)$ satisfies the constraints $U^\dagger U = UU^\dagger = I$, where $U^\dagger$ is the conjugate transpose of U.

In NISQ devices, gate noise, decoherence, and gate variability significantly impact circuit fidelity, particularly as circuit depth increases [31], [9], [16]. The circuit depth d for an amplitude embedding circuit directly correlates with error accumulation, leading to reduced fidelity in the final quantum state $|\psi_{out}\rangle$ due to decoherence effects. Gate error rates also

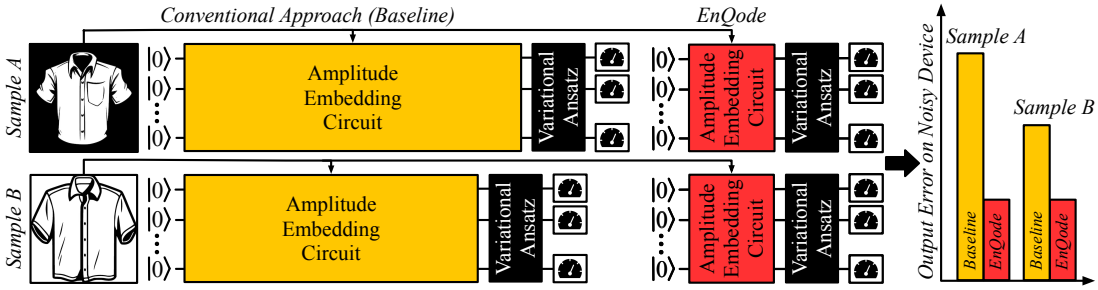

Fig. 1: *EnQode* provides short-depth and consistent circuits for amplitude embedding across different dataset samples.

vary across types of gates, with certain gates like SWAP being particularly error-prone – these gates do not add logical computation to the circuit but help connect distant qubits – which underscores the need for low-depth and reduced-SWAP implementations for reliable AE [3], [21], [37].

B. Variational Quantum Circuits and Optimization

Variational Quantum Circuits (VQCs) play a central role in QML, leveraging a combination of parameterized gates and classical optimization techniques to minimize an objective function [9], [18]. A typical VQC can be expressed as:

$$|\phi(\theta)\rangle = U(\theta)\,|0\rangle^{\otimes n}, \tag{1}$$

where $\theta = (\theta_1, \theta_2, \ldots, \theta_l)$ are trainable parameters and $U(\theta)$ is a unitary operator constructed from these parameters for an n-qubit state. The goal in variational optimization is to find parameters θ^* that minimize a given loss function $L(\theta)$, often achieved through gradient-based optimization:

$$\theta^{(t+1)} = \theta^{(t)} - \eta \nabla_\theta L(\theta^{(t)}), \tag{2}$$

where η is the learning rate.

C. Quantum Data Encoding and Amplitude Embedding

AE is a technique that encodes classical data into the amplitudes of a quantum state, mapping a classical vector $\vec{f} = (f_1, f_2, \ldots, f_{2^n})$ to a quantum state $|\psi\rangle$ such that:

$$|\psi\rangle = \textstyle\sum_{i=1}^{2^n} f_i\,|i\rangle\,, \tag{3}$$

where $\sum_{i=1}^{2^n} |f_i|^2 = 1$ to satisfy the normalization constraint of quantum states. This process allows classical data to be represented as quantum amplitudes, making it possible to utilize quantum algorithms for ML tasks. In practice, AE requires unitary operators to construct the quantum state $|\psi\rangle$ from an initial state $|0\rangle$ [8], [34], [28].

D. Challenges with Amplitude Embedding on NISQ Devices

The reliance on precise amplitude encoding leads to challenges on NISQ devices, where variable-depth circuits introduce inconsistencies in noise exposure across samples. Given that an amplitude embedding circuit for a sample $\vec{f}$ may require $d(\vec{f})$ layers of gates, where $d(\vec{f})$ varies with the encoded values, noise variability becomes an inherent issue:

$$\left|\psi(\vec{f})\right\rangle = U(\vec{f})\,|0\rangle^{\otimes n}, \tag{4}$$

where $U(\vec{f})$ is the unitary operator tailored for encoding $\vec{f}$, and n is the number of qubits required for the embedding. As demonstrated in Fig. 1, traditional AE circuits lack uniform depth, leading to inconsistent fidelity across samples when used for a downstream variational QML task [11], [12], [25].

The effectiveness of VQCs is contingent on the data encoding, which impacts the circuit's ability to represent the problem space accurately. Inconsistent and noisy amplitude embeddings degrade the training process, as each sample faces a different noise profile depending on the circuit depth and composition of its AE circuit. This dependence on high-quality, low-noise encoding underscores the need for efficient AE techniques.

E. Need for EnQode: Low-Depth Approach to Consistent AE

EnQode is designed to overcome the limitations of traditional AE by clustering data samples and representing each cluster with a machine-optimized, low-depth ansatz. By clustering samples into k clusters, *EnQode* represents the mean state of each cluster $\vec{c}_i$ using a low-depth ansatz that is optimized offline. For each cluster, we solve for a unitary operator $U(\vec{c}_i)$ that approximates AE with high fidelity:

$$|\psi(\vec{c}_i)\rangle = U(\vec{c}_i)\,|0\rangle^{\otimes n}. \tag{5}$$

This approach can then be used to perform fast AE for any given dataset sample. Additionally, *EnQode* reduces and standardizes the depth across all AE circuits, ensuring that each sample experiences consistent noise exposure, as depicted in Fig. 1. By achieving high-fidelity, low-noise embeddings, *EnQode* provides a robust framework for scalable QML applications, mitigating the issues faced by traditional AE methods on NISQ devices. We describe *EnQode* next.

III. Key Concepts and Design

We begin by describing the ansatz that *EnQode* leverages to amplitude embed any given quantum states from a dataset.

A. EnQode's Ansatz for Hardware-Efficient Implementation

The *EnQode* ansatz is designed to leverage the IBM quantum computing hardware basis for optimal efficiency and fidelity (but can be designed for any other hardware basis). On IBM quantum devices, the native gate set consists of the ECR two-qubit gate and the $R_z(\theta)$, X, and SX one-qubit gates. Since R_z gates are implemented virtually in software through a frame-of-reference change, they introduce no additional error, making them ideal for parameterized rotations in our ansatz.

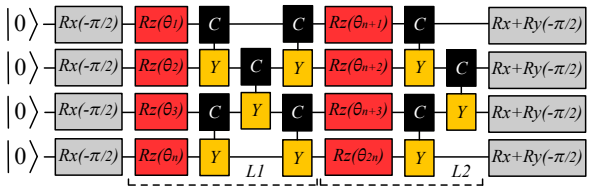

Fig. 2: *EnQode*'s ansatz design to reduce the circuit depth and the number of physical gates. CY gates are indicated with C for the control qubit and Y for the target qubit.

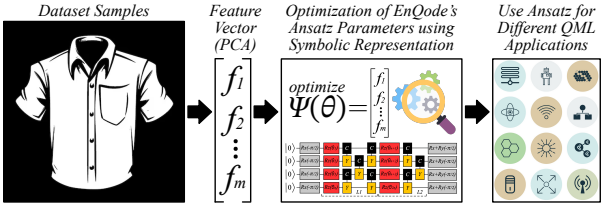

Fig. 3: *EnQode* employs symbolic representation for fast optimization of its amplitude embedding circuit ansatz.

Because amplitude-embedded states are real-valued with no complex phase, we first apply $R_x(\frac{-\pi}{2})$ gates to each qubit to rotate them from the $|0\rangle$ state in the z-x plane to the $|+i\rangle$ state in the x-y plane on the Bloch sphere (Fig. 2). This setup aligns the qubits in the plane and is suitable for purely R_z-based parameterization. Following this, we implement the ansatz shown in Fig. 2, which consists of parameterized R_z gates to maintain fidelity, as R_z gates introduce no noise.

For entanglement, we employ controlled-Y (CY) gates. Although controlled-X, Y, and Z gates all require a similar number of ECR and one-qubit gates, thus having similar noise cost, CY gates are preferred here due to their specific interaction properties that preserve the x-y plane alignment in the Bloch sphere post-rotation.

The CY gates are arranged in a compact layout that alternates from layer to layer, as depicted in Fig. 2, enabling interaction among all qubits within each layer of the ansatz while minimizing gate count. Through extensive experimentation, we identified this alternating configuration as the optimal sparse arrangement on IBM's heavy-hexagonal connectivity layout (linear section). It requires no additional SWAP gates, maximizing fidelity and minimizing error per layer.

We apply multiple layers of this structured ansatz, with each layer refining the AE while ensuring consistent qubit interactions. Finally, $R_x(-\frac{\pi}{2})$ and $R_y(-\frac{\pi}{2})$ gates are applied to return the qubits to the z-x plane, completing the embedding process with minimal depth and maximal fidelity. This hardware-efficient design directly reduces error-prone physical gates and provides a high-fidelity, low-noise AE circuit.

B. Symbolic Representation for Efficient Optimization

A key innovation in *EnQode* is its use of symbolic representation to achieve fast and accurate amplitude embedding. Unlike traditional approaches that rely on numerical approximations for each optimization step, *EnQode* represents the parameters of all R_z gates symbolically, allowing the amplitude embedded state vector $|\psi(\theta)\rangle$ to be fully expressed as an analytical function of these parameters. Given n qubits, let $\theta = (\theta_1, \theta_2, \ldots, \theta_l)$ denote the set of R_z gate parameters in the ansatz. The intermediate state vector $|\psi(\theta)\rangle$ that is optimized in the ansatz can be written as:

$$|\psi(\theta)\rangle = \frac{1}{\sqrt{2^n}} \begin{bmatrix} k_1 e^{i\frac{\sum_{j=1}^{l} p_{1j}\cdot\theta_j}{2}} \\ k_2 e^{i\frac{\sum_{j=1}^{l} p_{2j}\cdot\theta_j}{2}} \\ \vdots \\ k_{2^n} e^{i\frac{\sum_{j=1}^{l} p_{2^n j}\cdot\theta_j}{2}} \end{bmatrix}, \tag{6}$$

where $p_{rj} \in \{-1, 0, 1\}$ and $k_r \in \{-1, -i, i, 1\}$, for all $1 \leq r \leq 2^n, 1 \leq j \leq l$.

We make this symbolic representation to leverage the following insight: by converting the amplitudes into relative phases, we are able to have a compact expression with explicit, simple partial derivatives (as we simply take the derivative of an exponential function composed with a linear function), which we can leverage in gradient-based optimization. After optimizing the fidelity for our statevector in this compact representation, we perform a change of basis to convert the relative phases back to real-valued amplitudes used for amplitude embedding.

This approach allows for direct calculation of the impact of each R_z parameter on the state vector, providing an efficient and precise mapping from the circuit's symbolic parameters to the target amplitude values. This symbolic linkage between parameters and output state is unique in that it eliminates the need for repeated numerical recalculations, which are computationally expensive and prone to rounding errors in conventional approaches.

The optimization task in *EnQode* is to match each element $\psi_i(\theta)$ of the parameterized state vector to the target real amplitude value x_i, representing the cluster mean. Specifically, *EnQode* seeks the optimal parameters θ^* such that $\psi_i(\theta^*) \approx x_i$ for each i, where x_i are the target values from the data vector. The symbolic representation with simple derivatives enables *EnQode* to leverage an efficient gradient-based optimization algorithm. For this work, we use the Limited-memory BFGS algorithm because it empirically performed the best compared to other algorithms we tested [38] [23]. As a quasi-Newton method, it relies on accurate Jacobian computations, which are computed efficiently through our symbolic representation. We compute gradients and estimate the inverse Hessian using finite differences, which proved sufficient for effective optimization. However, this work can easily be extended by computing the Jacobian symbolically before running the optimization.

As visually represented in Fig. 3, this approach dramatically accelerates convergence, allowing *EnQode* to complete training faster than traditional iterative methods that require extensive numerical calculations and lack direct control over each parameter's effect on the final state. This unique design forms the foundation of *EnQode*'s ability to achieve rapid, high-fidelity amplitude embeddings.

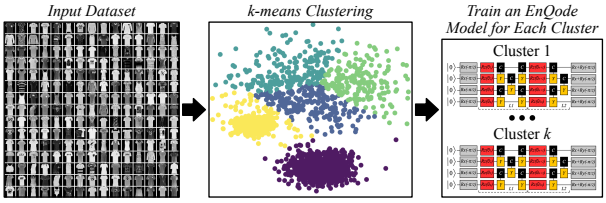

Fig. 4: *EnQode* divides a dataset into multiple clusters and trains a symbolic representation model for each cluster.

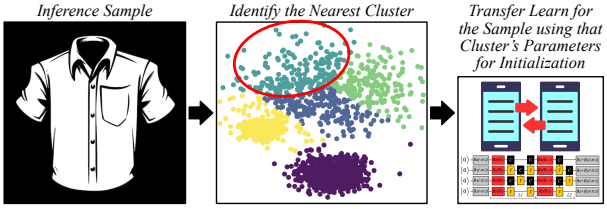

Fig. 5: An inference sample gets matched to one of the clusters, and its amplitude embedding circuit is quickly trained using the cluster's trained model to initialize the parameters.

C. EnQode's Use of Clustering for Offline Training

To enable efficient and noise-resilient AE, *EnQode* uses k-means clustering [22] to partition the dataset into k clusters. Each sample $\vec{x}$ in the dataset is assigned to one of these clusters based on its similarity to the cluster centroids, producing k clusters of similar data samples. For each cluster, we calculate the mean sample, $\vec{c}_i$, representing the central characteristics of that cluster. This mean sample serves is used to train the embedding circuit for each cluster.

Once the clusters are defined, *EnQode* performs "offline" training by applying the hardware-optimized ansatz discussed previously to the mean sample of each cluster. Using the symbolic representation optimization technique, the ansatz parameters for each cluster's mean sample $\vec{c}_i$ are optimized to maximize fidelity with minimal circuit depth. As this training approach leverages symbolic representations, it significantly reduces the computational overhead, completing the training for all clusters for a given class in a dataset in under 2 seconds. This rapid optimization allows each cluster's ansatz to be fine-tuned to capture the structure of its mean sample, effectively encoding the main features of all samples within the cluster.

As shown in Fig. 4, this clustering-based approach allows *EnQode* to achieve high-fidelity amplitude embedding efficiently across diverse datasets. By training on cluster means, *EnQode* reduces redundant computations and ensures that the embedding circuit depth and noise profile remain consistent, thereby providing a scalable solution for QML applications.

The trained cluster models are then stored and used to support "online" training and inference, as we describe next.

D. Transfer Learning for Fast Amplitude Embedding

With thousands or millions of samples in a dataset, it is critical that these states are able to be amplitude embedded into quantum circuits as quickly as possible (in "real-time") for fast training and inference. *EnQode* uses transfer learning from pre-trained cluster models to enable fast amplitude embedding for incoming samples. When a new sample $\vec{x}_{\text{new}}$ arrives, it is assigned to the nearest cluster based on its Euclidean distance to the cluster centroids. This quick assignment identifies the most relevant pre-trained model for the sample, allowing *EnQode* to initialize $\vec{x}_{\text{new}}$'s embedding circuit with the optimized parameters of the corresponding cluster mean. The parameters are then fine-tuned from that initialization using the same algorithm described in Section III-B.

As shown in Fig. 5, this initialization provides a close approximation for the embedding of $\vec{x}_{\text{new}}$, minimizing the need for further optimization and significantly accelerating the embedding process. By beginning with cluster-trained parameters, *EnQode* achieves high-fidelity AE with consistent circuit depth and noise profile across samples, all without retraining from scratch. This transfer learning approach ensures that *EnQode* can embed both training and inference samples rapidly, making it well-suited for large datasets and real-time quantum machine learning workflows.

E. Putting All of EnQode's Design Elements Together

EnQode integrates clustering, symbolic optimization, and transfer learning to create an efficient AE framework. By clustering data and training a hardware-optimized ansatz for each cluster mean using symbolic representation, *EnQode* achieves a rapid, low-overhead setup with optimized parameters. For each new sample, transfer learning initializes its embedding circuit using the pre-trained parameters of the nearest cluster, enabling consistent, fast embedding without extensive re-optimization.

The ansatz design maximizes hardware efficiency through virtual R_z gates and a sparse CY layout, minimizing circuit depth and noise. **Together, these elements provide *EnQode* with a scalable, high-fidelity solution suitable for real-time quantum machine learning on NISQ devices, maintaining uniform performance across samples.**

IV. Methodology

A. Experimental Setup and Framework

We run our compliation experiments and classical processing tasks on our local computing cluster. The cluster consists of nodes with the AMD EPYC 7702P 64-core processor with x86_64 architecture and a 2.0 GHz clock. We spawn virtual machines (VMs) on these nodes consisting of 8 cores, 32 GB memory, and 32 GB storage for each of our experiments, providing more than sufficient resources for each experiment. The VMs are resource-bounded and not overprovisioned, ensuring that each experiment has exclusive access to the hardware resources assigned to it without any interference, which helps us provide accurate and consistent timing analysis.

For implementing and evaluating *EnQode*, we wrote Python modules. We used `qiskit` [2] for representations of symbolic and parameterized circuits, as well as for density matrix fidelity calculations. We used `qiskit_aer` to perform ideal and noisy density matrix simulations given the characteristics of the `ibm_brisbane` quantum computer [5]. We used

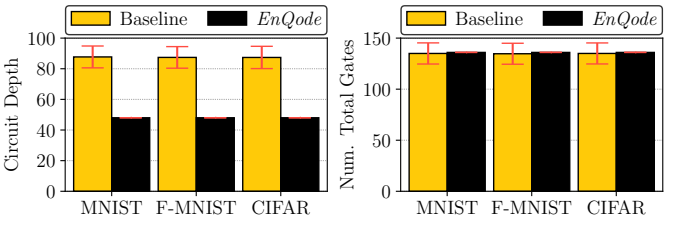

Fig. 6: *EnQode* achieves lower circuit depth and an almost identical total number of gates than the Baseline, with no variability due to fixed circuit – the Baseline displays high variability for both metrics.

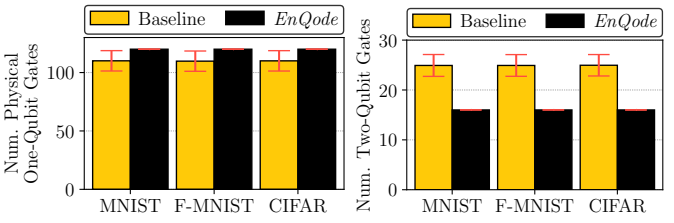

Fig. 7: *EnQode* also achieves similar one-qubit and lower two-qubit physical gates than the Baseline and has no variability due to a fixed circuit design – in contrast, the Baseline displays high variability for both the metrics.

`scipy` [38] to implement the L-BFGS optimization algorithm. For all experiments, we used 4 qubit circuits, with a 4 layer ansatz structure as depicted in Fig. 2. The number of clusters is chosen such that the *state fidelity* (defined below) between any datapoint and its nearest cluster is at least 0.95.

For implementing and evaluating the Baseline, we use the `qiskit` state preparation algorithm [2] [14]. For transpilation onto IBM hardware, we use the transpilation optimization level of 0 to eliminate the influence of confounding factors such as synthesis techniques for our analysis. All of our metrics are evaluated using circuits transpiled to `ibm_brisbane`.

B. Evaluation Datasets

To evaluate *EnQode*, we use three standard image datasets: MNIST [10], Fashion-MNIST (F-MNIST) [42], and CIFAR-10 (CIFAR) [17]. We randomly sampled 5 classes for each dataset, and for each class, we randomly sampled 500 images from that class. For each dataset, we apply Principal Component Analysis (PCA) [24] to reduce dimensionality, focusing on retaining the most significant features. The resulting features are then normalized to ensure compatibility with AE. This preprocessing step allows for efficient, high-fidelity embedding of each dataset in *EnQode*'s framework.

C. Assessment Metrics

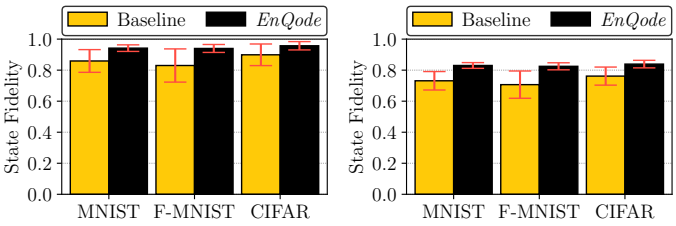
We compare *EnQode*'s performance to the conventional exact amplitude embedding technique [30] [14] – referred to as Baseline. For all circuit-based metrics, we exclude R_z gate counts, as these can be implemented virtually. First, we assess the *circuit depth* and the *total number of gates* used for amplitude embedding with Baseline and *EnQode* – we examine the mean and standard deviation behaviors. These are the key metrics that affect circuit fidelity on NISQ devices. We also look at the *number of physical one-qubit and two-qubit gates*. Second, we evaluate the *compilation times* to generate the amplitude embedded circuits. We also investigate the *state fidelity* of how closely the amplitude embedded state matches the desired state. We use a common metric for mixed states defined as $F(\rho,\sigma) = \left(tr\sqrt{\sqrt{\rho}\sigma\sqrt{\rho}}\right)^2$ [15], where ρ and σ are the two quantum states (one desired and one measured). We perform these assessments in ideal and noisy scenarios.

V. Evaluation and Analysis

A. EnQode Reduces the Circuit Depth and Two-Qubit Gate Count (and Their Variability) Over the Baseline Approach

As shown in Fig. 6, *EnQode* achieves a significant reduction in circuit depth (45%) on average compared to the Baseline, with the added advantage of complete consistency across data samples. The Baseline approach suffers from variability in circuit length due to the data-dependent nature of traditional AE, resulting in fluctuations in both circuit depth and the number of gates required. In contrast, *EnQode* standardizes the ansatz length and gate composition, ensuring a fixed circuit structure for each dataset.

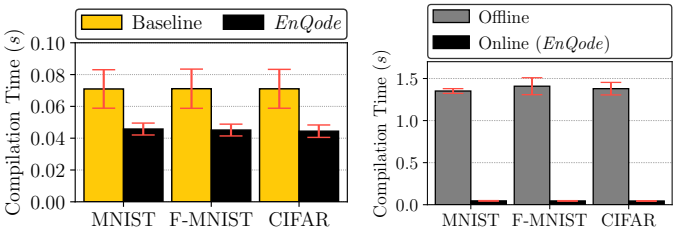
Similarly, Fig. 7 illustrates that *EnQode* slightly increases one-qubit but considerably reduces two-qubit gate counts compared to the Baseline while completely eliminating gate count variability. By using a fixed arrangement of one-qubit R_z gates and a sparse CY entangling structure, *EnQode* ensures that each sample faces a uniform noise profile, essential for stable performance in QML applications. The Baseline approach shows high variability in both gate types, with some samples requiring up to 10% more gates than others.



The reduction in circuit depth, two-qubit gate count, and variability provided by *EnQode* directly enhances reliability in noisy quantum computing environments. With a fixed circuit structure, *EnQode* minimizes exposure to noise, ensuring that each sample is treated uniformly. This consistency is particularly beneficial on NISQ devices, where circuit variability directly impacts fidelity. The stability and reduced complexity of *EnQode*'s circuits are expected to yield improved performance under noise, a hypothesis we test next.

B. EnQode's Generated Circuits Achieve High and Consistent State Fidelity in the face of Hardware Noise Effects

To assess *EnQode*'s effectiveness in representing a given data point state, we evaluate state fidelity across ideal simulations and noisy hardware simulation executions.



In ideal simulations (Fig. 8(a)), *EnQode* achieves a higher state fidelity of 9.6% than Baseline circuits when transpiled to real IBM hardware. This improvement highlights the high simulated fidelity that *EnQode* offers. Although Baseline circuits have near-perfect fidelity as they logically synthesize the state, when transpiling the circuit to the hardware basis set and connectivity, the ideal state fidelity was decreased.

In addition, under noisy simulation conditions (Fig. 8(b)), *EnQode* significantly outperforms the Baseline (by 13%). The Baseline circuits, which rely on deep circuits with variable

(a) Ideal Simulation (b) Noisy Simulation

Fig. 8: (a) *EnQode* achieves high state fidelity in ideal simulation. (b) In addition, it also achieves a higher fidelity than the Baseline in noisy NISQ simulation settings.

(a) Compilation Times (b) *EnQode*'s Time Overhead

Fig. 9: (a) *EnQode* achieves lower compilation times than the Baseline. (b) *EnQode*'s online compilation time is low. Its offline compilation time (for training the clusters) is also low.

lengths, suffer from high error accumulation in noisy environments, leading to substantial variability in state fidelity across samples. In contrast, *EnQode* maintains higher fidelity and reduced variability due to its consistent, low-depth circuit design. This stability in noisy settings underscores the advantage of *EnQode*'s fixed-length ansatz, which minimizes and standardizes exposure to noise-induced errors.

Overall, *EnQode*'s ability to maintain higher fidelity in noisy hardware environments demonstrates its practicality for quantum machine learning on NISQ devices. By ensuring lower circuit depth and consistent gate structure, *EnQode* provides a reliable amplitude embedding approach that is more robust to noise, a crucial attribute for achieving stable performance in real-world quantum applications.

C. EnQode Achieves Lower Compilation Time Compared To the Baseline and has a Low Offline Compilation Time

To evaluate *EnQode*'s efficiency in generating AE circuits, we compare its compilation times with the Baseline, breaking down the online and offline components. Fig. 9(a) shows that *EnQode* achieves an average speedup of 36% per sample compared to the Baseline due to *EnQode*'s symbolic representation and transfer learning from pre-trained cluster means. Since *EnQode*'s online compilation starts optimization using parameters from the closest cluster mean, it remains highly efficient for embedding new samples in real-time.

In Fig. 9(b), we provide a comparison of *EnQode*'s offline and online compilation times. The offline compilation step involves training the ansatz for each cluster mean, which is performed only once per dataset and class and thus introduces a minimal overhead of less than 2 seconds.

As a result, *EnQode* achieves rapid online compilation without sacrificing fidelity or adding significant preprocessing costs. The combination of low offline and online compilation times underscores *EnQode*'s practicality for real-time QML applications, where speed and efficiency are crucial.

VI. Related Work

The challenge of encoding classical data onto quantum circuits has spurred numerous methods for state preparation and feature embedding, but none directly address the unique requirements of AE with noise resilience and consistency across samples. Existing approaches primarily focus on general state preparation techniques [13], [43], [26], [4], [35], [41], which can lead to variable-depth circuits that suffer from inconsistencies in noise exposure and fidelity.

Quantum transfer learning [27] offers valuable insights into high-dimensional data adaptation but does not cater to AE's demand for low-noise, standardized circuit structures. Similarly, applications in drug discovery [19] and image classification [1] integrate quantum embedding methods. Yet, they rely on embedding mechanisms that often lack circuit depth control, making them unsuitable for AE, where consistent noise handling is critical for uniform sample treatment.

More recent efforts have tackled feature-specific embeddings [36] and variational techniques [6], optimizing for fidelity and efficiency in QML. However, these methods do not account for AE-specific needs like fixed circuit depth and low-noise environments for high-fidelity encoding. *EnQode* introduces the first AE-specific approach that achieves consistent, high-fidelity embeddings by clustering data samples and designing a low-depth, machine-optimized ansatz. By standardizing circuit depth and minimizing gate variability across samples, *EnQode* ensures uniform noise resilience, setting a new standard for practical AE in scalable QML.

VII. Conclusion

In this work, we introduced *EnQode*, an efficient AE framework designed to address the limitations of the traditional AE method on quantum devices. By employing a cluster-based approach with low-depth, symbolic representation ansatz, *EnQode* achieves consistent circuit depth and gate composition across samples, effectively mitigating noise variability and high error rates. Our solution delivers over 94% fidelity in the fast embedding of classical data, providing a robust foundation for QML. As an open-source tool, *EnQode* offers a practical pathway for more reliable data encoding, making it well-suited for diverse applications on quantum platforms.

***Abstract*—Processing-in-Memory architecture presents a promising solution to alleviate the data movement bottleneck that arises from transferring data between memory and compute units in traditional processor-centric systems, particularly for DNN applications. However, this architecture introduces two inherent overheads: PIM code offloading and data transferring between CPU and memory. To address these issues, we propose two register-based addressing modes, indexed and base-offset addressing, for DMA descriptor-based in-DRAM PIM ISAs. Our full-system performance evaluation demonstrates that the approach significantly reduces the overheads, resulting in up to 1.94x speedup compared to the baseline PIM, additionally only with 4.65% area and 8.61% power consumption.**

***Index Terms*—PIM ISA, Register-based Addressing Mode, Processing-in-DRAM, Look-up Table, Code Offloading.**

I. Introduction

Processing-in-Memory (PIM) is one of the attractive solutions to alleviate the data movement bottleneck caused by data transfer between memory and compute units in traditional computing systems. This bottleneck has become more severe over time due to the widening performance gap between processors and memory and the rapid growth in the size of transformer model parameters, which increase tenfold each year [1]. To address this challenge, memory manufacturers like SK Hynix and Samsung have developed PIM prototypes [2]–[4], and some companies like UPMEM [5] have brought commercial products to market. Although the rapid increase in model parameters provides a significant opportunity for PIM acceleration, current PIM architectures have two intrinsic performance overheads from the PIM code offloading and minimal PIM execution capability.

Fig. 1 shows the execution time breakdown using our PIM-testbed platform, which is used in Section IV. In this setup, we computed Generalized Matrix-Vector multiplication (GeMV), Generalized Matrix-Matrix multiplication (GeMM), and element-wise operations on the PIM, represented as PIM execution in the figure, and the remaining operations on the CPU. We further categorized the remaining, i.e., the non-PIM-capable operations, into two categories: 1) CPU execution (Unary: unary function execution) and 2) CPU execution (the Others). By offloading the PIM-capable operations comprising BLAS levels 1, 2, and 3 to PIM, we fully exploited DRAM's internal bandwidth and the PIM's computation parallelism, achieving an average speedup of 2.23x across four different transformer models over the CPU-only execution. However, the PIM code offloading overhead incurs an average of 9.65%, and the data transfer does an average of 35.97% of the total execution time. These two overheads represent a significant portion, making up 45.61% of the total execution time, thus preventing the PIM's performance scalability.

The following two structural characteristics in DNN's Computational Graph (CG) negatively impact PIM's performance.

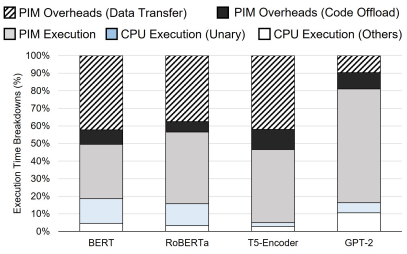

Fig. 1. The execution time breakdown of the transformer-based models in the PIM+CPU platform [6] with a sequence length of 16.

First, activation functions such as GeLU and SwishGLU [7], along with other unary operators like sqrt, reciprocal, and power, which PIM cannot execute, are often interspersed with operators that PIM can perform, like GeMV(M) and element-wise Add/Sub/Mul. Although the execution times of these functions are relatively short, their positioning between PIM-executable operators leads to significant data transfer overhead between the CPU and PIM. Second, the GeMM operations use nearly identical operation sizes ({p, q, r}) in specific model execution, and PIM codes represent the static physical addresses as operands. However, due to the dynamic allocation of input matrices (tensors), it is necessary to offload PIM codes each time, even though we repeatedly execute the same function with identical input sizes using PIM [2], [4], incurring the code offloading overhead.

In this paper, we introduce two register-based addressing modes, indexed and base-offset addressing for the DMA descriptor-based in-DRAM PIM ISAs called PISA [6], to maximize the operator capability and minimize the PIM code offloading overhead, which is critical to PIM performance. The original PISAs utilize statically generated absolute addressing, embedding the entire physical address within PIM instructions to denote operands [6]. In contrast, our register-based modes use PIM register values to reconstruct PISAs at runtime. While this technique is widely used in CPU execution, it is less common in PIM execution. Each addressing mode offers substantial performance improvements, as detailed below.

An indexed addressing mode: The current DNN models include various unary operators, some highly computationally intensive. We can execute the unary operators using Look Up Tables (LUTs), which is very well-suited to the execution characteristics of DRAM-based PIM. DRAM's large capacity allows us to use an unlimited number of large-sized LUTs to provide high accuracy and perform many LUT-based executions simultaneously. More importantly, while executing memory-intensive applications like DNN models, it is essential to reduce memory requests as much as possible. Therefore,

instead of exhaustive accessing the entire LUT ($2^{16} \times 2$ bytes for bfloat16 [8]), we build an address to access the LUT by concatenating the unary function's LUT start address and the computed PIM results (R_{vACC}), thus providing the tolerant performance during the multi-workload execution while accelerating the unary execution using PIM over CPU. Also, the PIM support of the unary operators, i.e., increasing the PIM's operator capability, provides the PIM operator fusion opportunity to a compiler while minimizing the data transfer between the CPU and PIM.

A base-offset addressing mode: PIM repeatedly executes the same operators with the same input sizes in the recent models [9]–[12]. Statically generated PIM codes use absolute addressing for operands, resulting in overhead from reloading the PIM code each time when the function is executed with different operands. To address this, we introduce argument registers, R_{args}s, in the PIM Interface Unit (PIU) to store the start address of operands. Functions are programmed using these argument registers and operand offsets. Like indexed addressing, the PIU combines the argument registers and the offsets at runtime to generate operand addresses. This approach eliminates the need to reload the PIM codes repeatedly, significantly reducing the code offloading overhead.

We implemented a system-level evaluation platform based on an ARM SoC using the PIM-emulated FPGA to validate our proposal and conducted a complete system stack evaluation using four transformer-based models, BERT [9], RoBERTa [10], T5-Encoder [11], and GPT-2 [12]. As a baseline, i.e., without supporting our proposal, PIM [6] achieved a speedup of 1.76x to 3.59x compared to the CPU. Our base-offset addressing mode almost eliminated the code offloading overhead, and indexed addressing mode for supporting LUT-based unary operators in PIM significantly reduced data transfer overhead and accelerated their execution simultaneously. Also, the LUT-based PIM execution allowed us to fuse PIM operators aggressively, thus eliminating memory spill between them. As a result, we could achieve 1.26x to 1.94x speedups only with 4.65% of the total area and 8.61% of the overall power consumption overhead compared to the baseline PIM design.

The remainder of this paper consists of the following: In Section II, we explain our baseline PIM architecture and the characteristics of recent transformer-based models for motivating our work. In Section III, we describe the proposed register-based addressing PIM architecture, and in Section IV, we evaluate our PIM design's performance. Finally, Section V concludes the paper.

II. Background

A. Baseline PIM Architecture: Silent-PIM and PISA-DMA

Many state-of-the-art in-DRAM PIMs [2], [5] target accelerator-based rather than memory-centric designs, thus not servicing the memory requests from other processes during the PIM computation and possibly necessitating modifications to the overall architecture layer. To overcome the disadvantages, Silent-PIM [13] has been proposed, which aimed for a memory-centric design, i.e., using a per-bank approach. It preserves the standard JEDEC DRAM interface, thus guaranteeing the simultaneous execution of both PIM and non-PIM processes and requiring little system modification, which is why we selected it as the baseline platform for our work.

PIM workloads sequentially read large amounts of data from memory to perform the same repetitive computations, such as MAC. This memory access characteristic is the same as

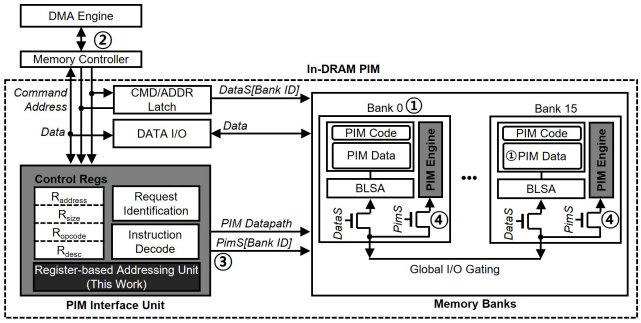

Fig. 2. Overview of the baseline architecture, including the PIM interface unit and the PIM engine. The gray blocks depict the extra components integrated into DRAM for PIM operations, with some darker ones, including the white text, representing the outcomes of this study.

DMA, so Silent-PIM utilizes DMA as an operand offloading engine by representing the operand address and its size and utilizing the unused fields to represent PIM opcodes in the DMA descriptor. Therefore, the PIM ISA was developed using the DMA descriptor, called PISA-DMA, and the PIM code was presented as the sequence of the DMA descriptors. Intuitively, completing the DMA transaction is the same as committing an instruction.

Silent-PIM's execution sequences using PISA-DMA are shown in Fig. 2 as follows: ① CPU stores the PIM code consisting of PISA-DMA descriptors in PIM memory and its start address and size in the descriptor register (R_{desc}) of PIU. Each PISA-DMA descriptor has the operand information such as the source/destination operand start addresses and the operand size, the PIM opcode, and other unused fields. ② CPU activates the DMA engine to start the DMA transaction. ③ The DMA engine fetches the descriptor from the PIM memory. The PIU stores the fetched descriptor in a descriptor latch forwarded to the DMA engine. At the same time, PIU determines whether it is the PISA-DMA descriptor by matching with the information in R_{desc}. If it is, the PIU stores the operand information in the operand registers ($R_{address}$, R_{size}) in the request identification unit of the PIU to distinguish the PIM memory requests from the non-PIM memory ones and the opcode in an opcode register (R_{opcode}) to configure the PIM datapath. ④ During the DMA engine transfers memory requests, the PIU recognizes the PIM operand by address matching using the information in the operand registers and turns on the pimS switch to provide the operand to the PIM engine for computation. ⑤ The pre-configured datapath computes with incoming operands and stores the results in the accumulator registers, R_{vACC}.

B. Characteristics of Recent Transformer Models

As the datasets used to train transformer-based models evolve, their models are increasing, and operators are becoming more complex due to the evolution of datasets to include images, text, code, and human language [14]–[16].

The PIM architecture enhances the efficiency of DNN models by leveraging MACs for GeMV(M) and element-wise operations. However, its design constraints limit its ability to support more intricate functions such as trigonometric, hyperbolic, and exponentiation. Consequently, these complex operations necessitate offloading to a CPU, resulting in data transfers to and from PIM memory and even preventing the compiler from fusing consecutive PIM operators. Such data

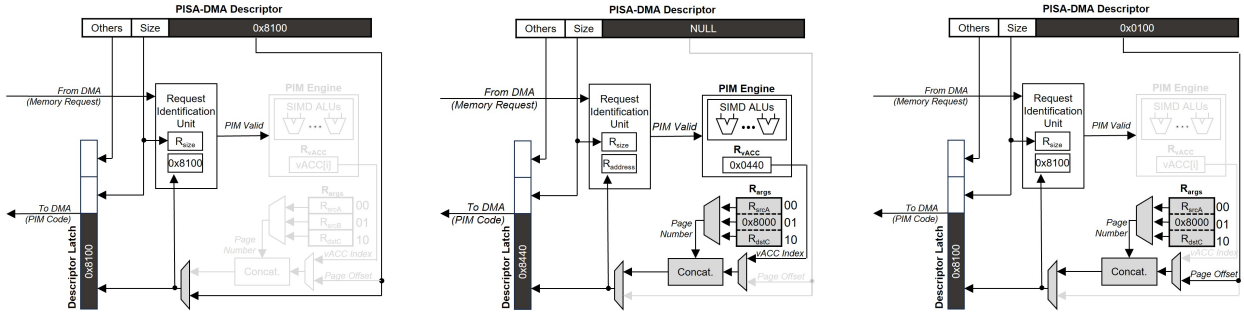

Fig. 3. The overall information flow of the proposed register-based addressing PIM, modifying the source field of the PISA-DMA descriptor at runtime (colored in black) and adding the circuit (colored in gray). (a) Absolute addressing. (b) Indexed addressing. (c) Base-offset addressing.

TABLE I
THE PIM OPERATOR SEQUENCE LENGTH AND THE RATIOS OF PIM-CAPABLE NODES.

Model		BERT		RoBERTa		T5-Encoder		GPT-2	
		Set (A)	Set (B)	Set (A)	Set (B)	Set (A)	Set (B)	Set (A)	Set (B)

transfers are particularly detrimental to PIM's performance since we allocate the PIM memory uncacheable.

To gain deeper insights into and quantify the limitations of the PIM architecture, we introduce the concept of PIM Operator Sequence Length (OSL), reflecting the number of consecutive PIM operators. The longer the PIM OSL, the less the data movement between CPU and PIM, and the higher the opportunity a compiler fuses. We investigated the PIM OSL using four representative transformer-based models and classified their ONNX operators into two sets. Set(A) involves the operators intrinsically performed by PIM, such as BLAS operations (GeMV, GeMM, Add, Sub, Mul), and Set(B) does Set(A) *plus unary operations*, such as Reciprocal, Sqrt, Log, Abs, Neg, and so on. Table I shows that by supporting the unary operators in PIM, we can significantly increase the ratio of PIM-capable nodes from a minimum of 10.2% (17.4% - 7.2% in GPT-2) to a maximum of 29.5% (70.3% - 40.8% in RoBERTa) and the PIM OSL, which implies substantial performance improvement by eliminating the data transfer, accelerating the unary execution, and applying the operator fusion.

Applying LUT operations in DRAM-based PIM architectures faces a few drawbacks. AIM [2] utilizes one specific DRAM row as LUT; therefore, the DRAM row size constrains the LUT size, and the constraint limits the accuracy of LUT operations. To compensate for this accuracy drop, it adopts a Piecewise Linear Approximation (PLA) technique. Also, since it uses all-bank execution, it stores identical LUT contents (pre-computed results) across all banks. HBM-PIM [4] does not support any specific LUT operation, and instead, it uses the RISC-type core in DRAM to compute the unary operations. Therefore, the computation takes a considerable time.

Given that many PIM workloads, especially GeMV in transformer models, repeatedly execute operations with identical operand sizes, it is possible to eliminate the need for code offloading by simply changing the starting address of the tensor rather than re-generating and re-loading the entire PIM code. For example, in the case of GPT-2 [12], only 4 different sizes of GeMV operations ({p,768,768}, {p,768,2304}, {p,768,3072}, and {p,3072,768}) are used, and each is called 12 times. In more extreme cases, for RoBERTa [10] and T5-encoder [11], the GeMV operation with {p, 768, 768} requires offloading the PIM code 48 times. Thus, there is an excellent opportunity to reduce the code offloading overhead by applying a register-based addressing mode, such as using an argument register to use the base address of tensors.

III. DESIGN OF REGISTER-BASED ADDRESSING MODES

A. Operational Concept

Fig. 3 illustrates the information flow of the register-based addressing PIM system.

Our proposal reconstructs the DMA's source or destination operand address, called an effective address (EA), by introducing three argument registers, R_{args}, and by using the computation results in R_{vACC} in the PIM datapath. In addition to the absolute addressing in the baseline PIM, we proposed two more addressing modes; thus, our register-based addressing unit supports three addressing modes: ① Absolute addressing: EA ← $R_{address}$ (unchanged) (Fig. 3(a)), ② Indexed addressing: EA ← R_{args}[i] | R_{vACC} (Fig. 3(b)), and ③ Base-offset addressing, EA ← R_{args}[i] | [operand offset] (Fig. 3(c)).

Fig. 3(a) depicts an example of the operation in the absolute addressing mode, as in the baseline PIM [13]. In this mode, we load the PISA-DMA descriptor (e.g., 0x8100) into the descriptor latch without any change and store the operand's start address and size into the $R_{address}$ and R_{size} registers. Once the DMA engine fetches the operands from 0x8100 to 0x8100+size, the PIU recognizes the PIM memory requests and sends a valid signal to the PIM engine for computation.

In indexed addressing mode (Fig. 3(b)), we reconstruct the PIM source operand address by concatenating one of the argument register values (R_{args}[i]) to indicate the start address of a table and R_{vACC}. It is suitable for LUT operations. For example, to compute $sin(x)$, we store the starting address of the LUT for a sine function (0x8000) in R_{args}[01] and the PIM computation result x (0x0440) in R_{vACC}.

The base-offset addressing mode (Fig. 3(c)) is the reverse of the index addressing mode. The source operand address is determined by concatenating the argument register's value and a partial value of the operand address in the descriptor, i.e., the value of R_{args}[01] (0x8000) with the value (0x0100) in the

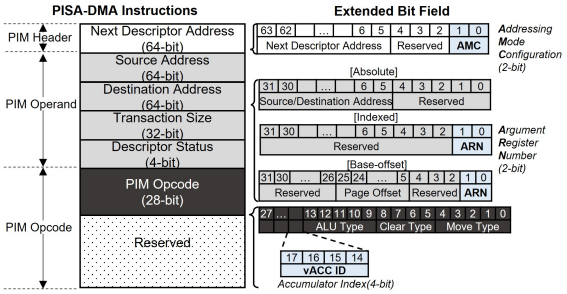

Fig. 4. PISA-DMA extension for supporting register-based addressing mode. The blue-colored component represents the modified fields in this study.

descriptor. The same function with the same operand size but a different operand can perform the computation without newly offloading PIM code into memory but only by changing the argument register values, like the CPU's linkage convention, and using the partial value as the operand offset in code.

B. PISA-DMA and Hardware Extension

1) Addressing Modes: We categorized the PISA-DMA descriptor according to its role into a header, an operand, and an opcode (Fig. 4). The 64-bit header stores the next descriptor's address; in the header, we use 2 bits out of the unused 5 Least Significant Bits (LSBs) to store Addressing Mode Configuration (AMC) information. The AMC value of 2'b00 indicates absolute addressing, 2'b01 indicates indexed addressing, and 2'b10 indicates base-offset addressing. The register-based addressing unit decodes the AMC bits to determine how to construct an effective address.

2) Argument Registers: For reconstructing an operand's effective address at runtime, i.e., to support the indexed and base-offset addressing modes, we introduce three 11-bit argument registers, R_{args}s, since 1) our PIM computation library uses at most three operands (two sources of srcA and srcB and one destination of dstC), and 2) we allocate PIM operands as 2M-byte huge pages using the PIM MemPool [6], resulting in an 11-bit page number and a 21-bit page offset. We distinguish R_{args}s by a 2-bit Argument Register Number (ARN), and 2'b00, 2'b01, and 2'b10 correspond to srcA, srcB, and dstC, respectively, in the 2-bit source/destination address field (bit 0 to 1) in the descriptor.

Given our 4G-byte memory system, we use only 32 bits out of the 64-bit source/destination address field in the descriptor, ignoring the LSB 5 bits due to the 32-byte DRAM access granularity. The absolute addressing mode uses the 27-bit source/destination address (bit 5 to 31) without any change to represent the read and write operand's start address, i.e., its effective address; thus, the mode does not use any R_{args}s.

3) Indexed Addressing Mode: We implemented an indexed addressing mode for computing unary operators in PIM, specifically in the form of $y = f(x)$, where x is the computation result from an immediate predecessor node, and $f(\cdot)$ represents a lookup table of pre-computed values. We store a start address of f in one of R_{args}s using ARN, take x from one of 16 R_{vACC}s within a bank, and concatenate them to make an effective address, i.e., a PISA-DMA descriptor's source address. We extend one more PIM opcode field, a 4-bit R_{vACC} index (bit 14 to 17), to access x, and thus, compute 256 distinct input x values, i.e., take x 256 times (16 elements per bank across 16 banks) instead of accessing an entire size of LUT.

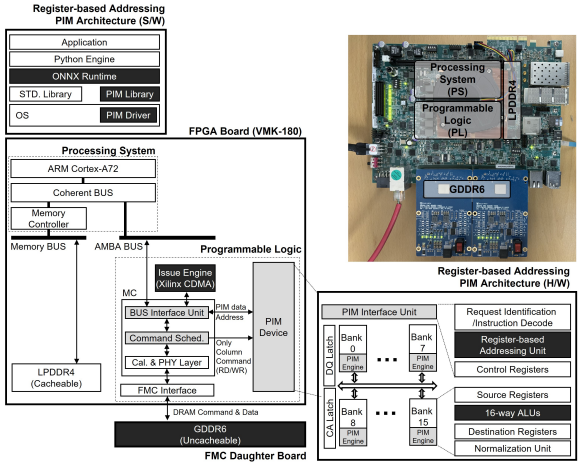

Fig. 5. The register-based addressing PIM architecture evaluation platform.

4) Base-Offset Addressing Mode: By adopting a base-offset addressing mode, we can pre-store descriptors, i.e., PIM codes in memory with a constant huge page offset (bit 5 to 25 source/destination address field in the descriptor) in the at compile time and update a huge page number at runtime using R_{args}s. This runtime address binding allows us to reuse PIM code and eliminate code offloading overhead. General PIM computations use three PIM operands (A, B, C), each associated with different R_{args}s.

IV. Performance Analysis

A. Experimental Methodology

Fig. 5 shows our PIM-based emulation platform and its specification for system-level performance evaluation. We evaluated the area and power overheads using a $65nm$ Samsung CMOS PDK, with a 200MHz cycle time constraint for the PIM device, due to the lack of a publicly available DRAM cell library. For FPGA implementation, we used the Xilinx Vivado [19] to synthesize the PIM device hardware and the PetaLinux to deploy Linux-based full-system software, including the PIM driver. We used four pre-trained transformer models for the experiment: BERT (29M parameters: 4 layers, 512 hidden dim), RoBERTa (125M: 12 layers, 768 hidden dim), T5-Encoder (220M: 12 layers, 768 hidden dim), and GPT-2 (117M: 12 layers, 768 hidden dim).

B. Transformer-based Models

Fig. 6 shows the speedups of the proposed register-based addressing PIMs over a baseline PIM architecture, PISA-DMA [6], and their time breakdowns with sequence lengths of 1 and 16 while running four transformer-based models. Our baseline PIM architecture (Ⓐ) achieves a speedup of 1.76x to 3.59x over a CPU. However, its PIM code offloading overhead results in 14.63% and 9.65%, and data transfer overhead does 16.81% and 35.97% of the total execution time on average at sequence lengths of 1 and 16, as discussed in Section I. As a sequence length grows, the amount of data transfer between CPU and PIM memory increases, thus dominating the overall overhead.

Our proposed base-offset addressing mode (Ⓑ) almost eliminated the code offloading overhead in all the models and sequence lengths, thus achieving the speedups of 1.11x, 1.23x, 1.14x, and 1.21x over the baseline (Ⓐ) with a sequence length

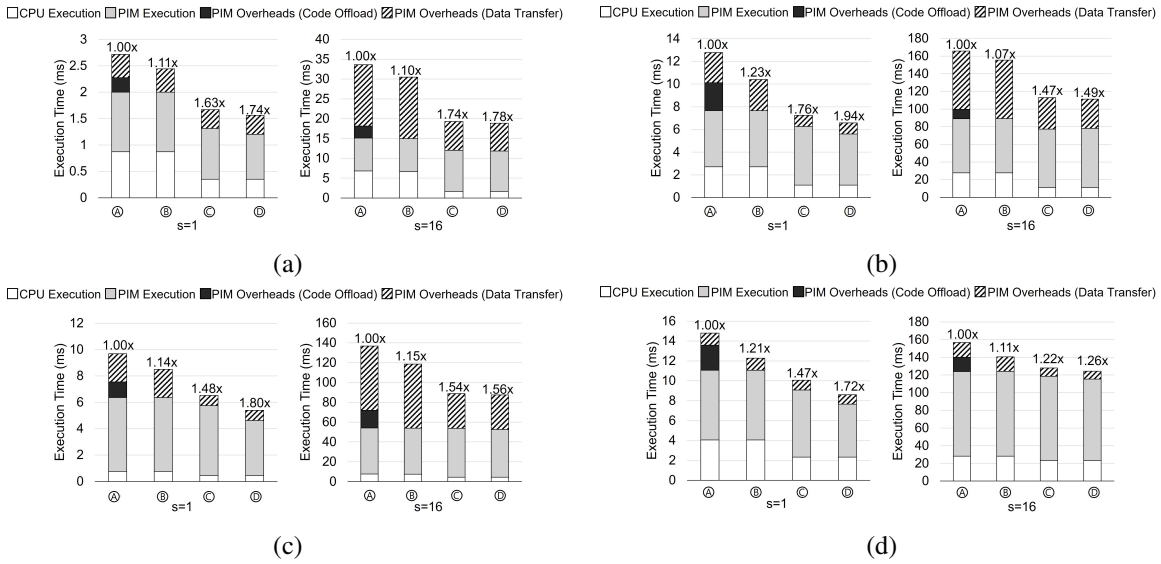

Fig. 6. The speedups of the proposed register-based addressing PIMs over a baseline PIM architecture [6] and their time breakdowns with two sequence lengths (s) of 1 and 16. (a) BERT. (b) RoBERTa. (c) T5-Encoder. (d) GPT-2. Ⓐ: PISA-DMA (baseline) [6], Ⓑ: Baseline+Base-offset addressing, Ⓒ: Baseline+(Base-offset+Indexed) addressing, Ⓓ: Baseline+(Base-offset+Indexed) addressing+Operator fusion).

of 1 in BERT, RoBERTa, T5-Encoder, and GPT-2, respectively, and an average of 1.17x. The larger the size of the PIM-capable operator, the higher the code offloading overhead; thus, the higher the performance gain from the base-offset addressing mode, as shown in RoBERTa and GPT-2, which use larger weight matrices. As the sequence length increases to 16, the data transfer dominates the total overhead; thus, the performance gain from the base-offset addressing decreases slightly, achieving speedups of 1.10x, 1.07x, 1.15x, and 1.11x.

Our indexed addressing mode for supporting LUT-based unary operators in PIM (Ⓒ) to expand PIM's computational capabilities reduced data transfer overhead and accelerated their execution simultaneously. We could apply LUT-based PIM execution to 40, 112, 91, and 148 nodes, which allowed us to obtain more speedups of 0.52x, 0.53x, 0.34x, and 0.26x with a sequence length of 1 and 0.64x, 0.30x, 0.39x, and 0.11x with a sequence length of 16 in BERT, RoBERTa, T5-Encoder, and GPT-2, respectively than Ⓑ. By using the mode, we could reduce the data transfer overhead of Ⓑ by 3.52% to 43.36%.

The higher PIM capability from the indexed addressing mode provides more opportunities to apply operator fusion to reduce spills, appearing as (Ⓓ) in the figure. Compared to Ⓒ, we achieved 0.11x, 0.18x, 0.32x, and 0.25x higher speedups in BERT, RoBERTa, T5-Encoder, and GPT-2, respectively, and 0.22x on average with a sequence length of 1, and slightly less performance gain with a sequence length of 16 due to intrinsic larger data transfer overhead than a sequence length of 1. We applied operator fusion for successive PIM-capable operators, where each operator has only one successor. Compared to the PIM OSL analysis in Table I, the operator fusion's performance impact is relatively limited. We observed that in many cases, the PIM-capable operator has more than one successor, resulting in data flow divergence that requires storing outgoing edge values (i.e., spills) for other successors anyway, thus diminishing the advantage of the operator fusion. The proportion of memory spills due to operator fusion within the total PIM memory requests required to execute the graph decreases as the sequence length increases.

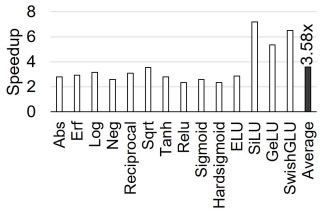

Fig. 7. Speedup of the proposed indexed-addressing based LUT execution in various unary functions over CPU.

C. Unary Functions

Fig. 7 shows the speedup achieved by applying the indexed addressing mode-based LUT technique to execute various unary functions on the PIM, compared to the CPU. Unlike the CPU, which exhibits varying execution times depending on the computational complexity of each unary function, the PIM achieves constant execution times due to using the LUT technique and an average speedup of 3.58x. For SiLU, GeLU, and SwishGLU, we observed up to a 7.19x speedup compared to the activation functions used in state-of-the-art large language models such as Bloom [21] and LLaMA [22]. The smaller the LUT size, the lower the accuracy. However, it's important to note that the LUT size does not impact the execution time, as we access the LUT using indexed addressing mode.

The proposed LUT approach accesses only one element in LUT corresponding to the input addresses, i.e., only 256 times (16 elements in R_{vACC} per bank $times$ 16 banks) per unit computation, resulting in lower memory bandwidth usage than accessing all LUT elements. This effectively minimizes memory interference between PIM applications and non-PIM applications. The higher the memory interference in a multi-workload scenario, the more significant the increase in execution time overheads. We selected the SPEC benchmarks as non-PIM applications to validate this impact alongside a single

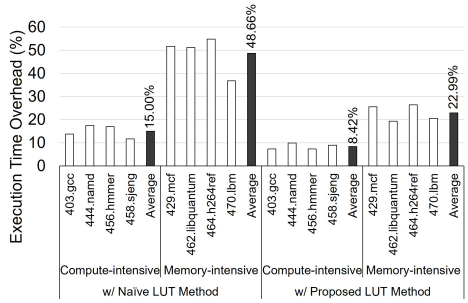

Fig. 8. Execution time overheads of the proposed indexed addressing-based and naïve LUTs when running multi-workload.

unary node's PIM execution. We excluded the benchmarks that caused out-of-memory errors in our experimental setup. We grouped the benchmarks into two categories: memory-bound applications (mcf, libquantum, h264ref, and lbm), which generate a high number of LLC misses, and compute-bound applications (gcc, namd, hmmer, and sjeng).

Fig. 8 shows the execution time overheads of each SPEC benchmark with executing the proposed and naïve LUT operation methods, compared to single workload execution. The naïve method accesses and broadcasts all LUT elements (i.e., $2^{16} \times 2$ bytes) to R_{vACC}s without the indexed addressing mode and matches the value in R_{vACC} with the LUT element address for the unary computation. The naïve LUT approach incurred an average overhead of 15.00% for the compute-intensive and 48.66% for the memory-intensive workloads. However, the proposed LUT technique, which consumes less memory bandwidth, resulted in lower overheads, i.e., 8.42% and 22.99%, respectively. The naïve LUT approach, even with a $2^{11} \times 2$-byte smaller LUT for higher throughput but less accuracy, still incurred much higher overhead of 9.72% and 29.35%, respectively. As a result, the proposed LUT method is more tolerant of the memory-intensive workload environment since it generates a lower memory interference overhead.

D. Area & Power Overheads

Compared to the baseline architecture [13], we only modified the PIU, introducing the argument registers, integrating a concatenation circuit to recompute an effective address, and adding circuits to support indexed addressing for LUT operations. The modified components contributed an overhead of 4.65% of the total area and 8.61% of the overall power consumption, highlighting the simple design.

V. Conclusion

This paper introduced two register-based addressing modes to an in-DRAM PIM-DMA architecture, enabling PIM register values to reconstruct PIM ISAs at runtime. Our indexed addressing maximized the PIM computational capabilities, thus reducing data transfer, accelerating the PIM unary operations, and enabling more operator fusion. Also, the base-offset addressing mode eliminated the code offloading overhead. Our system-level evaluation showed that we could speed up 1.26x to 1.94x compared to the baseline PIM, with a small area and power consumption overhead, while tolerating the memory-intensive workload environment.

In the future, we would support sparse data processing using the PIM-based indexed addressing mode, which is always challenging for all communities beyond the PIM research community.

***Abstract*—In advanced nodes, the optimization of Power, Performance, and Area (PPA) is becoming increasingly complex, requiring significant resources and time for circuit design and optimization using Electronic Design Automation (EDA). As a key approach to overcome these challenges, Machine Learning (ML) techniques have been widely studied in the field of EDA. However, security concerns around Intellectual Property (IP) limit access to real-world circuit data, making it difficult to gather sufficient data for training ML models. This lack of available circuit benchmarks restricts progress in ML research. In this study, we propose *FedEDA*, which, to the best of our knowledge, is the first Federated Learning (FL) aggregation algorithm specifically designed for EDA. *FedEDA* addresses concerns about IP security by exchanging model weights among FL participants instead of sharing raw data. Furthermore, *FedEDA* leverages Rent's Rule and circuit size to capture the hierarchical structure of circuits, mitigating issues related to data imbalance among participants and improving the quality of weight aggregation on EDA data. We demonstrate the applicability of *FedEDA* across various EDA tasks, including routability, parasitic RC, and wirelength prediction. *FedEDA* outperforms existing FL algorithms in EDA tasks, demonstrating superior performance.**

I. Introduction

Recent technological advancements have significantly increased transistor integration density [1]. As chip designs become more complex, the costs and efforts in Integrated Circuits (IC) development also rise, with resource shortages for optimizing servers and license scheduling presenting significant bottlenecks in this process [2]. Machine Learning (ML) has emerged as an effective solution to these problems, significantly reducing the time required for IC design [3]–[5].

In ML, model performance typically improves with larger and more reliable datasets [6]–[8]. However, unlike famous application fields such as computer vision and natural language processing, which have large accessible datasets [9]–[11], ML in Electronic Design Automation (EDA) suffers from data scarcity. This is due to a lack of data sharing in the EDA community to protect one's intellectual property (IP) from illegal duplication [12]–[16]. Centralized data collection for ML training can lead to IP infringement, as malicious users could access the database and extract patented circuit information [17]–[19]. This security issue limits data diversity in ML for EDA (ML-EDA).

To address data privacy concerns, Federated Learning (FL) [20] was developed, focusing on data localization and remote model training. FL is a distributed computing approach where independently trained models are aggregated without direct access to private data. In this setup, clients send their locally trained model weights to a central server, which aggregates these weights to update the global ML model. This method ensures secure ML model training without risking data leakage, as private data remains strictly within each client's local environment. However, since local clients hold data that differs in both quantity and label distribution, the issue of data imbalance arises, leading to significant performance degradation of the global model when aggregating the locally trained model weights.

P. Jingyu *et al.* introduced FLNet [21], which demonstrates the application of FL in the routability prediction task. FLNet alleviates the effects of data imbalance by reducing the number of model parameters, thus mitigating performance degradation in FL aggregation. However, it is a **model-based** approach that addresses data imbalance issues simply by modifying the model. Additionally, it does not leverage the unique characteristics of EDA data. This approach cannot integrate state-of-the-art models designed to improve prediction accuracy in the EDA domain, limiting the broad application of FL in the field.

In this work, we propose a novel model aggregation algorithm called *FedEDA*, specifically designed for EDA tasks. *FedEDA* incorporates the unique complexity and hierarchical characteristics of circuit data into the algorithm. This approach addresses data imbalance issues in distributed ML-EDA environments in the weight aggregation process, which is independent of the conventional model-based approach [21]. To demonstrate the applicability of *FedEDA*, we evaluate its performance across various prediction tasks and widely used ML models in the EDA domain. The contributions of our research can be summarized as follows:

- We present *FedEDA*, which to the best of our knowledge, is the first FL **aggregation algorithm** designed specifically for EDA. *FedEDA* addresses the challenges of data scarcity and imbalance in ML-EDA by considering the unique characteristics of EDA data in its weight aggregation process while ensuring data privacy and security.
- We recognize that circuit heterogeneity is the key factor leading to performance degradation. To capture circuit complexity, we consider Rent's Rule [22] along with circuit size. *FedEDA* systematically incorporates these characteristics into its loss function.
- *FedEDA*'s applicability is demonstrated across a wide range of EDA prediction tasks, including routability, parasitic RC, and wirelength prediction, using various models.

*These authors equally contributed to this work. This work was supported by the Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT) (No. RS-2023-00222085, Development of memory module and memory compiler for non-volatile PIM) and by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No.2019R1A5A1027055).

It outperforms conventional model merging algorithms like *FedAvg* [20], *FedProx* [23] and achieves up to an 8.74% improvement in prediction accuracy compared to FLNet in routability prediction.

II. Preliminaries

A. Merging Independently Trained Models

Model merging is an ML technique that combines the experiences of independent training runs without additional training or fine-tuning. The primary concept behind this strategy is to integrate various models, each trained on local data, to enhance performance by utilizing the collective expertise of multiple models. A key benefit of model merging is its contribution to data privacy, as it allows independently trained models to be combined without the need for centralized data storage. A notable example of this approach is FL [20]. A well-known algorithm that exemplifies this approach is *FedAvg* [20], an effective FL algorithm that aggregates locally trained models at each iteration. This process can be summarized as follows:

$$w_{t,j}^k \leftarrow w_{t,j-1}^k - \eta \sum_{b=1}^{B} \nabla_w F(y_b, f_{w_{t,j-1}^k}(x_b)), \tag{1}$$

where B is batch size, t is global round, j is local round, k is client, and w is model weight. At every global round t, for each client $k \in \{1, ..., K\}$, the local checkpoints $w_{t-1,0}^k$ are initialized to the aggregated result w_t. Every client updates their local checkpoints for each local step $j \in \{1, ..., E\}$ by mini-batch gradient descent for a learning rate of η. Locally trained weights w_t^k are transmitted to the host, which is then merged to form the global model, as follows:

$$w_{t+1} = \frac{1}{K} \sum_{k=1}^{K} w_{t,E}^k. \tag{2}$$

Global training rounds are repeated by a specified global epoch T defined by the host. Upon convergence, the globally trained weights are broadcast to each client for local inference.

B. Related work

FedAvg is one of the simplest and most effective aggregation algorithms in FL [24] when data is Independent and Identically Distributed (IID) among clients. However, in most real-world scenarios, data tends to be heterogeneously distributed, or non-IID and training models on such data using *FedAvg* can lead to biased or sub-optimal models [25]. As a result, the local optima for each client diverges from the global optimum, a phenomenon known as *drift* in local updates. Naive aggregation of models with *FedAvg* does not always ensure that the averaged model closely approximates the global optimum which leads to performance degradation.

Alternative aggregation algorithms such as *FedProx* [23], *FedNova* [26] and *SCAFFOLD* [27] have been studied to address the challenge posed by non-IID data. *FedProx* [23] incorporates an L2 regularization term into the loss function, directly limiting the drift between the local optima and global optimum. *FedNova* [26] assumes the varying number of local steps (τ_k) among participants, thus normalizing the local updates based on the number of preceding local updates before updating the global model. The *SCAFFOLD* [27] algorithm estimates local training divergence by subtracting the global model update direction from the local models, integrating this drift to refine local updates. However, these algorithms were developed primarily for conventional ML data, such as images and text.

P. Jingyu *et al.* designed a customized ML model called FLNet [21] to apply FL to routability prediction, an ML application in EDA. FLNet addresses the data heterogeneity issue in FL by removing batch normalization operators, proposing a model-based solution. However, this **model-based** approach cannot be applied to various ML-EDA models developed for performance enhancement, thus limiting the general application of FL in the field of EDA.

C. Rent's Rule

Rent's Rule [22], as one method to represent the characteristics of circuits, describes a power-law relationship between the number of input/output (I/O) terminals, denoted as T, and the number of gates, N, in a logic block. This relationship is expressed by the following equation:

$$T = kN^p, \tag{3}$$

where k and p are Rent's constant and exponent, respectively. These parameters are derived empirically and p is a measure of the interconnection complexity of the circuit. Its value ranges between 0 and 1; higher values mean higher complexity. Understanding the relationship between the number of gates and terminals allows designers to manage circuit complexity and connectivity more effectively, thereby enhancing overall design efficiency and performance [28].

In the context of FL for ML-EDA, leveraging Rent's Rule enables a systematic way to capture circuit complexity and integrate it into model aggregation algorithms like *FedEDA*. This helps address challenges arising from data heterogeneity, as circuit complexity significantly influences the distribution and behavior of EDA datasets.

III. Proposed Method

A. FedEDA for EDA based Federated Learning

We propose *FedEDA*, a robust model merging algorithm that accounts for the unique feature distribution of EDA data in FL. The key parameters used in *FedEDA* are described in Table I. Circuit designs typically exhibit a hierarchical structure [29], [30], where multiple small circuit modules are interconnected to form the top module, as depicted in Fig. 1 (a). Larger designs include more submodules and connections, expanding the diversity of new characteristics in the EDA feature space. For example, in Fig. 1 (b), circuit A offers a limited feature space, whereas a larger circuit C provides a significantly broader one. Since both A and C are hierarchically structured, the majority of the feature space introduced by A can also be represented by C, as illustrated by the red region in Fig. 1 (b). If local models are independently trained on A, B, and

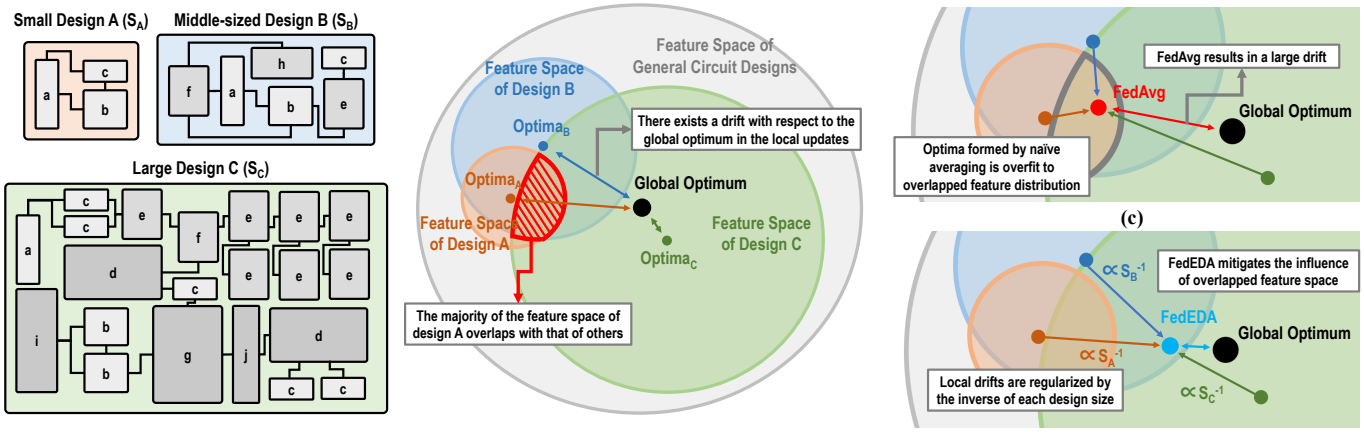

Fig. 1. Motivation for *FedEDA*. (a) shows the hierarchical characteristics of circuit designs. Larger circuits tend to have more diverse modules and number of connections. For each design i, S_i represents the circuit design size. (b) represents the feature space for designs A, B, and C. The red area on the middle left represents features shared among these three designs. (c) The averaged updates generated by *FedAvg* [20] has a considerable drift with respect to the global optima. (d) *FedEDA* alleviates this drift by taking the hierarchical information in EDA data, into account for each local update.

TABLE I
DESCRIPTION OF KEY PARAMETERS USED IN *FedEDA*

Notation	Description
p	Rent's exponent
σ	Standard deviation of p in submodule
μ	Mean of p in submodule
CM	Circuit metadata (p, σ and circuit size)
α	Inverse min-max normalization value
K	Set of clients ($k \in K$)
D^k	Local database of client k
T	Number of global iterations for FL
γ	Relative weight of importance of α
F	Original local loss function [20]
f	ML model
B	Batch size
(x_b, y_b)	Data sample from batch B

C, and averaged *FedAvg* [20], the resulting global model will be biased towards the feature space of A, since it contains the majority of the shared features, as shown in Fig. 1 (c). This significant *drift* between the averaged updates and the global optimum can lead to performance degradation when evaluated on other circuit designs. Therefore, we identify circuit size as a major factor of data heterogeneity for EDA data and incorporate this characteristic in formulating *FedEDA*.

However, circuit size alone is insufficient to capture characteristics of circuit data distribution since larger designs often consist of repetitive structures of identical submodules. We address this issue using Rent's Rule [22] by calculating Rent's parameter p for each submodule of the netlist and then computing the standard deviation σ as follows:

$$\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(p_i - \mu)^2}. \tag{4}$$

The value of σ represents the diversity of submodules, while p indicates the complexity of the circuit. A small σ implies that the circuit contains submodules with similar characteristics, resulting in a repetitive data distribution. Similarly, a small p indicates a simple circuit with a less diverse data distribution. From a distributed environment perspective, circuits with small σ and p contribute to a biased feature space in the overall circuit dataset. Therefore, in *FedEDA*, these factors are integrated into the local loss function, applying a penalty to circuits with smaller sizes (number of cells), low σ, and low p. The factors σ, p, and circuit size are collectively referred to as circuit metadata (*CM*) and represent the circuit complexity and hierarchical characteristics. CM is unique to each circuit dataset and rescaled using min-max normalization to stabilize the drift-based regularization term. Clients transmit their *CM* to the host and the host calculates the maximum and minimum *CM* values to get CM_{max} and CM_{min}, which are returned to every client. Clients calculate the inverse min-max normalization values α_{size}, α_σ, and α_p for each circuit data using the following equation:

$$\alpha = \frac{\mathrm{CM_{max}} - \mathrm{CM_{min}}}{\mathrm{CM} - \mathrm{CM_{min}}}. \tag{5}$$

As a weighted sum, α_{size}, α_σ, and α_p are combined with the L2 regularization term $\|w_t - w^k_{t,j-1}\|^2$, which represents the *drift* of the converged model and global optima [23]. The regularization term is integrated into the modified local loss function L^k_B as follows:

$$L^k_B = \sum_{b=1}^{B} F(y_b, f_{w^k_{t,j-1}}(x_b)) + (\alpha_{size}\gamma_{size} + \alpha_\sigma\gamma_\sigma + \alpha_p\gamma_p)\|w_t - w^k_{t,j-1}\|^2. \tag{6}$$

This approach ensures that if the local weight $w^k_{t,j-1}$ deviates significantly from the global weight w_t, the loss function increases, thus reducing the *drift* of each local update. As shown in Fig. 1 (d), the regularization of local updates per design is scaled with the inverse of its α values. Consequently, in circuit datasets where most of the features overlap with one another, the influence of local weight updates is reduced, so that the model merged by the *FedEDA* algorithm has a smaller *drift* from the global optimum.

Algorithm 1: $FedEDA$ (Proposed Method)

1 **Input:** $w^k_{t-1,0}, D^k, \alpha_{size}, \alpha_p, \alpha_\sigma, \gamma_{size}, \gamma_p, \gamma_\sigma, f$
2 **Phase 1: Initialization**
3 **Client executes:**
4 **for** *client* $k \in K$ **do**
5 return CM^k to host
6 **end**
7 **Server executes:**
8 $CM_{\max} \leftarrow \max\{CM^1, \ldots, CM^k\}$
9 $CM_{\min} \leftarrow \min\{CM^1, \ldots, CM^k\}$
10 Distribute w_0, ML model, CM_{max}, CM_{min} to $\forall k \in K$
11 **Client executes:**
12 **for** *client* $k \in K$ **do**
13 Extract D^k from Layouts
14 Initialize $w^k_{t-1,0} \leftarrow w_t$
15 **end**
16 **Phase 2: Federated learning**
17 **for** $t \leftarrow 1$ **to** T **do**
18 **Client executes:**
19 **for** *client* $k \in K$ **do**
20 **for** $j \leftarrow 0$ **to** E **do**
21 $w^k_{t,j+1} \leftarrow w^k_{t,j} - \eta \sum_{b=1}^{B} \nabla_w L^k_B$
22 **end**
23 return $w^k_{t,E}$ to host
24 **end**
25 **Server executes:**
26 $w_{t+1} \leftarrow \frac{1}{k} \sum_{k=1}^{K} w^k_{t,E}$
27 Distribute w_{t+1} to $\forall k \in K$
28 **end**
29 **Phase 3: Application**
30 **Server executes:**
31 Distribute w_{T+1} $\forall k \in K$
32 **Client executes:**
33 Result $\leftarrow$ ML model($dataset, w_{T+1}$)

B. Federated Learning Framework

The overall framework of the FL for ML-EDA is described in Algorithm 1. It involves a single administering host and multiple clients with different IC designs. This framework consists of three stages: (1) the Initialization phase, (2) the FL phase, and (3) the Application phase.

*1) **Initialization phase (Algorithm 1, lines 1-15)**:* Initially, clients provide the FL host with CM (circuit size, p, σ) (line 5). Upon receiving metadata from each participant, the host returns processed global metadata (lines 8-9), along with design feature extractors, model architectures, and initialized weights (line 10). Each client then extracts relevant features to train their local ML models (line 13). Models for each client are initialized with the same weights to ensure consistency across participants and promote stable convergence.

*2) **FL phase (Algorithm 1, lines 16-28)**:* After initialization, the local model is trained on the client's database with the local training epoch E and learning rate η. Initial weights w_0 are updated to w^k_1 using *FedEDA* (line 21). Afterward, clients send their locally trained weights to the host for weight aggregation (line 23), where they are merged into the central server model (line 26). These weights are then broadcast to each client, initiating a new global round with a shared checkpoint across all participants. This global round of training is iterated for global epochs T.

*3) **Application phase (Algorithm 1, lines 29-33)**:* In the last phase, the final weights of the converged model are distributed to each client (line 31), where they are applied to their local ML algorithm for inference (line 33). This allows clients to predict EDA outcomes early in the physical design process, helping them assess the design validity.

Security is maintained throughout the process since no raw circuit data is exchanged. By training ML models within the FL framework, clients can enhance their models' performance by leveraging the EDA experiences of others while ensuring their own data's privacy. Furthermore, *FedEDA* can be integrated with complementary approaches, such as FLNet [21] or personalization techniques [31], broadening the applicability of FL in ML-EDA and enabling more versatile solutions.

IV. Experimental Results

A. Experimental Setup

We utilized 21 *OpenCores* [32] circuit designs as shown in Table II to train and test our ML-EDA model. We employed two commercial tools, *Design Compiler v18.06* [33] for synthesis and *Innovus v21.16* [34] for P&R. We generated 160 layouts for each circuit by sweeping the cell height, utilization, top routing layer, and P&R clock period of the layout for our experiment. Designs were processed using the *ASAP 7nm* [35] Process Design Kit (PDK) with 6-track cells and 7.5-track cells. The distributed training environment was simulated on 2.8 GHz AMD EPYC 7402P CPU with 256GB RAM, and experiments were conducted on an NVIDIA Titan RTX GPU.

B. ML Tasks for EDA

We evaluated our framework on various ML-based EDA prediction tasks, including routability, parasitic RC, and Wirelength (WL) prediction, using different ML models such as CNNs, MLPs, and GNNs. The CNN and MLP models were implemented using Python's PyTorch library, while the GNN models were implemented using the deep graph library [36]. The overall prediction task configuration and model architecture for evaluating our framework is shown in Fig. 2.

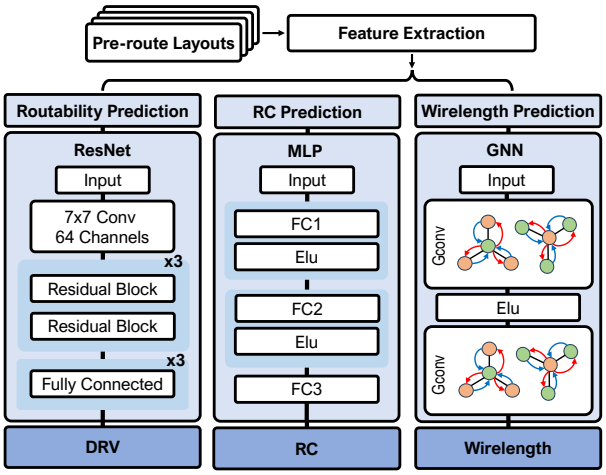

Fig. 2. ML-EDA prediction tasks to evaluate our FL framework.

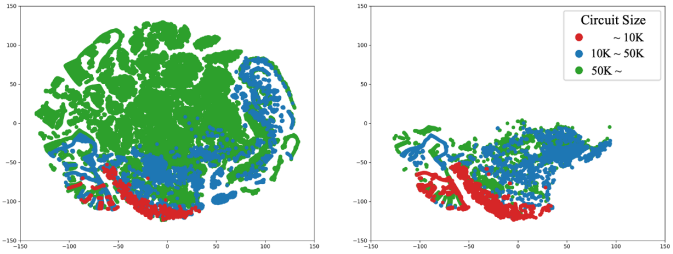

We validated the applicability of our framework to ML-EDA by incorporating it into tile-level routability prediction methods [37]. Instead of directly predicting delay, we applied our approach to RC prediction, which is used for timing prediction [38], to handle extensive output slew data. Furthermore, due to the straightforward conversion of netlists into graphs, we employed GNNs, which are extensively used in the EDA domain [39], to construct the FL framework. Our EDA-based FL framework can be seamlessly applied to various state-of-the-art ML-EDA models, as demonstrated through its application to several commonly used ML models in EDA.

C. Data distribution of EDA Data

We analyzed the distribution of dataset feature space used in ML-EDA through t-SNE visualization. Here, Rent's parameters were calculated by performing min-cut partitioning on each submodule of the gate-level netlist using ML Part [40].

Fig. 3 shows the distribution of data according to circuit size, with small circuits shown in red, medium-sized circuits in blue, and large circuits in green. In Fig. 3 (a), when the standard deviation of the Rent's parameter p of the submodules is 0.05 or higher, indicating that the circuit is composed of various submodules, the feature data distribution illustrates a hierarchical structure from the lower left to the upper area according to circuit size. Conversely, Fig. 3 (b) illustrates that when the standard deviation of the Rent's parameter p is below 0.05, leading to redundant and similar submodule circuits, the feature data distribution remains clustered in the lower-left corner, regardless of increasing circuit size. Here, the standard deviation of 0.05 is the mean of the standard deviations of p for all benches used in the experiment. This highlights the hierarchical nature of EDA data, shaped by design size and complexity. By using *FedEDA* to increase the model's aggregation quality for large and complex designs, it is possible to learn from various data distributions, as shown in the upper region of Fig. 3 (a), thereby improving overall model performance.

This raises the question of whether identifying circuit complexity is meaningful for EDA datasets and how it compares to commonly used ML datasets. To explore this, we compared

(a) (b)

Fig. 3. T-SNE visualizations of DRV prediction feature data based on circuit size. Using a standard deviation threshold of 0.05 for the Rent's parameter p of the submodules, (a) represents designs with a higher standard deviation, while (b) represents designs with a lower standard deviation.

TABLE III
COMPARISON OF ENTROPY VALUES FOR DATASETS ACROSS DIFFERENT ML DOMAINS

Dataset	MNIST [41]	DBpedia [42]	Circuit data
Entropy	3.320	3.807	2.740

the characteristics of commonly used ML datasets with circuit data by analyzing entropy values across three datasets: the MNIST [41] vision dataset, the DBpedia [42] language dataset, and a circuit dataset used for DRV prediction. Higher entropy values indicate a greater degree of randomness in the data distribution [43]. As shown in Table III, the circuit dataset exhibits the lowest entropy value. This suggests a more concentrated distribution with less randomness, indicating that certain features are overly represented. By incorporating key factors contributing to this concentration in *FedEDA*, such as circuit size and complexity, we enhance its evaluation performance.

D. Performance Evaluation

We evaluate the effectiveness of *FedEDA* by comparing its performance against other FL methods on both classification and regression tasks. For the DRV prediction task (classification), we used accuracy and F1 score as evaluation metrics, while for the regression tasks of predicting parasitic RC and WL, we evaluated performance using the R2 score. The training dataset consisted of 18 circuits with a total of 2,280 layouts, while the test dataset included 3 circuits with a total of 480 layouts that were not used in training. For each γ value described in Eq. (6), we optimized the ideal values from the restricted candidate set $\{0.001, 0.01, 0.1, 1\}$. We tested and compared model performance with other weight aggregation techniques, *FedAvg* [20], and *FedProx* [23].

Under the IID condition, the training data was randomly shuffled and distributed in equal quantities among the clients. We adopted three different cases to emulate data heterogeneous environments. For Quantity Skew (QS), the training data was shuffled and randomly allocated to each client in unequal quantities. In the case of Label Skew (LS), the data was distributed in equal quantities to each client with no overlapping circuit designs among them. Lastly, for Label and Quantity Skew (LS+QS), the data was randomly distributed in unequal quantities with no overlapping circuit designs among the clients.

TABLE IV

The best results are highlighted in **bold**.

To equate the total exposure of the dataset across the three schemes—Federated Learning (FL), Centralized Learning (CL), and Local Training (LT)—the product of the global epochs and local epochs in FL was set to be equal to the number of epochs in CL and LT per client k, as follows:

$$Epoch_{CL} = Epoch_{LT}^{k} = GlobalEpoch_{FL} \times LocalEpoch_{FL}. \quad (7)$$

As shown in Table IV, Local Learning, where each client trains on their own data, results in a 41.39% decrease in average performance metrics compared to the centrally trained model (Central Learning). By applying *FedEDA* in FL under the same data distribution conditions as Local Learning, the average performance metrics decrease by just 1.98%, achieving results comparable to centralized learning. Moreover, *FedEDA* provides a privacy-preserving environment with minimal impact on model performance. Additionally, compared to previous FL model merging algorithms, *FedEDA* achieves the best performance in 12 out of 12 scenarios for DRV prediction (Accuracy), 6 out of 12 for RC prediction (R2), and 12 out of 12 for WL prediction (R2), across various data distributions and client configurations. Notably, in the LS+QS distribution, which is most similar to real-world conditions, the maximum improvement in average (AVG.) F1 score and R2 score for DRV, RC, and WL prediction are 11.5%, 74.5%, and 33.5%, respectively, compared to conventional model merging algorithms [20], [23]. The γ values that yielded the best performance were 0.1 for γ_{size}, and 0.001 for both γ_σ and γ_p, suggesting that circuit size is the primary factor contributing to data heterogeneity in circuit data. These results demonstrate that our proposed model merging algorithm effectively addresses the data heterogeneity challenge in EDA datasets, making it highly effective and broadly applicable in ML-EDA.

E. Routability Prediction Performance Comparison

We applied our proposed *FedEDA* to a recently developed routability prediction model [37] and compared its performance with FLNet [21], since FLNet was originally targeted routability prediction. As shown in Fig. 4, *FedEDA* consistently outperformed FLNet in both accuracy and F1 score, achieving up to an 8.74% improvement in accuracy. These findings emphasize the effectiveness of our model aggregation algorithm in overcoming the limitations of model-specific approaches, which often struggle to adapt to diverse ML models designed for performance optimization. By addressing this challenge, *FedEDA* enhances the flexibility and applicability of FL in the EDA domain. Moreover, this improvement is expected to enable *FedEDA* to support newly developed ML-EDA models, further widening the performance gap compared to model-based approaches.

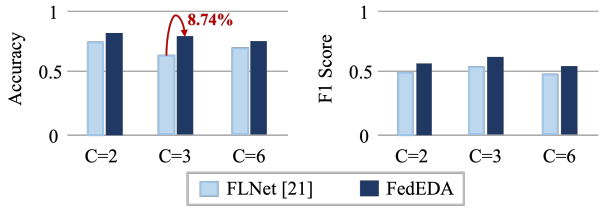

Fig. 4. Comparison of routability prediction performance between FLNet [21] and *FedEDA* in an non-IID (LS+QS) data distribution. C is the client number.

V. CONCLUSION

In conclusion, our study introduces a novel FL aggregation algorithm, *FedEDA*, to address the issues of data heterogeneity and privacy concerns in the ML-EDA domain. To the best of our knowledge, this is the first work proposing an FL **algorithm** specifically for ML-EDA. Unlike previous research focused on model-based solutions [21], *FedEDA* leverages Rent's Rule and circuit size to incorporate the hierarchical characteristics of EDA data into the aggregation process, enhancing the performance of FL models and providing a more general approach. We demonstrate the effectiveness of *FedEDA* by achieving an average improvement of up to 74.5% in R2 score compared to existing aggregation algorithms. [20], [23], and up to an 8.74% improvement compared to the model-based solution, FLNet [21], across a wide range of ML-EDA tasks and various prediction scenarios.

***Abstract*—Serverless computing is increasingly adopted for its ability to manage complex, event-driven workloads without the need for infrastructure provisioning. However, traditional resource allocation in serverless platforms couples CPU and memory, which may not be optimal for all functions. Existing decoupling approaches, while offering some flexibility, are not designed to handle the vast configuration space and complexity of serverless workflows. In this paper, we propose `AARC`, an innovative, automated framework that decouples CPU and memory resources to provide more flexible and efficient provisioning for serverless workloads. `AARC` is composed of two key components: Graph-Centric Scheduler, which identifies critical paths in workflows, and Priority Configurator, which applies priority scheduling techniques to optimize resource allocation. Our experimental evaluation demonstrates that `AARC` achieves substantial improvements over state-of-the-art methods, with total search time reductions of 85.8% and 89.6%, and cost savings of 49.6% and 61.7%, respectively, while maintaining SLO compliance.**

***Index Terms*—serverless computing, resource configuration, automatization.**

I. Introduction

Serverless computing [1], [2] is emerging as a new paradigm in cloud computing, offering distinct advantages over traditional models like Infrastructure-as-a-Service [3], [4] and Platform-as-a-Service [5], [6]. Unlike these earlier services, serverless computing, or Function-as-a-Service (FaaS), breaks down applications into smaller, more manageable functions. This approach significantly reduces the maintenance burden on developers and enables service providers to maximize the use of underlying hardware resources. Complex applications often require more than one function, which is where serverless workflows come into play [7]. Visualized as directed acyclic graphs (DAGs), serverless workflows can scale based on demand, providing both operational flexibility and cost-effectiveness. Each function within the workflow operates independently, allowing for efficient resource allocation and management.

Despite its reputation for flexible and granular resource allocation, FaaS is still predicated on user-defined quotas for resource configuration. We characterize existing resource management strategies within FaaS frameworks into three primary categories. First, memory-centric configurations in AWS Lambda[1], allow developers to set memory quotas, with vCPU and network bandwidth allocated in proportion to the memory allocation. Second, Google Cloud Functions[2] providers offer a selection of predefined resource combinations. Third, there are flexible yet limited configurations, like Alibaba Cloud Function[3], which enforces a memory-to-CPU ratio within a specified range. It is speculated that these constraints aid cloud providers in the efficient management of resources and potentially reduce the need for extensive physical infrastructure.

However, the existing coupled resource allocation mechanism may not be optimal for all serverless functions. Bilal *et al.* [8] highlight the benefits of resource decoupling, which can potentially reduce execution costs by up to 40% when compared to coupled configurations. However, their study is limited to individual functions and does not extend to workflows. We analyze three serverless workflows [9] with decoupled CPU-memory resources to evaluate their performance in §II-A. Our findings indicate that a coupled CPU-memory mechanism can result in resource inefficiency and increased costs due to the varying resource requirements of different workflows. For instance, in the ML Pipeline workflow, a decoupled configuration of 4 vCPUs and 512 MB memory achieves optimal cost by reducing memory usage by 87.5%, substantially decreasing the overall cost compared to the coupled approach.

While decoupling CPU and memory seems a promising strategy for adaptive resource provisioning, it significantly broadens the configuration space, presenting substantial challenges in finding optimal settings. Previous research [8] suggests a Bayesian optimization-based method for resource allocation, yet this method is geared towards individual functions. We extend the method to workflows and evaluate it with a Chatbot application in §II-B. After 100 rounds of sampling, with the algorithm still not converging, we observe a 32.13% reduction in cost, but the total runtime extends to 9.76 hours, indicating a struggle to reach an optimal solution. Moreover, the cost exhibits frequent fluctuations and nearly half of these changes are increases. These challenges have spurred our efforts to develop a more automated, stable, and efficient resource configuration scheme for the decoupling of resources

[1]https://aws.amazon.com/lambda/pricing/
[2]https://cloud.google.com/functions/pricing-1stgen
[3]https://www.aliyun.com/product/fc/

and workflows.

In this paper, we introduce AARC, an automated framework designed to configure resources with affinity awareness for serverless workflows. Our key insight lies in the decoupling of computation and storage resources, which enhances flexibility in provisioning resources for serverless workloads. AARC offers three distinct advantages over existing methods. Firstly, AARC surpasses memory-centric allocation schemes [9]–[11] by decoupling memory and CPU, thereby increasing resource flexibility and efficiency through a comprehensive exploration of serverless workflows' resource affinities. Secondly, in contrast to peer works utilizing Bayesian optimization for decoupled configurations [8], our method efficiently manages complex workflows and minimizes the sampling iterations required. Lastly, AARC's resource allocation centers on Service Level Objectives (SLOs), which specify end-to-end latency limits, eliminating manual resource allocation by developers and automating the process.

Specifically, AARC integrates Graph-Centric Scheduler and Priority Configurator to optimize serverless workflow costs using a heuristic algorithm. The Graph-Centric Scheduler starts by breaking down the workflow to find the critical path, which the Priority Configurator then schedules with priority techniques. This is followed by Graph-Centric Scheduler setting sub-SLOs for related sub-paths and determining resource configurations for functions within them. Cloud vendors can use AARC to find optimal resource configurations that meet end-to-end SLOs upon receiving workflows from developers. Our experiment illustrates that during searching for the optimal configuration, AARC reduces the total runtime by around 85% compared to SOTA methods. When comparing the optimal configurations, AARC achieves cost savings of around 50% compared to SOTA methods, while still meeting the SLO requirements.

Our contributions are highlighted as follows.

- Firstly, we identify that memory-centric resource configuration schemes on mainstream serverless computing platforms are not a one-size-fits-all approach, and existing methods for decoupled resource configuration don't work for workflows because of the larger search space.
- Secondly, we propose AARC, a framework for decoupled resource configuration in serverless workflows automatically. Leveraging critical path decomposition and priority scheduling, the framework provides a cost-efficient resource allocation strategy with SLO compliance.
- Finally, our experiment demonstrates that AARC reduces total runtime by 85% and achieves 50% cost savings compared to SOTA methods while meeting SLOs.

II. Motivation and Challenge

A. *Motivation*: Decoupling for Flexibility

While memory-centric resource configurations like AWS Lambda simplify resource management, they may not suit all serverless workloads. Bilal *et al.* [8] demonstrate that resource decoupling can reduce execution costs by up to 40% compared

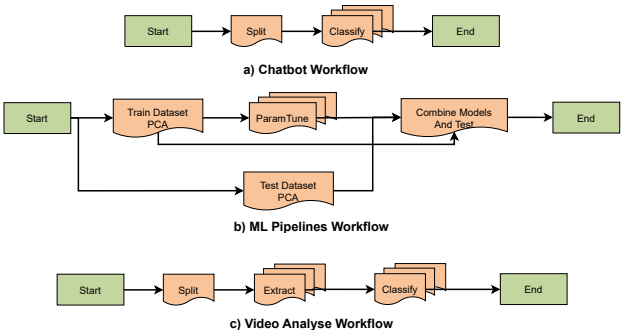

Fig. 1: Architecture of Three Workflows.

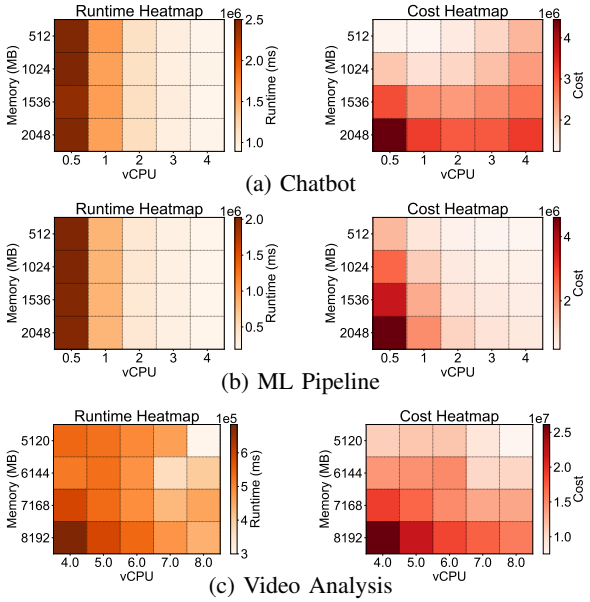

Fig. 2: Runtime and Cost with Decoupled Resources.

to coupled configurations. However, their analysis is restricted to individual functions and does not consider workflows. To explore the impact of decoupled CPU-memory resources for workflows on runtime and cost, we conduct experiments with three different workflows [9], Chatbot, ML Pipeline, and Video Analysis. Fig. 1 illustrates the architecture of these workflows. The Chatbot workflow processes input, trains classifiers in parallel, and uses remote storage for real-time intent detection. The ML Pipeline workflow achieves machine learning by performing dimensionality reduction, model training, and testing. The Video Analysis workflow splits input videos, extracts key frames, and classifies them.

Fig. 2 demonstrates the impact of decoupling CPU and memory on the runtime and cost of the workflows. Fig. 2a and Fig. 2b show that the runtime for Chatbot and ML Pipeline remains unchanged despite memory variations, indicating inefficiency in memory-centric resource allocation for computation-intensive tasks. Notably, in the ML Pipeline workflow, a decoupled configuration of 4 vCPUs and 512 MB memory achieves the lowest cost, reducing memory usage by 87.5% compared to the coupled approach, underscoring the need for decoupled strategies. Additionally, comparing Fig. 2a and Fig. 2c reveals distinct resource affinities across

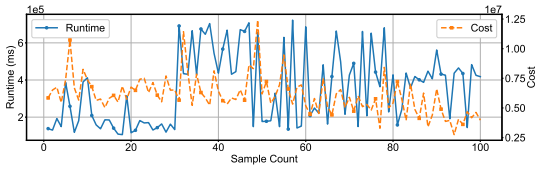

Fig. 3: Bayesian Optimization Search for Chatbot.

workflows. For example, Chatbot minimizes costs with 512 MB memory and 1 vCPU, while Video Analysis achieves cost efficiency with 5120 MB memory and 8 vCPUs. Thus, resource configurations should be tailored to each workflow to minimize costs while meeting SLOs.

B. ***Challenge***: *Larger Configuration Space after Decoupling*

Decoupling CPU and memory improves resource utilization and reduces costs but significantly expands the configuration space, complicating optimal resource provisioning. Profiling-based methods [9], [12], [13] face increased sampling challenges as configurable resources grow. The complexity of serverless applications is further exacerbated by the fact that 46% of applications involve multiple functions [7]. While prior work [8] explores Bayesian optimization for decoupled resource configuration, it focuses on individual functions, overlooking the unique demands of workflows.

We extend the Bayesian Optimization (BO) method from this study to serverless workflows, specifically testing the Chatbot application, to observe changes in runtime and cost with increased sampling. As depicted in Fig. 3, while the cost decreases by 32.13% over 100 sampling rounds without converging, the total runtime extends to 9.76 hours. Additionally, the cost experiences frequent fluctuations, with over half of the changes being increases. The average fluctuation amplitude, calculated as the mean absolute difference between consecutive values, accounts for 18.3% of the mean, which highlights its significant instability. This instability stems from the expansion of the search space when applying decoupling to workflows, which complicates the identification of the optimal solution using Bayesian Optimization. Consequently, current methods struggle to optimize serverless workflows effectively.

III. Design

A. Overview

Fig. 4 depicts the overall architecture of AARC consisting of two main components: Graph-Centric Scheduler and Priority Configurator. Graph-Centric Scheduler decomposes the input workflow and identifies its critical path, along with all the sub-paths linked to it. Priority Configurator configures each function along the critical path and sub-paths.

In our proposed framework, developers submit ❶ their workflow to the cloud platform along with the SLO. First, the Graph-Centric Scheduler profiles the user-defined workflow based on dummy input, calculating the runtime for each function in the workflow. This runtime is then used as the weight of each node, converting ❷ the workflow into a weighted DAG. Next, the Scheduler extracts the critical path and its SLO from the weighted DAG and passes ❸ this information to the

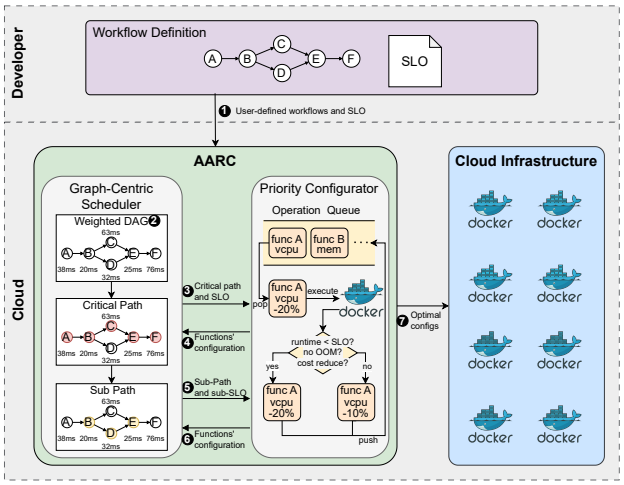

Fig. 4: System Architecture.

TABLE I: Functions in Algorithm 1 and Algorithm 2.

Functions	Description
deallocate(op)	According to the type and step of the given operation op, deprive a portion of the function's resources and return the runtime and cost under this configuration.
allocate(op)	According to type and step of the given operation op, allocate a portion of resources to the function and return a new step and trail of the op.
find_critical_path(G)	Given a weighted DAG, return the critical path of this DAG.
find_detour_subpath(G, critical_path)	Given a DAG and its critical path, return all the sub-paths connected to the critical path.
runtime_sum(path, start, end)	Given the start and the end of a path, calculate the overall duration time between the start and the end.

Priority Configurator. Priority Configurator then incrementally reduces the memory and CPU allocation for each function through priority-based scheduling to determine ❹ the optimal resource configuration that meets the SLO. Based on the optimal configuration of the critical path and the SLO, Graph-Centric Scheduler substitutes functions on the non-critical path onto the critical path to generate ❺ sub-paths and corresponding SLOs. Similarly, Priority Configurator calculates ❻ the optimal resource configuration of the functions in sub-paths, ensuring that the critical path's SLO is not violated. Finally, Graph-Centric Scheduler finalizes ❼ the resource configuration for subsequent container resource allocation, which ensures SLO compliance with optimal cost efficiency.

B. Detailed Design

Graph-Centric Scheduler employs *Overall Scheduling Algorithm* to process the workflow and SLO, performing critical path-based decomposition of the workflow. It then invokes the Priority Configurator to allocate resources for functions along the paths. Priority Configurator uses *Priority Configuration Algorithm* to handle the function paths and SLO, achieving decoupled resource allocation through priority scheduling. The pseudocode for the *Overall Scheduling Algorithm* and

Algorithm 1: Overall Scheduling

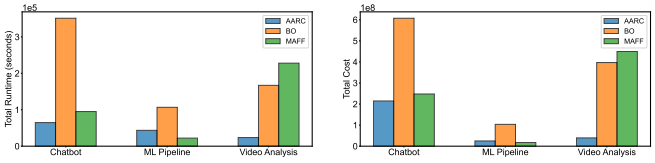
25 **return** configs
26 **End Function**

Priority Configuration Algorithm is provided in Algorithm 1 and Algorithm 2, with their functions explained in TABLE I.



Algorithm 1 presents the whole scheduling process. Given a function workflow and the target end-to-end SLO, the algorithm operates as follows: Firstly, each function in the workflow is initially assigned an over-provisioned base configuration to ensure the workflow meets the SLO in most cases (Line 2-4). The workflow is then executed, and the runtime for each function is used as the weight in a DAG to identify the critical path (Line 5-6). The critical path and the end-to-end SLO are then utilized as inputs for the Priority Configurator, which in turn generates optimized configurations for each function along the critical path (Line 7-9). Through a full DAG traversal, the algorithm identifies sub-paths linked to the critical path, defined by their start and end nodes within the critical path, and no intersections with other nodes (Line 10). For each sub-path, the algorithm calculates the sub-SLO as the time interval between critical path nodes, ensuring critical path consistency during scheduling (Line 12). The Priority Configurator configures each function along the sub-path, following the same method as with the critical path (Line 19-20). To prevent conflicts and ensure each function only schedules once, the algorithm sets a scheduled flag for every function. After scheduling a function, the algorithm removes it from the path and adjusts the SLO accordingly (Line 13-18).

Algorithm 2 presents *Priority Configuration Algorithm*, which adopts priority scheduling to optimize the configuration of sequentially executed functions subject to SLO limitation. The algorithm initializes a priority queue PQ to manage operations for each function (Line 2), which requires two distinct operations to adjust CPU and memory quotas (Line 3-10). Based on the operation type, the algorithm modifies the function's resources, continuously executing operations from PQ and monitoring their impact on runtime and cost (Line 12-13). If an operation violates the SLO, increases cost, or encounters an error, the algorithm reverts the resource (Line 14-18). Simultaneously, an exponential backoff mechanism reduces the step size to ensure convergence while avoiding over-scheduling (Line 15). Operations consistently causing violations (trail $= 0$) are removed from PQ (Line 16), while those with potential are re-enqueued with adjusted priorities (Line 17, 20-21). The loop terminates when PQ is empty or a user-defined iteration limit, $\text{MAX}_{\text{TRAIL}}$, is reached (Line 11).

IV. Performance Evaluation

A. Experiment Setup

a) Environment: The experiments run on a machine with 4-socket Intel Xeon Gold 6248R (96 physical core),

(a) Total Runtime (b) Total Cost

Fig. 5: Overall Sample Cost and Runtime Comparison.

TABLE II: Average Runtime and Cost Comparison.

	Chatbot		ML Pipeline		Video Analysis	
	Runtime (s)	Cost	Runtime (s)	Cost	Runtime (s)	Cost
AARC	103.7±3.2	2390.9k	77.1±2.6	435.0k	316.8±6.6	53.6k
BO	114.7±1.9	4275.2k	60.0±0.7	863.5k	519.9±8.3	82.4k
MAFF	115.3±3.1	3477.5k	109.5±2.0	1136.6k	578.2±19.3	98.8k

and 512GB memory. Workflows execute in separate Docker containers, enabling CPU and memory allocation decoupling.

b) Baselines: We compare our approach with two baselines: Bayesian Optimization (BO) [8] and MAFF gradient descent [14]. Originally designed for single-function resource configuration and memory-centric tasks, these methods have been adapted for workflow optimization. In the Bayesian Optimization method, configuration parameters are discretized to limit the search space. Memory allocation is available in 64 MB increments from 128 MB to 10,240 MB, while vCPU cores range from 0.1 to 10, independently of memory. The MAFF gradient descent method iteratively minimizes cost, allocating vCPU cores proportionally (1 core per 1,024 MB of memory). If a workflow's SLO is violated, the process reverts to the previous step and terminates.

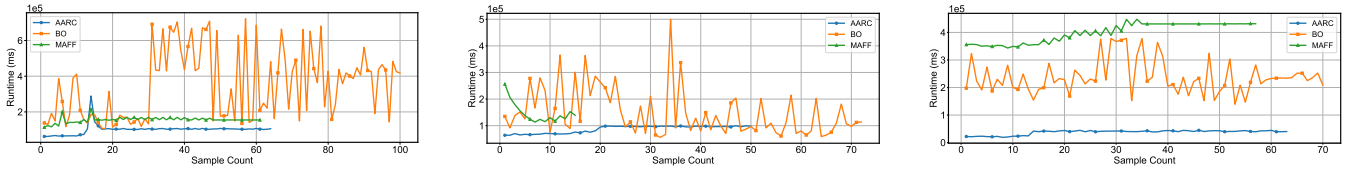
c) Workloads: Our experiments utilize three workflows (Chatbot, ML Pipeline, and Video Analysis), with SLOs set to 120s, 120s, and 600s, respectively. These applications capture key characteristics of serverless DAGs. Specifically, Video Analysis and Chatbot exhibit a scatter communication pattern, while ML Pipeline follows a broadcast pattern [9].

d) Metrics: We evaluate performance using runtime and cost metrics, extending the pricing model of AWS Lambda to decoupled resources. Let $\texttt{cost}_{\texttt{ij}}$ represent the cost of serverless function $\texttt{v}_\texttt{i}$ configured to $(\texttt{cpu}_\texttt{j}, \texttt{mem}_\texttt{j})$ with runtime $\texttt{t}_{\texttt{ij}}$. We denote the price per vCPU-second as μ_0, the price per GB-second as μ_1, and the price for function requests and orchestration as μ_2. All are constants. The cost equation is then $\texttt{cost}_{\texttt{ij}} = \texttt{t}_{\texttt{ij}}(\mu_0 \cdot \texttt{cpu}_\texttt{j} + \mu_1 \cdot \texttt{mem}_\texttt{j}) + \mu_2$. Here, μ_0, μ_1, and μ_2 are set to 0.512, 0.001, and 0, respectively.

B. Effectiveness of Configuration Search

In the configuration search experiment, we set the initial configurations for each workflow. Then, we perform the configuration search using three methods: AARC, Bayesian Optimization, and MAFF.

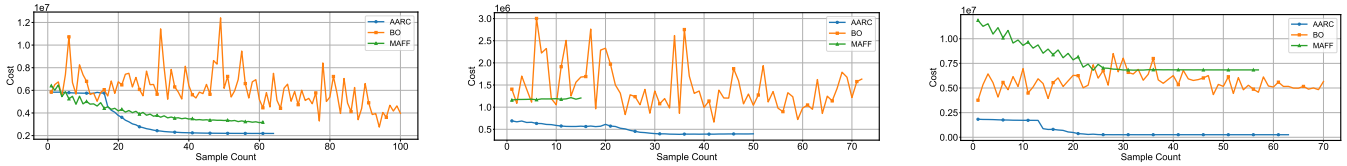
a) Overall Efficiency: Fig. 5 shows the total runtime and cost of the sampling process. In all workflows, AARC outperforms the Bayesian Optimization, especially in the Video Analysis workflow, reducing runtime by 85.8% and cost by 90.1%. This improvement stems from AARC's priority scheduling strategy for decoupled resources, which expands the configuration search space while requiring fewer samples. In the Chatbot workflow, AARC performs 64 samples, slightly more than MAFF's 61, but achieves a 31.9% reduction in runtime and 13.4% in cost. This is because MAFF's proportional allocation scheme reduces the search space but risks local optima, leading to higher runtime and costs due to resource coupling. In the Video Analysis workflow, AARC reduces runtime and cost by 89.6% and 91.3% compared to MAFF. However, in the ML Pipeline workflow, AARC samples 50 times compared to MAFF's 15, resulting in lower runtime and cost for MAFF. This is due to the ML Pipeline's high CPU and low memory demands, where proportional adjustments often hit local optima, requiring fewer samples to meet exit conditions.



b) Sampling Efficiency: We further illustrate the effectiveness of optimal configurations calculated by each method as the sampling count increases, evaluating these outcomes through workflow runtime and cost. Fig. 6 shows the change in runtime with sampling count under different configurations for each workflow. Our goal is to minimize cost while meeting the SLO, so runtime shows an upward trend using AARC. The Bayesian Optimization method has the highest sampling count and significant instability, as its efficiency decreases due to the large search space created by resource decoupling. In contrast, our priority scheduling strategy maintains search efficiency while accelerating convergence. Fig. 7 depicts the change in cost with sampling count under different configurations. Using AARC, cost shows a downward trend and converges with fewer samples. In the ML Pipeline workflow, the MAFF method quickly falls into local optima due to its coupled resource configuration search approach, making it difficult to discover more cost-effective configurations.

C. Performance of Optimal Configuration

To validate the performance of AARC in meeting the SLO requirements and execution cost, we execute the workflow 100 times using the configurations generated by the aforementioned methods and calculate its average runtime and cost.



a) SLO Violation: All methods meet the SLO constraints, with the average runtime and standard deviation shown in TABLE II. AARC satisfies SLO because the algorithm reverts resources during configuration search when SLO violations occur and incorporates sub-paths into the critical path, ensuring both critical path consistency and SLO compliance. This demonstrates the effectiveness of our approach in meeting SLO requirements and its potential for integration into real-world systems with high reliability and performance standards.

b) Cost Reduction: TABLE II shows the execution cost of workflows with configurations found by different methods. In the Chatbot, ML Pipeline, and Video Analysis workflows, AARC reduces costs significantly compared to Bayesian Optimization and MAFF. The reductions are 44.0% and 31.2% for Chatbot, 49.6% and 61.7% for ML Pipeline, and 34.9% and 45.7% for Video Analysis, respectively. Compared to the Bayesian Optimization method, our approach uses priority scheduling, which allows for more stable identification of suitable decoupled resource configurations. Unlike MAFF's

(a) Runtime (b) Cost

Fig. 8: Performance Across Input Sizes in Video Analysis.

proportional configuration method, our approach achieves decoupled resource allocation, resulting in lower-cost configurations. Since the ML Pipeline has high CPU demands and low memory demands, decoupling resources yields better results.

*D. **Discussion**: Input-Aware Configuration*

Considering that workflow execution efficiency can be input-sensitive, we further enhanced our design by adding an Input-Aware Configuration Engine Plugin. The Video Analysis workflow is input-sensitive, where different input video sizes correspond to different optimal configurations. If developers trigger the plugin, the Engine analyzes the characteristics of the input data, such as video bitrate and duration. Based on the identified features, the Engine sorts the inputs and invokes Graph-Centric Scheduler and Priority Configurator to determine the optimal resource configuration scheme for each input. When a request arrives, the Engine analyzes the input scale and allocates the input to different configurations.

To validate our design, we evaulate Video Analysis workflow using three input sizes: light, middle, and heavy. Fig. 8a shows workflow runtime with light, middle, and heavy inputs in sequence. Since MAFF does not adjust configurations for input-sensitive workflows, it may violate the SLO under heavy inputs, while our method consistently remains within SLO limits. Fig. 8b shows the average cost of the workflow under the three input sizes. Because our method can select configurations based on input size, it optimizes cost by 89.9% and 89.8% compared to MAFF and Bayesian Optimization under light input, and by 45.7% and 34.9% under heavy input.

V. Related Work

a) Serverless Resource Configuration: Configuring resources in serverless computing involves optimizing memory and CPU allocations to balance performance and cost. Offline approaches like MAFF [14] and COSE [12] rely on optimization algorithms and performance modeling to determine configurations. Bilal *et al.* [8] explores decoupling memory and CPU configurations, leveraging diverse VM types to enhance optimization but still faces challenges with workload variability. To address such dynamism, online configuration methods have emerged. Sizeless [15] uses real-time performance data and prediction models to adjust resources dynamically. FaaSDeliver [16] further refines this by monitoring per-invocation metrics and employing advanced estimators for resource allocation. However, these methods introduce overhead from continuous monitoring and data processing, potentially inflating costs for serverless applications.

b) Serverless Workflows Optimization: Due to the prevalence of workflows in serverless workloads, workflow configuration optimization has gained attention from academia and industry [17]–[19]. SLAM [20] uses distributed tracing to detect relationships between functions and leverages execution times under different memory configurations to estimate overall application execution time. Raza *et al.* [21] improve COSE for serverless workflows, optimizing performance and cost across the entire workflow. StepConf [13] provides dynamic memory allocation for serverless workflows, considering intra-function and inter-function parallelism to fully utilize the parallel capacity of serverless functions. However, these methods still do not effectively decouple resources, leaving room for further optimization.

VI. Conclusion

We propose AARC, an affinity-aware resource configuration framework for serverless workflows, capitalizing on the concept of resource decoupling within the serverless paradigm. By leveraging our framework, developers are relieved of the burden of manual serverless workflow configuration. Experimental results indicate that, during the process of searching for the optimal configuration, AARC achieves a total runtime reduction of 85.8% and 89.6% compared to Bayesian Optimization and MAFF, respectively. Additionally, it reduces resource usage by 49.6% and 61.7% while satisfying the SLO requirements.

Curvilinear Optical Proximity Correction via Cardinal Spline

Su Zheng[1], Xiaoxiao Liang[2], Ziyang Yu[1], Yuzhe Ma[2], Bei Yu[1], Martin Wong[3]
[1]Chinese University of Hong Kong, [2]Hong Kong University of Science and Technology (GZ), [3]Hong Kong Baptist University

***Abstract*—This paper presents a novel curvilinear optical proximity correction (OPC) framework. The proposed approach involves representing mask patterns with control points, which are interconnected through cardinal splines. Mask optimization is achieved by iteratively adjusting these control points, guided by lithography simulation. To ensure compliance with mask rule checking (MRC) criteria, we develop comprehensive methods for checking width, space, area, and curvature. Additionally, to match the performance of inverse lithography techniques (ILT), we design algorithms to fit ILT results and resolve MRC violations. Extensive experiments demonstrate the effectiveness of our methodology, highlighting its potential as a viable OPC/ILT alternative.**

I. Introduction

Integrated circuit (IC) manufacturing is a highly complex process that transforms raw materials into tiny chips. It begins with the design of the circuit layout, which is then transferred onto a photomask. Lithography plays a central role in printing the mask patterns onto the silicon wafer. As IC designs become more complex and feature sizes continue to shrink, the demand for well-optimized masks increases significantly.

Mask optimization [1]–[12] is a crucial process in semiconductor manufacturing, involving techniques like rule-based optical proximity correction (OPC), model-based OPC, sub-resolution assist features (SRAF), and inverse lithography technology (ILT). Rule-based OPC [13]–[15] uses predefined rules to correct distortions. Model-based OPC [16]–[18] adopts lithography simulation to guide the correction. SRAFs [19] are small, sub-wavelength features added to the mask that impact the behavior of light passing through them. ILT [20]–[30] treats mask optimization as an inverse problem and iteratively modifies the mask to get desired wafer patterns.

Although ILT is recognized for its high pattern fidelity, model-based OPC offers several advantages in terms of efficiency, reliability, and mask manufacturability. OPC is more computationally efficient and converges better, as the optimization problems of ILT are more complex and resource-intensive. Additionally, OPC primarily relies on geometric operations, whereas ILT typically requires intensive image-based processes. This allows researchers to integrate mask rule checking (MRC) into model-based OPC flows, resulting in mask patterns with improved manufacturability. While multi-beam mask writers (MBMW) can support curvilinear mask patterns, ILT-generated masks often suffer from poor manufacturability due to complex non-Manhattan geometries. Therefore, a methodology that combines the efficiency, reliability, and mask manufacturability of OPC with the high pattern fidelity of ILT would be highly beneficial.

Curvilinear OPC [31], [32] aims to bridge the gap between OPC and ILT by allowing curvilinear mask shapes in OPC. It maintains the ability to handle curvilinear shapes and any-angle edges while having lower computational complexity than ILT. Furthermore, it can produce more manufacturable masks, as the mask patterns can be optimized to better comply with mask rules. This approach strikes a balance between the simplicity of OPC and the precision of ILT, providing a more practical solution for mask optimization.

In this paper, we propose a novel curvilinear OPC framework, **CardOPC**. By representing mask patterns with control points connected through cardinal splines, our approach allows for flexible and precise mask representation. This method leverages the inherent smoothness and adaptability of splines to accurately capture intricate geometries. As illustrated by Fig. 1, the control point representation in curvilinear OPC can inherit the advantage of fewer variables from traditional OPC while gaining the flexibility of curvilinear shapes from ILT. Compared to the existing methods using Bézier splines [31], [32], cardinal splines offer significant advantages, particularly in terms of computational efficiency, without sacrificing the strengths of Bézier splines like local control and smoothness. This reduces the computational overhead and simplifies the optimization process.

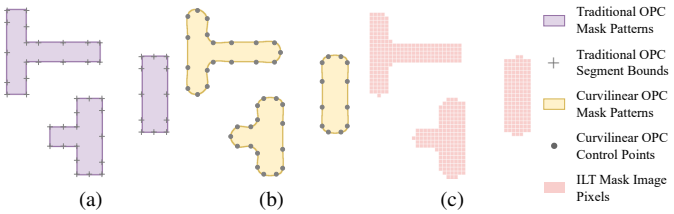

Fig. 1 Illustration of the mask pattern representation in (a) traditional OPC; (b) curvilinear OPC; (c) ILT. Curvilinear OPC combines the reduced number of variables from traditional OPC and the flexibility of curvilinear shapes from ILT.

The iterative adjustment of control points, guided by lithography simulation, achieves high-quality mask optimization. This process ensures that the wafer patterns closely match the target design, minimizing deviations that could affect the quality of products. The utilization of control points and splines can maintain a small number of variables while being able to optimize complex shapes, offering superior efficiency and adaptability in mask optimization.

For the manufacturability of masks, we propose comprehensive methods for checking MRC violations, covering width, space, area, and curvature rules. We demonstrate that the analytical spline-based representation simplifies mask rule checking and makes curvilinear OPC superior to ILT in terms of MRC. Additionally, our framework incorporates techniques to fit ILT results and resolve MRC violations, positioning it as a promising alternative to traditional ILT methods. By integrating ILT fitting capabilities, our approach can leverage the strengths of ILT while mitigating its limitations. This hybrid approach allows for more robust and effective mask optimization, combining the best aspects of both OPC and ILT.

The major contribution of this paper can be summarized as follows:

- We propose a curvilinear OPC framework based on cardinal splines. It combines the computational efficiency of traditional OPC and the flexibility of ILT.
- We derive the methods for curvilinear mask rule checking, which are the foundation of curvilinear OPC's advantages in addressing MRC violations.
- By integrating ILT fitting capabilities, the framework leverages the strengths of ILT while mitigating its limitations, offering a more robust and effective mask optimization solution.
- Extensive experiments reveal the superiority of the proposed framework over existing methods, showcasing higher precision, better scalability, and greater efficiency.

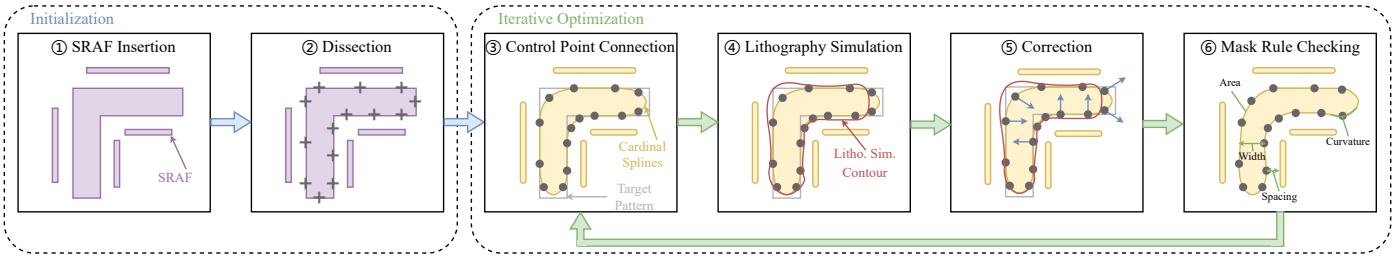

Fig. 2 Overview of our CardOPC. In the initialization phase, we ① insert SRAFs and ② dissect the polygons as traditional OPC does. The segments are converted to the control points of cardinal splines. During the optimization phase, we ③ connect the control points with cardinal splines to form the mask patterns, which are subsequently input to the ④ lithography simulation engine. According to the lithography simulation contours, we ⑤ estimate the edge displacement and correct the distortions by moving the control points. After that, ⑥ mask rule checking and MRC violation resolving are performed to ensure the mask manufacturability.

II. Preliminaries

A. Lithography Simulation

Lithography simulation is a crucial step in mask optimization, essential for obtaining the desired printed patterns on the wafer. The process starts with the input mask $\boldsymbol{M}$, which is projected through an optical system to form the aerial image $\boldsymbol{I}$. For example, the Hopkins diffraction model [33] can be employed to efficiently approximate the projection behavior. In this model, the aerial image $\boldsymbol{I}$ is obtained by applying a set of optical kernels $\boldsymbol{H}$ to the mask $\boldsymbol{M}$ with:

$$\boldsymbol{I}(x,y) = \sum_{k=1}^{N_h} w_k \left| \boldsymbol{M}(x,y) \otimes \boldsymbol{h}_k(x,y) \right|^2 . \tag{1}$$

N_h is the number of optical kernels, $\boldsymbol{h}_k$ is the k-th optical kernel in $\boldsymbol{H}$, and w_k is the corresponding weight. $\boldsymbol{I}$ can be binarized using the intensity threshold I_{th} that indicates the exposure level. After the binarization, the contour $\boldsymbol{C}$ of the lithography simulation result can be extracted and utilized to guide the OPC process.

B. Optical Proximity Correction

When light passes through a photomask and projects onto a wafer, various optical phenomena such as diffraction and interference can cause deviations from the intended pattern. These deviations, known as optical proximity effects, can lead to issues such as line width variations and pattern displacement. These effects become more significant as feature sizes shrink, making it challenging to achieve the desired pattern fidelity. OPC addresses this issue by modifying the mask patterns to compensate for distortions brought by lithography. Model-based OPC [17] typically involves the following steps:

1) Dissection (or fragmentation): The edges of the input polygons are dissected into smaller segments, usually with more segments around corners to allow for finer control.
2) SRAF insertion: SRAFs are inserted based on rules regarding the width and distance of the assist features from the main features, in order to improve the printability and process window.
3) Iterative optimization: The algorithm iteratively retrieves lithography simulation results and adjusts the segments to minimize edge placement error (EPE) violations.

EPE is a metric that evaluates the difference between the lithography simulation contour and the target pattern. To calculate EPE, a series of points are sampled along the edges of the target design, and the distance between each point's position in the target pattern and its position in the lithography simulation contour is measured. If the EPE of a point exceeds a specified threshold, it is counted as an EPE violation. L2 is another way to estimate the error of the printed patterns. It is the sum of the squared errors between the lithography simulation result and the target pattern. Furthermore, under varying lithography conditions, the printed patterns can be different. Therefore, process variation band (PVB) is also widely adopted as a metric of OPC, which evaluates the maximum discrepancy between the printed patterns under varying process conditions.

C. Mask Rule Checking

Mask Rule Checking (MRC) is a common practice in the semiconductor industry to ensure the manufacturability of photomask data before mask writing. Traditional MRC checks the rectilinear mask patterns for compliance with mask rules, such as minimum feature sizes, minimum distances, corner-to-corner distance, etc. As the industry moves towards curvilinear mask shapes to improve printed patterns, the traditional MRC approach needs to be adapted.

Reference [34] introduces the following curvilinear mask rules:

1) Spacing and width constraints: These rules ensure minimum distances between patterns and minimum widths of the shapes.
2) Area constraint: It accounts for the resolution limits, as the patterns may fail to print reliably if they are too tiny.
3) Curvature constraint: This rule limits the range of the curvilinear patterns' curvatures to ensure reliability.

Combining these constraints provides a comprehensive set of rules to ensure the manufacturability of curvilinear mask patterns.

III. CardOPC Methodology

A. Overview

Fig. 2 outlines the proposed curvilinear OPC flow. Initially, we insert SRAFs into the mask and dissect the edges of polygons into segments, following traditional OPC. These segments are then transformed into the control points. During optimization, these control points are connected using cardinal splines to generate mask patterns, which are subsequently fed into lithography simulation. Based on the lithography simulation contours, edge displacements are estimated, and distortions are corrected by adjusting the control points. Finally, mask rule checking and MRC violation resolving are performed to ensure the manufacturability of the mask.

B. Initialization

Fig. 3 summarizes the initialization phase of CardOPC. Fig. 3(a) shows an example of simple rule-based SRAF insertion. It creates an SRAF with a length of $l_s = r \times l_m$, where l_m is the length of the main pattern edge and r is a constant that controls the ratio between the SRAF and main pattern. The SRAF is placed at a distance of d_{ms} from the main pattern. Note that SRAF insertion can

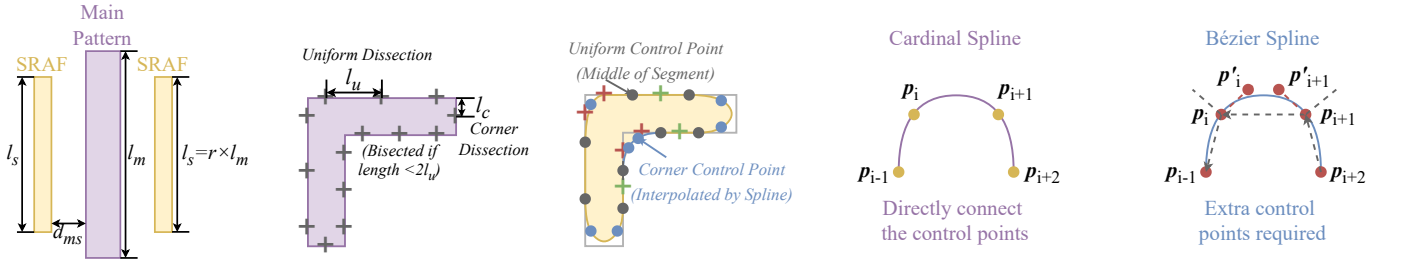

Fig. 3 Illustration of the initialization phase of our curvilinear OPC flow. (a) An example of simple rule-based SRAF insertion. The SRAF is placed at a certain distance from the main pattern, with a shorter length than the main pattern. (b) Basic dissection method of our OPC flow. It creates shorter segments around corners, and longer segments for the remaining parts of the edges. (c) Generation of control points. Most control points are chosen as the middle points of the segments. However, around corners, it interpolates the segment boundary points with cardinal splines to generate the control points.

Fig. 4 Comparison between cardinal splines and Bézier splines in curvilinear OPC. Using cardinal splines, the curve can pass through all the control points $\boldsymbol{p}_{i-1}$, $\boldsymbol{p}_i$, $\boldsymbol{p}_{i+1}$, and $\boldsymbol{p}_{i+2}$. However, when using Bézier splines, two extra control points $\boldsymbol{p}'_i$ and $\boldsymbol{p}'_{i+1}$ should be generated to ensure that the curve can pass through $\boldsymbol{p}_i$ and $\boldsymbol{p}_{i+1}$. This introduces non-negligible computational overhead.

also be completed by calling external tools (e.g. Calibre) or fitting ILT results (see Section III-G). Fig. 3(b) demonstrates our basic dissection method. Specifically, it creates shorter segments with a length of l_c around corners, where finer control is needed, and longer segments with a length of l_u for the remaining parts of the edges. Fig. 3(c) illustrates the generation of control points. Most control points are chosen as the middle points of the segments obtained from the dissection step. However, around corners, it interpolates neighboring segment boundary points using cardinal splines to generate the control points for the corner regions. Additionally, we also convert the SRAFs to cardinal splines to achieve a uniform pattern representation.

C. Cardinal Splines for Control Point Connection

Cardinal spline is a type of spline that is used in mathematics and computer graphics to create smooth and flexible shapes. This type of interpolating spline can pass through a given set of control points. This feature makes cardinal splines particularly useful for creating smooth curves that follow a specified path.

In this paper, we adopt cardinal splines for the following reasons:

1) The curve passes through each control point, ensuring that the shape of the curve is influenced directly by these points.
2) Cardinal splines include a tension parameter s that controls the tightness of the curve. This allows users to finetune the curvilinear shapes without moving the control points.
3) The tangents, normals, and curvatures of cardinal splines can be analytically computed, ensuring efficient edge displacement checking and mask rule verification in curvilinear OPC.

To connect two points $\boldsymbol{p}_i = (x_i, y_i)$ and $\boldsymbol{p}_{i+1} = (x_{i+1}, y_{i+1})$ with cardinal spline, we need their predecessor $\boldsymbol{p}_{i-1}$ and successor $\boldsymbol{p}_{i+2}$. Any point between $\boldsymbol{p}_i$ and $\boldsymbol{p}_{i+1}$ can be given by:

$$\boldsymbol{p}(t) = \begin{bmatrix} 1 & t & t^2 & t^3 \end{bmatrix} \begin{bmatrix} 0 & 1 & 0 & 0 \\ -s & 0 & s & 0 \\ 2s & s-3 & 3-2s & -s \\ -s & 2-s & s-2 & s \end{bmatrix} \begin{bmatrix} \boldsymbol{p}_{i-1} \\ \boldsymbol{p}_i \\ \boldsymbol{p}_{i+1} \\ \boldsymbol{p}_{i+2} \end{bmatrix}, \quad t \in [0,1],\ \boldsymbol{p}(0) = \boldsymbol{p}_i,\ \boldsymbol{p}(1) = \boldsymbol{p}_{i+1}. \tag{2}$$

In practice, we connect each pair of control points $(\boldsymbol{p}_i, \boldsymbol{p}_{i+1})$ by sampling multiple points in $t \in [0,1]$ evenly. For simplicity, we can represent equation (2) using $\boldsymbol{p}(t) = \begin{bmatrix} 1 & t & t^2 & t^3 \end{bmatrix} \boldsymbol{S}_{card}\, \boldsymbol{P}_{i-1:i+3}$. The computation can be accelerated by GPU using PyTorch.

Fig. 4 compares cardinal splines and Bézier splines in curvilinear OPC. With cardinal splines, the curve can seamlessly traverse all the control points, namely $\boldsymbol{p}_{i-1}$, $\boldsymbol{p}_i$, $\boldsymbol{p}_{i+1}$, and $\boldsymbol{p}_{i+2}$. Conversely, Bézier splines, necessitate the generation of two additional control points, $\boldsymbol{p}'_i$ and $\boldsymbol{p}'_{i+1}$, to guarantee the passage through $\boldsymbol{p}_i$ and $\boldsymbol{p}_{i+1}$ [34]. This requirement incurs a non-trivial computational overhead.

D. Lithography Simulation

Our experiments involve two lithography simulation tools. One of them is from the ICCAD-13 contest [35], which is implemented using equation (1) with GPU acceleration [36]. The other one is Calibre, with the same settings as the previous works [8], [9].

E. Correction

As introduced by [37], the primary goal of OPC is to minimize the edge placement error (EPE) by modifying mask edges. Given E EPE checking points, we can represent the EPEs with a function $\boldsymbol{f}_{EPE}(\boldsymbol{M})$, which contains the distances between checking points' positions in the target pattern and their positions in the lithography simulation contour. It can be decomposed using Taylor expansion:

$$\boldsymbol{f}_{EPE}(\boldsymbol{M}_{\tau+1}) = \boldsymbol{f}_{EPE}(\boldsymbol{M}_\tau) + \boldsymbol{f}'_{EPE}(\boldsymbol{M}_\tau) \times \boldsymbol{\Delta M}_\tau + \epsilon(\boldsymbol{M}_\tau), \tag{3}$$

where τ is the current iteration, $\boldsymbol{M}_\tau$ is the current mask, $\boldsymbol{\Delta M}_\tau$ is the modification of the mask at the current iteration, and $\epsilon(\boldsymbol{M}_\tau)$ represents the high order terms. To guarantee a manageable complexity, the high-order terms can be ignored, and equation (3) becomes:

$$\boldsymbol{f}_{EPE}(\boldsymbol{M}_{\tau+1}) \approx \boldsymbol{f}_{EPE}(\boldsymbol{M}_\tau) + \boldsymbol{f}'_{EPE}(\boldsymbol{M}_\tau) \times \boldsymbol{\Delta}\text{Positions}_\tau. \tag{4}$$

$\boldsymbol{\Delta M}_\tau$ in equation (3) becomes $\boldsymbol{\Delta}\text{Positions}_\tau$ in equation (4), which represents the moving distance of the segments or control points. The matrix $\boldsymbol{f}'_{EPE}(\boldsymbol{M}_\tau)$ reflects how movements affects the EPE. Given D segments or control points, $\boldsymbol{f}'_{EPE}(\boldsymbol{M}_\tau)$ can be defined as:

$$\boldsymbol{f}'_{EPE}(\boldsymbol{M}_\tau) = \begin{bmatrix} \frac{\partial e_1}{\partial d_1} & \frac{\partial e_1}{\partial d_2} & \cdots & \frac{\partial e_1}{\partial d_D} \\ \frac{\partial e_2}{\partial d_1} & \frac{\partial e_2}{\partial d_2} & \cdots & \frac{\partial e_2}{\partial d_D} \\ \cdots & \cdots & \cdots & \cdots \\ \frac{\partial e_E}{\partial d_1} & \frac{\partial e_E}{\partial d_2} & \cdots & \frac{\partial e_E}{\partial d_D} \end{bmatrix}, \tag{5}$$

where $\frac{\partial e_i}{\partial d_j}$ is the partial derivative of the i-th EPE with respect to the moving distance of the j-th segment or control point. Since our target

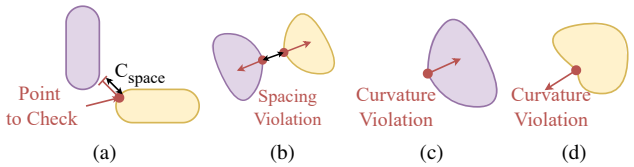

Fig. 5 Illustration of mask rule checking and MRC violation resolving. (a) shows how to create a line segment to test the spacing rule violation. (b) moves the control points to resolve spacing rule violations. (c) and (d) resolve curvature rule violations by moving the control points in and out, respectively.

is to make $\boldsymbol{f}_{EPE}(\boldsymbol{M}_{\tau+1}) = 0$, the moving distance of segments or control points at each iteration can be given by:

$$\boldsymbol{\Delta}\text{Positions}_{\tau} = -\boldsymbol{f}'_{EPE}(\boldsymbol{M}_{\tau})^{-1} \times \boldsymbol{f}_{EPE}(\boldsymbol{M}_{\tau}). \tag{6}$$

In a basic OPC solver, we can check EPE for each segment or control point, which means that $E = D$. Moreover, we can assume that $\frac{\partial e_i}{\partial d_i}$ is a constant and $\frac{\partial e_i}{\partial d_j} = 0$ if $i \neq j$. Under these settings, $\boldsymbol{f}'_{EPE}(\boldsymbol{M}_{\tau})^{-1}$ becomes a diagonal matrix $\boldsymbol{f}'_{EPE}(\boldsymbol{M}_{\tau})^{-1} = \gamma \boldsymbol{I}$, where γ is the moving distance of each segment or control point. To improve the moving smoothness and mimic multi-segment solvers, we can take a weighted average on the moving distances/directions of neighboring points. For instance, given moving distance Δd_i from equation (6) and $2W + 1$ neighboring points $\{d_{i-W}, d_{i-W+1}, ..., d_{i+W}\}$ from the same shape, the final moving distance $\overline{\Delta d_i}$ is:

$$\overline{\Delta d_i} = \sum_{k=-W}^{W} w_k \Delta d_k. \tag{7}$$

In curvilinear OPC, to guarantee the support of any-angle edges, we need to calculate both the moving distance Δd_i and the moving direction $\boldsymbol{n}_i$ for each control point. We use the normal vectors $\boldsymbol{n}(t)$ of the cardinal splines as the moving directions, which can be derived from the derivatives, $\boldsymbol{g}(t) = \boldsymbol{p}'(t)$, with the following equations:

$$\boldsymbol{g}(t) = \begin{bmatrix} 0 & 1 & 2t & 3t^2 \end{bmatrix} \boldsymbol{S}_{card} \boldsymbol{P}_{i-1:i+3}. \tag{8a}$$

$$\overline{\boldsymbol{g}}(t) = (\overline{g}_x(t), \overline{g}_y(t)) = \frac{\boldsymbol{g}(t)}{\|\boldsymbol{g}(t)\|}, \tag{8b}$$

$$\boldsymbol{n}(t) = (n_x(t), n_y(t)) = (-\overline{g}_y(t), \overline{g}_x(t)). \tag{8c}$$

The moving direction $\boldsymbol{n}_i$ can be given by the normal vector at the corresponding t, and the moving step is $\Delta d_i \boldsymbol{n}_i$. In practice, we can take the weighted average among $\Delta d_i \boldsymbol{n}_i$ rather than Δd_i to allow the control points to move in more directions, providing a higher degree of freedom. Note that GPU acceleration is also applicable for computing moving directions. Additionally, our curvilinear OPC framework is compatible with other gradient-based OPC algorithms like the MEEF-based OPC [38] and differentiable OPC [12] methods.

F. Mask Rule Checking and MRC Violation Resolving

Mask Rule Checking. We focus on the following mask rules:

1) Spacing rule: The spacing between two shapes should be larger than the spacing constraint C_{space}.
2) Width rule: The width of each shape should not be smaller than the width constraint C_{width}.
3) Area rule: The area of each shape should exceed the area constraint C_{area}.
4) Curvature rule: The curvature at each point should be less than the curvature constraint C_{curv}.

Algorithm 1 Fitting Method for ILT-Optimized Masks

Input: ILT-optimized mask image $\boldsymbol{M}$, cardinal spline function $\boldsymbol{F}(\cdot)$, ratio r_Q and r_R, learning rate α.

```
//Initialization;
Q = ∅;   //Control point set;
R = ∅;   //Reference point set;
for each shape S_i in the mask image M do
    Extract the boundary points of S_i, denoted by P_i;
    Sample r_Q|P_i| points from P_i evenly, add them to Q;
    Sample r_R|P_i| points from P_i evenly, add them to R;
end for
//Optimization;
for k ∈ {1, 2, ....., K} do //K iterations in total;
    Interpolate Q with F(·) to have |R| points;
    Compute the loss L(Q, R) = ‖F(Q) − R‖²;
    Optimize Q with Q ← Q − α ∂L(Q,R)/∂Q;
end for
return Q;
```

Among these rules, we provide basic solutions for space, width, and area checking, which are common topics in existing works like mask rule checking [39] and design rule checking [40]. We leave the well-optimized checking of these rules for future works. As for the curvature rule, we derive the analytical method for its checking, which is efficient because it can be accelerated by GPU.

For spacing and width checking, we construct an R-tree [41] using all shapes of the mask patterns. R-tree is a type of data structure used for indexing multi-dimensional information such as geographical coordinates, rectangles, or polygons. It stores spatial objects in a hierarchical manner using bounding rectangles. Each node in the tree represents a bounding rectangle that contains its child nodes. This structure allows for efficient querying of spatial data, such as querying the nearest shape and finding all objects that intersect a given area.

As demonstrated by Fig. 5(a), to check whether a point has a spacing violation, we build a line segment with a length of C_{space} that starts from the checking point, with its direction specified by its normal vector. If the line segment touches a shape, it has a spacing violation. It can be done efficiently using R-tree's querying algorithm. We implement width checking in a similar way, but create the line segment in the directions opposite to the point's normal vector.

The area of each shape can be calculated by the shoelace formula, which enables the checking of the area constraint. Both R-tree construction and area computation are provided by Shapely.

The curvature at a point can be defined as:

$$\boldsymbol{\kappa}(t) = \begin{vmatrix} p'_x(t) & p''_x(t) \\ p'_y(t) & p''_y(t) \end{vmatrix} / \|\boldsymbol{p}'(t)\|^3, \tag{9}$$

where $\boldsymbol{p}'(t) = (p'_x(t), p'_y(t))$, $\boldsymbol{p}''(t) = (p''_x(t), p''_y(t))$, $\boldsymbol{p}'(t)$ is calculated by equation (8), and $\boldsymbol{p}''(t)$ is given by:

$$\boldsymbol{p}''(t) = \begin{bmatrix} 0 & 0 & 2 & 6t \end{bmatrix} \boldsymbol{S}_{card} \boldsymbol{P}_{i-1:i+3}. \tag{10}$$

If one point has $\boldsymbol{\kappa}(t) > C_{curv}$, it has a curvature violation. This checking is used to ensure that the mask patterns are smooth enough and friendly for mask manufacturing.

MRC Violation Resolving. When MRC violation occurs, we can address it according to its type. As shown in Fig. 5(b), when a spacing violation occurs between two points, we try to move the corresponding control points in the directions opposite to their normal vectors, enlarging the spacing between the points. In the trials, the

moving distance is chosen from small to large. The violation can usually be resolved in a few trials. For width violations, we use a similar method but move the control points in the directions specified by their normal vectors.

If an area rule violation occurs after moving the control points, we can cancel the move to avoid the violation. If it occurs after fitting ILT results, we remove the shape since it is usually a small and non-printable pattern.

When a curvature violation occurs at a point, we try to move the corresponding control point in and out according to the normal vector. Fig. 5(c) and Fig. 5(d) visualize this strategy. The violation can usually be resolved within a few attempts.

G. ILT-OPC Hybrid Approach

Continuous transmission mask (CTM) [12], [19], [42] is utilized to generate SRAFs for model-based OPC. Since CTM relies on ILT, it can serve as a hybrid method that combines ILT and OPC. However, existing methods can only generate rectilinear SRAFs according to the continuous mask intensity distribution from ILT, which can not fully utilize the ILT's ability. In this paper, we propose to fit ILT results with cardinal splines, which can mimic the complex curvilinear shapes in ILT-optimized masks, and resolve MRC violations using the strategies described in Section III-F. Our hybrid approach allows for more robust and effective mask optimization, combining the best aspects of both OPC and ILT.

As presented by Algorithm 1, our fitting method consists of the following steps:

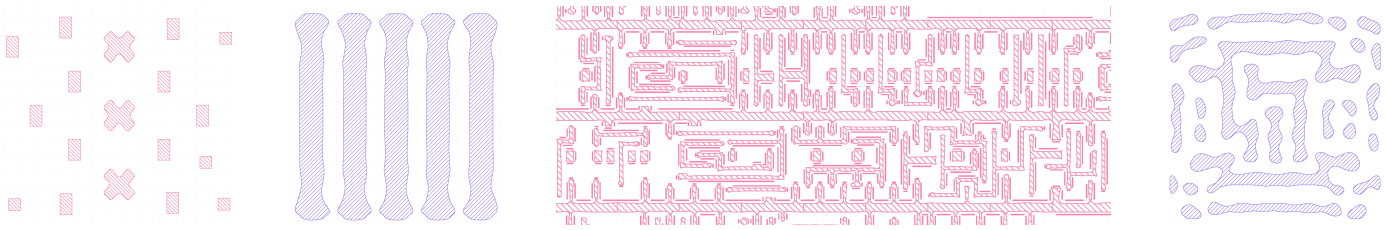
1) Initialization: For each shape $\boldsymbol{S}_i$ in the mask image $\boldsymbol{M}$, we find the contour of $\boldsymbol{S}_i$ using the border following algorithm [43] (line 5), which is already implemented in the OpenCV toolbox. After that, we uniformly sample control points $\boldsymbol{Q}$ and reference points $\boldsymbol{R}$ from each shape's contour (lines 6-7). During optimization, we move the control points using gradient descent to fit the reference points.
2) Optimization: At each optimization step, we interpolate $\boldsymbol{Q}$ using the cardinal spline function $\boldsymbol{F}(\cdot)$ given by equation (2) (line 11). With the interpolated results, we can compute the mean squared error loss (line 12) between the interpolated points $\boldsymbol{F}(\boldsymbol{Q})$ and the reference points $\boldsymbol{R}$. Finally, we move $\boldsymbol{Q}$ using gradient descent (line 13) to minimize the distance between $\boldsymbol{F}(\boldsymbol{Q})$ and $\boldsymbol{R}$.

Note that the fitting algorithm can be implemented using PyTorch so that this process can be accelerated by GPU. Optimizers like Adam [44] can be adopted for the gradient descent in our method to accelerate the convergence.

TABLE III Large-scale OPC result comparison on EPE violations and PVB (μm^2)

Testcase	#Tiles ($30 \times 30 \mu m^2$)	Calibre		SimpleOPC [45]		CardOPC	
		EPE	PVB	EPE	PVB	EPE	PVB
gcd	1	3657	35.6651	3454	37.3002	3507	34.2606
aes	144	2722	27.7226	2571	29.4301	2578	27.3485
dynamicnode	144	2088	26.1663	1941	27.1213	1923	25.5011
Average	-	2409	26.9746	2260	28.3069	**2255**	**26.4519**
Ratio	-	100.0%	100.0%	93.8%	104.9%	**93.6%**	**98.1%**

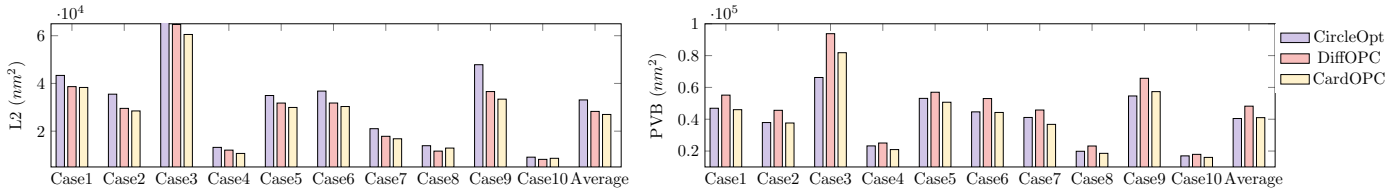
After fitting the ILT-optimized masks, we obtain the control points $\boldsymbol{Q}$ of all mask patterns. The MRC violation resolving algorithms discussed in Section III-F are employed to address the MRC violations in the curvilinear shapes.



IV. Experiments

A. Comparison with Existing Works

Previous works focus on the OPC for metal-layer and via-layer patterns [8], [9]. We adopt the same testcases as them. For the experiments on via-layer patterns, we use 13 test layout clips [46], each of which is $2 \times 2 \mu m^2$. SRAFs are inserted by Calibre before the OPC algorithm launches. For metal-layer patterns, the dataset has 10 clips, each of which is $1.5 \times 1.5 \mu m^2$. The EPE measure points are selected following conventional strategies. For via-layer patterns, the center of each edge corresponds to a measuring point. For metal-layer patterns, the EPE measure points are evenly placed on the edges along the primary direction with $60nm$ spacing.



For the via layer, we dissect the polygons with $l_c = 20nm$ and $l_u = 30nm$. The moving distance is $2nm$. For the metal layer, we dissect the polygons with $l_c = 30nm$ and $l_u = 60nm$. The moving distance is $4nm$. We use 32 optimization iterations for both layers, and decay the moving distance by a factor of 0.5 at the 16-th step. A tension parameter $s = 0.6$ is adopted for the cardinal splines.

In our experiments on the via layer, we compare our CardOPC framework with existing OPC methods such as DAMO [29], RL-OPC [8], and CAMO [9], as well as the commercial tool Calibre. For the metal-layer experiments, we compare CardOPC with RL-OPC, CAMO, and Calibre. As shown in TABLE I, our framework outperforms existing methods on the via layer, achieving a 39.7% improvement in EPE and a 0.2% enhancement in PVB. Similarly, TABLE II demonstrates that our framework surpasses existing methods on the metal layer, with a 50.0% improvement in EPE and a 4.2% enhancement in PVB. Compared to these state-of-the-art (SOTA)

(a) (b) (c) (d)

Fig. 6 Examples of our curvilinear OPC results: (a) via-layer OPC; (b) metal-layer OPC; (c) large-scale OPC; (d) ILT-OPC hybrid method.

(a) (b)

Fig. 7 Comparison between our ILT-OPC hybrid approach and SOTA methods. Our method demonstrates superior performance on the L2 metric and delivers competitive PVB results. Additionally, our approach achieves an average of 1.4 EPE violations, outperforming CircleOpt (3.9) and DiffOPC (2.2).

methods, the proposed curvilinear OPC framework offers significant advantages in EPE, along with improvements in PVB. Additionally, Fig. 6(a) and Fig. 6(b) present examples of via-layer and metal-layer OPC results, respectively, which can show that our method is able to produce smooth curvilinear main patterns.

B. Large-Scale OPC Results

We conduct experiments to verify that our CardOPC can be employed in large-scale OPC applications. Following [45], we use the `gcd`, `aes`, and `dynamicnode` layouts generated by OpenROAD [47] with NanGate 45nm PDK [48]. Each layout is cropped into $30 \times 30 \mu m^2$ tiles before we perform OPC for its metal layer. In CardOPC, we dissect the polygons with $l_c = 40nm$ and $l_u = 40nm$. The moving distance is set to $8nm$. We use 10 optimization iterations, and decay the moving distance by a factor of 0.5 at the 8-th step. A tension parameter $s = 0.6$ is adopted for the cardinal splines.

We compare our method with Calibre, which uses the same configuration in [8], [9], and runs for 20 iterations. The PVB and EPE metrics are computed by Calibre. As shown in TABLE III, CardOPC surpasses Calibre, with a 6.4% improvement in EPE and a 1.9% enhancement in PVB. Our method also outperforms the previous work [45]. These results indicate that CardOPC is promising for large-scale applications, offering advantages in EPE and PVB. As an example, Fig. 6(c) shows a local region of `gcd`'s OPC result.

C. ILT-OPC Hybrid Approach Results

Following SOTA methods like [7], [12], [49], we use the lithography source and testcases from ICCAD-13 contest [35] in this experiment. We build our ILT flow based on the OpenILT framework [36] and fit its results using our ILT-OPC hybrid approach described in Section III-G. The proposed method is compared with CircleOpt [49] and DiffOPC [12], each of which has mechanisms to avoid MRC violations like CardOPC. As shown in Fig. 7, our approach excels in the L2 metric and offers competitive PVB results. In term of EPE, it achieves an average of 1.4 EPE violations, surpassing CircleOpt (3.9) and DiffOPC (2.2). Additionally, our MRC resolving strategies successfully reduce the average number of violations from 43.8 to 0. These results can validate the effectiveness of our framework. Fig. 6(d) shows an example of our results, which is similar to the corresponding ILT result but without MRC violations.

D. Ablation Study

In this experiment, we compare Bézier [31] and cardinal splines in curvilinear OPC. The primary difference in runtime between Bézier and cardinal splines lies in the control point connection process. For the `gcd` large-scale testcase, the Bézier method takes 3.6 seconds to connect the control points of 1,776 shapes at the first iteration, while our cardinal method only needs 1.9 seconds. This results in an 89% runtime overhead for the Bézier method compared to our approach. The reason for this overhead is that the Bézier method necessitates the creation of additional points when connecting two adjacent control points, which involves extra operations such as vector rotation. In terms of performance, the Bézier method obtains an EPE of 3,532 and a PVB of 34.9088, while our cardinal method achieves an EPE of 3,507 and a PVB of 34.2606. By combining runtime and performance results, we demonstrate the superiority of our curvilinear OPC framework based on cardinal splines.

V. Conclusion

In this paper, we develop a novel curvilinear OPC framework, CardOPC. After representing the mask patterns with control points, cardinal splines are employed to connect the control points. Guided by lithography simulation, the efficient correction method enables our CardOPC to achieve a 50.0% improvement in EPE and a 4.2% enhancement in PVB when compared to the SOTA OPC method. We further demonstrate the scalability of CardOPC by testing it on large-scale layout tiles. Moreover, by fitting ILT results and resolving MRC violations, our ILT-OPC hybrid method outperforms other tested algorithms. Finally, the comparison between different splines reveals that cardinal splines can offer a faster speed and better performance than Bézier splines. CardOPC shows promise as a viable ILT/OPC alternative and opens various avenues for future curvilinear OPC research, including spline types, MRC methods, MRC violation resolution strategies, and large-scale optimization.

***Abstract*—Register Transfer Level (RTL) simulation is widely used in design space exploration, verification, debugging, and preliminary performance evaluation for hardware design. Among various RTL simulation approaches, software simulation is the most commonly used due to its flexibility, low cost, and ease of debugging. However, the slow simulation of complex designs has become the bottleneck in design flow. In this work, we explore the sources of computation overhead of RTL simulation and conclude them into four factors. To optimize these factors, we propose several techniques at the supernode level, node level, and bit level. Finally, we implement these techniques in a novel RTL simulator GSIM. GSIM succeeds in simulating XiangShan, the state-of-the-art open-source RISC-V processor. Besides, compared to Verilator, GSIM can achieve speedup of 7.34x for booting Linux on XiangShan, and 19.94x for running CoreMark on Rocket.**

***Index Terms*—RTL simulation, optimization, large-scale**

I. Introduction

Register Transfer Level (RTL) simulation is essential in hardware design. It is widely used in various aspects, including design space exploration, verification, debugging, and preliminary performance evaluation [1] [2] [3]. It has become an indispensable step in the chip development workflow.

There are currently three main approaches to RTL simulation: software simulation, FPGA prototyping, and hardware emulation. Among them, FPGA prototyping is the fastest, but debugging tools are limited. Hardware emulation offers high speed along with good debugging ability, but it is extremely expensive. Software simulation provides 100% signal visibility, low cost and ease of debugging, but is the least efficient. Despite this drawback, software simulation remains the most commonly used method for RTL simulation [2].

With the increasing scale of modern digital circuits, the simulation speed of the software approach decreases dramatically, and becomes the bottleneck in verification [4]. Table I presents the simulation speed of processors at different scales using Verilator [5], a widely used open-source simulator. In this table, "IR node" refers to nodes in the RTL graph (including registers and logic units), and "IR edge" represents the number of connections between nodes, together indicating the complexity of each processor. As shown, the simulation speed for large-scale designs is typically limited to only a few kHz. Therefore, accelerating RTL simulation would significantly benefit the workflow for large-scale designs.

However, it is challenging to accelerate RTL simulation for large-scale designs. A software RTL simulator must simulate the signal propagation across all nodes in the circuit by computation. The heavy computation is the primary cause of the slow speed of RTL simulation. ESSENT [3] proposes an essential signal simulation approach that significantly accelerates RTL simulation. We aim to further explore opportunities to reduce computation demands.

TABLE I: Verilator (single thread) simulation speed of booting Linux on different processors. The host CPU is Intel i9-9900K. stuCore is designed by undergraduate student.

Name	Configuration	IR node	IR edge	Speed
stuCore	In-Order Single-Issue	9933	17369	$\sim$ 900KHz
Rocket [6]	In-Order Single-Issue	234807	293164	$\sim$ 30KHz
BOOM [7]	Out-of-Order Triple-Issue	571038	827619	$\sim$ 9KHz
XiangShan [8]	Out-of-Order Six-Issue	6218427	9007005	$\sim$ 0.9KHz

To identify the sources of computation, we further analyze the essential signal simulation approach. Listing 2 shows the behavior of simulating a single cycle. Each node is associated with an `active` bit. During each cycle, the simulator traverses all nodes in the graph. If the `active` bit of a node is not set (Line 7), its value can be reused and the evaluation is skipped to reduce computation. Otherwise, the value of this node needs to be evaluated (Line 3). If the value changes after evaluation, its successors will be activated (Line 4-5).

```
eval1():
  update new value
cycle():
  eval1()
  eval2()
```

Listing 1: Simulation framework in Verilator.

```
1  eval1():
2    save old value
3    update new value
4    if (old != new)
5      active[succ] = true
6  cycle():
7    if (active[1]) eval1()
8    if (active[2]) eval2()
```

Listing 2: Simulation framework in ESSENT.

From the analysis above, the sources of computation can be concluded to four factors: ❶ the accessing of `active` bits, including checking and updating, ❷ the value evaluation in each node, ❸ the total number of nodes, ❹ the activity factor, which is the ratio of active nodes to the total number of nodes.

This paper proposes a novel RTL simulator, GSIM, which aims to reduce the overhead of the four factors mentioned

above through three levels of granularity, including supernode level, node level and bit level.

❶ **At the supernode level**, one challenge is to determine which nodes should be grouped into a supernode. A supernode is a set of nodes that are activated simultaneously, with the aim of reducing the activation overhead, but it may increase the activity factor. To balance this trade-off, we propose a novel partitioning algorithm to group nodes with strong correlations. This approach reduces the activation overhead while maintaining a low activity factor.

❷ **At the node level**, GSIM employs several techniques. First, GSIM eliminates redundant nodes and optimizes expressions during value evaluation by data flow analysis. Second, we observe that although inlining the value evaluation of one node into another helps to reduce the number of nodes, it may introduce additional computation. To determine whether inlining is beneficial, GSIM constructs a cost model and selects the choice with lower cost. Finally, GSIM moves reset handling to the slow path, which reduces the number of checking reset signals by orders of magnitude.

❸ **At the bit level**, we find that bits within each node may not be accessed simultaneously. By applying data flow analysis to each bit and splitting nodes according to their accessing patterns, GSIM can further reduce the activity factor.

GSIM successfully simulates XiangShan [8], the state-of-the-art open-source RISC-V processor. When booting Linux on XiangShan, GSIM achieves a 7.34x speedup compared to Verilator. When running CoreMark [9] on Rocket [6], GSIM reaches 19.94x of Verilator, outperforming the best between ESSENT [3] and Arcillator [10] by 2.52x.

II. Background and Analysis

A. RTL Simulation

To perform RTL simulation, the input design is represented as a directed graph. In this graph, each node corresponds to a register or logic unit, and each edge represents the propagation of signals between nodes. During simulation, the circuit's behavior is modeled as evaluation of signal values that propagate between nodes along the edges. The work of determining the evaluation order of nodes is called scheduling.

RTL simulation can be categorized into two types based on the scheduling policy [11]. In event-driven simulation, nodes are dynamically scheduled at runtime, with signal changes propagated as events. When the value of a node changes, an event is generated and sent to all its successors. This approach can flexibly model arbitrary delays, and is widely used in post-synthesis gate-level simulation. However, frequent scheduling in complex designs incurs high overhead. Commercial simulators like VCS [12] employ the event-driven simulation model.

In contrast, for full-cycle simulation, nodes are statically scheduled at compile time and evaluated in a fixed order at runtime. This eliminates the overhead of runtime scheduling. Although the minimum granularity of simulation is one clock cycle, it still suffices to perform functional verification for large-scale designs like processors. The open-source simulator Verilator [5] employs full-cycle simulation. Generally, full-cycle simulation is faster than event-driven simulation [13].

In a basic implementation of full-cycle simulation, to build a directed acyclic graph (DAG), registers are often split into two nodes (one for reading and one for writing) to break cycles in the graph. Then a topological sort is performed on this graph. In each cycle, all nodes are evaluated in the topological order, as shown in Listing 1. Verilator employs this approach.

To further improve the efficiency of full-cycle simulation, ESSENT [3] introduces an essential signal simulation approach. This approach is effective, because only a few nodes have their value changed in a cycle. Listing 2 shows the implementation. Each node is associated with an `active` bit. During a cycle, all `active` bits are examined. A node is evaluated only when its `active` bit is set. If the value of the node changes after evaluation, the active bits of its successors will be set to indicate the need of re-evaluation.

B. Modeling and Analysis

Inspired by ESSENT, we further explore optimization potential by identifying the sources of computation. According to the simulation framework in Listing 2, the simulation overhead per cycle T can be modeled as $T = ((E + A_{succ}) * af + A_{exam}) * N$, where E is the computation overhead of value evaluation in a node, A_{succ} is the overhead of activating successors, af is the activity factor, A_{exam} is the overhead of examining the `active` bit, and N is the number of nodes.

E represents the computation required to evaluate the value of a node based on its predecessors. It contains various operations, including arithmetic, shifting, bitwise, and conditional operations. A_{succ} and A_{exam} are introduced by the essential signal simulation approach. Each node requires an additional examination before evaluation and an activation step after evaluation. The former adds a branch instruction, while the latter involves a branch and several memory access instructions. N and af are determined by the circuit design. They together indicate the number of nodes with the `active` bit set in a cycle, which require evaluation. As the complexity of the circuit increases, N may grow a lot, but af remains low in most designs. According to our evaluation, af is about 4.61% when running CoreMark on XiangShan.

Although E, A_{succ}, A_{exam} and af seem negligible, their impact on T is amplified by a large N. Therefore, reducing N can significantly improve simulation performance. Additionally, small improvements on the other factors can still yield substantial performance gains. For example, during the simulation of Xiangshan, 82.26% of all executed branch instructions are dedicated to examining the `active` bits. Therefore, it is important to further optimize these factors.

III. GSIM Design

To accelerate RTL simulation, GSIM employs a series of optimization techniques targeting the factors above at three levels: super-node level, node level, and bit level. Note that some techniques may improve one factor while degrading another. In such cases, GSIM balances the trade-offs among these factors with corresponding strategies.

A. Supernode Level Optimization

Checking the `active` bit of each node separately will incur high overhead for A_{exam} (Listing 2). To reduce A_{exam}, nodes are typically grouped into supernodes [3]. Each supernode is associated with a single `active` bit. Nodes inside a supernode share an `active` bit and are evaluated together (Listing 3). As a result, activating any node within a supernode leads to the evaluation of all nodes in it. We define the size of a supernode to be the number of nodes inside it. A supernode with larger size helps to reduce A_{exam}, but it may increase af.

```
eval_super1():
  eval1()
  eval2()
cycle():
  if (active[1])
    eval_super1()
```

Listing 3: Supernode level activation.

```
if (active[7:0] != 0)
  if (active[1])
    eval_super1()
  if (active[2])
    eval_super2()
  ...
```

Listing 4: Check multiple bits with a single condition.

To keep af low, GSIM tries to group nodes that are likely to be activated simultaneously into the same supernode. We observe that nodes in close proximity in the RTL graph often exhibit strong correlations and tend to be activated together. To find such nodes, a traditional graph partitioning algorithm may be a solution, such as Kernighan's Algorithm [14]. However, the goal of the traditional algorithm usually conflicts with building supernodes. This is because it tries to minimize the number of cut edges between partitions. It tends to divide nodes connected with a small number of edges into different partitions (the left of Figure 1). However, such nodes may be activated together during simulation, and they should be grouped into the same supernodes (the right of Figure 1).

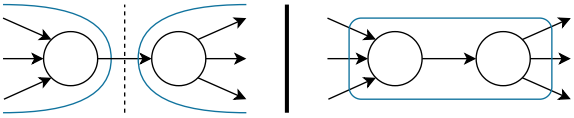

Fig. 1: Traditional partitioning algorithms fail to group nodes connected with few edges into the same partitions.

To address this challenge, GSIM employs an enhanced version of Kernighan's Algorithm. Specifically, the enhanced algorithm initially groups nodes with strong correlations based on certain rules, protecting them from being divided into different supernodes in the subsequent steps. These rules are derived from the following observations: ❶ A node with an out-degree of 1 is typically activated along with its successor. ❷ A node with an in-degree of 1 is usually activated when its predecessor is activated. ❸ Siblings with the same predecessors are always activated simultaneously. Subsequently, GSIM adopts the original Kernighan's Algorithm to construct supernodes. The maximum size of a supernode can be controlled by a parameter in the algorithm.

Additionally, to take advantage of the low af, GSIM speculatively assumes multiple `active` bits are clear, and uses a single condition to examine them on the fast path (Line 1 in Listing 4). If the condition holds, GSIM can skip the individual examination of each `active` bit to reduce A_{exam}.

B. Node Level Optimization

Redundant node elimination. To reduce N, we eliminate the following types of redundant nodes (Figure 2) by applying data flow analysis. ❶ **Alias Nodes** are duplicate nodes representing the same signal. ❷ **Dead Nodes** are nodes not used by other nodes. ❸ **Shorted Nodes** are nodes not selected due to another signal. ❹ **Unused Registers** are registers not used by other nodes, but they may be self-updated.

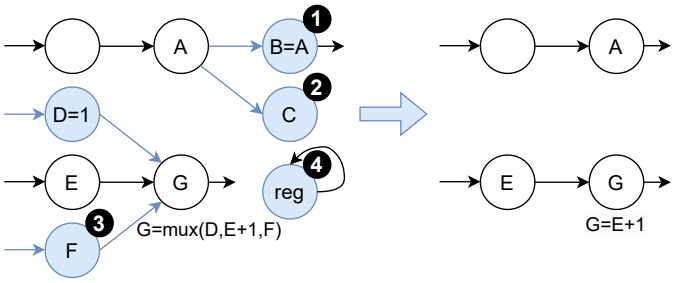

Fig. 2: Examples of eliminating redundant nodes.

Node inline and extraction. For non-redundant nodes, GSIM considers whether to inline the evaluation of one node into its successors. This is a trade-off between N and E. Extracting common parts of evaluation can reduce E by reusing the value stored in an extra intermediate node. For example, in the left part of Figure 3, node B stores the result of f(A), and its successors (C and D) can directly use the value in B without re-evaluating f(A). Conversely, reducing N may increase E. As shown in the right part of Figure 3, nodes C and D must re-evaluate f(A) without the intermediate node.

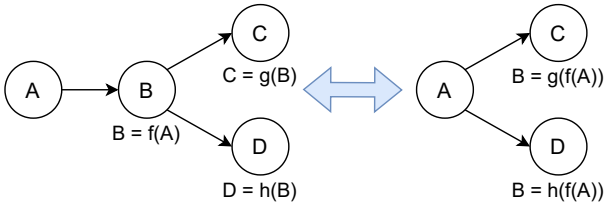

Fig. 3: Transform between node inline and extraction.

To address the trade-off above, GSIM models the cost of each decision and chooses the best one. Specifically, GSIM estimates the evaluation overhead of f(A), $cost(\text{f(A)})$, and the overhead of introducing a new node, $cost_{node}$, in terms of the number of operators involved, and the reference count of f(A), $\#\text{f(A)}$. If $cost(\text{f(A)}) \times \#\text{f(A)} > cost(\text{f(A)}) + cost_{node}$, f(A) is extracted as an extra node to reduce E. Otherwise, f(A) is inlined to reduce N.

Activation overhead optimization. To optimize A_{succ}, ESSENT replaces the condition checking (Line 4 and 5 in Listing 2) with logical operations to relieve the pressure of the host branch predictor [3]. However, we find that it may cause

performance degradation when there are too many successors to activate, since this technique introduces extra operations for each successor to activate. To handle this trade-off, GSIM models the cost of each decision and chooses the optimal one, which is similar to the approach mentioned above.

Reset handling optimization. During the evaluation of each register with reset port, the reset signal must be checked every cycle to determine the value to be written (Listing 5). However, the number of reset signals is usually small, and they are hardly valid during simulation. Based on this observation, GSIM first speculatively assumes reset does not happen, and updates the register with the value evaluated based on its predecessors (Listing 6). This can remove the checking of reset signals from the fast path during evaluation, which helps to reduce E. After that, the reset signals are checked at the end of every cycle. In this way, GSIM can reduce the number of checking reset signals by orders of magnitude, from the number of registers with reset port to the number of reset signals in the design.

```
eval1():
  reg1 = reset ? 0 : new_val
  ...
cycle():
  if (active[1]) ...
  ...
```

Listing 5: Before reset optimization.

```
eval1():
  reg1 = new_val
  ...
check_reset():
  if (reset)
    reg1 = 0
    reg2 = init_val2
    ...
    activate_all_succ()
```

Listing 6: After reset optimization.

Expression simplification. GSIM employs various techniques to optimize expressions during evaluation, such as constant propagation and recognition of complex patterns. For example, it is common to generate a one-hot signal and check each bit of it in RTL design. This may result in two nodes: one to evaluate `B = 1 << A`, and the other to evaluate `C = bits(B, k, k)`, where `k` is a constant. GSIM detects this pattern and optimizes it to `C = (A == k)`.

C. Bit Level Optimization

An activation is unnecessary if the value of the node remains the same after evaluation. We find that in many long signals, only certain bits change each cycle. If a successor only uses the unchanged bits, activating it will be unnecessary. As shown in the left part of Figure 4, if node A changes while B and C are inactive, both D and E will change, leading to the activation of F and G. However, the value of G remains unchanged, since it does not depend on A. Therefore, the activation of G is unnecessary. According to our statistics, among nodes with multiple bits in XiangShan, 23.7% of them are composed of concatenations from other nodes, and 23.2% of the references to these nodes only access a subset of their bits.

To address this issue, GSIM adopts a bit-level node splitting policy. Specifically, GSIM applies data flow analysis to each bit. For a node P_0, if there exists a bit set S in P_0 and a path $P_0P_1 \dots P_n$, where P_n does not depend on $\overline{S}$ (the complementary bit set of S in P_0), GSIM can split all nodes on the path according to S and $\overline{S}$. In this way, we can remove the unnecessary activation of node P_n when only bits in $\overline{S}$ change, thereby reducing af. As shown in the right part of Figure 4, node A will no longer trigger the activation of G.

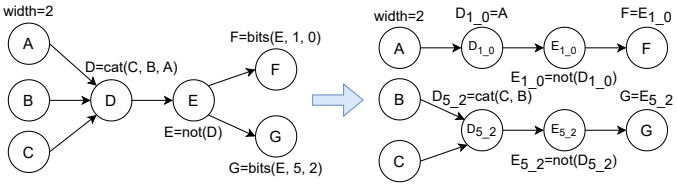

Fig. 4: Example of splitting nodes at the bit level.

Note that although splitting nodes may increase N, we can apply node level optimization techniques mentioned above to the generated nodes.

D. Implementation Details

GSIM accepts circuits in Firrtl [15], an intermediate representation for hardware that various HDL can be converted into. GSIM includes a Firrtl parser that converts the input design into an abstract syntax tree (AST) and further transforms it into a graph. Most optimizations are performed on this graph. After optimization, GSIM emits C++ simulation code. Additionally, GSIM allows users to adjust the maximum size of a supernode from the command line.

IV. Evaluation

A. Evaluation Setup

We compare GSIM with the following simulators. ❶ **Verilator** [5] is the most widely used open-source Verilog simulator. We use version v5.026 with `-O3` flag to generate C++ files. It also supports multi-threaded simulation. ❷ **Arcilator** [10] is an MLIR [16] simulator developed as part of the CIRCT [17] project. ❸ **ESSENT** is a single-threaded Firrtl [15] simulator, with `-O3` flag to generate C++ files.

We evaluate the simulators on processors in Table I. Table II shows their versions. All processors are mainly developed in Chisel [18]. For a few Verilog modules, we replace them with Chisel implementations. As shown in Figure 5, each design is first converted into Chirrtl IR, and then translated into Firrtl, Verilog, and MLIR files using the FIRRTL [15] compiler or CIRCT [17] compiler. ESSENT and GSIM accept Firrtl as input, Verilator accepts Verilog, and Arcilator accepts MLIR.

TABLE II: The version of the processors.

	commit hash (truncated)	commit date
Rocket	e3773366a5c473b6b45107f037e3130f4	Sep 26, 2023
BOOM	9459af0c1f6847f8411622dac770ac78f	Oct 17, 2023
XiangShan	a42a7ffe5e4be903c75d53cf243761ce7	Mar 1, 2024

We choose CoreMark [9] and Linux as the software workloads. The former exhibits hot spots, while the latter does

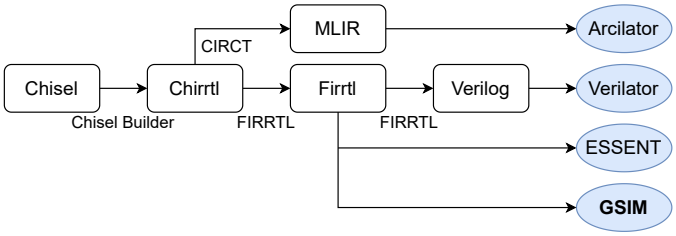

Fig. 5: The input of different simulators.

not. The host configuration is Intel 8-core i9-9900K CPU at 3.60GHz with 64GB of RAM. The host OS is Debian 12.

B. Overall Performance

Figure 6 shows the performance of different simulators on various processors and software workloads. Since Verilator is the most widely used open-source RTL simulator and successfully simulates all selected processors, we use Verilator as the baseline and normalize the other results to it.

In terms of correctness, aside from Verilator, GSIM is the only simulator that can successfully simulate XiangShan. ESSENT and Arcilator fail to simulate some of the designs due to errors during emitting C++ files or wrong simulation results. For performance, GSIM achieves speedup of 7.34x for booting Linux on XiangShan, and 19.94x for running CoreMark on Rocket. We also evaluate Verilator with multi-threading. GSIM significantly outperforms multi-threading Verilator on most of the designs.

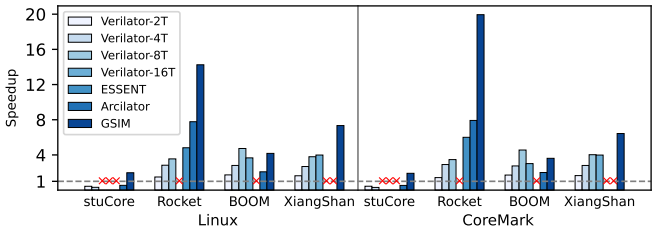

Fig. 6: Overall performance. The speedup is normalized to the single thread version of Verilator. '2T' means simulating with 2 threads. '×' means failing to perform the simulation.

C. Running SPEC CPU2006

In CPU simulation, checkpoints have long been used to accelerate performance evaluation [8] [19]. We sample SPEC CPU2006 [20] using SimPoint [21] and extract 40M-instruction segments to create checkpoints. The selected benchmarks cover various types of workloads, including streaming and irregular memory access, integer and floating-point computation, branch-intensive operations, and instruction-cache-intensive [22]. We run these checkpoints on XiangShan using both Verilator and GSIM. As shown in Figure 7, GSIM is 3.72x faster than single-threaded Verilator across all checkpoints on average, and achieves an average 1.18x of 8-threaded Verilator.

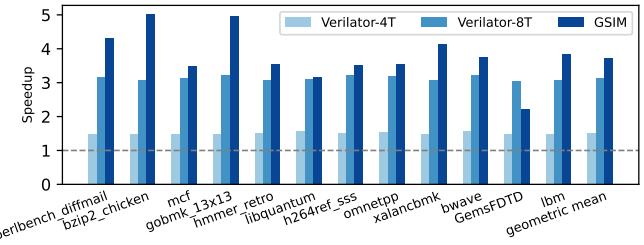

Fig. 7: SPEC CPU2006 performance on XiangShan. The speedup is normalized to the single thread version of Verilator.

D. Performance Breakdown

To evaluate the contribution of each optimization technique adopted in GSIM, we apply all techniques incrementally, starting with a baseline with no optimizations. In this way, we get a series of performance data $P_0, P_1, \ldots, P_n$. In Figure 8, the height of the bar for the ith technique is calculated as $\log_{10}(P_i/P_{i-1})$. As shown in the figure, introducing supernode significantly improves performance for all designs. Splitting nodes at bit level delivers substantial improvement for BOOM and notable gains for XiangShan, but has little impact on stuCore and Rocket.

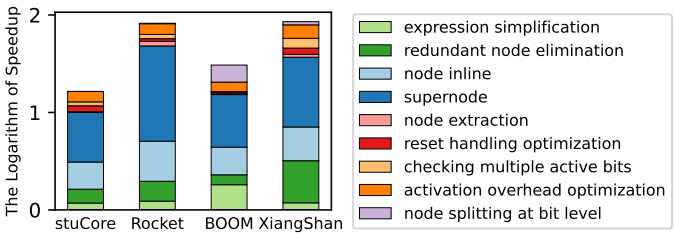

Fig. 8: Performance breakdown for each technique.

E. Selecting the Maximum Size of Supernode

We also investigated the relationship between the maximum size of supernode and the simulation performance. As mentioned above, a larger size of supernode reduces A_{exam} but increases af. The optimal size depends on the circuit design. To find the optimal size, we try different sizes with all other optimization techniques enabled. For the designs we select, the optimal size ranges from 20 to 50, as shown in Figure 9.

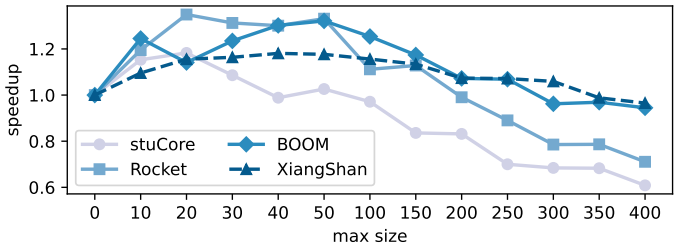

Fig. 9: Performance with respect to maximum supernode size.

F. Different Algorithms to Build Supernode

We compare the enhanced partitioning algorithm used in GSIM against the original Kernighan's Algorithm and ESSENT's partitioning algorithm (noted as MFFC-based). These algorithms are implemented on GSIM with all other optimization techniques disabled to show their effectiveness. They are evaluated by running CoreMark on BOOM under their own optimal parameters. We measure the number of supernodes, the number of times to active a successor, and the number of active node. These metrics can reflect A_{exam}, A_{succ} and E respectively. As shown in Table III, our algorithm performs the best in terms of the simulation speed, by achieving a better balance among the three factors above.

TABLE III: Comparison of different partitioning algorithms by running CoreMark on BOOM.

	partition time (s)	supernode	activation times	active node	speed (Hz)
None	–	536721	64044	42398	913
Kernighan	1.3	21769	13104	93327	4522
MFFC-based	88.9	36478	7310	124202	6802
GSIM	1.6	14261	8169	114255	8184

G. Resource Usage

For the emission time, we measure the time required to emit simulation files. As shown in Table IV, although GSIM outperforms Verilator, GSIM still delivers comparable emission time to Verilator. ESSENT requires more time to generate C++ files. One reason may be the slow execution of Scala programs. Arcilator requires more than 100GB memory to emit code for BOOM, which leads to accessing swap with a very long emission time. It even fails to emit code for XiangShan due to out-of-memory.

For the code size, we measure the size of the `.text` section of the binary reported by `readelf`. As shown in Table IV, GSIM emits the least amount of code among all simulators, as it employs more optimization techniques.

For the data size, we use `sizeof` to obtain the size of the top-level design class in C++ files, whose members contain all variables used for simulation, and we exclude the array used to simulate the main memory (128MB). As shown in Table IV, GSIM generates slightly larger data than Verilator.

V. Related Work

Verilator [5] is a widely used open-source, full-cycle RTL simulator. It supports multi-threading by partitioning the RTL design. Arcilator [10], an RTL simulator based on CIRCT, applies optimizations at various IR levels. Both of them evaluate all signals in the circuit every cycle and improve simulation speed through various expression optimization techniques. In contrast, GSIM skips the evaluation of a signal when it is inactive. Khronos [2] employs cross-cycle optimizations to reduce memory access overhead during simulation, which performs well in circuits with many pipeline registers. However, GSIM targets more general designs. ESSENT [3] leverages the low activity factor in circuits, partitioning the design and filtering out inactive regions to efficiently reduce the computation overhead. GSIM further explores the potential of accelerating RTL simulation. It reduces the computation overhead from four factors with optimization techniques across three levels.

TABLE IV: Comparison of resources across various designs. Instances labeled with '*' mean failing to run.

Design	Simulator	Emission Time(s)	Code Size(B)	Data Size(B)
stuCore	Verilator	1.1	394K	15K
	*ESSENT	7.7	659K	21K
	Arcilator	0.4	131K	13K
	GSIM	0.4	133K	16K
Rocket	Verilator	5.8	2.9M	62K
	ESSENT	37.8	1.6M	107K
	Arcilator	2.9	305K	49K
	GSIM	9.8	1.4M	72K
BOOM	Verilator	22.9	7.7M	954K
	*ESSENT	-	-	-
	Arcilator	4194.6	2.8M	799K
	GSIM	31.3	4.4M	976K
XiangShan	Verilator	374.6	40.7M	22.2M
	*ESSENT	-	-	-
	*Arcilator	-	-	-
	GSIM	389.1	25.4M	22.3M

RepCut [1] is a multi-threaded RTL simulator based on ESSENT. It reduces inter-thread synchronization overhead by introducing redundant computation. [13] proposes a coarse-grained circuit deduplication method to improve throughput for a batch of simulation tasks. GSIM focuses on improving the performance of single-threaded simulation under a single task. These works are orthogonal to GSIM and provide directions for future work.

VI. Conclusion

This paper proposes GSIM, a novel RTL simulator based on the essential signal simulation approach. GSIM employs a series of optimization techniques at the supernode level, node level, and bit level. GSIM successfully simulates XiangShan, the state-of-the-art open-source RISC-V processor. Compared to Verilator, GSIM achieves a 7.34x speedup when booting Linux on XiangShan, and a 19.94x speedup when running CoreMark on Rocket.

***Abstract*—In modern digital circuit design, verifying the equivalence of arithmetic circuits is a significant and challenging task. This paper introduces a new circuit solver based on the Conflict-Driven Clause Learning (CDCL) algorithm, which integrates structural elimination techniques to reduce the number of variables and clauses while maintaining the circuit structure. Additionally, branching heuristics have been enhanced specifically for the structure of arithmetic circuits. Experimental results demonstrate that X-SAT significantly outperforms best previous circuit solver could be found on all benchmarks. Further, X-SAT performs better than the state-of-the-art CNF-based SAT solvers on complex arithmetic circuits, underscoring its significant potential in the field of circuit design verification.**

***Index Terms*—Boolean satisfiability, Equivalence checking, Circuit-based SAT, EDA.**

I. Introduction

Boolean Satisfiability (SAT) is a fundamental problem in computer science with wide-ranging applications, especially in electronic design automation (EDA). Logic equivalence checking (LEC) [1], logic synthesis [2], bounded model checking, and automatic test pattern generation (ATPG) [3] commonly rely on SAT solvers. Typically, circuits are encoded into conjunctive normal form (CNF) for SAT solving.

Modern CNF solvers [4]–[6] are based on the Conflict Driven Clause Learning (CDCL) method, and equipped with numerous powerful and efficient techniques, including the two-literal watching scheme [7] for efficient Boolean Constraint Propagation (BCP), Bounded Variable Elimination (BVE) [8], variable selection heuristics such as VSIDS [7], learnt clause reduction, among others. However, these strategies and optimizations are designed based on the CNF data structure and do not take into account any information from the circuit.

When solving problems arising from EDA tasks, the transformation to CNF discards the structural information of the original circuit, limiting optimization potential. To address this issue, QuteSAT [9] improves the BCP process, enabling propagation directly on circuits and supporting both simple and complex gates. Additionally, the solver supports a circuit-structure-based branching strategy called **J-frontier**. Zhang et al. [2] introduced a SAT solver tailored for logic synthesis, which was built upon the CNF-based solver Glucose [5]. Besides performing BCP in circuit format, it also employs improved data structures to maintain the J-frontier branching heuristic. Hu et al. [10] used logic synthesis techniques for circuit rewriting before SAT solving.

*Corresponding author

This paper presents a novel circuit SAT solver that is lightweight and efficient, with the focus on arithmetic circuits. Our contributions are summarized as follows:

- We propose a structural elimination technique to simplify the circuits before SAT solving. Specifically, we reduce variables by identifying XOR gates and synthesizing non-XOR gates into multi-input gates. This technique is effective for both arithmetic and non-arithmetic circuits. It also improves the search efficiency of the CDCL framework through a more compact circuit representation and distinguishes our method from traditional solvers that operate directly on the original circuit structure.
- We design a new branching heuristic method based on VSIDS [7] called **XVSIDS**. During conflict analysis, we increase the branching weights of neighboring XOR gates for the analyzed variables, enhancing the heuristic's locality. It has achieved good performance on arithmetic circuits, more robust than the J-Frontier heuristic.
- We develop a circuit SAT solver based on the CDCL framework, which integrates these two techniques. Our circuit SAT solver has significantly outperformed the best previous circuit solver we could find on both arithmetic and non-arithmetic circuits. Moreover, our solver surpasses the state-of-the-art CNF SAT solver Kissat [4] on arithmetic circuits, noting that Kissat and its variants dominates the main tracks of recent SAT competitions from 2020. This is the first time that a circuit SAT solver is compared to state-of-the-art CNF SAT solver (previous works usually compared to MiniSAT [6] or Glucose [5]) and achieves better results.

The rest of the paper is organized as follows: Section II introduces the background on SAT solving, AIG graph, circuit-based SAT solving and CEC problem. Section III presents the main methods used in the design of our solver, including the motivating example, solving framework and the implementation of structural elimination and the XVSIDS branching strategy. Section IV presents experimental results while Section V concludes the paper.

II. Background

A. Boolean Satisfiability

The Boolean Satisfiability (SAT) asks whether there is an assignment to the variables of a Boolean formula in Conjunctive Normal Form (CNF) that makes it true. A literal is either

Algorithm 1: Basic framework of CDCL Algorithm

```
Input: CNF formula F
Output: SAT or UNSAT
α = {};
dl ← 0;
if BooleanUnitPropagation( F, α ) == CONFLICT
 then
    return UNSAT ;
end
while ∃ unassigned variables do
    (x, v) ← SelectBranchVar( F, α ) ;
    dl ← dl + 1 ;
    α ← α ∪ {(x, v)} ;
    if UnitPropagation( F, α ) == CONFLICT then
        bl ← ConflictAnalysis( F, α ) ;
        if bl < 0 then
            return UNSAT ;
        end
        else
            Backtrack(F, α, bl) ;
            dl ← bl ;
        end
    end
end
return SAT ;
```

a Boolean variable or its negation. A formula is represented as a conjunction of clauses, where each clause is a disjunction of literals:

$$\phi = (C_1 \wedge C_2 \wedge \cdots \wedge C_m), \quad C_i = (l_{i1} \vee l_{i2} \vee \dots)$$

The goal is to find an assignment $\mathbf{x}$ such that $\phi(\mathbf{x}) = 1$ or prove none exists. SAT is NP-complete, making it computationally challenging for large instances, while it remains a fundamental problem in hardware verification.

B. SAT Solving Framework

Modern SAT solvers, such as MiniSAT, Glucose, and Kissat are based on the Conflict-Driven Clause Learning (CDCL) framework [11]. Key techniques in CDCL-based SAT solvers, including efficient Boolean Constraint Propagation (BCP), conflict analysis, clause learning, rephasing, restarts, learnt clause reduction, and Bounded Variable Elimination (BVE), have significantly enhanced their performance in practical applications.

The pseudo-code in Algorithm 1 represents the basic framework of the Conflict-Driven Clause Learning (CDCL) algorithm. The key functions include **BooleanUnitPropagation(**F**,** α**)**, which propagates unit clauses in the formula F based on the partial assignment α and returns 'CONFLICT' if a contradiction occurs; **SelectBranchVar(**F**,** α**)**, which selects an unassigned variable x and assigns it a value v; **ConflictAnalysis(**F**,** α**)**, which analyzes conflicts and determines the backtrack level bl; and **Backtrack(**F**,** α**,** bl**)**, which reverts the assignment to the backtrack level bl. The algorithm starts with an empty partial assignment and decision level, iteratively selects variables, propagates unit clauses, and uses conflict analysis and backtracking to resolve conflicts. It terminates when a satisfiable solution is found (SAT) or the formula is unsatisfiable (UNSAT).

C. And-Inverter Graph

And-Inverter Graph (AIG) is a representation of Boolean logic circuits that uses AND gates and inverters (NOT gates) as the basic components. AIGs are a popular choice for circuit representations because they provide an efficient way to model and manipulate Boolean functions. AIGs are particularly useful for circuit verification, as they allow for efficient manipulation of logic functions and can be easily transformed into Conjunctive Normal Form (CNF) for SAT solvers.

D. Circuit-based SAT Solving

Circuit-based SAT solving shares the same CDCL framework as SAT solvers for CNF formulas, with most techniques being interchangeable. The primary differences lie in how decisions and propagations are performed. In circuit solvers, decisions are made directly on wires in the circuit structure, and assignments are propagated through the circuit, rather than through the CNF representation as in conventional SAT solvers. This approach eliminates the overhead of converting circuits into CNF, making circuit solvers more efficient for scenarios requiring repeated invocations. Additionally, circuit solvers can employ structure-aware branching heuristics, such as the J-frontier heuristic [9], to improve decision-making and enhance solving efficiency.

E. CEC Problem

Combinational Equivalence Checking (CEC) is the problem of determining whether two Boolean circuits or logic functions are functionally equivalent. It is a fundamental task in EDA with applications in formal verification, circuit optimization, and hardware testing. To perform CEC, the two circuits are first combined into a *miter circuit*, where the inputs of both circuits are shared, and their outputs are XORed. The output of the miter circuit is used to detect discrepancies: if it is always 0 for all input combinations, the circuits are equivalent; otherwise, they are not.

Once the miter circuit is constructed, the problem is encoded as a SAT instance and solved using a SAT solver. A key optimization is *SAT-Sweeping* [12], [13], which iteratively calls a SAT solver to verify the equivalence of potentially equivalent internal nodes, and merges equivalent nodes to reduce complexity.

III. Proposed Method

A. Motivating Example

Although AIG provides a convenient expression for circuits, it is usually too basic for complex circuits such as arithmetic

circuits. By identifying the structure and re-rewrite the circuits using more compact gates, we can significantly reduce the number of variables in the circuits, making the circuit SAT solving faster.

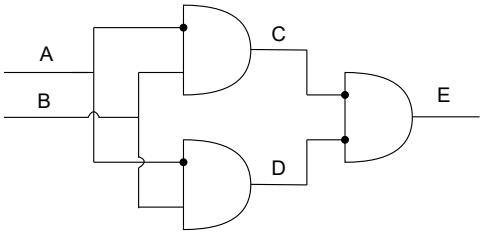

Fig. 1. An example of a small subcircuit in AIG format

As illustrated in Figure 1, the given circuit demonstrates a scenario where the value of E is determined by inputs A and B. In an And-Inverter Graph (AIG), due to its limited expressive power, additional variables C and D must be introduced to construct the complete circuit. However, an alternative approach is to directly construct a 2-input LUT gate with A and B as inputs and E as the output. More generally, by merging the circuit into multi-input LUT gates, it is possible to significantly reduce the number of variables while maintaining the overall structure of the circuit. This observation inspired the development of the **Structural Elimination** method, which will be discussed in detail in the following sections.

Furthermore, XOR gates exhibit unique properties that can be leveraged in circuit analysis. Building upon the VSIDS heuristic, we introduce specific enhancements tailored for XOR gates, leading to a new heuristic named **XVSIDS**.

B. Overview of Our Circuit-based SAT Method

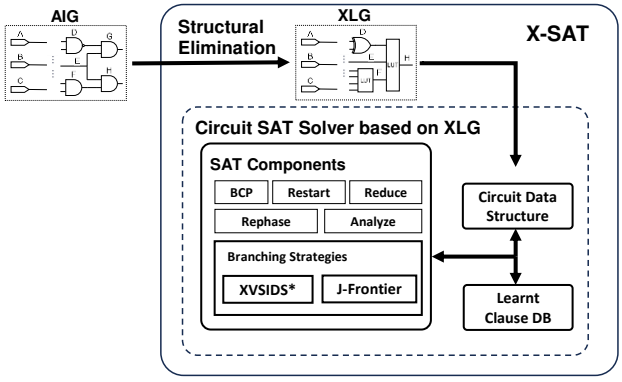

Fig. 2. Main framework of X-SAT

We develop an efficient circuit-based SAT solver. The solver is composed of two parts, a rewriting procedure and a CDCL-based solver.

In contrast to other circuit solvers that operate directly on AIG circuits, our method transforms AIG circuits into XLG circuits, preserving the circuit structure while reducing variables. This lightweight approach is particularly advantageous for iterative and frequent invocations, making our solver well-suited for SAT-sweep processes and model checking. It is particularly effective for arithmetic circuits.

For SAT solving, we introduce the XVSIDS branching strategy, adapted from VSIDS and optimized for the compact XLG circuit representation. For comprehensive benchmarking, we also incorporate a j-frontier branching heuristic, similar to those utilized in other circuit solvers, to enable direct and meaningful comparisons.

C. Circuit Structural Elimination

Our method first identifies the binary XOR relationships in the AIG and then rewrites the original AIG circuit by incorporating XOR gates to express the circuit. This type of circuit is referred to as Xor-And-Inverter Graph (XAG).

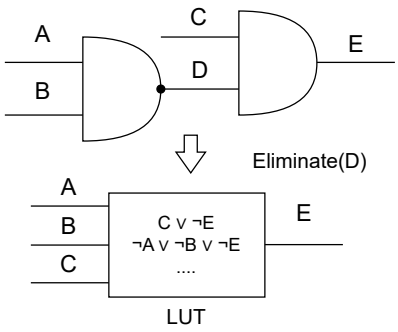

Fig. 3. An example of the elimination process

In addition to XOR gates, the non-XOR parts of the circuit could be further simplified. We merge binary gates into multi-input gates to simplify the circuit. The logical relationships between the inputs and outputs of multi-input gates can be expressed using CNF formulas, which have greater expressive power and are better suited for the CDCL solving framework. As shown in Figure 3, we eliminate the variable D and express the relationship between the inputs and the output of the introduced three-input gate using a CNF formula. Here we borrow a concept from FPGA and refer to the merged multi-input gates as LUTs. Such multi-input gates, represented in CNF, can express any relationship between inputs and outputs, rather than being restricted to well-known logical circuit gates such as multi-input AND, multi-input XOR, or MUX. Ultimately, we obtain a graph that includes both LUTs and XOR gates, which we refer to as the the Xor-Lut-Inverter Graph (XLG).

The selection of variables for elimination and the order in which they are eliminated have significant impact to the algorithm's performance. Our algorithm relies on a concept called *elimination score*, which measures the change on the number of literals, noting that some literals would be deleted while new literals are introduced when a variable is eliminated.

Algorithm 2: Circuit Structural Elimination

Input: AIG format circuit A
Output: XLG format circuit L

```
1  xag ← identify xor gates and rewrite A;
2  heap ← a max heap sorted by the elimination score
     associated with each variable;
3  L ← xag;
4  while heap is not empty do
5      gate ← gate with max elimination score in heap
6      if gate is not a single fan-out gate then
7          continue;
8      end
9      fanout_gate ← single fanout gate of g;
10     if gate or fanout_gate is XOR gate then
11         continue;
12     end
13     new_input_num ← fan-in numbers of gate +
         fan-in numbers of fanout_gate - 1
14     if new_input_num > θ then
15         continue;
16     end
17     L ← perform elimination for gate in L
18     update new elimination score for fan-in and fan-out
         gates of gate
19 end
```

This transformation method is described in Algorithm 1. Initially, we identify the XOR gates and construct an XAG (XOR-AIG) graph (line 1). Next, we compute the elimination scores for all gate variables and maintain a max heap for efficient access (line 2). During each iteration, we select the gate variable with the largest score from the heap for elimination, but those gates with more than one fanout or the inputs of the newly merged gate exceeds a predefined limit (denoted as θ) are not eligible. Based on our observations, setting θ to 7 proves to be effective. When a gate variable is eliminated, the elimination scores of adjacent gate variables are affected and will be recalculated (lines 4-19). At this stage, the XAG is successfully simplified into an XLG graph composed of LUT and XOR gates.

D. XVSIDS: A Branching Heuristic Based on Circuit Structure

SAT solvers usually do not perform well on instances with a large amount of XORs, because the CDCL framework is not well-suited for handling XOR information effectively.

The traditional VSIDS algorithm updates the variable scores during conflict analysis by incrementing the scores of all the variables involved in the conflict [14]. To optimize this process for XOR gates in circuits, we propose a novel branching heuristic called **XVSIDS**.

After converting the circuit into its XOR Logic Graph (XLG) representation, we define "XOR edge" variables as those corresponding to XOR gates or directly influenced by XOR gates in their fan-in or fan-out. Since there are many "XOR edge" variables in arithmetic circuits, most variables have XOR neighboring variables.

To leverage this structure, our XVSIDS strategy modifies the variable score bumping mechanism: when a variable's score is increased, its adjacent XOR gates are also increased with a increment of half value of the primary variable's increment. This adjustment aims to enhance the locality of the CDCL search by prioritizing variables that are structurally significant in arithmetic circuits. Experimental results demonstrate that this approach yields substantial performance improvements.

IV. Experimental Results

In this section, we present the experimental setup, dataset sources and solvers in our experiments. Then, we report the evaluation results and perform experimental analysis of the proposed ideas.

A. Experimental Settings

We implement our X-SAT solver in C++ language and compile it with GNU g++ (version 10.5.0). It can be accessed from our GitHub repository [1]. All tools and competitors are written in C/C++ and compiled in the same environment as X-SAT.

All experiments were conducted on a high-performance computing cluster equipped with two AMD EPYC 7763 CPUs @ 2.45 GHz, totaling 128 physical cores, and 1TB RAM. The system runs Ubuntu 20.04 LTS (64-bit). A single core and less than 10GB was used for any test case considered in this section.

To validate and compare the performance of the solvers, we use Combinational Equivalence Checking (CEC) problems for testing. The dataset for testing is categorized into two groups: arithmetic circuits and non-arithmetic circuits, all in AIG format. The dataset can also be accessed through GitHub [2]. To enable the CNF solver to solve the AIG, we used the AIGER tool [15] to convert them into CNF format.

- **Arithmetic Circuits:** We use 22 industrial instances with the application of long bit-wise optimization, which are datapath circuits with adders and multipliers. Both SAT and UNSAT circuits are included. The vast majority are UNSAT instances, with `b27` being the only SAT instance.
- **Non-Arithmetic Circuits:** We select 13 academic miter circuits which are generated from the ISCAS85, ISCAS89, and ITC99 benchmark suites, emphasizing circuits of moderate complexity for demonstration. The method for generating miter circuits involves first converting the circuit into a combinational circuit using scan chains. Then, logic synthesis is performed using the ABC tool [16] before creating the miter circuit. The logic synthesis commands [17], `&st; &dch; &if -K 6; &mfs;`, are executed three times iteratively. This sequence is executed three times iteratively. Specifically, the selection criterion is based on the solving time of the

[1] https://github.com/shaowei-cai-group/X-SAT
[2] https://github.com/shaowei-cai-group/X-SAT/tree/main/data

moderately capable Glucose solver. Instances are selected if they can be solved within the time limit (2000 seconds) and have a solving time greater than 1 second.

B. Evaluation Metrics and Solvers

We evaluated our proposed solver, X-SAT, against three state-of-the-art CNF solvers and one advanced circuit solver.

- **abc-cirsat** [2]: The latest advanced circuit SAT solver, integrated into ABC. The official name of the solver could not be found, so it is referred to as abc-cirsat in this paper.
- **kissat** [4]: A state-of-the-art CNF SAT solver that dominated the main track of the 2020, 2021, 2022 and 2024 SAT competition. The latest version kissat-sc2024 is selected.
- **glucose** [5]: A widely-used SAT solver that improves upon several techniques introduced by MiniSat.
- **minisat** [6]: A SAT solver widely-used in industries, frequently used as a benchmark for performance evaluation.

Our X-SAT solver and abc-cirsat belong to circuit based SAT solver, while kisssat, glucose and minisat belong to CNF based SAT solvers.

The performance metrics are summarized using PAR2 (penalized average runtime). If a solver fails to solve a case within the 2000-second time limit, its runtime is recorded as 4000 seconds; otherwise, the actual runtime is used.

C. Results and Analysis

Table I summarizes the performance results for arithmetic and non-arithmetic circuits. It provides the following details for each instance: instance name, gate count, and execution times for each solver: kissat, glucose, minisat, abc-cirsat and x-sat.

Arithmetic Circuits: The results show that our proposed X-SAT solver, utilizing the structural elimination technique with the XVSIDS branching strategy, achieves an **38.26x** speedup compared to the other circuit SAT solver abc-cirsat. Furthermore, it delivers a **1.36x** improvement over the state-of-the-art CNF solver kissat.

Non-Arithmetic Circuits: X-SAT achieves a 7.08x speedup over abc-cirsat, while 2.01x slower than the best CNF based SAT solver kisssat on non-arithmetic circuites. However, X-SAT still outperforms glucose by 3.19x and minisat by 17.45x. For circuit-based SAT solvers, we have significantly reduced the performance gap with kissat for the first time.

D. Validation of Effectiveness

As shown in Table II, we compared two different solver configurations: one with structural elimination disabled (No-elim) and one with structural elimination enabled (Elim). For each configuration, we tested three different branching heuristics (J-Frontier, VSIDS, XVSIDS) and recorded the solving time for each instance.

Structural Elimination: Compared to circuits in AIG format, the XLG format reduces the number of variables by an average of 61.39% for arithmetic circuits and 61.90% for non-arithmetic circuits. For arithmetic circuits, enabling structural

elimination resulted in improvements of 1.70x, 1.29x, and 1.77x for the three heuristics(J-Frontier, VSIDS, XVSIDS), respectively. For non-arithmetic circuits, the improvements were 2.11x, 1.58x, and 1.48x. This demonstrates that structural elimination is a fundamental optimization, providing a positive impact across all circuits and heuristics.

XVSIDS: With structural elimination enabled, XVSIDS outperforms the traditional J-Frontier branching method, achieving a 19.39x improvement on arithmetic circuits and a 2.52x improvement on non-arithmetic circuits. This demonstrates that XVSIDS has a clear advantage over the traditional method. Similarly, with structural elimination enabled, XVSIDS achieves a 2.84x improvement over VSIDS on arithmetic circuits. On non-arithmetic circuits, the two methods show little difference, with PAR2 values of 13.47(VSIDS) and 14.41(XVSIDS), respectively.

V. CONCLUSION

In this paper, we proposed an efficient circuit SAT solver, named X-SAT. We introduced elimination strategies to rewrite the AIGs into a new format, XLG, which reduces variables. Additionally, we improved the traditional VSIDS strategy by considering XOR gates, leading to the XVSIDS heuristic, which demonstrated substantial performance gains for both arithmetic and non-arithmetic circuits.

X-SAT marks a significant milestone in circuit SAT solving by being the first solver to outperform the state-of-the-art CNF solver, Kissat, on arithmetic circuits. Moreover, its performance on non-arithmetic circuits remains competitive with the most advanced CNF SAT solvers, demonstrating its versatility and robustness across diverse circuit types.

Future work includes extending X-SAT's application to EDA tasks and designing a parallel circuit SAT solver to address even more complex and computationally demanding problems.

***Abstract*—Compute Express Link (CXL) is a promising technology that addresses memory and storage challenges. Despite its advantages, CXL faces performance threats from external interference when co-existing with current memory and storage systems. This interference is under-explored in existing research. To address this, we develop CXL-Interplay, systematically characterizing and analyzing interference from memory and storage systems. To the best of our knowledge, we are the first to characterize CXL interference on real CXL hardware. We also provide reverse-reasoning analysis with performance counters and kernel functions. In the end, we propose and evaluate mitigation solutions.**

I. Introduction & Related Work

Compute Express Link (CXL) [8] provides a comprehensive solution to existing memory wall problems [13] and has garnered significant attention from both industry and academia. CXL offers several advantages, including high bandwidth density and a standardized interface for memory expansion and pooling [23]. These features make it an ideal solution to address the limitations of current cloud storage architectures, and have the potential to revolutionize data center architectures [4]. In industry, leading companies are actively exploring and adopting CXL to improve the efficiency and scalability of their data center products, including Intel [9], Samsung [25], and SK Hynix [19]. Academically, researchers are investigating various aspects of CXL, including its architecture [26], performance implications [28], [29], and potential security concerns [1].

However, in coexisting with current memory and storage systems in the server architecture, CXL faces understudied performance threats from external interference, which are not adequately reflected in existing research. Zooming out from CXL itself and considering its operational environment, CXL can potentially be affected by interference from 1) interactions between Main Memory (**MMEM**) and CXL and 2) interactions between neighboring storage components and CXL. Avoiding interference and maintaining performance isolation are critical for performance-sensitive applications. For instance, MT^2 [34] tries to explore the interference between persistent memory (PMEM) and DRAM, and it identifies noisy neighbors among concurrent applications to mitigate memory traffic interference. To the best of our knowledge, this ***interference issue for CXL has not been extensively studied in existing research***. Current CXL simulators typically introduce delay factors manually to simulate memory delays [20], [33], which neither reflects the real world environment nor considers interference. Moreover, existing hardware profiling studies on CXL primarily focus on evaluating the behavior of CXL under different operations and applications [17], [28], [29], without considering the impact of external environmental factors.

*The authors contributed equally to this work.
**Shuwen Deng and Teng Ma are co-corresponding authors.

Given that, we develop CXL-Interplay, which ***systematically characterizes and analyzes the potential reasoning of interference between memory/storage systems and CXL memory*** using carefully designed microbenchmarks and tailored real applications. We also discuss potential effective regulation that can be applied to fit real CXL interference scenarios.

First, in order to clearly identify and characterize CXL interference with memory and storage system, we develop a configurable microbenchmark and systematically go through the basic interference condition of CXL with MMEM and SSD system using *two different real CXL hardware setups*. As shown in Table I, we are the first to demonstrate and characterize the CXL interference using real CXL devices.

Furthermore, we conduct reverse-reasoning based on profiling evaluation results, exploring kernel functions and hardware performance counters, including the new CXL-related counters.

For the real testing setup, we explore file system, database, and machine learning applications for storage-related testing environment. For the memory-related testing environment, we focus on large-language model (LLM), in-memory database, and graph computing applications.

Given the interplay results, we further explore software and discuss hardware intervening solutions to provide effective regulation for the system to mitigate the interference impact. Based on our evaluation, it is feasible to restore bandwidth of the MMEM by 204GB per second, which reaches 99% of its original level, using software solutions, at the cost of a 5GB per second reduction in CXL bandwidth.

To summarize, this work makes the following contributions:

1) Systematically characterize the interference issue in current server architectures among CXL, MMEM, and storage devices. To the best of our knowledge, this is the first study examining interference of CXL on real hardware.
2) Conduct comprehensive microbenchmarks, evaluate memory-related and storage-related real applications and perform reverse-reasoning analysis for evaluation results.
3) Explore and evaluate software-based intervention solutions to address the interference problem and mitigate its impact on real hardware.

The code used in this paper will be released under open-source license at https://github.com/THU-HAS/CXL-Interplay.

II. Background & CXL-Interplay Setup

A. Compute Express Link (CXL)

Compute Express Link (CXL) [8], first developed in 2019, is an open standard interconnect designed to enhance the performance of

TABLE I: Comparison of CXL-Interplay with state-of-the-art CXL characterization work. To the best of our knowledge, we are the first to investigate interference and regulation of real CXL devices and conduct reverse-reasoning analysis.

	Real ASIC Device	Inter-ference	Regulation	Reverse-reasoning Analysis
Emulation works [16], [27], [33]	✗	✗	✗	✗
Sun [28]	✓	✗	✗	✗
Tang [29]	✓	✗	✗	✗
Liu and Wang [17]	✓	✗	✗	✗
Our Work	✓	✓	✓	✓

data-centric applications by enabling high-speed, low-latency communication between CPU/accelerators, memory, and storage.

The CXL protocol stack is divided into three parts: CXL.io, CXL.cache, and CXL.mem, each serving distinct purposes to facilitate various types of data transmission and memory access. CXL.io ensures compatibility with PCIe, enabling traditional I/O operations and device discovery. CXL.cache supports accelerators accessing CPU's internal caches and host memory. CXL.mem allows direct memory access and pooling, extending memory across multiple devices.

CXL devices are classified into three types, each tailored for specific applications. Type-1 devices, such as SmartNICs, utilize CXL.io and CXL.cache to facilitate communication with host DDR memory. Type-2 devices, including GPUs, ASICs, and FPGAs, use CXL.io, CXL.cache, and CXL.mem to share memory resources with the processor. Type-3 devices rely on CXL.io and CXL.mem to enable memory expansion and pooling. Type-3 devices enable extra DRAM capacity and bandwidth.

There are currently two types of CXL devices: FPGA-based and ASIC-based. Intel Agilex FPGA integrates CXL hard IP, which is a standard component in recent CXL studies (e.g., Sun et al [28], Zhong et al [36]). Besides, emerging ASIC-based CXL memory devices are becoming available, with promises from several vendors such as Samsung [25], Montage [31] and Micron [18].

B. Memory System and CPUless Node

DRAM is widely used in memory systems as the main memory. It is typically interconnected via a parallel interface. However, the limited capacity and bandwidth blocks its scalability for memory-intensive applications.

Secondary memory such as persistent memory (PMEM) can meet the demands of memory-intensive applications, and its large capacity makes it an alternative to DIMM. PMEM can be identified as the memory of an additional node without CPU.

As a type of secondary memory, CXL memory provides CPUless node interface. However, unlike PMEM, CXL devices rely on PCIe, utilizing its physical layer and provide multiplexing features, resulting in physical topologies akin to those of PCIe.

C. CXL-Interplay Hardware Setup

In this work, we systematically characterize and explore how CXL memory interferes with other memory-related access, specifically MMEM access, and storage-related access such as NVMe or SAS SSD, using microbenchmarks and real applications.

Table II demonstrates the experimental setup of CXL-Interplay. We have two systems that will be referred to later as System A and System B respectively. System A has SAS SSD and an ASIC-based CXL memory device manufactured by Montage. System B consists of NVMe SSD and an Intel FPGA-based CXL memory device.

TABLE II: Experimental setup of CXL-Interplay.

	System A	System B
CPU	4th Gen Xeon Platinum 4.0 GHz	4th Gen Xeon Gold 4.0 GHz
Number of physical cores per socket	48	32
Memory per socket Channels Speed	1TB, 8 Channel, DDR5-4800	256GB, 8 Channel, DDR5-4800
Storage	SAS SSD	NVMe PCIe 4.0 MLC SSD
File System	XFS	XFS
CXL memory device	Montage ASIC 64GB	Intel Agilex FPGA 32GB DDR4-2400
OS	CentOS 7	Ubuntu 22.04.4 LTS

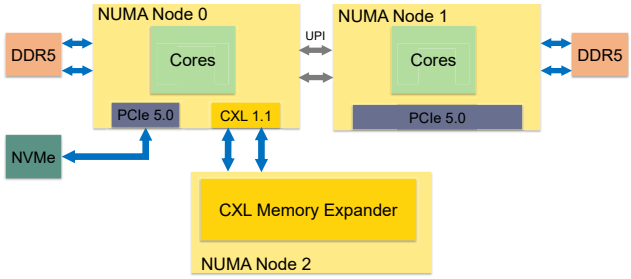

Fig. 1: Schematic illustration of hardware setup

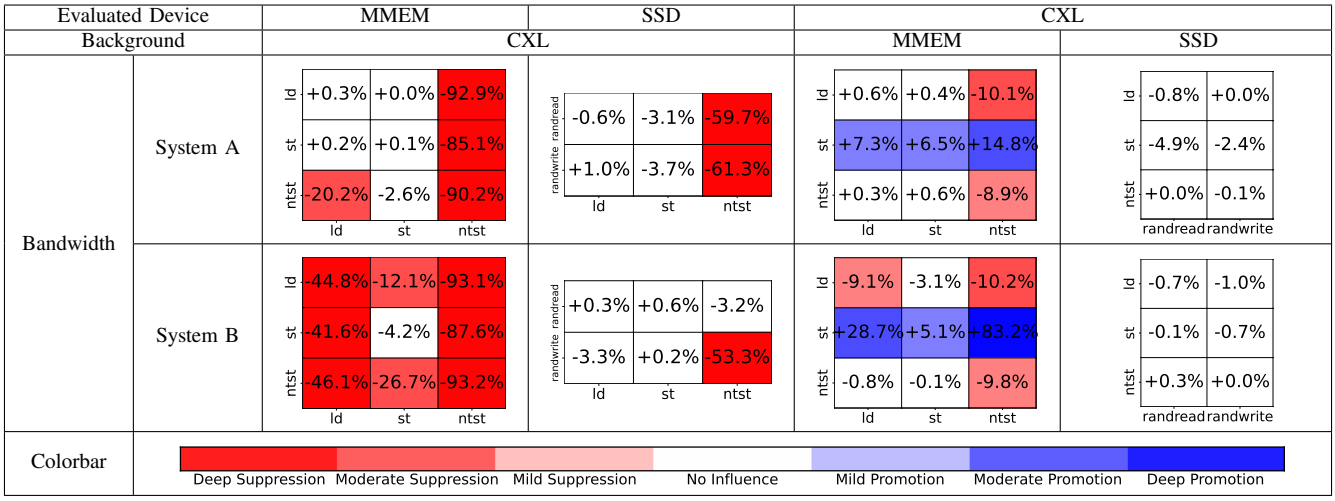
Figure 1 illustrates the topology of our hardware setup, where NUMA node 0 and NUMA node 1 each possess their own cores and DDR5 DRAM, while the CXL Memory Expander is situated on NUMA node 2 with zero processor core, directly connected to Node 0. Therefore, tasks are always allocated to the cores on Node 0.

III. CXL-Interplay Microbenchmarks

In this section, we set up comprehensive microbenchmarks to examine the CXL interference problem with SSD and MMEM.

A. Microbenchmark Setup



In our microbenchmark, three different memory-related operations (load (*ld*), store (*st*), and non-temporal store (*ntst*)) [1] and two different storage-related operations (random-read (*randread*) and random-write (*randwrite*)) are cross-evaluated.

For memory-related operations, we develop our microbenchmark by measuring the bandwidth of CXL memory and MMEM with cxlMemTest [28]. We carry out our experiments with all possible numbers of threads. For better measurement, we disable Hyperthreading [5], lock CPU's frequency to 2GHz, and clear cache before each test. We also allocate main process and interfering process to separate cores of the same NUMA node. The measurement is repeated multiple times and get average. We also carry out case studies on random/sequential storage access pattern and `MOVDIR64B` instruction.

For storage-related operations, we employ FIO [3] with *libaio* as *ioengine* to perform sustained *randread*/*randwrite* operations with an *iodepth* of 16 and a *block size* of 4KB for 20 seconds.

[1] We do not have non-temporal load mainly considering its sparse applicability, which are demonstrated in a lot of works [12], [21], [22]

TABLE III: The schematic illustration of bandwidth across different systems and configurations. In each box, the x-axis and y-axis represent the operation of the background and the device under test, respectively. We categorize the influence into seven types, each represented by a color in the colorbar: "Deep Suppression", below -40%; "Moderate Suppression", -40% to -10%; "Mild Suppression", -5% to -10%; "No Influence", within -5%; Promotion follows the same pattern.

B. Microbenchmark Characterization and Evaluation

1) MMEM/SSD with CXL Traffic: The left half of Table III illustrates the trends of MMEM/SSD's bandwidth under the interference of CXL. Each value represents the maximum interference observed across all thread count configurations. Our observations are as follows: a) The bandwidth of MMEM/SSD suffers significant interference when CXL performs *ntst*, reaching up to 93.2%. b) CXL *ld* and *st* can also be disruptive to MMEM, especially on System B, where over 40% interference is observed. c) As for SSD, the interference from CXL *ld* and *st* traffic is relatively mild.

INSIGHT #1: CXL traffic (especially non-temporal store (*ntst*)) significantly impairs bandwidth of concurrent MMEM and SSD traffic, with MMEM experiencing greater degradation than SSD.

2) CXL with MMEM/SSD Traffic: The right half of Table III illustrates the bandwidth trends of CXL under the interference of MMEM/SSD. Our observations are as follows: a) CXL bandwidth experiences performance boost when CXL performs *st* operations alongside MMEM traffic; b) In other MMEM cases, *ntst* operations exert a moderate to mild negative impact on CXL bandwidth. c) The bandwidth of CXL is not significantly influenced by SSD.

C. Reverse-reasoning Analysis

Figure 2 illustrates the datapath for CXL memory, SSD and MMEM workloads. Figure 2 depicts workload mixes involving SSD traffic and CXL traffic, where the CXL memory expander and storage device share the PCIe interface. It also shows workload mixes between CXL memory and MMEM, where interfaces are not shared, but sharing of network-on-chip (NoC) can lead to interference.

Performance counters. We discover that when SSD is under interference of CXL, its L2 and local LLC miss average latency becomes much higher than the no interference scenario, which prompts an investigation into the PMU counters listed in Table IV. It can be observed that there is a significant increase in L2 miss latency, up to a factor of 15, accompanied by a notable reduction in bandwidth. However, the L3 miss latency remains relatively constant. This suggests that an examination of network-on-chip (NoC) between the L2 and L3 will be necessary. CPUs need to maintain a record of in-flight transactions that access the L3 slices that are attached to other cores. This record table presumably will, however, become a bottleneck.

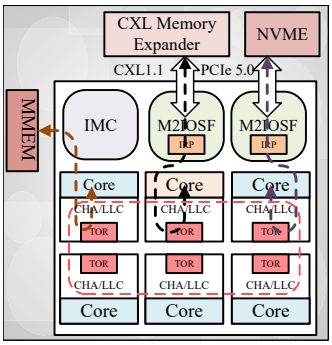


Fig. 2: Datapaths in filesystem, CXL and MMEM workloads.

From the discovery and the results in Table III and the datapaths in Figure 2, we then focus on: a) Table of Request (TOR), a queue between cores and LLC, tracking pending Cache Home Agent (CHA) transactions [15] of each core and PCIe interface; b) some OS *kernel functions*.

Correspondingly, we collect performance monitor unit (PMU) listed in Table IV, where $\frac{unc_cha_tor_occupancy.ia_miss}{unc_cha_tor_inserts.ia_miss}$ represents the average latency from cores that miss the LLC [15]. We can deduce that data transferred by CXL can be propagated throughout the entire LLC, causing congestion in TOR due to TOR's high occupancy behavior and affecting memory accesses of other cores. This can be demonstrated from value change of *unc_cha_tor_inserts.ia_miss* and *unc_cha_tor_occupancy.ia_miss*.

INSIGHT #2: CXL traffic occupies Table Of Request (TOR) for a lengthy period, causing congestion in TOR with other multicore process.

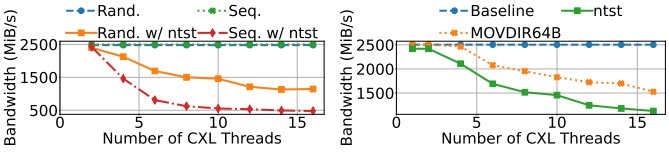
CXL counters. We also evaluate CXL performance in both instruction level (with tools we used above) and hardware level. We collect CXL-related PMU counters to compute CXL bandwidth. The results are consistent. For example, when CXL traffic with 16 *ntst* threads run under the interference of SSD traffic with 16 *randwrite* threads in System B, the bandwidth of CXL measured by cxlMemTest is 13169 MB/s, and the result computed by *cxlcm_txc_pack_buf_inserts.mem_data* is 13342 MB/s. The close agreement between the two values proves the reliability of our data.

TABLE IV: Ratio of related event and function of NVMe.

Related Event and Function	Description	Interference to No-interference Ratio
Load_L2_Miss_Latency	Average Latency for L2 cache miss demand Loads	15.2×
L3_Cache_Access_BW	Average per-core data access bandwidth to the L3 cache	0.14×
Load_L3_Miss_Latency	Average Latency for L3 cache miss demand Loads	1.01×
unc_cha_tor_occupancy.ia_miss	Occupancy number of TOR when request from iA misses LLC	4090×
unc_cha_tor_inserts.ia_miss	Inserts number of TOR when request from iA missses LLC	155×
memmove_sse2_unaligned_erms()	Memory move with Enhanced REP MOVSB, used in memcpy()	1.96×
copyout()	Kernel-to-User buffer copy	1.29×

Kernel functions. By profiling both SSD traffic alone and with CXL, two hotspot functions show significant changes. We notice that the time taken by *memmove_sse_unaligned_erms* and *copyout* (kernel-to-user copy) increases by 96.2% and 28.7%, respectively, when CXL is in the background. These functions, called by *memcpy* to move data in parallel, indicate that memory copy operations of system kernel processing data from devices are influenced.

D. Microbenchmarks on Other Configurations



1) Sequential vs. Random Access: We also explore whether the interference differs when SSD performs sequential writes versus random writes. Results in Figure 3a highlight that SSD is more susceptible to CXL interference when performing sequential writes (up to 80.9% performance loss) compared to random writes (up to 54.5% performance loss). The reason is attributed to the greater spatial locality of data in sequential writes. Random operations presumably encounter a large number of cache line conflicts and are limited by the small number of available DDIO ways. Consequently, random operations result in an increased number of cache misses and occupy a smaller proportion of LLC space (2MB) than sequential accesses (4MB), which makes sequential writes more vulnerable to interference from the cache side, originating from CXL.

INSIGHT #3: SSD sequential writes exhibit greater LLC occupancy, which is interfered more by CXL traffic than random writes.

2) `MOVDIR64B` Operations: `MOVDIR64B` [12] is a specialized instruction that moves 64 bytes of data directly from source memory to destination memory with write atomicity. [2] Compared to *ntst*, `MOVDIR64B` adheres to the Write Combining (WC) memory type protocol and is weakly ordered. We wonder whether direct-store instructions like `MOVDIR64B` perform similarly to *ntst*. Figure 3b shows the influence of CXL `MOVDIR64B` operations on SSD *randwrite* in comparison with SSD performance alone and with CXL *ntst*. The results indicate that the interference from `MOVDIR64B` is similar to that of *ntst*, but imposes relatively less suppression on SSD performance than *ntst*. The presumable underlying cause is that unlike *ntst*, `MOVDIR64B` is capable of immediate eviction from the WC buffer [12]. As a result, data of `MOVDIR64B` spends a shorter time within the WC buffer, reducing the cost of tracking outstanding instructions. Therefore, the impact of `MOVDIR64B` is less significant than that of *ntst*. It is noteworthy that when the destination address of `MOVDIR64B` is local memory, thereby performing a normal load operation on CXL, the suppression disappears. This observation corroborates that the primary source of interference from CXL is its impact on the cache side.

INSIGHT #4: CXL `MOVDIR64B` operations cause less SSD performance suppression than *ntst* due to immediate WC buffer eviction, reducing instruction tracking costs.

[2]This operation is available on the 4th generation Intel® Xeon® Scalable Processor Family based on Sapphire Rapids microarchitecture.

(a) NVMe randwrite and sequential write bandwidth under the interference of CXL non-temporal store.

(b) NVMe randwrite bandwidth across different memory access instructions.

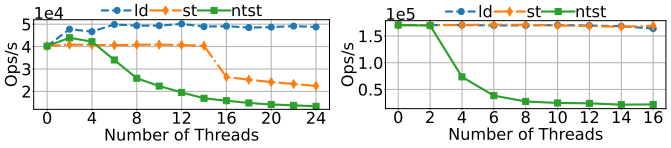
Fig. 3: Microbenchmark case studies

TABLE V: Description of the selected applications.

Category	Application	Description
File-related	Filebench [32]:	An open-source file system benchmark
	fileserver	Large files with 1:2 read/write ratio
	varmail	Small files with 1:1 read/write ratio
	RocksDB [30]	Log-structured merge-tree database 20-byte key size and 100-byte value size **Metric:** Operations per second
	MLPerf Storage [6]	Storage benchmark for deep learning **Metric:** Accelerator Utilization
Memory-related	GAPBS [7]	A graph computing benchmark PageRank Algorithm **Metric:** Trial time (lower is better)
	Redis [24]	An open-source in-memory database 50% read and 50% update **Metric:** Operations per second
	Large Language Model	TinyLlama [35], a decoder-only LLM **Metric:** Inference time (lower is better)

IV. CXL-Interplay Real Application Evaluations

We select a wide range of applications with different characteristics to study the interference problem. There are 4 types of interference scenarios: filesystem-related applications under CXL traffic, CXL-related applications under SSD traffic, MMEM-related applications under CXL traffic and CXL-related applications under MMEM traffic. We denote them as Type A, Type B, Type C and Type D respectively. The description of the selected applications is shown in Table V. The overview of the largest performance decline percentage evaluation result for each application is depicted in Figure 4. The key takeaway from this figure is that in most cases there is solid contention and interference across different access types and systems.



A. Filesystem-Related Applications

We select RocksDB database, Filebench, and machine learning workload MLPerf as our representative applications, while using CXL traffic as background to measure the interference for filesystem.

Figure 4 demonstrates that CXL's traffic has a considerable effect on the performance of most applications (Type A), with an observed

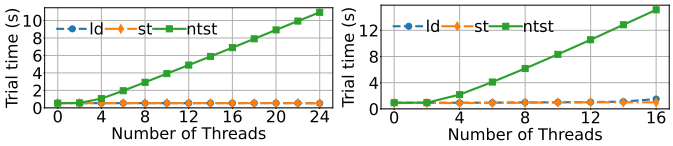


Fig. 4: CXL-related interference on real applications. The suffixes "-A/B/C/D" indicate the type to which the experiment belongs. We use different colors to differentiate background traffic types. For Type A, C and D, the background runs memory traffic which have three different types: *ld*, *st* and *ntst*. As for Type B, its background is file system and has four traffic types: *read*, *randread*, *write* and *randwrite*. We also use hatches to differentiate results from different systems. The height of the bars represents the maximum percentage of performance decline observed across all number of background thread count configurations for the corresponding scenarios. The y-axis is on logarithmic scale. [3]

(a) System A (b) System B

Fig. 5: The performance (operations per second) of RocksDB under CXL traffic. The x-axis indicates the number of background threads.

(a) System A (b) System B

Fig. 6: The performance (trial time) of GAPBS benchmark in Type C. The x-axis indicates the number of background threads.

detrimental impact reaching up to 90% for *ntst*. For *ld* and *st*, the impact can also be as high as 20% and 44% respectively. Moreover, the results presented in Figure 5 indicate an interesting and unexpected phenomenon that CXL's ld traffic can even enhance RocksDB's performance by up to 21.2% on system A.

Discussion. It can be observed that an increase in the thread count—and consequently the bandwidth—of the background CXL *ld* workload is associated with improved performance. To verify this, two other methods are applied to adjust CXL memory bandwidth: periodic cache flushing and injecting numerous `nop` instructions. We observe that the performance enhancement is directly linked to CXL memory bandwidth, occurring only when it exceeds 8 GB/s. Between 8 GB/s and 20 GB/s, the promotion grows linearly, while beyond that, the enhancement plateaus.

Albeit system-specific, we try to explore the root cause for promotion in System A with performance counters. for RocksDB, running a fixed number of operations both with and without CXL *ld* interference. The most notable observation is a 24% reduction in the number of instructions, especially memory instructions, under interference. This reduction in instructions plays a key role in the performance improvement.

INSIGHT #5: SSD workload bandwidth can benefit from a reduced instruction count when having sufficient CXL *ld* memory bandwidth as background.

B. Memory-Related Applications

We select graph benchmark GAPBS, in-memory database Redis and an LLM as our representative memory applications, covering Type B, C and D. It can be clearly observed that CXL memory's operations have a substantial impact on MMEM (Type C), consistent with microbenchmark results. Figure 6 shows a representative with up to 20.8× performance decline.

Conversely, the impact of MMEM on CXL memory is significantly less pronounced than that observed in Type C. We hypothesize that the observed limited impact is due to the fact that, although MMEM traffic is high, the low latency of MMEM does not result in significant consistence overhead, allowing CXL to operate normally.

Regarding SSD applications, their impact on CXL memory is insignificant, potentially due to the fact that the LLC consumed by SSD is a relatively small section (4MB) in comparison to those occupied by MMEM (50MB). Nevertheless, it should be noted that in some cases, particularly under *read* operation background, up to 12% decline in CXL performance can be observed.

INSIGHT #6: The interference from CXL memory to MMEM is significant. However, MMEM and SSD have mild impact on CXL memory in most cases due to DRAM's lower latency and SSD's lower LLC utilization.

V. Intervent the interference and Experiment on CXL-Related Regulation

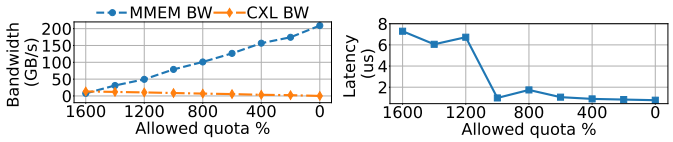
Given the interference discussed in Section III and Section IV, we have observed and analyzed various interplay between CXL and SSD, as well as CXL and MMEM. In this section, we provide different trials and solutions to mitigate the interference with real CXL hardware. We consider using CPU usage restriction, such as time quota allocating, frequency scaling, memory bandwidth restriction, etc., to demonstrate the effectiveness of regulation on CXL real hardware.

A. CPU Usage Restrictions

To validate the functionality of CPU usage restriction, we choose three scenarios of severe interference: MMEM *ld*, MMEM GAPBS and filebench *varmail*, all influenced by 16 CXL *ntst* threads. We first use the counters mentioned in Section III-C and bandwidth monitoring tools [11] to identify the processes causing high CXL traffic and LLC occupancy periodically. Then we use Linux's *cgroups* [14] to limit their CPU quota. If the process still causes severe impact in the next period, we further adjust its resource allocation to achieve dynamic control.

As illustrated in Figure 7, reducing the allowed CPU usage quota leads to a recovery in MMEM bandwidth and a decrease in latency. Specifically, when the distribution of CPU cycles for CXL is restricted to 100% (1/16 of the time originally occupied), the

[3]In certain scenarios, the results are unstable and exhibit significant fluctuations. In such cases, the maximum decline is not meaningful, and we represent it as 0 in the figure.



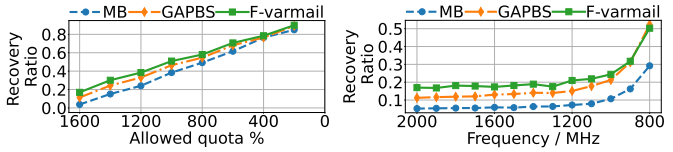


Fig. 7: Bandwidth and latency of MMEM when applying different CPU usage quotas to CXL threads. The horizontal axis is the allowed percentage of CPU usage.

(a) CPU usage restriction (b) Frequency Scaling

Fig. 8: Effectiveness of the two methods. Vertical axis is normalized to the performance without interference.

MMEM bandwidth recovers to 190 GB/s, which is approximately 92% of the bandwidth observed without interference. Additionally, latency returns to nearly its original level. This improvement in MMEM performance comes at the cost of a bandwidth reduction of about 10 GB/s on CXL. The results for the three applications are illustrated in Figure 8a. The linear and consistent impact observed across the three applications is due to the characteristic of CPU usage regulation, which influences a wide range of instructions. This approach facilitates a satisfactory and adjustable degree of recovery, albeit with varying degrees of performance decline in the background process.

B. Frequency Scaling

We also consider frequency scaling as a potential solution to mitigate the interference between CXL and MMEM. As is shown in Figure 8b, the recovery of MMEM threads is observed to be within the range of 30% to 52% when the background is constrained to very low frequency. This phenomenon can be explained by the fact that, except for very low frequency cases, memory instructions continue to fill the load/store queue. Consequently, memory-intensive tasks tend to demonstrate an exponential effect as the frequency decreases, yet still exhibit a suboptimal recovery rate. Although this method is less effective, it does not cause any damage to the memory-only background program.

C. Memory Bandwidth Restriction

The solution of regulating time slice and frequency is purely software-based and universal. But it also restricts the execution of memory-unrelated instructions, which causes additional performance degradation. On the other hand, memory bandwidth restriction presents a promising approach to mitigate interference between CXL and MMEM. We evaluate the effectiveness of using Intel MBA [10], which is a feature that allows users to allocate a portion of the memory bandwidth to specific processes. Limited by the I/O block configuration, it is only possible to restrict the CXL bandwidth to approximately less than half of its original value, which corresponds to a reduction of 5GB/s. This approach proves highly effective, enabling the three applications to recover to 99%, 95%, and 98% respectively, without affecting the compute instructions. However, this method is unable to provide control in a responsive manner and takes seconds to take effect, making it more suitable for implementation on the CXL device side.

D. Discussions on Other Methods

There are multiple solutions proposed to restrict the noisy neighbors and mitigate their negative impact on other threads. Apart from the methods discussed above, other methods include 1) cache partitioning, which is enabled by CPU vendors, such as Intel's Cache Allocation Technology (CAT) and 2) specialized memory bandwidth restriction, such as AMD's Slow Memory Bandwidth Allocation (SMBA) [2] targeting CXL devices, which has not been released. However, cache partitioning has minimal impact on operations that bypass the cache hierarchy, such as *ntst* operations, where it proves ineffective.

For hardware implementation, additional latency can be inserted into CXL device side after CPU has detected actual interference and then write the control register to change the added latency. However, this modification can highly depend on specific hardware which makes it harder to quickly deploy and generalize to different vendors.

VI. Practical Takeaways

Given the characterization and regulation experiments of CXL interference above, we provide the following takeaways for software (S) and hardware (H) developers respectively when developing future CXL-related systems:

(S1) Limit the number of threads or bandwidth of CXL *ntst* operations when possible to minimize their impact on MMEM and SSD workloads. (#1)

(S2) When running under CXL *ntst* traffic, SSD workloads should consider the trade-off between different access patterns such as random vs. sequential writes to maintain bandwidth. (#3)

(S3) For some systems, it is beneficial of lifting bandwidth to schedule SSD workloads with workloads having intensive CXL memory *ld* operations. (#5)

(H1) Hardware vendors can develop specialized TOR for slow tier memory to mitigate CXL contention with MMEM and SSD workloads. (#2)

(H2) To regulate the interference, it is advised to monitor and regulate on the CXL.mem device side with a more fine-grained MBA-like regulator.

VII. Conclusion

Real devices utilizing the emerging CXL technology are now finally commercially available. Researchers have actively characterized their features as isolated components. In this paper, we propose that since CXL devices need to interact with other components, it is necessary to characterize them in a coexisting manner. We develop customized microbenchmarks as well as real applications to characterize the interference problem. Our evaluation shows that this interference can cause a performance drop of up to 93.2%, along with other interesting observations. We also delve deep into the root causes of these observations. We provide concrete insights for readers and takeaways for developers. To mitigate the impact of this issue, we propose software mechanisms to manage CXL traffic. The results demonstrate the efficacy and trade-off of several methods.

***Abstract*—Transformers have demonstrated outstanding performance across diverse applications recently, necessitating fine-tuning to optimize their performance for downstream tasks. However, fine-tuning remains challenging due to the substantial computational costs and storage overhead of backpropagation (BP). The existing fine-tuning techniques require the BP through the massive pre-trained backbone weights for computing the input gradient, resulting in significant computing overhead and memory footprint for resource-constrained edge devices. To address the challenge, this work proposes an algorithm-hardware co-design framework, DRAFT, for efficient Transformer fine-tuning by decoupling the BP from the backbone weights, thereby efficiently reducing the BP overhead. The framework employs Feedback Decoupling Approximation (*FDA*), an efficient fine-tuning algorithm that decouples BP into two low-complexity pathways: trainable adapter pathway and sparse ternary Bypass Network (*BPN*) pathway. The two pathways work collaboratively to approximate the conventional BP process. Further, a DRAFT accelerator is proposed, featuring a reconfigurable design with lightweight sparse gather networks and dynamic workflows to fully harness the sparsity and data parallelism inherent to the FDA. Experimental results demonstrate that DRAFT achieves a speedup of 4.9× and an energy efficiency improvement of 4.2× on average compared to baseline fine-tuning methods across multiple fine-tuning tasks with negligible accuracy loss.**

I. Introduction

In recent years, Transformers [1] have demonstrated outstanding performance on tasks of multiple domains, including Natural Language Processing (NLP) [2], [3] and Computer Vision (CV) [4]. Owing to their impressive capabilities, it is prevalent to fine-tune the pre-trained Transformers (referred to as ***backbone***) for various downstream tasks. The demand for local fine-tuning on edge hardware is rapidly growing. This enhances user privacy protection and reduces latency and energy consumption associated with data transmission.

The primary challenge of Transformer fine-tuning is that backpropagation (BP) nearly tripled the computational cost compared to feedforward (FF)-only inference due to the BP computation for both weight and input gradient [5], [6]. Unlike conventional full fine-tuning, which updates all the pre-trained weight as illustrated in Fig. 1(a), Parameter-Efficient Fine-Tuning (PEFT) [7]–[9] is a recent research direction aims to limit the number of trainable parameters for online learning. For instance, as illustrated in Fig. 1(a), Adapters [7] are small bottleneck modules inserted into Transformer layers, while LoRA [10] injects trainable parameters alongside the frozen backbone weights. They reduce the associated weight gradient computation and optimizer state storage efficiently.

However, Transformer fine-tuning remains challenging for two main reasons. First, FF accuracy is critical for effective weight updates, restricting the compression feasible for the pre-trained model prior to the fine-tuning process [11], [12]. As a result, the BP through the backbone, comprising millions to billions of parameters, incurs substantial computational overhead. Second, as shown by the red line in Fig. 1(a), existing optimizations primarily address the weight gradient computation yet overlook the input gradient computation, necessitating BP through the heavy but frozen backbone weight. This oversight limits the reduction of fine-tuning computation to a maximum of 31%, as illustrated in Fig. 1(b).

The reliance of BP on the backbone weight makes Transformer fine-tuning computationally intensive for resource-limited edge devices. Previous efficient DNN training accelerators based on asymmetric BP [13], [14] and sparse BP [15], [16] suggest that accurate, symmetric BP may not be essential. Inspired by this line of research, we investigate the potential to uniformly reduce the BP computation cost for both input and weight gradients across all linear layers in the Transformer model, thereby significantly improving fine-tuning efficiency.

We propose an algorithm-hardware co-design framework for edge Transformer fine-tuning called DRAFT. As shown in Fig. 2, the key idea of DRAFT is to decouple the BP through the backbone weight into two lightweight pathways. These pathways jointly approximate pre-trained weight with low complexity, eliminating BP through the backbone weight without trading off fine-tuning accuracy. The major contributions are summarized as follows:

- We propose Feedback Decoupling Approximation (*FDA*), an efficient fine-tuning technique that fully reduces BP overhead by skipping the BP through the backbone weight with a sparse ternary Bypass Network (*BPN*). Decoupled-initialized and trainable adapters bridge the separated FF and BP pathways, reducing the BPN's complexity while maintaining fine-tuning performance.

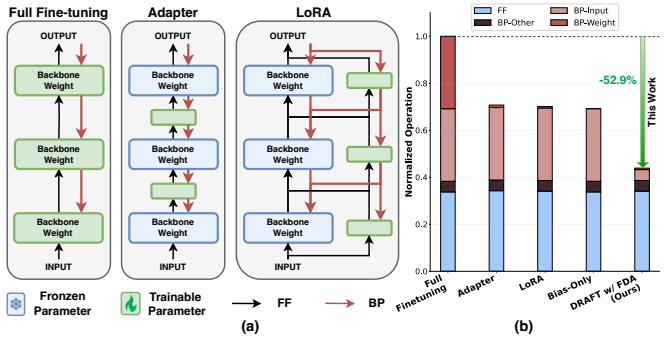

Fig. 1. (a) Illustration of the fine-tuning path of different fine-tuning methods with Full Fine-tuning, Adapter, and LoRA. (The compute paths of the linear layers are illustrated while the attention mechanism propagates primitively). (b) Fine-tuning operations comparison of Full Fine-tuning, Adapter [7], LoRA [10], Bias-only [8], and DRAFT (based on FDA) for the BERT-Base model.

- We design an efficient DRAFT accelerator for Transformer fine-tuning to leverage the sparsity and data parallelism inherent to the FDA. The reconfigurable processing element array supports lightweight gather networks and dynamic workflow to improve the throughput across different fine-tuning phases dynamically.
- We evaluate DRAFT on various models, datasets, fine-tuning algorithms, and hardware accelerators. Evaluation results illustrate that the FDA reduces the computational overhead of BP to below 15% with negligible accuracy loss. The algorithm-hardware co-design enables DRAFT to further reduce fine-tuning latency by 4.9× and substantially improve energy efficiency by 4.2× on average compared to the baselines.

II. Background and Motivation

A. Efficient Transformer Fine-tuning

Recently, numerous efficient fine-tuning techniques have been introduced to enable fine-tuning Transformers on commercial GPUs and even edge devices. A prominent parameter-efficient fine-tuning (PEFT) technique, LoRA [10], reduces the number of trainable parameters by integrating the trainable adapter along the linear layer. The computation output y of a linear layer on input X in LoRA is:

$$y = (W_o + \Delta W)X \approx (W_o + \frac{\alpha}{r} \cdot AB^\top)X \tag{1}$$

where W_o is the pre-trained weight matrix, ΔW is the weight update to W_o, and A and B are the low-rank approximation of ΔW initialized with random data and zeros, with a scaling factor of α and rank r. LoRA achieves near full fine-tuning accuracy by updating only a small fraction of the weights. However, prior efficient fine-tuning solutions [17]–[19] based on PEFT fall short of addressing the BP overhead associated with computing input gradients via the enormous backbone weight, which will be further discussed in Sec. II-C.

B. Training Techniques beyond Backpropagation

Substantial research has explored alternative training techniques to replace traditional BP. For example, the Google Brain team introduced Feedback Alignment [20], [21], which addresses the weights symmetry problem by proposing *asymmetric backpropagation*. This line of research focuses on producing high-quality gradients to achieve comparable performance to the conventional BP algorithm rather than exploring acceleration opportunities. Additionally, some strategies approximate weight gradients directly [22]. For instance, ADA-GP [5] predicts BP gradients using an auxiliary neural network. These techniques reveal that precise gradient computation via the chain rule is not always essential. However, most methods have primarily been validated on small-scale neural networks and suffer from significant accuracy loss when applied to larger, more complex models [21], [22].

C. Motivation

Backpropagation Computation Overhead: We begin by analyzing the network structure as a multi-layer perceptron (MLP): $Y = f_N(f_{N-1}(...f_2(f_1(x))...))$, where the output at layer i is given by $y_i = \mu_i(a_i) = \mu_i(W_i X_i)$. W_i is the pre-trained backbone weight for i-th layer, X_i denotes the input, and μ_i is the activation function, with the bias term omitted for simplicity. As illustrated in Fig. 3(a), the major computation overhead of conventional BP is to obtain the gradients of the input and the weights based on the loss function L:

$$\frac{\partial L}{\partial X_i} = \frac{\partial L}{\partial y_i}\frac{\partial y_i}{\partial a_i}\frac{\partial a_i}{\partial X_i} = \frac{\partial L}{\partial y_i}\mu_i' W_i^\top \tag{2}$$

$$\frac{\partial L}{\partial W_i} = \frac{\partial L}{\partial y_i}\frac{\partial y_i}{\partial a_i}\frac{\partial a_i}{\partial W_i} = \frac{\partial L}{\partial y_i}\mu_i' X_i \tag{3}$$

Current fine-tuning algorithms primarily optimize by reducing the number of trainable weights, thus decreasing the computation associated with the weight gradient term $\frac{\partial L}{\partial W_i}$ in Eq. (3) (denoted as G_W in Fig. 3). However, they fall short of addressing the computation of the input gradient $\frac{\partial L}{\partial X_i}$ in Eq. (2) (denoted as G_X in Fig. 3). Consequently, as illustrated in Fig.1 (b), BP computation costs remain nearly equivalent to those of the FF stage. Techniques such as Partial Tuning [23], [24] mitigate this issue by shortening the BP depth and tuning

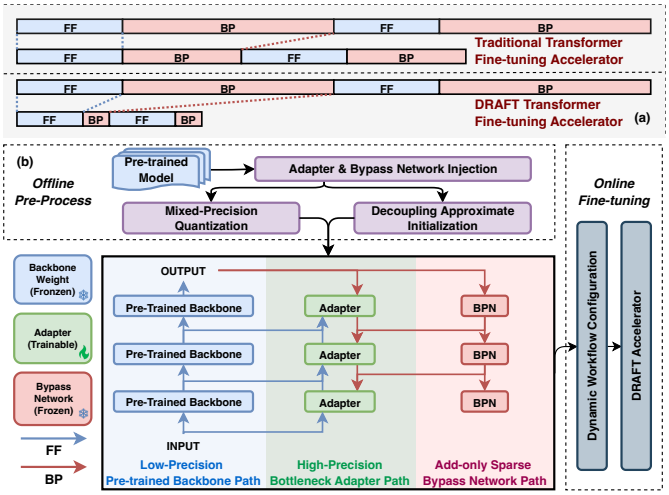

Fig. 2. (a) Comparison of DRAFT design concept with previous fine-tuning accelerator. (b) DRAFT framework overview, where the fine-tuning FF and BP pathways are decoupled and asymmetric compared to conventional BP.

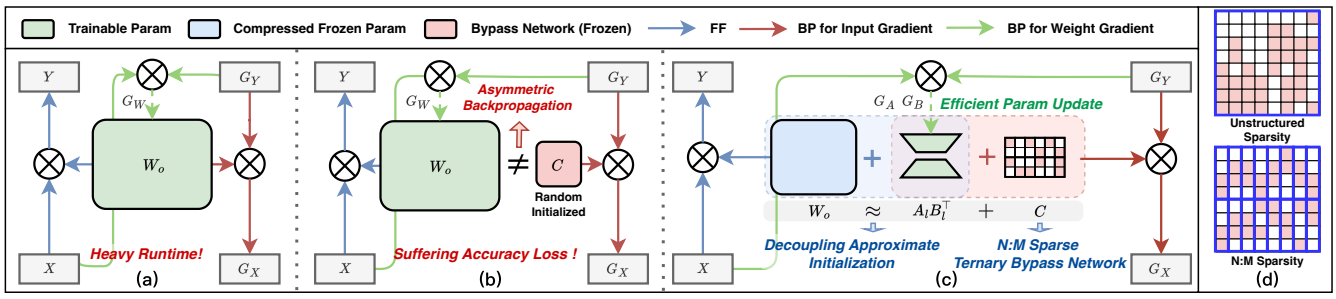

Fig. 3. The linear layer computation graph comparison of (a) conventional backpropagation, (b) asymmetric backpropagation based on Feedback Alignment, (c) approximate backpropagation based on Feedback Decoupling Approximation (FDA). The FDA delivers an accuracy-cost trade-off solution by decomposing and decoupling approximating the pre-trained weight. (d) Illustration of unstructured sparsity and N:M sparsity where N:M sparsity is more hardware-friendly.

the final few layers. However, these approaches limit updates to only a small subset of Transformer blocks, constraining the potential performance improvements. **In contrast, DRAFT fully reduces BP computation cost for input and weight gradient** by decoupling the BP from the backbone weight, striking a balance between hardware and algorithm efficiency.

III. Overview of DRAFT Framework

In this work, we propose DRAFT, an efficient algorithm-hardware co-design framework for Transformer fine-tuning on edge. The fine-tuning process based on DRAFT is illustrated in Fig. 2(b). **In the offline stage**, DRAFT pre-processes the pre-trained model in three steps: (1) Adapter and Bypass Network (*BPN*) Injection, (2) Pre-trained Model Compression, and (3) Decoupling Approximate Initialization. Based on the Feedback Decoupling Approximation (*FDA*) algorithm, DRAFT introduces an asymmetric fine-tuning pathway that skips the BP through the backbone weight with lightweight BPNs. The adapters bridge the gap between the separate FF and BP pathways, preventing accuracy degradation from the asymmetric BP, as detailed in Sec. IV-A. The BPN is an N:M sparse ternary network designed for both hardware and algorithm efficiency, as detailed in Sec. IV-B. **In the online stage,** DRAFT divides fine-tuning into three pathways. During the FF phase, the output is computed through the compressed frozen backbone and the trainable adapter. In the BP phase, the error gradient propagates through the BPN and adapter with minimum computation overhead. The reconfigurable DRAFT accelerator is designed to efficiently leverage the sparsity and parallelism inherent to the FDA, as detailed in Sec. V.

IV. DRAFT Fine-tuning Algorithm

A. Feedback Decoupling Approximation Algorithm

Asymmetric BP based on the Feedback Alignment [20], [21] has long been studied to produce synthetic gradients instead of conventional BP, eliminating the reliance on weight symmetry of BP. As illustrated in Fig. 3(b), this approach demonstrates the potential to bypass the BP through the backbone network by reformulating the input gradient computation in Eq. (2):

$$\frac{\partial L}{\partial X} = \frac{\partial L}{\partial y}\mu' C \tag{4}$$

In the conventional BP algorithm, $C = W_o^\top$, which is also referred to as *symmetric BP*. However, asymmetric BP uncovers redundancy in the standard approach, relaxing the constraint of weight symmetry, i.e. $C \neq W_o^\top$, thereby presenting an opportunity to perform BP without the backbone weight. Here, C can be a compressed version of the weight W_o or even random numbers, expressed as $C = \phi(W_o)$, where $\phi(\cdot)$ can be different compression algorithms or random number generators [21]. However, asymmetric BP is inherently prone to accuracy degradation as it lacks the ability to leverage pre-trained knowledge.

Feedback Decoupling Approximation for Lightweight Backpropagation: As illustrated in Fig. 3(c), to address the performance degradation of vanilla asymmetric BP, we propose the Feedback Decoupled Approximation (FDA) algorithm, which compensates for compression loss during the Bypass Network initialization with a trainable adapter. Different from the asymmetric BP, the FDA initializes the BPN by decoupling the backbone weight into two components:

$$\begin{aligned}\frac{\partial L}{\partial X} &= \frac{\partial L}{\partial y}\mu' W_o^\top = \frac{\partial L}{\partial y_i}\mu' \left[\phi(W_o) + l\right] \\ &\approx \frac{\partial L}{\partial y_i}\mu'(C + A_l B_l^\top)\end{aligned} \tag{5}$$

where C is the target BPN weight, and the initialization residual loss is denoted by $l = W_o^\top - \phi(W_o)$. We compensate the compression loss during initialization by decomposing the l into its low-rank approximation versions, A_l and B_l, with the singular value decomposition (SVD):

$$\begin{aligned} l &\approx \sum \sigma_{t,i} u_{t,i} v_{t,i}^\top \\ A_l &= [\sqrt{\sigma_{t,1}} u_{t,1}, \ldots, \sqrt{\sigma_{t,r}} u_{t,r}] \\ B_l &= [\sqrt{\sigma_{t,1}} v_{t,1}, \ldots, \sqrt{\sigma_{t,r}} v_{t,r}] \end{aligned} \tag{6}$$

where r is the rank of A_l, B_l. With the decoupling approximate initialization, the matrices A_l, B_l serve not only as the bridge between the separate FF and BP pathways but also as the trainable *adapters* for efficient parameter updates during fine-tuning. As shown by Fig. 3(c), along the blue FF path, the output Y is generated through the backbone and adapter. In contrast, following the red BP path, the input gradient G_X is computed through the adapter and BPN, independently of the backbone weights. The backbone weight and BPN weight are frozen during fine-tuning. By adjusting the adapter's rank, we can balance accuracy and computational complexity to achieve different compensation levels during initialization. Based on the FDA, we optimize input gradient computation through the BPN and alleviate the weight gradient computation cost

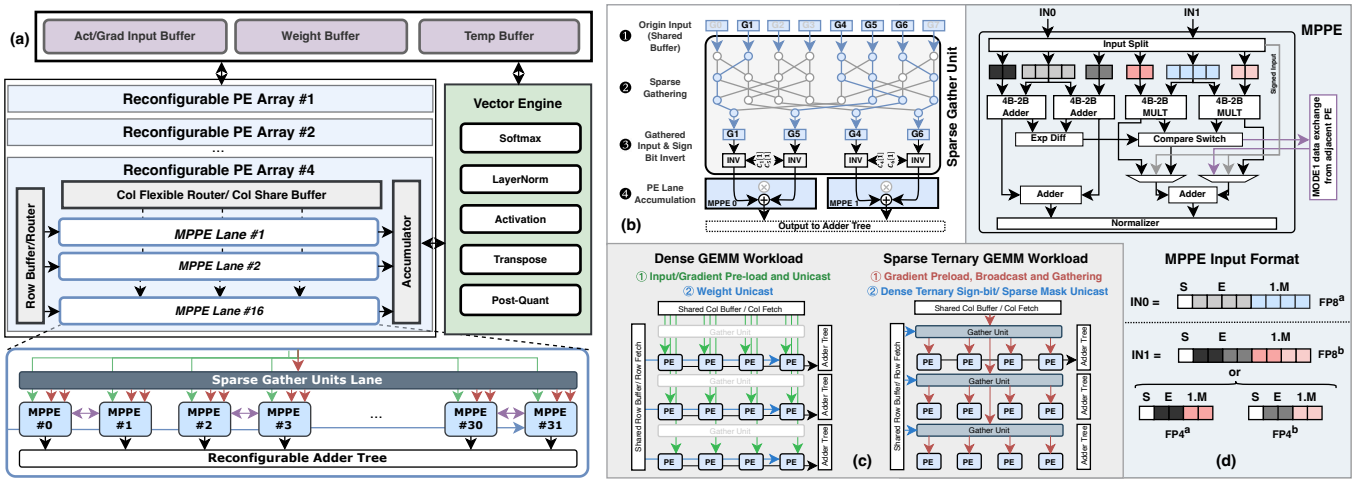

Fig. 4. (a) Overview of DRAFT Accelerator. (b) Illustration of the N:M sparse ternary compute flow in the BPN with an example of $S_t = 0.25$ and $m_t = 8$. (c) Accelerator workflow during the computation of different fine-tuning pathways. *left*: Weight stationary workflow for dense GEMM in backbone and adapter pathway. *right*: Input stationary workflow for sparse ternary GEMM in BPN pathway. (d) The design of MPPE and the input formats.

by the adapter. Collectively, the FDA uniformly reduces the computation overhead of BP, as illustrated in Sec. VI-A.

B. N:M Sparse Ternary Bypass Network

To ensure that the BPN remains lightweight with minimal memory and computational overhead, we employ an N:M sparse ternary quantization method for its initialization [25], [26], as the primary computational burden in BP stems from the floating-point GEMM. As illustrated in Fig. 3(d), this approach eliminates multiplications in the BPN while avoiding substantial routing hardware overheads required by unstructured sparsity, balancing algorithmic and hardware efficiency. We divide the pre-trained weight of each output channel into multiple blocks of size m_t. The BPN ternary weight $c_t^{(i,j,k)}$ for the j-th block in channel i is initialized as follow:

$$c_t^{(i,j,k)} = \begin{cases} 0 & ,|w_o^{(i,j,k)}| \le t^{(i,j,:)} \vee k \notin \text{TopK}(|w_o^{(i,j,:)}|) \\ +s^{(i,j,:)} & ,w_o^{(i,j,k)} > t^{(i,j,:)} \wedge k \in \text{TopK}(|w_o^{(i,j,:)}|) \\ -s^{(i,j,:)} & ,w_o^{(i,j,k)} < -t^{(i,j,:)} \wedge k \in \text{TopK}(|w_o^{(i,j,:)}|) \end{cases} \quad (7)$$

where the $s^{(i,j,:)}$ is the scaling factor of each block. The sparsity ratio of all blocks, denoted as S_t, defines the proportion of non-zero ternary values within the block and is controlled by adjusting the hyper-parameter threshold $t^{(i,j,:)}$ and the TopK selection. The ternary sparsity is determined and encoded at the pre-processing stage.

To further reduce the fine-tuning computation and memory overhead, we employ the widely adopted *Compressing-then-Tuning* scheme [12], [19], and integrate the Microscaling (MX) format [27] to compress each fine-tuning pathway. MX groups m data into a block with a shared exponent (i.e., shared scale 2^s) and normalizes each element in the block with this scale. Each element is either a low bit-width floating point or an integer. We employ mixed-precision MX formats to achieve optimal compression performance, quantizing the pre-trained backbone weights in MXFP4 (E2M1) and the adapter parameters, activations, and gradients in MXFP8 (E4M3). Additionally, the MX block size m is aligned with the N:M ternary quantization block size m_t, both set to 32, ensuring compatibility in hardware implementation.

V. DRAFT Hardware Architecture

A. Overview

Fig. 4(a) illustrates the DRAFT accelerator design, whose primary component is the parallel Reconfigurable Processing Element Arrays (RPEA). Each RPEA contains 16 Mixed-Precision Processing Element (MPPE) lanes, each equipped with 32 MPPEs, 8 Sparse Gather units, and a configurable adder tree. These PEs are interconnected via a dynamic data fetch network. Each RPEA includes row and column ports with local shared buffers and input routers. The pre-compiled configuration enables the scheduling of various workflows to optimize on-chip bandwidth and computational resource utilization. Vector Engines support vector-wise operations such as Softmax, Activation, and Layer Normalization. The total on-chip buffer size is 1 MB. Data is stored across the memory hierarchy using block mapping [28]. The temporary buffer accumulates outputs and supports the Vector Engine. At the start of each batch, weight and input data are pre-loaded into the respective on-chip buffers. DRAFT employs a ping-pong strategy to divide the batch into multiple processing phases if the data exceeds the on-chip buffer capacity.

B. Sparse Gather Unit

To fully leverage the N:M ternary sparsity introduced by the BFN, we design and integrate Sparse Gather units within each PE lane. This unit utilizes an inverse butterfly network [25] to compress gradient data G_Y corresponding to non-zero BFN weights, achieving this in $log(m_t)$ steps. Fig. 4(b) shows the computation process of a 3-stage inverse butterfly network with an input block size of 8 and a BFN sparsity ratio S_t of 0.5. In this setup, gradients with a block size of m_t are broadcast from the column-shared buffer to each gather unit. The gathered gradients are then fetched to the MPPE lane for accumulation directly without multiplication, while their sign bits are adjusted based on the sign bit of dense ternary weight. In the physical design, each lane includes 8 gather units configured with a 32-to-8 structure based on the algorithm sensitivity study in Sec. VI-A.

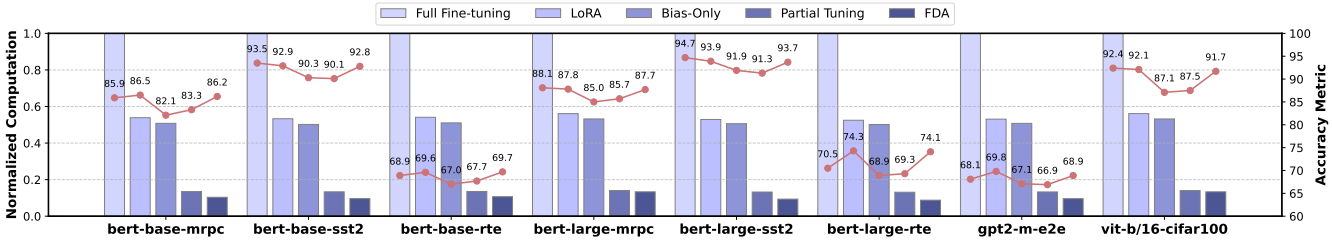

Fig. 5. Fine-tuning accuracy (red dots) and normalized BP computation reduction of different fine-tuning methods on various models and tasks.

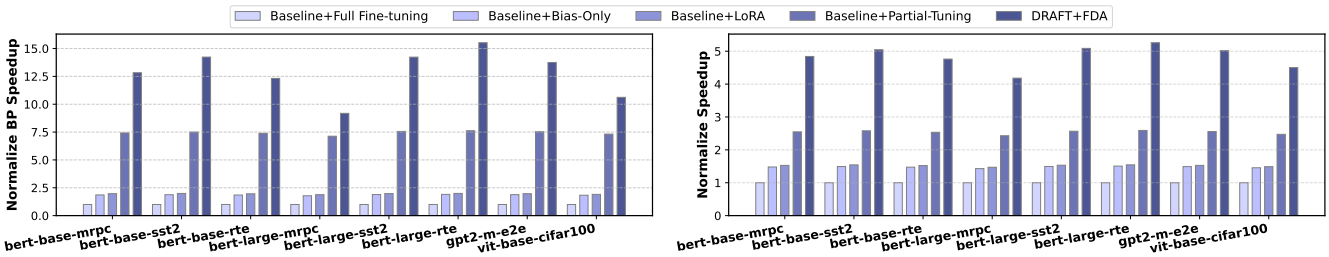

Fig. 6. (a) Normalized BP speedup and (b) normalized end-to-end fine-tuning speedup of DRAFT with FDA, compared to baseline hardware with Full Fine-tuning, LoRA, BitFit, and Partial Tuning (all normalized to Full Fine-tuning running on baseline hardware).

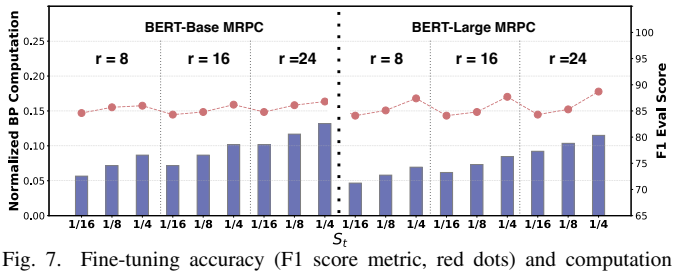

Fig. 7. Fine-tuning accuracy (F1 score metric, red dots) and computation reduction versus various (r, S_t) configurations in FDA.

C. Reconfigurable PE Array

Dual Workflow for Dynamic Fine-tuning Pathway. As illustrated in Fig. 4(c), to fully exploit data parallelism across different fine-tuning pathways, the RPEA can be reconfigured to operate in two distinct workflows: dense GEMM mode and sparse ternary GEMM mode. In the backbone and adapter pathways, all matrix computations are performed in dense mode, utilizing a weight-stationary workflow (shown in Fig. 4(c) left). Weights are pre-loaded into the row buffer and then unicast to each PE, while input data is unicast through a column router to each PE. In contrast, the BPN pathway requires sparse-to-dense gather operations, with each gather unit assigned unique sparsity masks. Sparse ternary matrix multiplication is performed here using an input-stationary workflow (shown in Fig. 4(c) right). Sparse input data is pre-loaded into a column buffer and broadcast to each gather unit, while pre-determined dense ternary sign bits and butterfly control signals are distributed to each gather unit horizontally.

Mixed-Precision Floating-Point PE. The architecture and input format of MPPE is illustrated in Fig. 4(d). The DRAFT fine-tuning process involves three types of matrix operations corresponding to the three modes of the MPPE. *Mode* 0: FP8×FP8, used in the trainable adapter pathway and attention mechanism of the Transformer block; *Mode* 1: FP8×FP4, applied in the pre-trained backbone pathway; *Mode* 2: FP8×Ternary, utilized in the BPN pathway. In Mode 0 and 2, both inputs, IN0 and IN1, are FP8. In Mode 1, IN1 is split into two FP4s to increase the throughput. Each PE receives two FP4 weights corresponding to two output channels, and the adjacent PEs compute the same pair of output channels, exchanging partial results through an inter-PE connection, as illustrated by the purple datapath. The MPPE shares mantissa multipliers and exponent adders across these modes by splitting the MSB and LSB computations.

VI. Evaluation

A. Algorithm Evaluation

Settings: To evaluate the fine-tuning accuracy of FDA, we fine-tuned BERT-Base and BERT-Large [2] models on the MRPC, SST-2, and RTE datasets from GLUE Benchmark [29]; ViT-B/16 model [4] on the CIFAR-100 dataset [30]; and GPT-2 Medium model [31] on the E2E task [32]. Regarding the end-to-end metric, we report the F1 for MRPC, the BLEU for E2E, and the accuracy for the others. We used Full-Finetuning (FT), Bias-Only [8], LoRA, and Partial-Tuning [23] under unified MXFP8 precision as baseline fine-tuning methods. FDA adopts a mixed-precision quantization as introduced in Sec. IV-B. For a fair comparison, the adapter ranks in LoRA, Partial-Tuning, and FDA are set to 16, and all fine-tuning methods have the same hyperparameter setting.

Performance Evaluation: Fig. 5 shows the overall comparison of accuracy metric and normalized BP operations across different fine-tuning methods with S_t in FDA set to 1/4. FT achieves the best accuracy across most tasks but incurs the heaviest BP computational load. LoRA outperformed FT on certain tasks and reduced BP computation to nearly half of FT. The Bias-Only achieved a lighter BP overhead by eliminating weight gradient computation, and Partial-Tuning approached FDA-level reductions by tuning the last few layers. However, both methods exhibited noticeable accuracy losses. In contrast, the FDA maintained an accuracy loss within 1% compared to FT, demonstrating robust performance while reducing BP computation to below 15%. This highlights the effectiveness of the FDA in improving the efficiency of edge fine-tuning.

TABLE I
AREA AND POWER BREAKDOWN OF DRAFT ACCELERATOR (500MHZ)

Module	Area (mm^2)	Power (mW)
RPEA - MPPE & Adder Tree	6.51	729.45
RPRA - Sparse Gather Unit	1.65	142.91
RPEA - Others	1.25	100.28
Vecer Engine	2.01	142.87
SRAM Buffer	2.86	146.06
Others	0.47	26.15
Total	**14.74**	**1287.72**

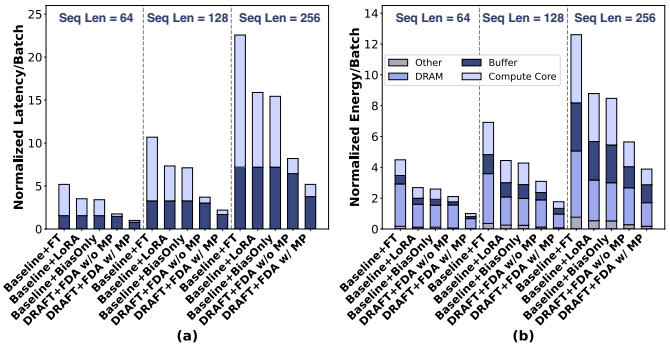

Fig. 8. (a) Latency and (b) Energy breakdown over different hardware with various fine-tuning algorithms for BERT-Base with different batch sequence lengths.

Fig. 7 shows the sensitivity analysis of S_t and r, conducted on BERT-Base and BERT-Large (MRPC). The result indicates that the FDA is more sensitive to BPN sparsity. Notably, when S_t reaches 1/16, a significant accuracy loss is observed, especially in the BERT-Large model. Moreover, a lower S_t incurs additional Sparse Gather unit overhead in hardware implementation. To balance hardware and algorithm efficiency, we keep S_t=1/4 for the following hardware evaluations.

B. Hardware Evaluation

Baseline Setting: We design the baseline hardware based on the SoTA systolic accelerator [18] dedicated to Transformer inference and fine-tuning, which can naturally run all the baseline fine-tuning methods. The baseline hardware is configured to match DRAFT in FP8 compute throughput and memory capacity under the same technology and frequency.

Hardware Implementation: We perform RTL design for the DRAFT and baseline accelerator and synthesized them using Synopsys Design Compiler with a 28nm CMOS technology. The entire DRAFT system operates at 500MHz, with on-chip buffers utilizing foundry-provided SRAM. Power consumption and area results were estimated from the synthesis reports. Additionally, we developed a cycle-accurate simulator and verified it against the RTL implementation. The simulator generates DRAM access traces, used with Ramulator [33] to evaluate DRAM access latency, and DRAMPower [34] to capture the corresponding DRAM power consumption.

Speedup: Fig. 6 illustrates the speedup of DRAFT compared with the baselines. We report both the speedup in the BP phase and the overall fine-tuning speedup. Full-Finetuning, LoRA, Bias-Only, and Partial-Tuning run on the baseline hardware, while FDA runs on DRAFT. During the BP phase, DRAFT achieved an average speedup of 14.1× and 8.3× compared to FT and LoRA running on baseline hardware, respectively. This improvement stems from the N:M sparse ternary BPN, where computational reductions at the algorithmic level align effectively with hardware efficiency. The fine-tuning end-to-end speedup is lower than that of the BP as the DRAFT is tailored to reduce the cost of the BP. DRAFT achieves an average overall speedup of 4.9× by leveraging mixed-precision quantization and the reconfigurable MPPE to improve the throughput of the FF phase.

Hardware Overhead: The hardware area and power consumption of DRAFT after synthesis are shown in Table I. The total power and area are $1.29W$ and $14.74mm^2$, respectively. The MPPE in the RPEA and the buffer significantly contribute to both area and power.

Latency and energy breakdown: Fig. 8 presents the fine-tuning latency and energy breakdown of each batch for BERT-Base with three typical sequence lengths across different fine-tuning algorithms and accelerator hardware. As shown in Fig. 8(a), DRAFT significantly lowers the computational latency of the BP phase, reducing batch latency close to the level of executing only the FF phase. Combined with Mixed-Precision (MP) optimization, DRAFT further reduces latency across all fine-tuning phases.

Fig. 8(b) illustrates the energy breakdown across the compute core, buffer, off-chip memory access, and other modules. By leveraging the FDA, DRAFT achieves 4.2× and 2.3× improvements in energy efficiency compared to FT and LoRA on the baseline hardware, respectively. Based on the algorithm-hardware co-optimization, DRAFT takes full advantage of the parallelism of each fine-tuning pathway, significantly compressing fine-tuning latency and reducing power consumption. Simultaneously, enhanced throughput and improved data reuse alleviate the repeated loading of the substantial weights and batch inputs, thereby lowering the power consumption associated with the expensive on-chip and off-chip data access. In summary, DRAFT significantly improves the throughput and power efficiency of Transformer fine-tuning by fully reducing the BP computational overhead.

VII. CONCLUSION

We propose DRAFT, an algorithm-hardware co-design framework for efficient transformer fine-tuning on edge. The proposed Feedback Decoupling Approximation (*FDA*) algorithm decouples the BP through the backbone weight into the adapter pathway and sparse ternary Bypass Network (*BPN*) pathway. Two lightweight pathways jointly approximate the information of pre-trained weight, uniformly lightening the BP computation overhead for input gradient and weight gradient. An efficient DRAFT accelerator with reconfigurable workflows and sparse gather networks is designed to support fine-tuning with the FDA. Experimental results demonstrate that DRAFT achieves an average speedup of 4.9× and an energy efficiency improvement of 4.2× across multiple fine-tuning tasks with negligible accuracy loss.

***Abstract*—Nowadays, there is a growing trend to deploy machine learning (ML) models on edge devices. To cope with the increasing resource requirements of current ML models, multi-accelerator edge devices that integrate CPU, GPU, NPU, or TPU in a single SoC gain popularity. However, we observe that existing ML inference serving frameworks are poor in utilizing the unique hardware architecture of these edge devices. In this paper, we present INFSCALER, an efficient ML inference serving framework tailored for multi-accelerator edge devices. INFSCALER discovers the architectural bottleneck of ML models and designs a bottleneck-aware asymmetric auto-scaling technique to facilitate efficient resource allocation for ML models on the edge. Furthermore, INFSCALER capitalizes on the hardware's unified memory feature inherent to edge devices, ensuring efficient data sharing between the asymmetrically scaled model partitions. Our experimental results show that INFSCALER achieves up to 126.59% throughput improvement and 27.32% resource reduction while satisfying the latency requirements compared with the state-of-the-art inference serving approaches.**

I. INTRODUCTION

Recently, deploying machine learning (ML) models on edge computing devices rather than the cloud has gained significant attention [1], [2], [3]. Building on this momentum, various merchants such as NVIDIA [4], AMD [5], and Google [6] present multi-accelerator edge devices to provide better ML inference performance. For example, the NVIDIA Jetson series leverages System-on-Chip (SoC) architecture that integrates a CPU, GPU, and NVIDIA Deep Learning Accelerator (NVDLA) onto a single chip. These multi-accelerator devices are now widely used in typical edge environments such as autonomous driving [7], [8] and edge video analytics [9], [10].

Nevertheless, the energy and space limitation of edge environments makes it hard to match the increasing resource demand of modern ML algorithms such as large language models (LLMs). Prior attempts for efficient inference serving on resource-constrained edge devices leverage model quantization [11], [12], pruning [13] or sparsity [14]. These approaches require modifying or retraining the original model, which will lead to an accuracy drop or excessive training overhead.

If we refer to ML serving approaches without modifying the model, which are mostly designed for the cloud, the primary solutions are request batching [15], [16] and instance auto-scaling [17]. The ingress requests are organized into batches to leverage the parallel processing capabilities of hardware accelerators to improve efficiency. Once the request bursts and results in the resource usage of an inference instance exceeding a pre-defined resource cap, the cloud server will scale out, i.e., spawn new serving instances, for higher parallelism.

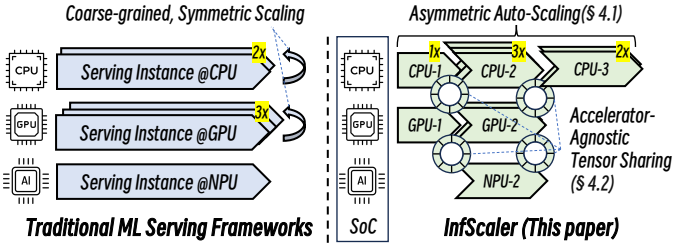

Fig. 1. Illustration of the difference between INFSCALER and existing works.

However, directly adopting these cloud-based solutions is problematic for edge environments because they do not take the unique hardware characteristics of edge devices into consideration. (1) Existing works [15], [16], [17] replicate the *whole ML model* to serve additional requests when scaling out, but edge devices may not be facilitated with enough resources for this coarse-grained scaling. For example, inferencing the `gpt2-medium` model requires ∼6GB memory. While NVIDIA Xavier NX, a typical edge device, is only equipped with 8GB which could not scale the whole model out for bursty requests. (2) Existing ML serving frameworks [18] treat accelerators such as GPU and NPU as peripherals with independent memory management. However, there is a new opportunity for multiple accelerators to cooperate more tightly due to the hardware unified memory design at the edge.

Towards the above problems, we present INFSCALER, an efficient ML inference serving framework tailored for edge devices. Specifically, INFSCALER aims to achieve better inference serving performance (i.e., throughput) while satisfying the latency constraint of requests under a given resource limitation. Considering the multi-accelerator architecture and resource-constrained nature of edge devices, the key idea of INFSCALER is scaling each group of ML operators, i.e., the building blocks of an ML model, with different scaling ratios for better resource efficiency. Unlike symmetrically scaling all operators as a whole model, we call this approach *asymmetric auto-scaling*, as shown in Fig. 1. This approach is based on our observation (cf. §II-B) that ML models inherently contain architectural bottlenecks due to the resource demands of ML operators and their affinity towards accelerators, which negatively impact overall inference performance. Selectively scaling out the bottlenecks can achieve similar, even better,

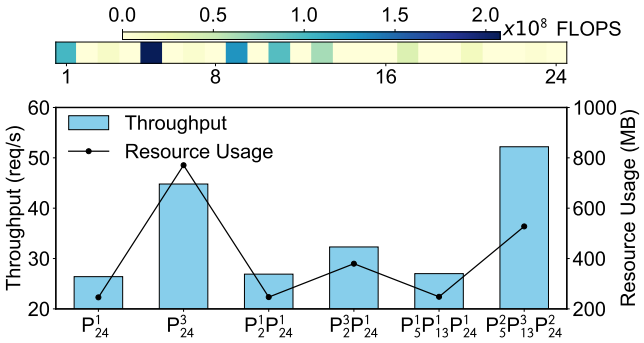

Fig. 2. Illustration of the computation complexity of AlexNet (top) and its inference performance under different settings (bottom). P_x^a denotes the model is partitioned at the end of operator #x and scaled out to a instances.

performance compared to whole model replication.

To facilitate asymmetric auto-scaling, we first identify the bottlenecks through offline profiling and partition the ML model into several groups of operators with fully aware of the bottleneck. At runtime, we perform the asymmetric auto-scaling and also take advantage of the hardware unified memory between heterogeneous accelerators to achieve efficient *accelerator-agnostic tensor sharing* between the partitioned models. Our contributions can be summarized as follows:

- We discover the architectural bottleneck of ML models and its negative impact on the inference performance. Based on this, we propose a *bottleneck-aware asymmetric auto-scaling* strategy to utilize the precious resources on the edge wisely for better performance.
- We advocate an *accelerator-agnostic tensor sharing* mechanism by taking advantage of the hardware unified memory property on edge devices.
- We implement INFSCALER and evaluate its performance extensively. Results show that INFSCALER can improve the inference throughput by 34.78%-126.59% and reduce 10.49%-27.32% resource usage while satisfying the latency constraints.

II. BACKGROUND AND MOTIVATION

A. Hardware Architecture of Edge Devices

Nowadays, edge devices are equipped with AI accelerators like GPUs, TPUs, and FPGAs to enhance performance while keeping energy efficiency in ML processing. The most prevalent edge ML devices are NVIDIA Jetson series, which are widely used in autonomous driving, VR/AR, and robotics. These devices include three generations identified as NVIDIA Jetson, Xavier and Orin. For example, on NVIDIA AGX Xavier, an 8-core Armv8.2 CPU, an integrated NVIDIA Volta GPU (iGPU), and two NVDLA accelerators are located on the same SoC, which is different from the desktop and servers.

Unified memory is originally a software concept in CUDA programming aimed at simplifying CPU RAM and dGPU VRAM management through unified addressing. NVIDIA Jetson series leverages a *hardware unified memory* architecture where all the accelerators share a common hardware main memory. From the second generation (Xavier) on, hardware cache coherence between CPU and iGPU further accelerates memory sharing. This distinct feature provides a promising starting point for our data-plane acceleration for serverless inference on edge devices.

B. Architectural Bottleneck of ML Models

ML bottlenecks. ML models include multiple computation operators such as convolution, pooling, and normalization. However, the computational complexity disparity among operators and their affinity towards heterogeneous accelerators results in some of them serving as a bottleneck of the whole model. To examplify, we use a representative ML model, AlexNet, and study its inference performance on the NVIDIA Xavier AGX multi-accelerator edge device in Fig. 2.

> **Observation 1:** ML models inherently contain bottlenecks due to the unbalanced distribution of the computation complexity, which hinders the overall inference performance.

We can see from the figure that certain operators (e.g., #1, #5, #13) exhibit notably higher complexity compared to others, resulting in their computation time being prominently longer than other parts, which lowers the overall inference throughput. We identify these layers are the "bottleneck" of AlexNet. To make things worse, the traditional auto-scaling mechanism of ML serving directly scales the whole model when confronted with burst requests. However, on resource-constrained edge devices, this coarse-grained scaling mechanism uniformly allocates additional resources to all layers, potentially resulting in a waste of precious resources. *Consequently, a novel fine-grained scaling approach is imperative for serverless ML inference on edge devices.*

Impact of asymmetric auto-scaling. Based on the above observation, we further investigate how to deal with the architectural bottleneck of ML models for better inference. We quantify the inference throughput and resource usage under the same predefined resource cap. Results in Fig. 2 show that $P_5^2P_{13}^3P_{24}^2$ achieves the best performance among the six configurations. It exhibits 16.5% throughput improvement against the second-performed baseline P_{24}^3, i.e., no partition and scaling to three instances, with 31.5% less resources used. The key takeaway of this improvement is this asymmetric scaling can leverage wiser resource usage, which is allocating more resources to the bottlenecks instead of distributing them equally. Moreover, this improvement is also fragile. Also, from the results of other partitioned baselines, we can see that it requires a prudent model partition and scaling policy to achieve optimal performance.

> **Observation 2:** Asymmetric auto-scaling, i.e., selectively scaling out the bottleneck with an appropriate ratio, can enhance the throughput performance with the same resources.

The above results demonstrate the potential for fine-grained, asymmetric auto-scaling on edge devices. *However, how to wisely partition the model considering bottleneck and scales out for optimized performance remains unsolved.*

III. INFSCALER OVERVIEW

A. Design Principles

Throughout our system design of INFSCALER, we adhere to the following guiding principles. **(1) User-transparent.** As an ML inference serving framework, INFSCALER should ensure users remain unaware of underlying complexities such

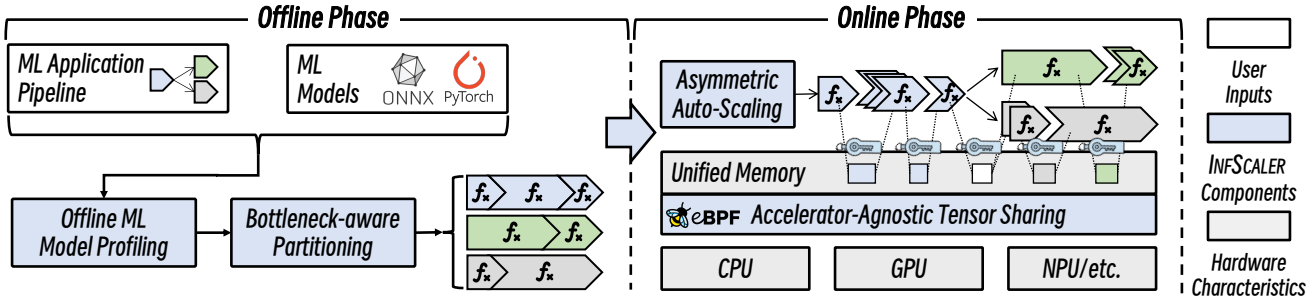

Fig. 3. System overview of INFSCALER framework.

as model partitions and fine-grained scaling mechanisms. Additionally, INFSCALER should maintain model accuracy without altering its structure to achieve this transparency. **(2) Hardware-oriented.** INFSCALER targets the ML inference on edge devices facilitated with heterogeneous accelerators such as the NVIDIA Xavier series. Hence, we should fully utilize the hardware characteristics of edge devices by design to achieve better performance. **(3) Throughput-aware.** Maximizing throughput ensures INFSCALER achieves an efficient usage of the limited resources on edge devices to process a high volume of concurrent requests. Hence, we design INFSCALER to maximize the throughput while satisfying the latency service level objective (SLO) specified by users.

B. INFSCALER *in a nutshell*

Fig. 3 depicts the bird's-eye view of INFSCALER system. It has an offline phase to generate the optimized function deployment and an online phase to further improve the performance.

Offline deployment optimization. In the offline phase, users submit their ML application to be deployed and the corresponding ML models. Similar to the existing practices such as the inference graph of KServe [19] and SageMaker Pipeline of AWS [20], INFSCALER supports submitting an ML application including multiple ML algorithms that formulate a *pipeline*. For example, an NLP pipeline needs to first run document classification, and then perform named entity detection downstream based on the previous classification results. As for ML models, INFSCALER do not require any modification to ML models and users can directly submit the *unmodified* ML models such as ONNX or PyTorch. One of the main design principles of INFSCALER is to maximize the inference throughput while satisfying the latency constraint. Hence, it is necessary to address the architectural bottlenecks of ML models during inference. A naïve idea is to allocate more resources to the bottleneck layers for better performance. However, traditional ML serving frameworks cannot precisely allocate additional resources only to the bottleneck because they leverage a coarse-grained scaling mechanism. Hence, to obtain the opportunity for precise resource allocation, INFSCALER first profiles for detailed performance metrics (e.g., FLOPs, execution time) and partitions the ML model into slices for asymmetric auto-scaling.

Online ML inference serving. During the online serving process, INFSCALER optimizes the inference performance in two ways. First, INFSCALER leverages asymmetric auto-scaling in correspondence to the ingress request variations. With the help of bottleneck-aware partitioning, INFSCALER can only scale up the bottleneck part of the model to achieve better resource efficiency. Second, INFSCALER achieves systematic support for multi-accelerator edge devices by allowing the asymmetric auto-scaling to scale part of the model to all accelerators. Furthermore, INFSCALER designs an accelerator-agnostic tensor sharing mechanism that leverages the hardware unified memory to efficiently share outputs between model partitions.

IV. DESIGN OF INFSCALER

A. Asymmetric Auto-Scaling of ML models

As we demonstrated in §II-B, ML models include (multiple) architectural bottlenecks that impede inference efficiency. In this section, we show our detailed designs about how to achieve asymmetric auto-scaling while fully aware of the bottlenecks of ML models. We first detect the bottleneck and figure out the optimal scaling-out policies. After that, we move on to the resource allocation problem with a given partition because the allocation of CPU and memory poses a significant influence on the overall performance.

Offline bottleneck-aware partitioning. Designing a wise partition algorithm requires us to consider the following trade-off, where more partitions lead to an excessive overhead for inter-partition communication but fewer partitions are not fine-grained enough for efficient resource allocation. According to §II-B, we find that computation complexity can be a source of inference bottlenecks. To address the partition granularity and overhead tradeoff, the main idea of INFSCALER's partitioning is to balance the computation complexity among the operators in a partition. The intuition here is each partition is also a minimum resource allocation unit. Operators inside a partition scale up and down at the same time, which means the resources are allocated evenly in a partition. If the partition contains several operators with massive different complexities, the largest operator will further become the new bottleneck in the partition that impedes the overall performance.

Therefore, our bottleneck-aware partitioning problem could be formulated as an optimization problem that minimizes the variance of the computation complexity of each group while keeping the latency satisfies the user-specified SLO:

$$\arg\min_{P_1,\cdots,P_k} \sum_{k=1}^{K} \sigma(P_k)$$
$$\text{s.t.} \begin{cases} \hat{T_o} + (K-1)T_p \leq SLO \\ P_k = \{c_n | n \in [p_{k-1}+1, p_k], c_n > \overline{C_N}\} \\ P_1 \cup \cdots \cup P_K = C_N \end{cases}, \quad (1)$$

Algorithm 1: Asymmetric auto-scaling policy

Input: $\mathcal{B} = \{B_1, \cdots, B_K\}$: set of bottleneck indicator;
$A_k^m \in \mathcal{A}_k$, u_k^m: hardware affinity and expected resource usage of partition k on accelerator m;
U^m, R^m: resource used and limit of accelerator m;
Output: Number of scaled instance $\mathcal{S} = \{S_1, \cdots, S_K\}$

1 **foreach** *SLO unsatisfaction detected* **do**
2 $\quad k^* \leftarrow \arg\max_{k=1}^{K} B_k, B_k^* \leftarrow \max_{k=1}^{K} B_k$;
3 $\quad$ **foreach** $A_{k^*}^m \in sort(\mathcal{A}_{k^*})$ **do**
4 $\quad\quad$ **if** $U^m \leftarrow U^m + r_{k^*}^m < R^m$ **then**
5 $\quad\quad\quad B_{k^*} \leftarrow \frac{B_{k^*} S_{k^*}}{S_{k^*}+1}$;
6 $\quad\quad\quad U^m \leftarrow U^m + r_{k^*}^m$; $S_{k^*} \leftarrow S_{k^*} + 1$;
7 $\quad\quad\quad$ **break**;

which partitions an ML model with N operators into K partitions. $\sigma()$ stands for the calculation of standard variance. P_k and p_k are the computation complexity set and the index of the last operator of partition k. $c_n \in C_N$ is the computation complexity of n-th operator. $\hat{T}_o$ means the predicted model execution time, T_p denotes the overhead introduced by partitioning. Instead of using all layers, INFSCALER only considers the representative layers whose complexity is bigger than the model average in this optimization (constraint #1). This is because compared with the bottleneck layers, these small layers have a very limited impact on the throughput and resource allocation.

Online asymmetric auto-scaling policy. By "asymmetric," we mean that (1) the scaling factors of each partition can differ from one another, and (2) partitions can be scaled to different types of accelerators.

Algorithm 1 depicts the auto-scaling policy. Once detected the serving performance cannot meet the user-specified latency SLO, INFSCALER starts auto-scaling. First, we identify the partition k with the maximum *bottleneck indicator* B_k (line 2), which is defined as the sum of the computation complexity of each operator in the partition $\sum P_k$, serving as the target for scaling out. This is because the partition with the highest B_k has the greatest computational complexity and thus requires scaling first. Then, INFSCALER determines on which accelerator to scale partition k with the help of the profiled hardware affinity, e.g., execution latency, and checks if the accelerator has enough resources to accommodate it (lines 3, 4). If yes, we reduce the bottleneck indicator of partition k to adjust its future priority in scaling (line 5), record the resource usage, and finally perform scaling (line 6). With this asymmetric auto-scaling policy, INFSCALER dynamically scales out the partition that needs more resources the most, which leads to better resource efficiency and inference performance.

B. Accelerator-Agnostic Tensor Sharing

Although asymmetric auto-scaling brings intrinsic performance gains, it also incurs more Inter-partition data transmission. Therefore, it is imperative to meticulously devise a systematic data flow design for sharing the input and output tensors of each function.

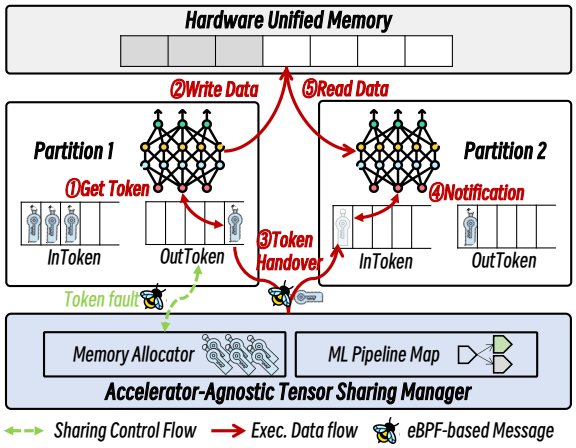

Fig. 4. Illustration of the accelerator-agnostic tensor sharing.

To improve data sharing efficiency, numerous works [21], [17] leverage the zero-copy technique for tensor sharing. Zero-copy means transferring solely an address pointer to shared data instead of transferring all the data itself. Nonetheless, these prior works of zero-copy data sharing devote less attention to the following two unique problems in INFSCALER. (1) The asymmetric auto-scaling technique leads the tensor sharing problem to a multi-producer, multi-consumer (MPMC) memory sharing scenario. For example, once a partition of an ML model scales out asymmetrically to multiple instances, its subsequent partition should acquire data from both the scaled instances, i.e., multi-consumer, and its preceding partition should share data with both instances, i.e., multi-consumer. For example, when a partition of an ML model scales out asymmetrically across multiple instances, it acts as multiple data producers to distribute data to subsequent partitions. by acquiring data from all involved instances. Conversely, its preceding partition also needs to share data to multiple consumers. (2) To make things worse, the data producers and consumers can reside on heterogeneous accelerators. Hence, INFSCALER proposes an *accelerator-agnostic tensor sharing* mechanism to address the aforementioned problems.

eBPF-based event-driven sharing. Towards the MPMC zero-copy sharing problem and preventing the data race between multiple instances, INFSCALER adopts an event-driven sharing mechanism. Specifically, to share the data between instances, the data producer should acquire a token (i.e., memory address) from INFSCALER before it can proceed with writing data. After completing the write operation, the producer then sends this token to the consumer as an event to trigger the reading.

This token-based sharing has two merits. On the one hand, compared with the widely-used polling-based zero-copy sharing approach [17], it reduces the frequency of memory access and achieves lower runtime overhead which is suitable for edge environments. On the other hand, it transforms the ad-hoc usage of shared memory into centralized management, which gives us the chance to holistically manage the load balancing among different scaled instances on heterogeneous accelerators. We further optimize the centralized scheduling overhead by leveraging eBPF for all the control flow communications. An eBPF map is introduced to intercept the

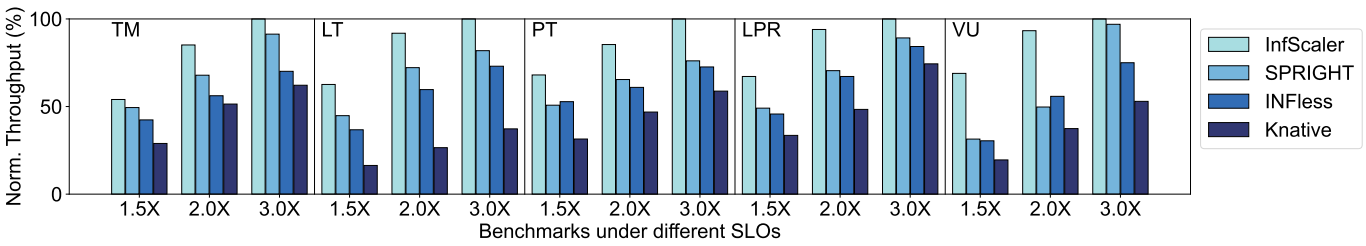

Fig. 5. Comparison of the normalized throughput of INFSCALER under different latency SLO settings against baselines. Here, 1.5× denotes that the SLO is set to 1.5 times of its normal inference time, which we refer to as high pressure. Similarly, 2.0× and 3.0× stands for medium and low pressures, respectively.

token fault for sidecar control flow and the token handover for execution control flow of the inter-partition data sharing. Here raises a new question: why not implement the memory sharing manager directly in an eBPF function? This is because eBPF functions reside in the kernel, which poses strict constraints on execution time. If we push all the logic in the memory sharing manager into an eBPF function, it incurs much overhead for the kernel and may expand the attack surface. Moreover, eBPF functions are not adaptive to the function deployment changes. As INFSCALER is a general ML serving system, applications deployed on top of our framework are versatile. Implementing the memory sharing manager in a separate service in user space is more adaptive for ever-changing applications.

Lazy sharing mechanism. Towards the data sharing between heterogeneous accelerators, we implement the above zero-copy mechanism on the hardware unified memory which all accelerators can access directly. Furthermore, INFSCALER adopts a lazy allocation mechanism to prevent excessive allocations of limited hardware unified memory on edge devices. Lazy means instead of allocating all the shared memory at once, INFSCALER allocates the memory when instances report a memory shortage. We argue that this approach will reach a dynamic balance of the input and output between consecutive partitions.

The whole tensor sharing process is illustrated in Fig. 4. The tensor sharing manager handles the overall new memory allocation and inter-instance token exchange. When partition 1 tends to share the output with partition 2, it first checks if the `OutToken` queue is empty. If there is a token, it writes data to the corresponding region and hands over the token to the consumer. If the `OutToken` is empty, partition 1 will send a token fault to the tensor sharing manager. The sharing manager will select an idle memory region and send its address back for further usage.

V. EVALUATION

A. Experimental Setup

Testbed. We conduct the experiments on the NVIDIA Xavier AGX development board, which is a widely used multi-accelerator edge device.

Baselines. We compare INFSCALER against the following baselines: (1) *INFless* [15]: An ML inference serving framework that leverages auto-scaling and batching to improve resource efficiency. (2) *SPRIGHT* [17]: A state-of-the-art application serving framework that focuses on efficient memory sharing mechanism for pipelined applications. (2) *Knative* [18]: A widely-used open-source ML serving system based on Kubernetes. We apply our partitioned and configured functions on Knative without the hardware-oriented memory sharing to see how it performs.

TABLE I
APPLICATION BENCHMARKS USED FOR EVALUATION.

Benchmark	ML Pipeline	Involved Models
Traffic Monitoring (TM)	❶→❷	Vehicle detection(❶SSD), Vehicle model recognition(❷ShuffleNet)
Language Translation (LT)	❶→❷→❸	Semantic feature extraction(❶Transformer), Cross-language conversion(❷Transformer), Target statement decoding(❸Transformer)
Person Tracking (PT)	❶→❷	Human detection(❶TinyYOLOv3), Person identity finding(❷VGG)
License Plate Recognition (LPR)	❶→❷	Image super-resolution(❶ResNet100), Character recognition(❷MobileNet)
Video Understanding (VU)	❶→❷	Video content analysis(❶Inception), Content Understanding(❷BERT)

Benchmarks. We excerpt five production ML applications from [15], [22] as benchmarks in our evaluation, as shown in Table I. Furthermore, to evaluate INFSCALER under real-world workloads, we replay the Microsoft Azure Functions (MAF) dataset [23] which records approximately 46,000 requests of Azure cloud services.

B. Evaluation Results

Throughput optimization. Fig. 5 shows the results of how INFSCALER optimizes the model inference throughput compared with existing approaches. We can see from the result that INFSCALER achieves 34.78%, 48.14%, and 126.59% average improvement on throughput compared with SPRIGHT, INFless, and Knative. We can also observe that INFSCALER perfoms better in harsh workloads. For example, under the low workload pressure (SLO=3.0x), INFSCALER achieves 23.87% throughput improvement against the best-performed counterparts, SPRIGHT. When it comes to high workload pressure (SLO=1.5x), INFSCALER can achieve 40.82% performance gain. This is because higher pressure makes efficient resource usage more critical; even slight inefficiencies can lead to substantial performance degradation.

We then elaborate more on the different improvements against different approaches. The most noticeable improvement is when compared with Knative and INFless. INFless leverages batch mechanism to improve resource efficiency, but its coarse-grained auto-scaling hinders the performance on edge devices. On the other side, SPRIGHT achieves the best performance among the baselines. As we all know SPRIGHT does not include a partitioning algorithm, it focuses on the

TABLE II

‡ Under the real-world workload, the state-of-the-arts fails to meet the SLO of VU application while INFSCALER succeed.

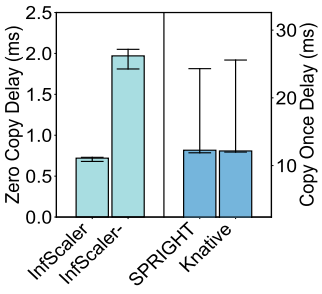

Fig. 6. Tensor sharing overhead against baselines.

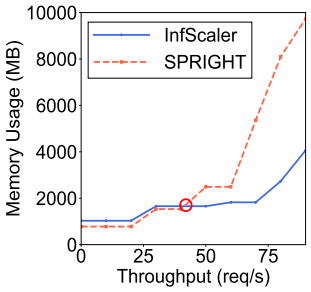

Fig. 7. Latency comparison among INFSCALER and baselines.

efficient data sharing between different serving instances. The ML applications we used as baselines are composed of several steps, which are suitable for SPRIGHT. However, similar to INFless, it also leverages coarse-grained scaling which misses the opportunity to achieve efficient resource usage.

Resource usage efficiency. We then move on to evaluate INFSCALER under real-world workloads and compare the resource usage efficiency against baselines. Table II shows the resource usage, i.e., memory, comparison against baselines. The workload pressure is set to medium, i.e., SLO=2.0x. We can see from the table that INFSCALER achieves 10.49%-27.32% of resource usage reduction against state-of-the-arts. More importantly, INFSCALER is the only framework that finishes the VU application under the SLO constraint. We attribute this improvement to the asymmetric auto-scaling which facilitates an unbalanced but efficient resource usage of different parts of ML models. Furthermore, the second-best approach varies between SPRIGHT and INFless, suggesting that solely focusing on scaling and data sharing may not always yield optimal performance. In addition to asymmetric auto-scaling, INFSCALER also optimizes the tensor sharing overhead, ultimately resulting in improved performance.

Overhead analysis. The overhead of INFSCALER mainly comes from the tensor sharing latency and the additional resources used for supporting multiple instances after partition.

We first evaluate the tensor sharing overhead in Fig. 6. INFSCALER– indicates the latency without our eBPF-based control-plane optimization. We can see that the data transferring overhead is reduced to less than 1 ms with our accelerator-agnostic tensor sharing mechanism, which is neglectable compared with tens or hundreds of milliseconds of inference latency. As for the resource overhead, we present a detailed measurement of the resource usage under different throughputs in Fig. 7. Comparing with SPRIGHT, the best-performed baseline, we observe that at low throughputs, the memory overhead leads to excessive resource usage because SPRIGHT does not include a partitioning strategy. As the throughput increases, the benefit of our asymmetric auto-scaling outweighs the overhead. We also argue that this runtime overhead could be further reduced with the runtime sharing approaches [24], which we identify as the future direction of INFSCALER.

VI. RELATED WORK

INFSCALER builds upon various projects and research. In this section, we summarize the existing works on ML inference serving that shed light on the design of INFSCALER.

To optimize the inference latency and achieve cost efficiency, some existing works use adaptive batching [25], [16], [26] while others focus on how to allocate resources of each ML serving instances [27]. The most related work to INFSCALER is INFless [15]. Instead of "patching" existing ML serving systems such as AWS Lambda [28] or Azure Functions [29], INFless presents a domain-specific inference system leveraging adaptive batching and cold-start mitigation mechanism to support ML inference tasks better. Compared with existing works, INFSCALER adopts an orthogonal view on inference serving, which is optimizing the structural bottleneck of AI models with auto-scaling. Another difference is INFSCALER targets the inference on edge devices that exhibit different hardware characteristics against cloud servers.

Due to the limited resources of edge devices, plenty of research on edge ML inference focuses on reducing resource usage or involving additional computing devices [1]. One of the well-studied optimizations is model pruning [13], [30]. It could reduce the model size and execution time to adapt to edge or IoT devices. For example, DyGNN [13] presents a software-hardware co-optimization approach for efficient GNN pruning and inference. However, model pruning approaches mostly need re-training or sacrifice accuracy limiting its utilization. There are also many works leveraging edge-cloud collaboration to improve inference performance. Several works [31], [32] split the ML model and distribute the ML partitions to edge and cloud for better latency and energy. Orthogonal to the above optimization attempts, INFSCALER takes the advantages of the auto-scaling technique and proposes an asymmetric auto-scaling approach with the help of bottleneck identification to make a wiser usage of limited edge resources.

VII. CONCLUDING REMARKS

This paper presents INFSCALER, a machine learning (ML) inference serving framework designed to address the challenges of inference on edge devices. By identifying architectural bottlenecks within ML models and implementing a bottleneck-aware asymmetric auto-scaling technique, INFSCALER facilitates fine-grained resource allocation on the edge, resulting in significant throughput improvements while adhering to latency SLOs. Leveraging the unified memory characteristic of multi-accelerator edge devices, INFSCALER efficiently reduces the partitioning overhead by an accelerator-agnostic tensor sharing mechanism. The experimental results underscore the effectiveness of INFSCALER by achieving 69.8% throughput improvement on average and up to 27.3% resource usage reduction, showcasing its potential to enhance edge-based ML inference capabilities while meeting stringent performance requirements.

***Abstract*— While multi-chiplet based many-core systems have emerged as a viable solution for heterogeneous integration and addressing manufacturing and technological challenges in the post-Moore's Law era, their design and optimization remain highly complex and challenging. Among the various subsystems, the cache hierarchy has significant implications for overall system performance, yet its vast design space presents substantial optimization challenges. This complexity arises from factors such as the large number of chiplets in the system, the number of cores per chiplet, memory hierarchy variations, cache size variability, caching strategies, and inter-chiplet interconnection networks. Existing design space exploration methods, such as NN-Baton and IntLP, fail to optimize cache subsystem performance or thoroughly explore the design space. To address these limitations, we propose a novel design space exploration method for cache subsystem optimization. Our approach models cache miss rates and network latency as functions of cache hierarchy and inter-/intra-chiplet interconnection network parameters. We then define an optimization problem to minimize the concurrent average memory access time (C-AMAT) under cost and power consumption constraints. This problem is addressed using a bilevel optimization algorithm, which iteratively solves two independent subproblems: (1) cache subsystem optimization, and (2) inter-chiplet interconnection network optimization. Experimental results show that our method reduces the application execution time by 39.7% and 39.2%, on average, compared to architectures similar to AMD Zen 4 and Intel Sapphire Rapids, respectively, and by 25.91% over IntLP. These results underscore the potential of the proposed method for optimizing cache subsystems in future multi-chiplet based many-core systems.**

***Index Terms*—Many-core Systems, Multi-chiplet System, Design Space Exploration.**

I. Introduction

Multi-chiplet based many-core systems have been a new design paradigm to overcome the area wall to provide high computation power for various applications. In multi-chiplet systems, multiple chiplets or dielets can be integrated on interposers or substrates, and chiplets communicate by die-to-die (D2D) interfaces. A key to multi-chiplet based many-core systems is the cache hierarchy design. The difference in the cache hierarchy between a multi-chiplet based many-core system and conventional single chip (SoC) many-core systems is two folds: (1) The chiplets are "clusters" where the inter-chiplet communication is much more inefficient than that of the intra-chiplet communication. For example, the transmission latency between two adjacent chiplets is an order of magnitude longer than those of two adjacent tiles inside one chiplet. Due to the much higher latency and much lower bandwidth in inter-chiplet communication, the cache access traffic should be localized as much as possible to avoid high inter-chiplet communication latency [1]. (2) The problem of designing an optimal cache hierarchy has numerous parameters and extremely high complexity, especially in a multi-chiplet system.

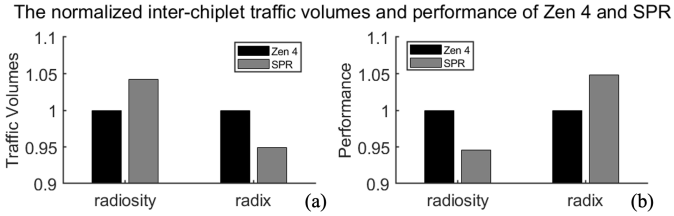

Fig. 1. Comparison of (a) inter-chiplet traffic volumes and (b) performance of AMD Zen 4 and Intel Sapphire Rapids.

Fig. 1 shows inter-chiplet traffic volumes for radiosity and radix applications on AMD Zen 4 [2] and Intel Sapphire Rapids (SPR) [3] systems. Zen 4 and SPR have different cache settings, e.g., whether the LLC in each chiplet is shared or not, and whether there is a centralized IO die for the memory controller or not. According to Fig. 1, for radiosity and radix, the inter-chiplet traffic volume of SPR is 1.042x and 0.949x of Zen 4 respectively, and correspondingly the performance of SPR is 0.946x and 1.048x of Zen 4 respectively. From this example, two observations can be made: (1) Higher inter-chiplet traffic volume leads to lower performance. (2) The configuration of cache and memory subsystem impacts the inter-chiplet traffic volume and thus performance. Therefore, it needs to explore the cache subsystem design space.

However, the design space of cache hierarchy is extremely huge, leading to an optimization problem with high complexity. For example, the design variables include chiplet number, the number of cores in each chiplet, memory hierarchy in each chiplet, cache size, different inter-chiplet interconnection networks, etc. Existing design space exploration methods like IntLP [4], NN-Baton [5], and Monad [6] cannot solve the above challenge since they cannot explore such a huge space.

Therefore, in this paper, we propose an efficient optimization algorithm for design space exploration of cache subsystems in multi-chiplet systems. In essence, (1) An analytical cache performance model based on C-AMAT [7] is proposed for multi-chiplet systems. (2) An optimization problem is formulated to select the parameters to optimize cache performance under the cost and power budgets. (3) A bilevel algorithm to efficiently solve the problem is proposed, where the optimization problem is decomposed into two subproblems: (a) cache subsystem optimization, and (b) inter-chiplet interconnection network optimization, and those two subproblems are optimized iteratively.

TABLE I
NOMENCLATURE

Symbol	Definition
v_{ijk}	The i-th cache in level j in chiplet k.
$e_{ijk,mno}$	The link connecting v_{ijk} and v_{mno}.
$w(v_{ijk})$	The weights of node v_{ijk}.
$n_{p,q}$	The p-th node in chiplet q.
$c(n_{p,q}, n_{r,s})$	The link between adjacent nodes $n_{p,q}$ and $n_{r,s}$.
$\omega(c(n_{p,q}, n_{r,s}))$	The transmission latency between $n_{p,q}$ and $n_{r,s}$.
$\|R_i\|$	The number of cores in chiplet i.
n_α	The chiplet number.
h_i	The total number of memory hierarchy in chiplet i.

The remainder of the paper is organized as follows. Section 2 reviews the related work. Section 3 analyzes and models multi-chiplet systems, and defines the cache performance optimization problem. Section 4 presents a bilevel optimization algorithm to solve the optimization problem. Section 5 provides experimental results. Finally, Section 6 concludes the paper.

II. Related Work

Concurrent average memory access time (C-AMAT) [7] refines the traditional average memory access time (AMAT) model by accounting for memory concurrency and categorizes memory cycles to better model memory access performance. Layered performance matching (LPM) enables hierarchical memory performance analysis, transforming overall optimization into a set of local optimizations for each cache level. In [8], researchers developed models to enhance cache miss rate estimation and cache partitioning for multi-core systems, addressing data-sharing, coherence, and runtime monitoring for efficient cache use. In [5], [6], [9], several methodologies, including NN-Baton, SASMM, and Monad, were proposed to optimize chiplet-based system design, focusing on functional partitioning, resource allocation, and performance optimization. IntLP [4] proposed an integer linear programming model for the design of multi-chiplet systems, which determines the optimal partitioning of functional components and chiplet selection. Existing methods struggle to optimize multiple cache parameters or explore sufficiently large design spaces, and most focus on narrow objectives. This paper proposes a comprehensive optimization to overcome these challenges.

III. Performance Modeling and Problem Definition

A. Systems Modeling

As shown in Fig. 2, the multi-chiplet based many-core system is modeled by two graphs: memory hierarchy graph and inter-chiplet interconnection network topology graph, characterizing its cache and interconnection subsystems.

Definition 1. Memory hierarchy graph $G_M(V, E)$. $G_M(V, E)$ is an undirected graph, where each node $v_{ijk} \in V$ is either a core, a cache unit, or a DRAM unit. v_{ijk} is the i-th cache in level j in chiplet k. The edge $e_{ijk,mno} \in E$ indicates the link connecting v_{ijk} and v_{mno} (between two levels of cache units, or the reachability of core). If v_{ijk} is connected to v_{mno}, then $e_{ijk,mno} = 1$, indicating v_{ijk} is related to v_{mno} (for example, inclusiveness), and 0 otherwise. As shown in Fig. 2 (a), each core with an L1 cache, an L2 cache, and the two cores sharing an L3 cache are shown as the memory hierarchy graph. There is an edge between v_{131} and v_{121}, indicating the inclusiveness of v_{131} over v_{121}. Otherwise, there is no connected edge between v_{131} and v_{321}, indicating that v_{131} is not inclusive over v_{321}.

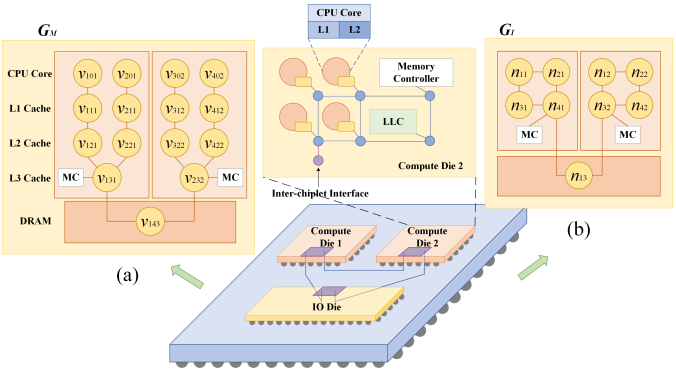

Fig. 2. The multi-chiplet based many-core system graph, (a) the $G_M(V, E)$ graph example and (b) the $G_I(N, C)$ graph example.

Define h_k as the total number of cache hierarchy in chiplet k. The weights $w(v_{ijk})$ of node $v_{ijk} \in V$ are as follows. The node v_{ijk} with $j = 0$ is a core, where $cpi(v_{ijk})$ is the ideal CPI (assuming no cache miss), which is the average number of clock cycles per instruction. The node v_{ijk} with $0 < j < h_k$ is a cache unit, where $cs(v_{ijk})$ is cache size, $cl(v_{ijk})$ is cache line size, $as(v_{ijk})$ is associativity, $rs(v_{ijk})$ is replacement strategy, and $ac(v_{ijk})$ is the cache access rate. The node v_{ijk} with $j = h_k$ is a DRAM unit, where $bw(v_{ijk})$ is DRAM bandwidth.

$$w(v_{ijk}) = \begin{cases} \langle cpi(v_{ijk}) \rangle, & j = 0 \\ \langle cs(v_{ijk}), cl(v_{ijk}), as(v_{ijk}), \\ rs(v_{ijk}), ac(v_{ijk}) \rangle, & 0 < j < h_k \\ \langle bw(v_{ijk}) \rangle, & j = h_k \end{cases} \tag{1}$$

Definition 2. Inter-chiplet interconnection network topology graph $G_I(N, C)$. $G_I(N, C)$ is also defined as an undirected graph where each node $n_{p,q} \in N$ is a node in chiplet q on the inter-chiplet network, which is composed of a core, an L1/L2 bank, a network interface, and a router, or is a D2D interface only. C is the set of network links, $c(n_{p,q}, n_{r,s}) \in C$ is the link between adjacent nodes $n_{p,q}$ and $n_{r,s}$. The chiplets in G_I are denoted as $R_1, \ldots, R_{n_\alpha}$, where each $R_i \subset N$, $i = 1, \ldots, n_\alpha$. n_α is the total number of chiplets. The number of cores in chiplet i is denoted by $|R_i|$.

Define $\omega(c(n_{p,q}, n_{r,s}))$ as the transmission latency between $n_{p,q}$ and $n_{r,s}$. If $q = s$, nodes $n_{p,q}$ and $n_{r,s}$ are in the same chiplet; otherwise, they are in different chiplets. Fig. 2 (b) shows an example of a three-chiplet system connected by an inter-chiplet network and its corresponding interconnection graph.

B. Miss Rate Modeling

In this paper, we model the miss rate with G_M where the parameters relate to cache miss rate of different cache levels.

Given G_M, the miss rate of node v_{ijk} $(0 < j \leq h_k - 1)$ is $M(v_{ijk})$. Define $\Pi(v_{ijk}) = \{\pi_1(v_{ijk}), \ldots, \pi_n(v_{ijk})\}$ as the set of nodes on entire reachable path from any core to v_{ijk} (excluding the cores), where $\pi_x(v_{ijk})$ is the x-th node on the reachable path and n is the total number of nodes. All upper-level nodes in cache hierarchy with connection relationships in v_{ijk} are included in $\Pi(v_{ijk})$.

According to [10], the cache miss rate $M(v_{ijk})$ of v_{ijk} is modeled as:

$$\Lambda(v_{ijk}) = \sum_{x=1}^{n} a_x \cdot cs\big(\pi_x(v_{ijk})\big)^{\alpha_x} + \sum_{x=1}^{n} b_x \cdot cl\big(\pi_x(v_{ijk})\big)^{\beta_x} + \sum_{x=1}^{n} c_x \cdot as\big(\pi_x(v_{ijk})\big)^{\gamma_x} \quad (2)$$

$$M(v_{ijk}) = \sum_{x=1}^{n} d_x \cdot \mathcal{S}\big(\Lambda(v_{ijk}), rs\big(\pi_x(v_{ijk})\big)\big)^{\delta_x} \quad (3)$$

$$\forall\, 0 < i \le |R_k|,\ 0 < j < h_k,\ 0 < k < n_\alpha,\ \pi_x(v_{ijk}) \in \Pi(v_{ijk})$$

where $\Lambda(v_{ijk})$ is a polynomial function of cache size, cache line size, and associativity. a_x, b_x, c_x, and d_x are miss rate model cache correlation coefficients, α_x, β_x, γ_x, and δ_x are polynomial orders, and $\mathcal{S}\big(\Lambda(v_{ijk}), rs\big(\pi_x(v_{ijk})\big)\big)$ is a mapping function that returns the miss rate, given $\Lambda(v_{ijk})$ and replacement strategy.

C. Delay Modeling

The delay model is used to estimate the transmission latency between two cores, which consists of two parts: (1) zero-load latency, which is related to the distance between the source and destination cores, (2) queuing delay, which is modeled by a queuing theory model.

1) Zero-load latency: By modeling the latency using G_I, $L(n_{p,q}, n_{r,s})$ is defined as the zero-load latency for node $n_{p,q}$ to access node $n_{r,s}$. The latency consists of two parts: the header packet latency $L_h(n_{p,q}, n_{r,s})$ and the serialization latency $L_s(n_{p,q}, n_{r,s})$ as follows.

$$L(n_{p,q}, n_{r,s}) = L_h(n_{p,q}, n_{r,s}) + L_s(n_{p,q}, n_{r,s}) \quad (4)$$

where the header packet latency $L_h(n_{p,q}, n_{r,s})$ is determined by the shortest path $l(n_{p,q}, n_{r,s})$ between node $n_{p,q}$ and node $n_{r,s}$ and the latency on the path. The serialization latency $L_s(n_{p,q}, n_{r,s})$ is related to the number of packet size (flit size). The formula for $L_s(n_{p,q}, n_{r,s})$ and $L_h(n_{p,q}, n_{r,s})$ is as follows.

$$L_s(n_{p,q}, n_{r,s}) = \mu \cdot \frac{s_i}{f} \quad (5)$$

$$L_h(n_{p,q}, n_{r,s}) = \eta \cdot l(n_{p,q}, n_{r,s}) \quad (6)$$

where μ is the transmission rate, s_i is the data packet size, f is the flit size, and η is the number of router pipeline stages.

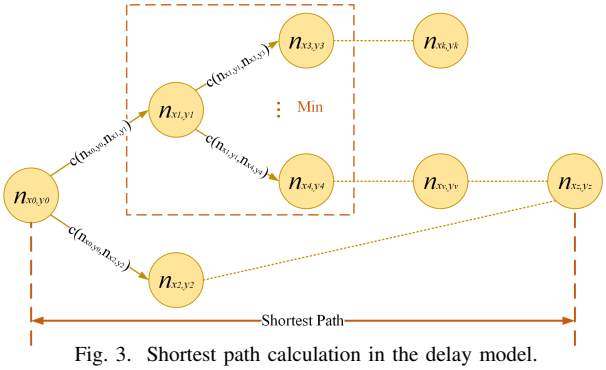

Fig. 3. Shortest path calculation in the delay model.

As shown in Fig. 3, the transmission latency of the shortest path is recursively derived using the Bellman equation [11], where the shortest path from node $n_{x_0,y_0} = n_{p,q}$ to node $n_{x_k,y_k} = n_{r,s}$ is referred to a sequence of nodes $\Gamma(n_{p,q}, n_{r,s}) = \Gamma(n_{x_0,y_0}, n_{x_k,y_k}) = \{n_{x_0,y_0} = n_{p,q}, n_{x_1,y_1}, \ldots, n_{x_z,y_z}, \ldots, n_{x_k,y_k} = n_{r,s}\}$. By comparing all possible paths between nodes, the shortest distance is ensured to be selected at each step of the recursion, as follows.

$$l^{(z)}(n_{x_0,y_0}, n_{x_z,y_z}) = \min\big\{l^{(z-1)}(n_{x_0,y_0}, n_{x_{z-1},y_{z-1}}) + c(n_{x_{z-1},y_{z-1}}, n_{x_z,y_z})\big\} \quad (7)$$

$$\forall n_{x_z,y_z} \in \Gamma(n_{x_0,y_0}, n_{x_k,y_k})$$

where $l^{(z)}(n_{x_0,y_0}, n_{x_z,y_z})$ is the shortest distance from n_{x_0,y_0} to n_{x_z,y_z} in the z-th step of recursion. $l^{(z)}(n_{x_0,y_0}, n_{x_z,y_z})$ is recursively updated until the optimal state is achieved.

Therefore, the calculation of $l(n_{p,q}, n_{r,s})$ follows the Bellman equation as follows.

$$l(n_{p,q}, n_{r,s}) = l(n_{x_0,y_0}, n_{x_k,y_k}) = \sum_{z=1}^{k} \min\big\{\omega\big(c(n_{x_{z-1},y_{z-1}}, n_{x_z,y_z})\big)\big\} \quad (8)$$

$$\forall n_{x_z,y_z} \in \Gamma(n_{x_0,y_0}, n_{x_k,y_k})$$

where $l(n_{x_z,y_z}, n_{x_z,y_z}) = 0$, and $\omega\big(c(n_{x_{z-1},y_{z-1}}, n_{x_z,y_z})\big)$ is the transmission latency between adjacent nodes $n_{x_{z-1},y_{z-1}}$ and n_{x_z,y_z}.

2) Queuing delay: The queuing delay of two nodes $n_{p,q}$ and $n_{r,s}$ is the summation of the queuing delay of each router n_{x_z,y_z} in the path $\Gamma(n_{p,q}, n_{r,s})$, obtained by the routing algorithm. In the G/G/1 model, a single-server queue with general arrival and service distributions, the flows $f_{a_c,b_c} = \{f_{a_1,b_1}, \ldots, f_{a_g,b_g}\}$ traversing n_{x_z,y_z} are analyzed. A router n_{x_z,y_z} consists of multiple input channels $IC_i^{n_{x_z,y_z}} = \{IC_1^{n_{x_z,y_z}}, \ldots, IC_q^{n_{x_z,y_z}}\}$ competing for a single output channel $OC_j^{n_{x_z,y_z}}$. The average queuing delay $T_{i\to j}(n_{x_z,y_z})$ of router n_{x_z,y_z} for a packet from $IC_i^{n_{x_z,y_z}}$ to $OC_j^{n_{x_z,y_z}}$ is as follows [12].

$$T_{i\to j}(n_{x_z,y_z}) = \begin{cases} \dfrac{\rho_j(n_{x_z,y_z})\left(C_A^2(n_{x_z,y_z}) + C_{S_j}^2(n_{x_z,y_z})\right)}{2\left(\mu_j(n_{x_z,y_z}) - \lambda_{i\to j}(n_{x_z,y_z})\right)}, & i = 1 \\ \dfrac{\lambda_j(n_{x_z,y_z})\left(C_A^2(n_{x_z,y_z}) + C_{S_j}^2(n_{x_z,y_z})\right)}{2\left(\mu_j(n_{x_z,y_z}) - \sum_{l=1}^{i-1}\lambda_{l\to j}(n_{x_z,y_z})\right)^2}, & 2 \le i \le q \end{cases} \quad (9)$$

where $\rho_j(n_{x_z,y_z})$ is the fraction of time that the $OC_j^{n_{x_z,y_z}}$ is occupied by packets from $IC_i^{n_{x_z,y_z}}$ in router n_{x_z,y_z}, $\lambda_j(n_{x_z,y_z})$ is the average packet rate to $OC_j^{n_{x_z,y_z}}$, $\lambda_{i\to j}(n_{x_z,y_z})$ is the average packet rate from $IC_i^{x_z,y_z}$ to $OC_j^{x_z,y_z}$, $\mu_j(n_{x_z,y_z})$ is the average service rate of the $OC_j^{n_{x_z,y_z}}$. $C_A^2(n_{x_z,y_z})$ and $C_{S_j}^2(n_{x_z,y_z})$ are the correlation coefficients between the corresponding packet arrival rate and service rate obtained based on the Allen-Cunneen approximation formula [12].

The total queuing delay $W(n_{p,q}, n_{r,s})$ is the sum of queuing delays of each router $n_{x_z,y_z} \in \Gamma(n_{p,q}, n_{r,s})$ from node $n_{p,q}$ to node $n_{r,s}$ for $OC_j^{n_{x_z,y_z}}$, calculated by the following formula.

$$W(n_{p,q}, n_{r,s}) = \sum_{z=0}^{k}\sum_{i=1}^{q} T_{i\to j}(n_{x_z,y_z}) \quad (10)$$

$$\forall n_{x_z,y_z} \in \Gamma(n_{x_0,y_0}, n_{x_k,y_k})$$

In summary, $D(n_{p,q}, n_{r,s})$ is the sum of zero-load latency $L(n_{p,q}, n_{r,s})$ and queuing delay $W(n_{p,q}, n_{r,s})$, represented as follows.

$$D(n_{p,q}, n_{r,s}) = L(n_{p,q}, n_{r,s}) + W(n_{p,q}, n_{r,s}) \quad (11)$$

D. Memory Concurrency Modeling

According to [7], define average hit concurrency $C_H(v_{ijk})$ and ratio of pure miss cycles over miss cycles $\kappa(v_{ijk})$ from a memory-centric perspective. $C_H(v_{ijk})$ and $\kappa(v_{ijk})$ can be modeled by a regression as follows [7].

$$C_H(v_{ijk}) = \sum_{x=1}^{n} f_x \cdot mpki\big(\pi_x(v_{ijk})\big)^{\vartheta_x} + \sum_{x=1}^{n} l_x \cdot ac\big(\pi_x(v_{ijk})\big)^{\iota_x} + g_x \cdot \big(\ln\big(bw(v_{ih_kk})\big)\big)^{\xi_x} \quad (12)$$

where f_x, l_x, and g_x are coefficients, ϑ_x, ι_x, and ξ_x are polynomial orders, $\pi_x(v_{ijk})$ is the x-th node on the reachable path from the core to v_{ijk}, $mpki\big(\pi_x(v_{ijk})\big)$ is the number of memory accesses per thousand instructions of $\pi_x(v_{ijk})$, $ac\big(\pi_x(v_{ijk})\big)$ is the cache access numbers of $\pi_x(v_{ijk})$, and $bw(v_{ihk})$ is DRAM bandwidth.

$$\kappa(v_{ijk}) = \sum_{x=1}^{n} m_x \cdot mpki\big(\pi_x(v_{ijk})\big)^{\varrho_x} + o_x \cdot \left(\ln\big(M(v_{i(h_k-1)k})\big)\right)^{\zeta_x} \quad (13)$$

where m_x and o_x are correlation coefficients, ϱ_x and ζ_x are polynomial orders, and $M(v_{i(h_k-1)k})$ is the miss rate of LLC, which is defined in Eq. (3) in section 3.B.

E. Performance Modeling

Given the memory hierarchy graph G_M and inter-chiplet interconnection network topology graph G_I of the multi-chiplet systems mentioned above, with the miss rate model, delay model, and memory concurrency model, the performance model is computed as follows.

The point-to-point latency between two nodes in the inter- and intra-chiplet interconnection system is calculated using the delay model, and the average delay between adjacent cache levels j and $j-1$ is as follows.

$$\overline{D}(j-1,j) = \frac{\sum_{c=1}^{g}\left(\sum_{k=1}^{n_\alpha}\sum_{i=1}^{|R_k|} D(v_{i(j-1)k}, v_{ijk})\cdot f_{a_c,b_c}\right)}{\sum_{c=1}^{g} f_{a_c,b_c}} + \frac{\sum_{c=1}^{g}\left(\sum_{k=1}^{n_\alpha}\sum_{i=1}^{|R_k|} D(v_{ijk}, v_{i(j-1)k})\cdot f_{a_c,b_c}\right)}{\sum_{c=1}^{g} f_{a_c,b_c}} \quad (14)$$

where f_{a_c,b_c} is the flow traversing $v_{i(j-1)k}$ to v_{ijk} and in reverse, $c = 1, \ldots, g$.

Define $\mathcal{C}(v_{i(j-1)k})$ as the average concurrent memory access time of cache layer $j-1$ within a CPU cycle. $\mathcal{C}(v_{i(j-1)k})$ is closely related to the average concurrent memory access time of the next level cache $\mathcal{C}(v_{ijk})$, and the recursive relationship is as follows [7].

$$\mathcal{C}(v_{i(j-1)k}) = \frac{H(v_{i(j-1)k})}{C_H(v_{i(j-1)k})} + M(v_{i(j-1)k})\cdot\kappa(v_{i(j-1)k})\cdot \big(\mathcal{C}(v_{ijk}) + \overline{D}(j-1,j)\big) \quad (15)$$

The C-AMAT $\sigma(G_M, G_I)$ is as follows [7].

$$\sigma(G_M,G_I) = \sum_{k=1}^{n_\alpha}\sum_{i=1}^{|R_k|}\left(\sum_{j=1}^{h_k-1}\prod_{t=1}^{j} M(v_{itk})\cdot\kappa(v_{itk})\cdot\left(\frac{H(v_{ijk})}{C_H(v_{ijk})} + \overline{D}(j-1,j)\right)\right) \quad (16)$$

where $H(v_{ijk})$ is the hit time of the j-th level cache of the chiplet k, $C_H(v_{ijk})$ is the average hit concurrency of the j-th level cache of the chiplet k, $M(v_{ijk})$ is the miss rate of the j-th level cache of the chiplet k, $\kappa(v_{ijk})$ is the ratio of pure miss cycles over miss cycles, $\overline{D}(j-1,j)$ is the average latency between adjacent $(j-1)$-th level and j-th level caches, n_α is the chiplet number, h_k is the total number of memory hierarchy in chiplet k, $|R_k|$ is the number of cores in chiplet k, and t is the recursive levels in the product up to j.

F. Cost and Power Consumption Modeling

The architecture cost is the cumulative cost of each component (die and DRAM) and the chiplet integration cost c_{int}. The cost of a die $C_{die}(v_{ijk})$ is as follows.

$$C_{die}(v_{ijk}) = \frac{A_i^{die}}{Y^{die}}\cdot c_1 \quad (17)$$

$$Y^{die} = \left(1 + \frac{\mathcal{D}\cdot\sum_{i=1}^{|R_i|} A_i^{die}}{a}\right)^{-a} \quad (18)$$

where A_i^{die} is the die area, c_1 is the cost per silicon area, Y^{die} is the asymptotic yield determined by the die area A_i^{die}, defect density $\mathcal{D}$, and clustering factor a.

The cost of DRAM $C_{dram}(v_{ijk})$ is expressed as:

$$C_{dram}(v_{ijk}) = \frac{bw(v_{ijk})}{U_{bw}}\cdot c_2 \quad (19)$$

where $bw(v_{ijk})$ is DRAM bandwidth, c_2 is the monetary cost of DRAM, and U_{bw} is the bandwidth provided by each unit.

The cost modeling of the multi-chiplet systems is as follows.

$$C(G_M,G_I) = \sum_{k=1}^{|R_k|} C_{die}(v_{ijk}) + C_{dram}(v_{ijk}) + c_{int} \quad (20)$$

The system power consumption is the cumulative power of each component. The power modeling of the multi-chiplet system is as follows.

$$P(G_M,G_I) = \sum_{i=1}^{n_\alpha} P_{core}(v_{ijk}) + P_{dram}(v_{ijk}) + \sum_{k=1}^{|R_k^{|}|} P_{router}(v_{ijk})\cdot r_k \quad (21)$$

where $P_{core}(v_{ijk})$ is the core power consumption, $P_{dram}(v_{ijk})$ is the DRAM power consumption, $P_{router}(v_{ijk})$ is the router power consumption, and r_k is the number of routers on each chiplet or interposer.

G. Problem Definition

With the performance, power, and cost model, under the constraints of cost and power, the optimization problem is defined to achieve the best performance of the multi-chiplet systems to minimize the C-AMAT $\sigma(G_M, G_I)$ with decision variables being G_M and G_I. The cost and power consumption of each chiplet should not exceed the respective threshold C_T and P_T. The optimization problem can be defined as follows.

$$\min\{\sigma(G_M,G_I)\} \quad (22)$$
$$\text{s.t.} \quad C(G_M,G_I) \le C_T, \quad P(G_M,G_I) \le P_T$$

The problem defined above has a huge search space. To efficiently solve this problem, a bilevel optimization algorithm is proposed in the next section.

IV. The Proposed Design Space Exploration Algorithm

A. Bilevel Optimization Algorithm Overview

The bilevel optimization algorithm works as follows. The problem defined in Eqn. (2)-(21) is decomposed into two subproblems: (1) cache subsystem optimization subproblem

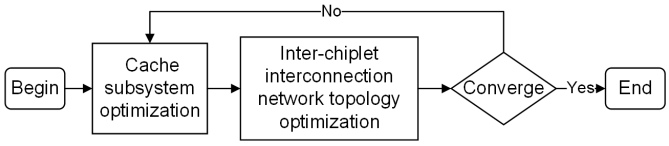

Fig. 4. Workflow of the bilevel optimization.

(P1), and (2) inter-chiplet interconnection network topology optimization subproblem (P2).

The workflow of bilevel optimization is shown in Fig. 4, which is performed iteratively. In each iteration, only one subproblem is solved, with the variables to the other subproblem fixed as constraints.

The optimization alternates between P1 and P2 until the target performance metric σ converges or a predefined maximum number of iterations $n_{\max}$ is reached. The convergence criteria are given by:

$$\sigma_i - \sigma_{i-1} \leq \delta \quad \text{or} \quad i \leq n_{\max} \tag{23}$$

where σ_i is the C-AMAT of the application in the i-th iteration, δ is the convergence condition, and $n_{\max}$ is the iteration limit.

B. Cache Subsystem Optimization (P1)

1) Search space definition: The objective of P1 is to select G_M parameters (cache level h_i, the numbers of cores $|R_i|$ in chiplet i, and parameters for each level of cache $w(v_{ijk})$), and it is defined as follows:

$$\min \left\{\sigma(G_M) = \sigma\big(h_i, |R_i|, w(v_{ijk})\big)\right\} \tag{24}$$
$$\text{s.t. } C(G_M) \leq C_T,\ P(G_M) \leq P_T$$

This subproblem can be solved by a branch-and-bound algorithm. In this algorithm, the decision variables in this subproblem are formed as a tree node g_b^a, which is the a-th node on the b-th layer and has a total of n search quantities $\hat{x_{cb}^a}$. A search tree is formed, where a tree node g_b^a is defined as follows.

$$g_b^a = \langle \hat{x_{1b}^a}, \hat{x_{2b}^a}, \ldots, \hat{x_{nb}^a} \rangle \tag{25}$$

Each node g_b^a is associated with an objective value $\sigma(g_b^a)$, and $C(g_b^a)$ and $P(g_b^a)$ are the cost and power consumption, respectively.

2) Branching rules: Each node g_b^a corresponding to $\hat{x_{cb}^a}$ assigned will branch a maximum of p_c branches, corresponding to $\hat{x_{c+1b}^a}$ assigned to be one of $\{y_1, y_2, \ldots, y_{p_c}\}$, which is the value range of $\hat{x_{c+1b}^a}$.

3) Cut rules: The cut rules are as follows.

- Pruned by optimality: When the currently searched node g_b^a is a leaf node and the feasible solution $\sigma(g_b^a)$ obtained by the current node is still greater than the current global minimum value, it is pruned.
- Pruned by infeasibility: When the currently searched node g_b^a does not meet the constraint conditions mentioned above, i.e., $C(g_b^a) \leq C_T$ or $P(g_b^a) \leq P_T$, where $C(g_b^a)$ and $P(g_b^a)$ return cost and power given the tree node g_b^a, it is pruned.
- Pruned by LPM mismatch: LPM [7] is an indicator of the matching of parameters of adjacent cache levels. If LPM rate is over a threshold of $x\%$, it indicates the match is low and leads to poor performance.

  Based on the performance model mentioned above, we use the LPM model [7] to verify the utilization of each cache layer. $LPMR(v_{ijk})$ is defined as the matching ratio at cache level j as follows.

Algorithm 1: Branch and Bound Algorithm

Input : The cache level h_i, the numbers of cores $|R_i|$ in chiplet i, and the parameters for each level of cache $w(v_{ijk})$.
Output: The cache access time of application σ^*.
Initialization:
- Initialize WQ as a working queue;
- Set g_b^a as the current node, and g_{b+1}^a as the newly branched node;
- Initialize $G^* = \emptyset$ as the best node;
- Set $\sigma^* = +\infty$ (optimal value found so far);
- Push root node into WQ;

while *WQ is not empty* **do**
  Pop the top node g_b^a out of WQ;
  if *g_b^a is not a leaf node* **then**
    Branch new tree nodes;
    for *each newly branched node g_{b+1}^a* **do**
      if *no cutting rules are met for g_{b+1}^a and WQ is not full* **then**
        Push g_{b+1}^a into WQ;
  else
    if $\sigma(g_b^a) \leq \sigma^*$ **then**
      Update $\sigma^* = \sigma(g_b^a)$;
      Set $G^* = g_b^a$;

$$LPMR(v_{ijk}) = \frac{f_{mem} \cdot \mathcal{C}(v_{i1k}) \cdot \prod_{j=1}^{h_k} \mu(v_{ijk})}{cpi(v_{ijk})} \tag{26}$$

where f_{mem} is the average number of memory accesses per instruction of the core, and $\mu(v_{ijk})$ is the ratio of miss cycles over memory active cycles, both of which can be obtained through the polynomial regression models.

Define a threshold of $x\%$ as the optimization target for the memory system, starting with matching at the L1 cache. Using the LPM model efficiently eliminates suboptimal branches. It ensures that only configurations meeting the performance threshold are explored, thus reducing search overhead.

- Pruned by Length of WQ: When the length of WQ is greater than W, it is pruned.

4) Workflow: Algorithm 1 outlines how the search process works. The algorithm works as follows.

- Initialization: Initialize σ^* to $+\infty$, which records the best objective function so far. Initialize g^* to an empty state ($\emptyset$), which will record the best node found so far in the search tree. The root node is enqueued into WQ.
- Search process: In each iteration of the search process, check if the work queue WQ is not empty. If WQ is not empty, g_b^a is dequeued from WQ. If g_b^a is not a leaf node, branch new tree nodes according to the branch rules. New nodes are enqueued into WQ if they don't meet the cut rules. If g_b^a is a leaf node, check if it is the best solution. If so, $\sigma^* = \sigma(g_b^a)$.
- Termination: If at any point the working queue WQ becomes empty, the search process terminates.

The time complexity of the BNB algorithm depends on the size of the search tree, determined by the branching factor p_c and the depth h_d. In the worst case, it explores $\mathrm{O}(p_c^{h_d})$ nodes, with each node involving $\mathrm{O}(1)$ operations for branching, pruning, and comparison. Pruning strategies (optimality, infeasibility, LPM, WQ length) significantly reduce the effective number of nodes, making the practical complexity

$O(\max\{|WQ|, p_c^{h_d}\})$.

C. Inter-chiplet Interconnection Network Topology Optimization (P2)

The objective of P2 is to select an inter-chiplet interconnection topology for G_I, and flit size f_i, and it is defined as follows.

$$\min\{\sigma(G_I)\} \quad \text{s.t. } C(G_I) \leq C_T,\ P(G_I) \leq P_T \tag{27}$$

To solve this problem, a few predefined topologies $t_i = \langle t_1, t_2, \ldots, t_j \rangle$, including Mesh, Ring, Torus, Crossbar, Clos, and Fat tree, and the flit size $f_i = \{32, 64, \ldots, 1024\}$, will be selected. An exhaustive search is performed to find the optimal topology and flit size.

V. Experimental Results

A. Experiment Setup

Experiments were performed on the sniper simulator with McPAT as the power simulator.

Table 2 lists the configurations of the multi-chiplet systems simulator. The benchmarks are from PARSEC, SPLASH-2, neural network, and database applications. The area and power model of routers are from DSENT, the area and power model of SRAM are from CACTI, and the area and power model of processor cores are from McPAT. The transmission energy consumption between adjacent chiplet is 1.17 PJ/bit [5], and the transmission latency between adjacent chiplets is composed of the following three parts: 1) packetization and depacketization overheads in the D2D interface, adopted from [13], 2) transceiver transmission latency, adopted from [14], and 3) interposer wire delay and power, adopted from [15].

As shown in Fig. 5, the selection of the $x\%$ threshold for the LPM model was obtained through experiments. Fig. 5 shows that $x = 65\%$ strikes a good balance of average application performance and algorithm search time, and thus is used in the experiments.

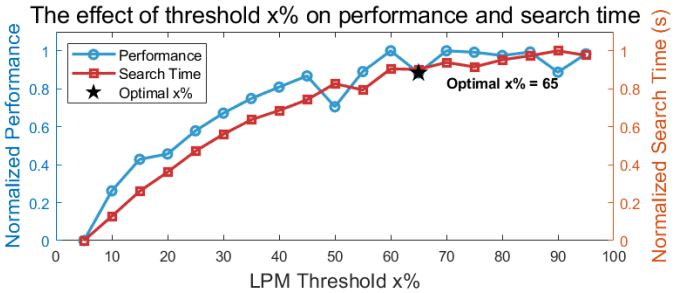

Fig. 5. The effect of a threshold of $x\%$ on the average application performance and the algorithm search time on the above benchmarks.

To evaluate the algorithm proposed in this paper, IntLP [4] is chosen for comparison. IntLP uses an integer linear programming model to determine the optimal partitioning of functional components and the selection of chiplets. In addition, Zen 4 and SPR are simulated in sniper to consider for comparison.

B. Performance Evaluation

In the subsequent experiments, the performance of the proposed method, Zen 4, SPR, and IntLP [4] were compared.

Fig. 6 (a) and (b) show the execution time comparison with power budgets of 200W and 160W respectively. From Fig. 6 (a), one can see that the execution time of the proposed method reduces 39.7%, 39.2%, and 25.91% over Zen 4, SPR, and IntLP, respectively. From Fig. 6 (b), one can see that at low power budget, the execution time of the proposed method reduces 40.61%, 39.49%, and 18.01% over Zen 4, SPR, and IntLP, respectively. The execution time of the four methods is normalized to that of Zen 4. The reason is that the proposed method can effectively explore the design space of cache subsystems in multi-chiplet systems, while Zen 4 and SPR are fixed designs, and IntLP can only optimize size and associativity for L1 and L2 caches, which fails to explore the design space well.

TABLE II
The Parallel Multi-Chiplet X86-64 Simulator Configuration for Design Space Exploration

Configuration	
Core architecture	x86-64
Main memory size	2GB
Get/Decode/Submit Size	4/4/4
Baseline frequency	3GHz
ROB size	64
L1 data cache (private)	16 KB, 2-way, 32B line, 2 cycles, 2 ports
L1 instruction cache (private)	32 KB, 2-way, 64B line, 2 cycles, 2 ports
Level 2 cache (shared)	64KB slices /core, 64 line, 6 cycles, 2 ports
Flit size	32, 64, 128, 256, 512, 1024 bits
Intra-chiplet communication latency	Router: 2 cycles; link: 1 cycle
Inter-chiplet communication latency	Router: 2 cycles
Buffer depth	4 flits
Benchmarks	
barnes, cholesky, fft, lu.cont, radiosity, radix, raytrace, streamcluster, swaptions, water.nsq, CNN, GCN, ResNet50, TPC_H	

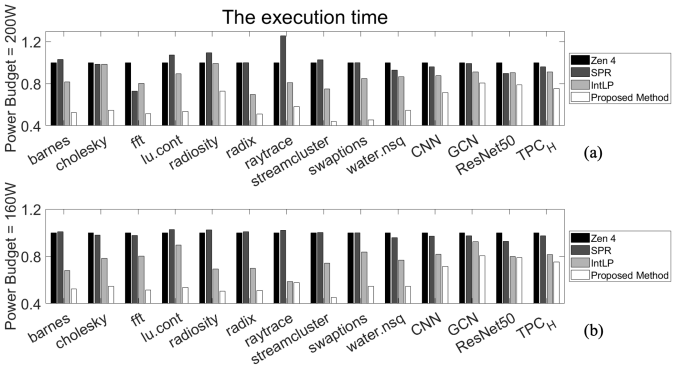

Fig. 6. The execution time of the different methods with (a) 200W and (b) 160W power budgets.

VI. Conclusion

In this paper, the problem of optimizing cache hierarchy in multi-chiplet based many-core systems was studied. Graph models were used to model the performance with respect to cache and inter-chiplet interconnection parameters. An optimization problem was formulated to minimize the cache access time of applications under cost and power constraints. A bilevel optimization algorithm was proposed to efficiently solve the above problem by iteratively solving two subproblems: (1) cache subsystem optimization and (2) inter-chiplet interconnection optimization. Experimental results confirmed the superiority of the proposed method over existing ones. Thus, it is suitable for cache hierarchy optimization for future large scale multi-chiplet systems.

***Abstract*—With the advancement of high-speed and energy-efficient optical interconnect and computation, photonic integrated circuits (PICs) have become a promising alternative to traditional CMOS circuits. A PIC can be synthesized by mapping the binary decision diagram (BDD) of target functions to optical switches and combiners. However, excessive signal attenuation along the light propagation may require extra optical-electrical signal conversion, thus introducing unwanted delays. In this paper, we aim to overcome this deficiency during logic synthesis: First, we optimize the signal efficiency factor by applying the concept of harmonic means to optimize DC combiners. Second, we eliminate redundant combiners by integer partition. Moreover, we properly arrange these proposed techniques in an optimal sequence of operations to form our main framework. Experimental results show that our framework outperforms the state of the art in terms of efficiency factor.**

***Index Terms*—Photonic integrated circuit, logic synthesis, efficiency factor, harmonic mean, integer partition**

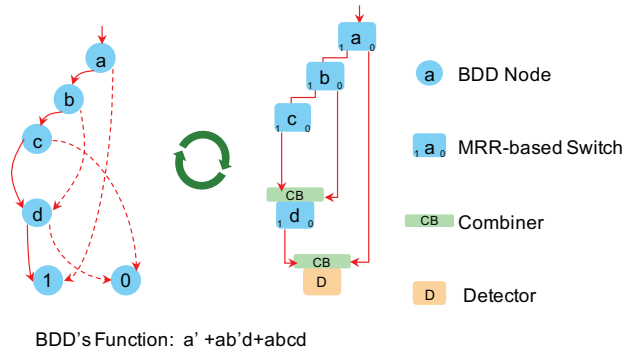

Fig. 1: Conversion between a binary decision diagram (BDD) and a synthesized photonic integrated circuit (PIC).

I. Introduction

Signal delay and energy consumption in integrated circuits have become the bottleneck of semiconductor technology advancement. Optical interconnect and computation, leveraging light-based transmission, is viewed as a promising alternative to conventional CMOS circuits, offering benefits in speed and energy efficiency. The automation of logic circuit design for photonic integrated circuits (PICs) has recently garnered considerable research attention [1]–[3]. The design flow of PICs can be divided into logic synthesis, optical component placement, and optical routing considering Wavelength Division Multiplexing (WDM) sharing. As the initial and foundational stage, logic synthesis critically impacts both placement and routing quality in the PIC design process. For instance, the power loss, timing delay, and hardware cost could be primarily determined in the logic synthesis stage [4]–[6].

Condrat *et al.* [4] pioneered the virtual gate concept in optical circuit synthesis, implementing Boolean functions through fundamental logical operations and Binary Decision Diagram (BDD) structures. Furthermore, to prevent significant light splitting loss incurred by [4], Wille *et al.* proposed a reverse BDD-based synthesis approach without using any splitters, which has become the backbone of optical circuit synthesis [5]. As depicted in Fig. 1, a target function is realized by implementing all of the paths from the root node of its BDD to the 1-terminal. Each BDD decision node is mapped to an optical switch controlled by its corresponding variable value, a node with multiple incoming signal paths requires a combiner, and the 1-terminal is replaced by a photo detector. The light source feeds to the top switch (the root node), traverses each switch (BDD node) and edge on the 1-paths, and finally arrives at the photo detector as the function output. Excessive signal attenuation during light propagation, however, can render the final output undetectable, necessitating solutions for effective signal management. Consequently, restoring the signal via additional optical-electrical (OE/EO) conversions becomes essential, involving either the insertion of OE/EO converters along BDD edges [7] or interconnecting partitioned subcircuits with these converters [8], albeit at the cost of added delays. (Meanwhile, BDD variable ordering can be optimized for enhancing the signal efficiency [9].) To further improve the synthesized circuit, Zhao *et al.* explored the use of combiners and directional couplers (DCs) as WDM, while Matsuo *et al.* leveraged WDMs to reduce hardware costs [10], [11].

In order to avoid the timing delays caused by additional OE/EO converters, the signal magnitude should be maximized, and thus, the efficiency improvement methodology was proposed. The efficiency improvement methodology is defined by the engineering approaches in a PIC to modify its optical components without changing functionality, including switches, combiners, and detectors. In Fig. 2(a), *Efficiency factor* is used to measure loss on a reversed BDD described in Section II-B. In Fig. 2(b), a directional coupler (DC) combiner can replace a Y-branch combiner to improve loss described in Section II-A. Based on this information, Zhao *et al.* proposed two algorithms in the efficiency improvement methodology [6], which were performed on node i in Fig. 2. In Fig. 2(c), the Combiner Elimination algorithm duplicates a sub-BDD multiple times to eliminate that sub-BDD's sourcing combiner. In Fig. 2(d), the Coupler Assignment algorithm takes advantage of DC usage on two selected combiners whose parameters are obtained from quadratically constrained programming. There is still a room for further efficiency improvement. Therefore, in this paper, we design two novel algorithms in the efficiency improvement methodology based on the theory of harmonic mean and integer partition. In Fig. 2(e), the Efficiency Adjustment algorithm can achieve optimal efficiency by harmonic mean on the parameters of a DC combiner. In Fig. 2(f), the Switch Duplication algorithm

traverses all switch duplication possibilities via integer partition and its factor permutations.

The remainder of this paper is organized as follows. Section II introduces the optical components, efficiency/loss model, and the addressed PIC logic synthesis problem formulation. Section III introduces the mathematical theories to design two algorithms and discusses their arrangement sequence. Section IV outlines our integrated framework. Section V demonstrates experimental results. Finally, Section VI concludes this work.

II. Preliminaries and Problem Formulation

This section introduces the optical components, details the efficiency factor computation, and states the problem formulation.

A. Optical Components

Fig. 3 illustrates the three key optical components used for implementing a BDD.

1) Detector: The detector, an essential element in every PIC, transforms the signal back into an electronic signal. It can detect light above a certain threshold. As signal falls below this threshold, an OE/EO converter will be added to restore power, which induces additional timing delay, hardware cost, and design complexity [7], [8]. Therefore, we should avoid OE/EO converters by improving the signal magnitude of optical circuits as much as possible.

2) Switch: Research in [6], [10] demonstrates that microring-resonator-based (MRR) optical switches are capable of synthesizing abstract BDD nodes. An optical terminator effectively resolves garbage output issues. Within the MRR-based switch architecture, resonance is utilized to direct light towards the second output, causing a certain transmission loss, as depicted in Fig. 3(a). By default, the first output (out1) is designated to the BDD node's positive edge, while the second output (out2) is for the BDD node's negative edge (else-edge). The signal magnitude ratio between out2 and out1 is 0.8, corresponding to a transmission loss of approximately $1dB$. Proper flipping the use of these two outputs may improve the signal efficiency, e.g., node g in Fig. 2. Other previous studies have incorporated different components. For instance, works by [4], [5] employed Mach-Zehnder interferometer (MZI), while [8] applied a DC for the BDD node.

3) Combiner: To aggregate incoming edges, combiners are designed as either Y-branch or directional coupler (DC) types. In Fig. 3(b), both N-input Y-branch combiners and DC combiners are in an array structure, and their efficiency degradation due to the mode mismatch ratio of 50% is calculated by $50\%^{\lg(N)} = N^{-1}$ [6]. Using a DC combiner allows adjustments to the efficiencies of incoming edges, optimizing overall performance. Consider a set of input efficiencies, $in_1, ..., in_N$, to an N-input DC combiner. Based on its functionality, we could adjust the input efficiencies by a scalar set, $k_1, ..., k_N$:

$$(in_1, ..., in_N) \rightarrow (k_1 in_1, ..., k_N in_N) \text{ w.r.t.} \sum_{j=1}^{N} k_j = N,$$

with an additional area of $N-1$ switches as hardware cost. For example, the scalar set of DC combiner at node i in Fig. 2(b) is $k_1, k_2, k_3, k_4 = 0.5, 0.5, 0.5, 2.5$; $0.5 + 0.5 + 0.5 + 2.5 = 4$. Interestingly, all of the aforementioned combiners can function as splitters via the reciprocal and the scatter matrix symmetry.

Based on the knowledge of these optical components above, we now introduce the efficiency factor model to estimate the loss in our work.

B. Efficiency Factor and Loss Model

Power loss in the synthesized PIC is estimated by calculating the efficiency factor of its BDD conversion, illustrated in Fig. 2(a) [6].

For each BDD, we compute the efficiency factor of each edge and node in topological order, denoted by γ: For edges,

the respective efficiency factor of a positive and negative edges is set to 1.0 and 0.8 due to the actual switch structure. For nodes, we consider the worst-case efficiency of their incoming edges. And, the efficiency $\gamma(in_1, ..., in_N)$ can be formulated as below:

$$\text{Y-branch Combiner: } \gamma = \frac{\min_{j=1}^{N}\{in_j\}}{N},$$

$$\text{DC Combiner: } \gamma = \frac{\min_{j=1}^{N}\{k_j in_j\}}{N} \text{ w.r.t. } \sum_{j=1}^{N} k_j = N.$$

For example, a Y-branch combiner is applied to node i in Fig. 2(a), while a DC combiner is used in Fig. 2(b).

Overall, the efficiency of a BDD is defined by the efficiency factor of its 1-terminal, γ_{Term}; the loss of a BDD is defined from its efficiency factor, $-10 * \log_{10}(\gamma_{\text{Term}})$. Also, the critical path within this BDD, from its source node to terminal one node exhibiting the worst-case (lowest) efficiency factor, is identified. Finally, a synthesized PIC's efficiency, loss, and critical path is the worst-case of efficiency, loss, and critical path to all BDDs.

C. Problem Formulation

To reduce power loss and elevate efficiency factors through logic synthesis, we address the following efficiency optimization problem:

The PIC Efficiency Optimization Problem: Given a circuit of Boolean functions and optical components, including switches, combiners, and detectors, the primary objective is to generate a logic circuit that maximizes the worst-case (lowest) efficiency factor, and the secondary objective is to minimize the number of additional OE/EO converters for power restoration.

III. Theoretical Foundations

In this section, we first introduce the harmonic mean and integer partition optimization to combiners, followed by an analysis of their optimization order and the design of our main algorithm.

A. Harmonic Mean Optimization

Sections II-A and II-B introduce an efficiency factor model for an N-input DC combiner, defined as $\gamma = \frac{\min_{j=1}^{N}\{k_j in_j\}}{N}$, subject to the condition $\sum_{j=1}^{N} k_j = N$. However, this model presents significant challenges. The objective is to determine the optimal scalar set, $k_1, ..., k_N$, which maximizes the efficiency factor of an N-input DC combiner, γ, called the **Efficiency Adjustment Problem**. Therefore, the harmonic mean is introduced as a solution method.

Theorem 1. *Let us first define the the harmonic mean of N-inputs, Harm$(in_1, ..., in_N) := \frac{N}{\frac{1}{in_1}+...+\frac{1}{in_N}}$. For an N-input DC combiner, the maximum value of the efficiency factor is equal to Harm$(in_1, ..., in_N) * \frac{1}{N}$.*

Proof. For a simpler representation, the numerator of the efficiency factor term is designated by f. Thus, $\gamma = \frac{f}{N}$ and $f(in_1, ..., in_N) = \min_{j=1}^{N}\{k_j in_j\}$ w.r.t. $\sum_{j=1}^{N} k_j = N$. Our objective is to prove that the harmonic mean represents the maximum value of f:

$$f \le k_j in_j \Leftrightarrow f * \frac{1}{in_j} \le k_j, \quad \forall j = 1, ..., N, \text{ w.r.t. } \sum_{j=1}^{N} k_j = N,$$

$$f * (\frac{1}{in_1} + ... + \frac{1}{in_N}) \le \sum_{j=1}^{N} k_j = N,$$

$$f \le \frac{N}{\frac{1}{in_1} + ... + \frac{1}{in_N}} = \text{Harm}(in_1, ..., in_N),$$

the last equality holds if and only if $k_j = \frac{\text{Harm}(in_1,...,in_N)}{in_j}, \forall j = 1, 2, ..., N$. Therefore, the maximum value of the efficiency factor is exactly Harm$(in_1, ..., in_N) * \frac{1}{N}$. □

Consequently, given an N-input DC combiner, we can calculate its maximum efficiency factor and corresponding scalar set in linear time complexity, called '**Efficiency Adjustment** by Harmonic Mean.' Now, we discuss another optimization issue.

B. Integer Partition Optimization

Expanding on prior research [6], the 'Combiner Elimination' algorithm eliminates an N-input combiner by applying an N-piece partitioning method, as shown in Fig. 2(c).

This action can be viewed as N-1 times duplication of a BDD switch node. An alternative approach is to duplicate the switch once, twice, thrice, etc. As a result, another problem arises. The objective is to enumerate all possible ways to duplicate switch nodes first and then arrange the incoming edges to the duplicated switches in order to optimize the efficiency factor, called the **Switch Duplication Problem**.

For the first objective, we propose a refined method using integer partition theory, which studies all possibilities for partitioning an integer number. For example, when $N = 4$ for node i in Fig. 2, the possible partitions include '4', '$3 + 1$', '$2 + 2$', '$2 + 1 + 1$', and '$1 + 1 + 1 + 1$'. Notably, the partition of '$1 + 1 + 1 + 1$' is exactly the special case corresponding to 'combiner elimination.' Typically, partition case enumeration can be executed using Depth-First Search (DFS), although this results in an exponentially large number of instances: $\frac{1}{4n\sqrt{3}} \exp(\pi\sqrt{\frac{2n}{3}})$ as $n \to \infty$, [12].

For the second objective, we introduce a greedy method for the optimal arrangement of input factors across all duplication possibilities. It can be formulated as follows:

The Factor Arrangement Subproblem: Suppose an N-input combiner, its input factors $in_1 \le ... \le in_N$, and an integer partition of N, $N = p_1 + ... + p_k$, where p_i is the number of factors required for the i-th switch. We aim to maximize the worst-case efficiency factor by arranging N-many incoming factors to k-many duplicated switches, that is:

$$\text{Through } \{in_1, ..., in_N\} \Leftrightarrow IN_{p_1} \sqcup IN_{p_2} \sqcup ... \sqcup IN_{p_k},$$

$$\text{To maximize } \min_{t=1}^{k} \frac{\min\{IN_{p_t}\}}{p_t},$$

where IN_{p_i} is the i-th partition of the set of input factors.

Theorem 2. *In the **Factor Arrangement Subproblem**, arranging the lowest input factor to the smallest partition is always optimal.*

Proof. Let us relabel $p_1 \le ... \le p_k$ for easier description. It is always true that the smallest partition must contain the lowest input factor in the optimal arrangement solution.

Suppose not, we may assign in_1 to some IN_{p_t} $(t > 1)$ to afford a larger partitioning efficiency factor. However, this assignment will break the lower bound to the worst-case efficiency factor:

$$\text{Suppose not: } \frac{\min\{in_1 \cup IN_{p_t}\}}{p_t} = \frac{in_1}{p_t},$$

$$\text{However: } \frac{\min\{IN_{p_1}\}}{p_1} = \frac{in_1}{p_1} \ge \frac{in_1}{p_t}, \frac{\min\{IN_{p_t}\}}{p_t} \ge \frac{in_1}{p_t}. \text{ ↯}$$

Leveraging the greedy property above, we can iteratively arrange the lowest input factor to the smallest partition to derive an optimal solution to the **Factor Arrangement Subproblem**. □

Combining insights from integer partitioning, DFS enumeration, and optimal assignment solutions, we theoretically propose

the 'Switch Duplication by Integer Partition' algorithm. The subsequent section shows the optimization order to implement the 'Efficiency Adjustment' and 'Switch Duplication' algorithms.

C. Optimization Order

The optimal sequence for performing operations warrants investigation. Potential approaches include: (A) Efficiency Adjustment only, (B) Switch Duplication only, (C) Efficiency Adjustment followed by Switch Duplication, and (D) Switch Duplication followed by Efficiency Adjustment. Again, we can answer this question through a theoretical examination.

Theorem 3. *To enhance the worst-case efficiency factor of an N-input combiner, the optimal operational sequence is ranked as follows: option (C) supersedes option (A), which in turn outperforms option (D), expressed as '(C) $\succeq$ (A) $\succeq$ (D).'*

Proof. First, (C) $\succeq$ (A) trivially holds since the possibility of not duplicating the switch (not partitioning integer) is also considered in the Switch Duplication algorithm. This means that option (A) is considered within option (C).

Secondly, we prove (A) $\succeq$ (D) now. Suppose an N-input combiner, its input factors $in_1 \leq ... \leq in_N$, and an integer partition of N, $N = p_1 + ... + p_N$ w.r.t. $p_1 \leq ... \leq p_N$, are given. Let us compare the numerators of the worst-case efficiency factors of (A) and (D), denoted by f and g respectively:
(D) - Duplicate Combiner first:

$$\{in_1, ..., in_N\} \xrightarrow{\text{Greedy Arrangement}} IN_{p_1} \sqcup IN_{p_2} \sqcup ... \sqcup IN_{p_k},$$
$$\Leftrightarrow \{in_1, in_2, ..., in_{p_1}\} \sqcup \{in_{p_1+1}, in_{p_1+2}, ..., in_{p_1+p_2}\} \sqcup ...$$
$$\Leftrightarrow IN_{p_t} = \{in_{p_1+...+p_{t-1}+1}, ..., in_{p_1+...+p_{t-1}+p_t}\}, \forall t = 1, ..., k.$$

(D) - Followed by Adjust Efficiency: $(\forall t = 1, ..., k)$
Efficiency factor of IN_{p_t}: $\text{Harm}(IN_{p_t})$,
Worst-case efficiency factor: $g \leq \text{Harm}(IN_{p_t})$,

$$\Leftrightarrow g \leq \frac{p_t}{\frac{1}{in_{p_1+...+p_{t-1}+1}} + ... + \frac{1}{in_{p_1+...+p_{t-1}+p_t}}},$$
$$\Leftrightarrow \frac{p_t}{g} \geq \frac{1}{in_{p_1+...+p_{t-1}+1}} + ... + \frac{1}{in_{p_1+...+p_{t-1}+p_t}}. \quad (*)$$

(A) - Efficiency Adjustment only:

Worst-case efficiency factor: $f = \frac{N}{\frac{1}{in_1} + ... + \frac{1}{in_N}}$,

$$\Rightarrow f = \frac{N}{\frac{1}{in_1} + ... + \frac{1}{in_N}} \overset{(*)}{\geq} \frac{N}{\frac{p_1}{g} + ... + \frac{p_k}{g}} = \frac{N}{\frac{p_1+...+p_k}{g}} = \frac{N}{\frac{N}{g}} = g.$$

Hence, we derive that the best sequence of operations is (C) $\succeq$ (A) $\succeq$ (D). □

Following this, the Switch Duplication algorithm could be simplified using the insights gained from above.

D. Simplified Switch Duplication

Adopting the strategy of 'Efficiency Adjustment followed by Switch Duplication,' it becomes possible to simplify the Switch Duplication algorithm using the information derived from the harmonic mean. For an adjusted N-input DC combiner, the **Factor Arrangement Subproblem** is no longer a difficulty since all input factors are $\text{Harm}(in_1, ..., in_N)$. Furthermore, it can be proved that only evenly dispersed partitions can be the optimal partition. For $N = 6$, feasible partitions include '6', '$3+3$', '$2+2+2$', '$2+2+1+1$', '$2+1+1+1+1$', and '$1+1+1+1+1+1$', excluding configurations such as '$5+1$' or '$3+2+1$'. This breakthrough reduces the partition instances from exponentially to linear and allows for replacing DFS enumeration with simple linear traversal.

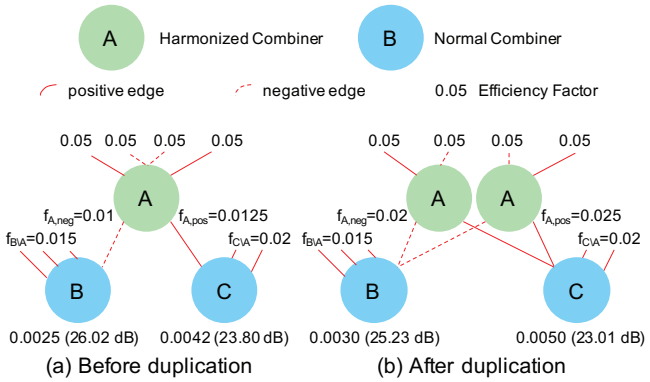

Fig. 4: In (a) is an adjusted 4-input DC combiner A, and its children switch nodes B and C. In (b), the Switch Duplication with respect to the $2+2$ partition is considered. Moreover, the hardware costs before and after duplication are the same.

Fig. 4 illustrates the operation of a Simplified Switch Duplication corresponding to a '$4 = 2+2$' partition. In Fig. 4(a), we observe that the input factors for the adjusted DC combiner A are uniform at 0.05, which acts as a lower bound on the efficiency of combiners B and C. In Fig. 4(b), through applying a '$2+2$' partition on the adjusted DC combiner, the efficiency at combiners B and C is seen to increase. Moreover, the hardware costs before and after duplication are $4+1+1$ and $2+2+1+1$ switches, which are maintained. This case study demonstrates the significant impact of partitioning on not just the adjusted DC combiner but also on children combiners.

To formulate this tradeoff, the efficiency factors of combiner A and its two derivatives, combiner B and C, are considered. The efficiency factor before partition is noted as f_A, f_B, and f_C, respectively. After duplication with respect to the partition of $N_A = \frac{N_A}{k} + ... + \frac{N_A}{k}$, we have:

$$f_A = \frac{\text{Harm}(in_1, ..., in_{N_A})}{N_A} \Rightarrow f'_A = \frac{\text{Harm}(in_1, ..., in_{N_A})}{\frac{N_A}{k}},$$
$$f_B = \frac{\min(f_A, f_{B-A})}{N_B} \quad \Rightarrow \quad f'_B = \frac{\min(f'_A, f_{B-A})}{N_B - 1 + k},$$
$$f_C = \frac{\min(f_A, f_{C-A})}{N_C} \quad \Rightarrow \quad f'_C = \frac{\min(f'_A, f_{C-A})}{N_C - 1 + k},$$

Objective function: $\log(\frac{f'_B}{f_B}) + \log(\frac{f'_C}{f_C})$,

where N_A, N_B, and N_C are the number of incoming edges of A, B, and C, respectively. To leverage the benefits of Switch Duplication effectively, we introduce normalization as a core concept to establish an objective function: $\log(\frac{f'_B}{f_B}) + \log(\frac{f'_C}{f_C})$. The aim is to select the partition that maximizes the objective function output in a Switch Duplication scenario. It is worth mentioning that in the base case, when $k = 1$, the function's output is precisely 1. The following work calls this algorithm 'Simplified Switch Duplication.'

IV. Our Synthesis Framework

In this section, we present our PIC logic synthesis framework, named Harrow.

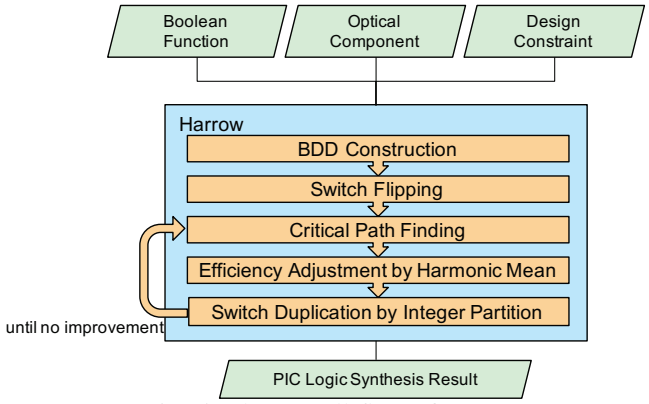

Fig. 5: The overall flow of Harrow.

  $n_i \leftarrow n_i$.argmin$(in_1, \ldots, in_N)$
return *False*

A. Overview

Fig. 5 depicts the overall flow of Harrow. First, we construct an abstract BDD from the given Boolean function. Subsequently, we properly flip the switch output assignment of positive and negative edges on the generated BDD to enhance loss. The framework proceeds with iterative identification of the critical path, wherein Efficiency Adjustment and Switch Duplication algorithms are applied to the respective BDD nodes, repeating the process until convergence is achieved with no further optimization.

B. Switch Flipping

Let us consider a BDD generated from the given single-bit Boolean function. As mentioned in Section II-A2, we can improve the efficiency by flipping the positive and negative edge output of a BDD switch node, corresponding to a (1.0, 0.8) exchange of the efficiency factor. The Switch Flipping is to flip BDD nodes located along the critical path. Empirical evidence indicates that the BDD's efficiency typically stabilizes after approximately a dozen iterations of switch flipping.

C. Critical Path Finding

To identify the critical path, one observation is the critical path could be dynamically changed during the BDD efficiency optimization process. Therefore, it is necessary to identify the critical path for each time. Critical Path Finding involves traversing the BDD from the terminal node back to the source node, iteratively identifying and backtracking through parent nodes with the minimum incoming efficiency, denoted as $\arg\min(in_1, ..., in_N)$. To analyze the time complexity of this algorithm, the maximum height equates to the variable count for any BDD.

D. Combiner Optimization

The Combiner Optimization includes Efficiency Adjustment by Harmonic Mean and Switch Duplication by Integer Partition, as depicted in Algorithm 2. In lines 1–18, we may leverage

the Critical Path Finding to traverse the BDD in search of nodes to apply the Efficiency Adjustment or Switch Duplication algorithms. Lines 10–16 integrate the methodology described in Section III-D to implement the **Simplified Switch Duplication algorithm** effectively.

Now, we can describe our Harrow as listed in Algorithm 1. Lines 1–5 employ the Switch Flipping algorithm to enhance efficiency, while lines 6–8 iteratively apply the Combiner Optimization until the process indicates no further potential for improvement.

V. Experimental Results

The proposed algorithm and the methods from [5], [6] were implemented in C++ programming language and integrated with the ABC engine [13]. All experiments were performed on an Apple M1 3.2GHz MacBook Pro with 16GB RAM. Consistent with previous works [6], [7], [10], we used the benchmark [14] in our experiment. In the experiment, the execution commands involved: 'read benchmark,' 'collapse,' 'Extra_ReorderCudd,' and a custom command of experimental algorithms. Certain benchmarks could not be tested: 'stpmotor (steppermotordrive)', 'spla,' 'alu4,' and 'misex3c' cases.

Table I provides a comparative analysis of the scalability of our proposed algorithms against [5], [6], highlighting significant improvements in net efficiency across various switch ratio limits. Since the detection threshold value was set to 15dB, 20dB, 25dB, and 40dB in previous works [7], [8], we only measured these efficiency improvement algorithms on BDDs whose terminal loss exceeded 15dB. The first line is the upper bound of the switch ratio cost (Limit) to every measured BDD. For these four methods, columns 2, 4, 6, 8 are the exact switch ratio cost, and columns 3, 5, 7, 9 are the average of measured BDDs' net efficiency improvement on these 14 benchmarks. For example, if the switch ratio cost is limited to no more than 1.5 on every BDD of benchmarks, the actual switch ratio cost of these four methods overall is 1.000, 1.199, 1.280, 1.288. Fig. 6 visualizes the scalability of net efficiency improvements with increasing switch ratio costs, demonstrating the superior performance of our proposed approach. The switch ratio cost of 1.3 represents an optimal balance between performance improvement and switch count cost, serving as a sweet point for algorithm scalability.

Table II indicates the effectiveness of our designed algorithms, benchmarking our results against [5], [6] when the switch ratio cost is restricted to 1.3. The initial three columns list the benchmark information, including the number of primary inputs (#PI) and outputs (#PO). For these four methods, columns 4, 8, 12, 16 are the exact switch ratio cost (#SW) on each benchmark; columns 5, 9, 13, 17 are the average of net efficiency improvement (Imprv) on each benchmark; columns 6, 10, 14, 18 outline the loss, which is calculated by $-10 * \log_{10}(\gamma_{\text{Term}})$, see Section II-B; columns 7, 11, 15, 18 list the CPU times in seconds. All experimental algorithms were performed independently on the measured BDDs of benchmarks in the entire experiment. For [6], iterations of combiner elimination and coupler assignment were set to 5 and 37, respectively. For our designed methods, Harrow-EA and Harrow-All, the iterations of switch flipping were set to 50, and the maximum partition count (k) was 1 and 6, respectively.

First of all, we compared [6] and Harrow-All. Our Harrow-All method achieved a double-digit net efficiency improvement over [6], with a seven times improvement and better loss on 13 of 14 benchmarks. However, when the switch ratio cost was limited to 1.05 or 1.1, Harrow-All underperformed due to insufficient switch quota for the 'Efficiency Adjustment' algorithm on small BDDs. Secondly, we compared Harrow-EA and Harrow-All. While Harrow-EA and Harrow-All performed better on 5 and 9 benchmarks, respectively, with average improvements tied for both. Our explanation is that despite the theoretical guarantee of no extra switch cost in a 'Switch Duplication' operation, the duplicated switches contribute additional edges, ultimately increasing the switch count and diminishing Harrow-All's performance. In summary, all three methods demonstrated the potential to enhance net efficiency, and our Harrow-All method indicated a substantial advancement in optimizing PIC logic synthesis.

VI. Conclusions

To mitigate the signal attenuation issue in PICs, this paper presents three novel techniques for signal efficiency improvement, including harmonic mean, integer partition, and optimal operational sequence. The harmonic mean provides an optimal method for adjusting combiner efficiency, the integer partition offers a systematic approach to exploring all switch-duplication possibilities, and the optimal operational sequence ensures the efficient arrangement of these techniques. Together, these techniques form the basis for the Efficiency Adjustment and Simplified Switch Duplication algorithms, advancing the field of PIC logic synthesis. Experimental results demonstrate that Harrow achieves a double-digit improvement in efficiency compared to state-of-the-art methods, while maintaining comparable hardware overhead.

***Abstract*—Transformer-based large language models (LLMs) have achieved impressive performance in various natural language processing (NLP) applications. However, the high memory and computation cost induced by the KV cache limits the inference efficiency, especially for long input sequences. Compute-in-memory (CIM)-based accelerators have been proposed for LLM acceleration with KV cache pruning. However, as existing accelerators only support static pruning with a fixed pattern or dynamic pruning with primitive implementations, they suffer from either high accuracy degradation or low efficiency. In this paper, we propose a ferroelectric FET (FeFET)-based unified content addressable memory (CAM) and CIM architecture, dubbed as UniCAIM. UniCAIM features simultaneous support for static and dynamic pruning with 3 computation modes: 1) in the CAM mode, UniCAIM enables approximate similarity measurement in $\mathcal{O}(1)$ time for dynamic KV cache pruning with high energy efficiency; 2) in the charge-domain CIM mode, static pruning can be supported based on accumulative similarity score, which is much more flexible compared to fixed patterns; 3) in the current-domain mode, exact attention computation can be conducted with a subset of selected KV cache. We further propose a novel CAM/CIM cell design that leverages the multi-level characteristics of FeFETs for signed multi-bit storage of the KV cache and in-place attention computation. With extensive experimental results, we demonstrate UniCAIM can reduce the area-energy-delay product (AEDP) by 8.2∼831× over the state-of-the-art CIM-based LLM accelerators at the circuit level, along with high accuracy comparable with dense attention at the application level, showing its great potential for efficient long-context LLM inference.**

I. Introduction

Large language models (LLMs) have recently demonstrated remarkable performance in a wide range of applications such as question answering, code completion, and dialogue systems [1]–[3]. The context length supported by LLMs is also growing progressively to support more applications like multi-turn chat, text summarization, etc. However, with the increase in sequence lengths, the KV cache size gradually exceeds the LLM parameter size and the attention computation latency is becoming increasingly dominant, both of which emerge as prominent bottlenecks in long-context LLM inference [4], as shown in Fig. 1.

Recently, various solutions have been proposed to reduce the KV cache overhead from the algorithm perspective, utilizing the highly sparse nature of attention [5], [6]. There are static and dynamic KV cache pruning policies, aiming to either reduce memory footprint by permanently evicting unnecessary tokens or reduce the computation load by only fetching the KV pairs with high attention scores, respectively [5]–[8]. Meanwhile, from the hardware perspective, the computing-in-memory (CIM) architecture which can perform the general matrix-vector multiplication (GEMV) operations within the memory array, has been proven to compute attention efficiently by reducing the data movement [9]–[12]. Besides, some works specifically adopt KV cache pruning policies with CIM architecture to further support sparse attention computation [13]–[18].

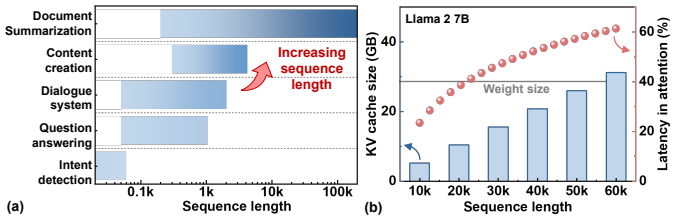

Fig. 1. (a) Various NLP tasks with increasing sequence length. (b) The impact of sequence length on KV cache size and attention latency in Llama-2-7B, which is a typical LLM, indicating the memory and computation challenges faced by long-context LLMs.

However, the current CIM-based LLM accelerators only focus on either static or dynamic KV cache pruning algorithms, hindering the simultaneous optimization of memory usage and computation overhead. Moreover, the existing hardware implementations are relatively primitive, suffering from the following challenges. On the one hand, the current CIM designs adopting static KV cache pruning only support fixed sparse attention pattern [13], [14], leading to accuracy degradation, especially for long sequences [19], [20]. Although there are advanced token-aware static KV pruning policies with better accuracy, they require the computation of accumulative attention scores, which will lead to a significant amount of extra computation and power consumption in current CIM architectures. On the other hand, to further support dynamic KV cache pruning, additional expensive operators such as top-k selection, are required, suffering from high hardware cost, latency, and energy consumption [15], [16]. Therefore, it is challenging for the current CIM architectures to efficiently support both dynamic and static KV cache pruning simultaneously, restricting the practical deployment of LLMs with increasing sequence length.

In this work, a unified content addressable memory (CAM) and CIM architecture called UniCAIM, featuring static-dynamic KV cache pruning for long-context LLM inference, is proposed through algorithm-hardware co-optimization. UniCAIM addresses the challenges mentioned above, and the main contributions can be summarized as follows:

- A hardware-friendly static-dynamic KV cache pruning framework is proposed, which can significantly improve the inference efficiency of LLMs without degrading the model. Firstly, the unimportant tokens are dropped permanently in the prefill stage, reducing the overall memory overhead. Moreover, during each decoding step, only the most relevant (i.e., top-k) tokens are selected for exact attention computation to reduce the computation load, and one token is evicted based on accumulative attention scores to enhance memory utilization and management when the generated length exceeds the reserved KV cache size.
- A UniCAIM architecture with CAM and CIM modes is proposed for efficiently implementing the static-dynamic KV cache pruning and sparse attention computing. Based on the CAM mode

of UniCAIM, attention scores can be approximately measured and compared to select the top-k tokens in $\mathcal{O}(1)$ time without the exact computations, and the attention scores can also be accumulated for static eviction by further leveraging the charge-domain CIM within the same operation cycle, leading to fast and energy-efficient static-dynamic KV cache pruning. Moreover, the current-based CIM is utilized for the exact attention score computation of selected tokens with high precision.

- The proposed UniCAIM is implemented based on emerging compact ferroelectric FET (FeFET) devices with carefully designed circuits in hardware for further area-energy-delay product (AEDP) reduction. Experiments and evaluations show that the proposed FeFET-based UniCAIM can achieve 8.2∼831× AEDP reduction compared with the state-of-the-art CIM-based LLM accelerators, showing its great potential for high speed, area- and energy-efficient long-context LLM acceleration.

II. Background

In this section, we review the sparse attention in transformer-based LLMs and exiting KV cache pruning policies from the algorithm and hardware perspectives, as well as the basics of FeFET and its advantages for CIM and CAM.

A. Sparse attention and KV cache pruning

*1) **Sparse attention and existing KV cache pruning algorithms**:* In transformers, the quadratic computational complexity of attention is one of the major bottlenecks [21]. Many recent research efforts have been devoted to exploiting the intrinsic sparsity in attention [22]. For long-context generation tasks, KV cache pruning becomes a promising solution for efficient sparse attention computation. Existing KV cache pruning methods can be roughly categorized into static pruning and dynamic pruning. Some static pruning policies predefine the positions of important tokens and remain consistent across decoding steps, such as StreamingLLM [19], while such fixed patterns lack flexibility for different LLMs and contexts. Other static pruning policies permanently drop some tokens and the dropped ones cannot be used in the subsequent decoding steps, such as SnapKV [8] and H2O [7]. However, only tokens that remain throughout the entire decoding process can be pruned, otherwise suffering significant accuracy degradation. On the other hand, dynamic pruning policies select unimportant tokens to drop at for different decoding steps, such as InfLLM [23] and LongCache [24]. Though dynamic pruning is more flexible than static pruning, it involves more expensive computations, such as attention score ranking and top-k selection, which pose greater challenges for efficient hardware implementation.

*2) **Existing hardware implementations for KV cache pruning**:* KV cache pruning in LLMs offers significant advantages by reducing memory usage and redundant computation. Recently, CIM-based transformer accelerators have attracted widespread attention for LLMs due to the largely reduced data movement overhead, with some studies exploring the implementation of KV cache pruning in hardware. On the one hand, some works implement fix-pattern KV cache pruning which is well-suited for CIM architecture, such as TranCIM [13] adopting the pruning algorithm proposed in StreamingLLM [19]. However, this approach performs computations on neighboring tokens within a predetermined fixed attention range defined in the algorithm, which lacks flexibility and fails to consider the varying contributions of different tokes to the final prediction. Consequently, the CIM with fix-pattern KV cache pruning designs suffers from suboptimal accuracy and efficiency, especially when processing different LLMs and contexts. On the other hand, some works have implemented

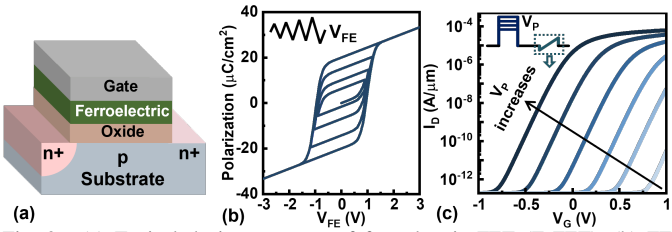

Fig. 2. (a) Typical device structure of ferroelectric FET (FeFET). (b) FE polarization-voltage loops with multilevel FE polarizations. (c) Gradually modulated I_D-V_G curves of FeFET for the multilevel storage capability.

Table I. Qualitative comparison of proposed FeFET-based UniCAIM with the state-of-the-art CIM-based LLM accelerators.

LLM accelerator	TranCIM [13]	CIMFormer [15]	Sprint [17]	UniCAIM (This work)
Technology	SRAM CIM	SRAM CIM	RRAM CIM	FeFET CAM/CIM
Static pruning	Yes (Fixed pattern)	No	No	Yes (Accumulate attention)
Dynamic pruning	No	Yes (Top-k selection)	Yes (Approximate attention)	Yes (Top-k selection)
Memory footprint reduction	Good	Bad	Medium	Excellent
Energy-efficiency improvement	Medium	Medium	Good	Excellent
Accuracy	Bad	Good	Medium	Good

dynamic KV cache pruning, primarily involving attention score ranking and selection, such as CIMFormer [15] adopting the top-k selection. However, it requires additional hardware overhead to achieve top-k selection with complex time complexity of $\mathcal{O}(nlogn)$ [25] or $\mathcal{O}(logn)$ with additional circuits for token gathering [15], resulting in high latency and power consumption. Besides, there are emerging non-volatile memories (NVMs)-based CIM designs for dynamic pruning by utilizing approximate attention scores [17], [18], but suffering the trade-off between energy efficiency and accuracy.

Therefore, current CIM-based LLM accelerators support either static or dynamic KV cache pruning policies, along with relatively primitive implementations, facing substantial penalties in terms of area, latency, and power consumption (Table I). Thus, while CIM-based KV cache optimization techniques bring new possibilities for efficient inference of long-context LLMs, there are still several challenges that need to be addressed.

B. FeFET for CIM and CAM

In recent years, various emerging NVMs, such as resistive random-access memory (RRAM), magnetic tunnel junction (MTJ) and FeFET, have triggered lots of attention for CIM, due to the high storage density and efficient GEMV operation via analog computing within the memory array [26]–[28]. On the other hand, CAM is a specialized memory architecture, where an input query is compared with entire stored entries simultaneously within the memory array [29]–[31]. Different from conventional CIM, CAM only identifies the matching entry or measures the matching degree without precise quantification, which is more energy efficient. Among the NVMs, the three-terminal FeFET has the advantages of low write energy due to the electric-field-driven write mechanism and high I_{ON}/I_{OFF} ratio due to the transistor structure, along with good CMOS compatibility [32]. Fig. 2(a) shows the structure of an FeFET device, with a HfO_2-based ferroelectric (FE) layer integrated into the gate stack of a MOSFET. Applying different program voltages (V_P) to the gate of FeFET will switch the FE polarization states (Fig. 2(b)), and thus gradually modulate the threshold voltage (V_{TH}) of FeFET, indicating the multilevel storage capability (Fig. 2(c)). Besides, by applying a relatively small read voltage (V_R), the channel conductance state can be non-destructively readout without FE polarization switching. Therefore, FeFET can achieve both storage and computation, making it a promising candidate for CIM and CAM designs [27], [31].

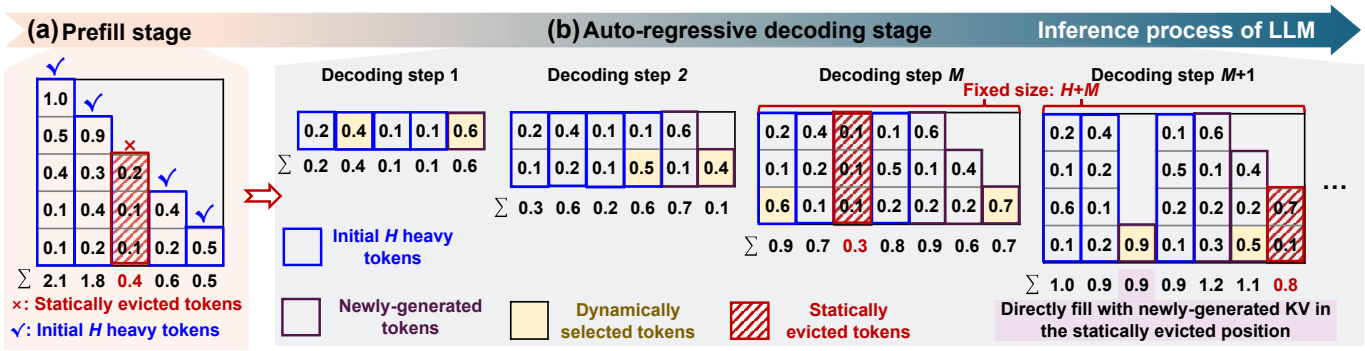

Fig. 3. Framework of the proposed hybrid static-dynamic KV cache pruning algorithm. (a) During the prefill stage, static pruning evicts unimportant tokens for the subsequent generation. (b) During the decoding stage, dynamic pruning preserves a subset of tokens for sparse attention computation, while static pruning evicts one token at each step when the generated length exceeds the reserved size for a fixed KV cache size.

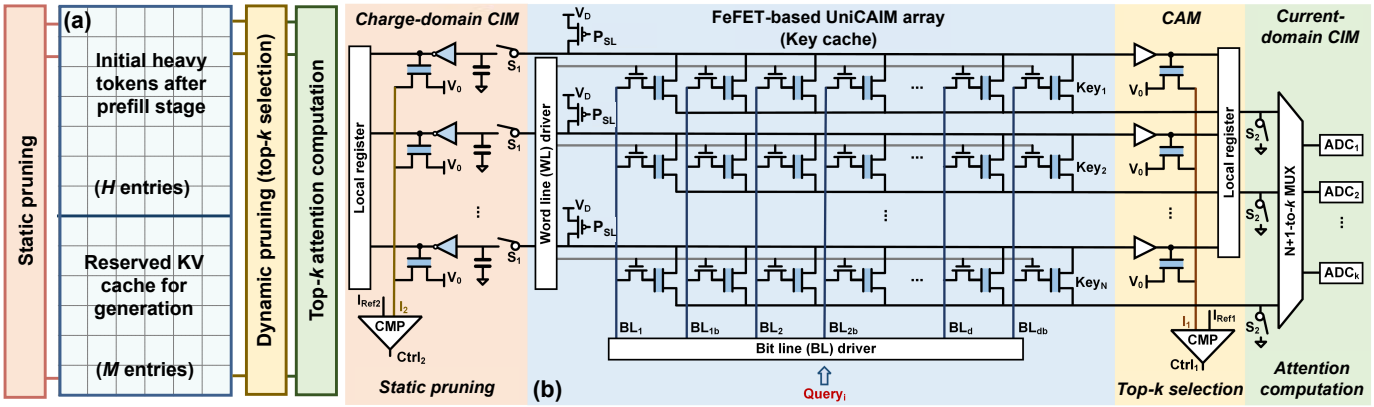

Fig. 4. (a) The proposed UniCAIM architecture for static-dynamic KV cache pruning and sparse attention computing. (b) The hardware design of UniCAIM based on FeFET, including FeFET-based UniCAIM array and carefully designed peripheral circuits for CAM, charge-domain and current-domain CAM.

III. UniCAIM Architecture with Static-Dynamic KV Cache Pruning

A. Hybrid Static-Dynamic KV Cache Pruning Algorithm

The framework of the proposed hybrid pruning algorithm is illustrated in Fig. 3, which combines static pruning during the prefill stage for an overall memory footprint reduction and static-dynamic pruning during the decoding stage for further efficient sparse attention.

*1) **Prefill stage with one-shot static pruning**:* During the prefill stage, we leverage static pruning to drop a part of tokens permanently which are almost unimportant throughout the entire decoding process, and remain the heavy tokens. Following [5], [7], [8], we determine which tokens to statically drop based on the accumulative attention scores as shown in Fig. 3(a). Specifically, we drop the tokens with the lowest accumulated attention scores, reducing the overhead of the entire inference process.

*2) **Decoding stage with step-wise static-dynamic pruning**:* Since the LLM attention exhibits high sparsity [5] and different queries can attend to different tokens [6], we propose to further selectively choose a subset of important tokens for efficient attention computation at different decoding steps (Fig. 3(b)). We adopt the most commonly used Cosine similarity as the attention score ($Attn$) to evaluate the importance of the KV cache for previous tokens as follows:

$$Attn(q, K) = q \cdot K^T, \tag{1}$$

where $q \in \mathbb{R}^{h\times 1\times d}$ denotes the query at the current step, $K \in \mathbb{R}^{h\times N\times d}$ denotes the key cache, and h, N, d represent the number of heads, the number of tokens in key cache, and hidden dimension, respectively. After the similarity measure, we leverage the top-k selection strategy to pick up the most important tokens for the subsequent sparse attention.

Moreover, when considering the memory limitation and hardware constraints, the consistently increasing KV cache size during the decoding process is not friendly. To address this problem, we always keep a table of the accumulated attention scores and statically drop one token with the lowest accumulated attention score when the generated length exceeds the reserved size for decoding, and directly fill with the newly-generated token in the statically evicted position. As a result, the KV cache size is fixed with enhanced memory utilization and management.

B. FeFET-based UniCAIM Architecture

*1) **Overview of FeFET-based UniCAIM**:* Fig. 4(a) shows the proposed UniCAIM architecture for static-dynamic KV cache pruning, which is specially optimized for the auto-regressive decoding stage, due to the memory-bound nature of the decoding stage. After one-shot static pruning at the prefill stage, H heavy tokens with the highest accumulated attention scores are retained and stored in the UniCAIM array, and M entries are reserved for newly generated tokens at the decoding stage. During each encoding step, the approximate attention scores are evaluated for dynamically selecting the top-k tokens with the highest scores, which will be accurately computed. Additionally, the accumulated attention scores are also evaluated for statically evicted the token with the lowest scores, when the number of generated tokens exceeds M. The step-wise static pruning during the decoding stage can maintain a fixed-size KV cache, resulting in higher area efficiency and better memory utilization. In this work, the proposed UniCAIM architecture is implemented using emerging FeFET in hardware (Fig. 4(b)), incorporating an FeFET-based UniCAIM array which is shared by CAM and CIM, along with

(c) The proposed encoding method for multilevel query expansion. (d) The computing results of local signed multiplication between 2-bit signed query and 2-bit signed key.

carefully designed peripheral circuits dedicated to dynamic pruning, static pruning, and attention computation.

*2) **FeFET-based UniCAIM cell**:* The proposed FeFET-based UniCAIM cell is composed of two 1-transistor-1-FeFET (1T1F) units (Fig. 5(a)), which can store the signed key and implement the local signed multiplication (i.e., attention score) between signed key and query. In the write stage, the signed key of "-1"/"+1" is programmed in two FeFETs (F_1 and F_{1b}) with complementary V_{TH} states (V_{TH1} and V_{TH1b}) by applying relatively large V_P for FE polarization switching (Fig. 5(b) and (c)). Then the signed query of "-1"/"+1" is represented by complementary non-destructive read voltages at bit-lines (BL_1 and BL_{1b}) with relatively small amplitudes. The signed multiplication result can be expressed through sense-line current (I_{SL}), where the low/high I_{SL} represents the result of "+1"/"-1", which is meticulously designed for efficient KV-cache pruning and attention computation which will be discussed in the following sections. Moreover, the Key of "0" can be represented by programming both FeFETs to the medium V_{TH} states, which will result in medium I_{SL} with both query inputs (Fig. 5(d)).

Furthermore, by utilizing the multilevel storage capability of

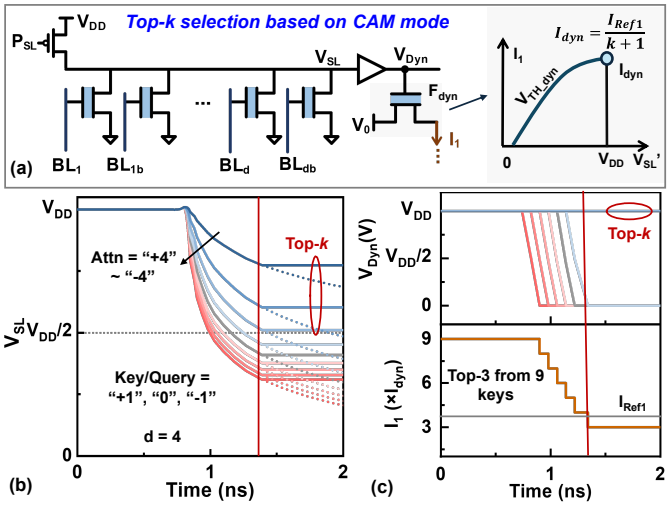

Fig. 7. (a) The main circuit of CAM mode for top-k selection. (b) The discharge speed of the sense-line (SL) is correlated with the attention scores, where the SL with higher attention discharges more slowly. (c) The sequence diagrams of top-k selection take the example of top-3 selection from 9 keys.

FeFET, the proposed FeFET-based UniCAIM cell supports signed multi-bit storage and in-place attention computation for higher area-efficiency. With multiple V_P applied to the gate of FeFET, the FE polarization can be gradually switched in succession, resulting in the continuous modulation of V_{TH}, and the multiple V_{TH} pairs (V_{TH1}, V_{TH1b}) in complementary form represent multilevel signed key states (Fig. 6a). For example, the (V_L', V_H') and (V_H', V_L') can represent keys of "+0.5" and "-0.5", respectively. The signed multiplication results with 3-bit signed keys are shown in Fig. 6b. Besides, the multilevel signed query expansion, including "0", can be implemented through bitwise expansion with the proposed mapping method as shown in Fig. 6(c), enabling signed multiplication with multilevel signed queries and keys (Fig. 6(d)).

*3) **CAM mode of UniCAIM for dynamic pruning**:* To implement the dynamic KV cache pruning, the CAM mode of UniCAIM is designed for fast and energy-efficient top-k selection. As shown in Fig. 7a, each row shares one precharge p-type transistor for precharging the SL and detecting circuits including one buffer and one FeFET (F_{dyn}) with properly programmed V_{TH} for top-k selection. In the dynamic pruning phase, all SLs are precharged to high voltage (i.e., V_{DD}) by setting the P_{SL} to ground, and then all BLs are prechraged to the corresponding voltages according to the proposed mapping method of the input query. Based on the proposed UniCAIM cell, the higher similarity between the query and the key (i.e., the higher attention score) will lead to the smaller I_{SL}, and thus result in a slower discharge speed of the SL. For a key/query with a dimension of 4, where each state is "+1", "-1" or "0", there are 9 possible attention scores ranging from "-4" to "+4", and the corresponding SL discharge processes for different scores are shown in Fig. 7b. The SLs with lower similarity will discharge to $V_{DD}/2$ more quickly, resulting in V_{Dyn} switching to ground, which turns off the corresponding F_{dyn}. In contrast, the SLs with higher similarity maintain V_{Dyn} at V_{DD}, which turns on the F_{dyn} with I_{dyn}. By setting the I_{Ref1} to $(k+1)I_{dyn}$, top-k selection can be performed, as shown in the example of top-3 selection from 9 keys (Fig. 7(c)). When k SLs with higher similarity maintain high voltage, the accumulated I_1 will be less than I_{Ref1}, causing the control signal ($Ctrl_1$) to switch (Fig. 4), which will disable the discharge process of SLs. The addresses of the top-k selected keys are stored in the local register for exact similarity computation in subsequent steps.

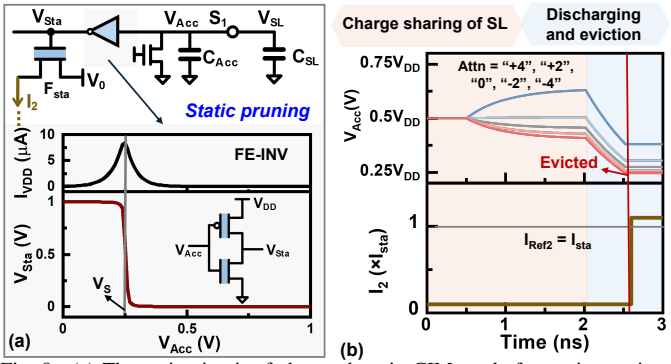

Fig. 8. (a) The main circuit of charge-domain CIM mode for static pruning. (b) The process and sequence diagrams of static pruning, including charge sharing of SL for accumulating attention scores and static eviction.

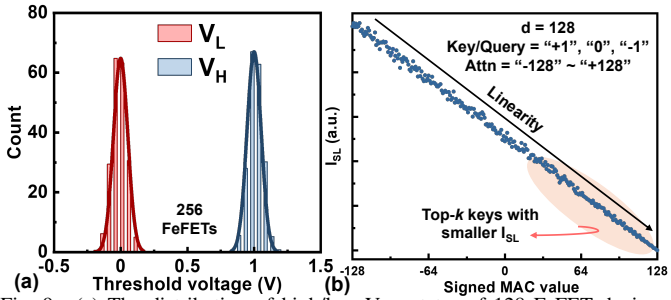

Fig. 9. (a) The distribution of high/low V_{TH} states of 128 FeFET devices. (b) The I_{SL} is linear to the singed multiply-accumulate (MAC) value.

The proposed FeFET-based CAM can achieve top-k selection with $\mathcal{O}(1)$ time complexity by comparing the similarity without the need for actual computation, which improves the speed and energy-efficiency compared with conventional designs. Moreover, k can be easily configured by programming the F_{dyn} without the additional hardware overhead, indicating the enhanced versatility for different LLMs and contexts.

*4) **Charge-domain CIM mode of UniCAIM for static pruning**:* During the decoding stage, different tasks will generate varying lengths of tokens, which poses significant challenges to memory overhead and management. Therefore, in this work, when the number of generated tokens exceeds the reserved KV cache size (i.e., M), the static KV cache pruning is applied. The charge-domain CIM is further designed for accumulating the similarity and evicting the smallest one. After implementing top-k selection based on CAM mode, the switch S_1 is closed and the charge sharing occurs between SL capacitor (C_{SL}) and accumulate capacitor (C_{Acc}) which has accumulated the previous similarity scores (Fig. 8(a)). To implement static pruning within the same operation cycle along with dynamic pruning, without the need to recharge SLs, an FeFET-based inverter (FE-INV) is designed with programmed switching voltage (V_S). The SL with the smallest accumulated similarity will discharge to V_S firstly through the discharge transistor, which will turn on the corresponding F_{sta} with I_{sta}. Consequently, the accumulated I_2 is larger than I_{Ref2} which is equal to I_{sta}, causing the control signal ($Ctrl_2$) to switch, which will turn off the discharge transistor (Fig. 8(b)). The address of the statically selected key is stored in the local register, which will be evicted after exact similarity computation at the current generation step. Moreover, to avoid swapping memory when the stored key is evicted, the newly-added key is directly overwritten by enabling the word-line (WL) of the corresponding row and applying the appropriate V_P on BLs with a single write cycle.

*5) **Current-domain CIM mode of UniCAIM for attention computation**:* To implement the exact attention computation for the top-k selected tokens after dynamic-static KV cache pruning, the FeFET-based current-domain CIM is proposed, where the I_{SL} is precisely quantized via the analog-to-digital converter (ADC) to calculate the accurate attention score. Fig. 9 shows the I_{SL} with 128 activated FeFET-based UniCAIM cells, which shows robust linearity with respect to the singed multiply-accumulate (MAC) value, when considering the device-to-device variation of FeFET devices with a standard deviation of 54mV [33]. Benefiting from the dynamic pruning, only the I_{SL} of top-k most similar keys need to be quantized by the ADCs, which can be selected through a Multiplexer (MUX). It can significantly reduce the computational overhead and the power consumption of the ADC, which is the primary source of power usage in analog CIM systems. Moreover, due to the meticulous design of FeFET-based UniCAIM cell, the I_{SL} is smaller when the attention score is larger, and thus the dynamically selected top-k tokens which need to be precision computed have relatively small I_{SL}, leading to lower energy consumption for attention computation.

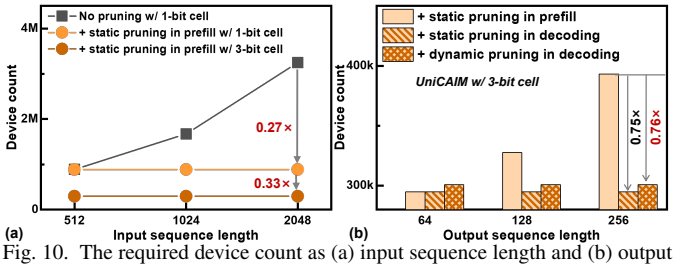

Fig. 10. The required device count as (a) input sequence length and (b) output sequence length increases with different pruning conditions.

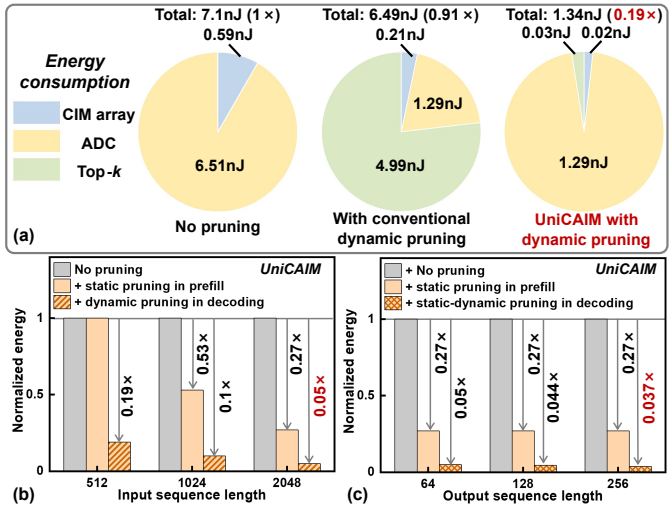

Fig. 11. (a) The impact of dynamic pruning on power consumption, with a 20% pruning ratio. The energy consumption as (b) input sequence length with an output sequence length of 64 and (c) output sequence length with an input sequence length of 2048 increases with different pruning conditions.

IV. Experimental Results

In this section, we validate and evaluate the proposed FeFET-based UniCAIM architecture for LLM acceleration. Firstly, the key performance metrics for attention including area, energy, and delay are evaluated and compared with the state-of-the-art CIM-based designs at the circuit level. Subsequently, the impact of the proposed dynamic-static KV cache pruning algorithm on the accuracy of LLM applications is evaluated.

A. Circuit-level Evaluations

The circuit-level experiments and evaluations of proposed FeFET-based UniCAIM are carried out based on typical emerging FeFET devices with circuit simulation in HSPICE. The 45nm BSIM model

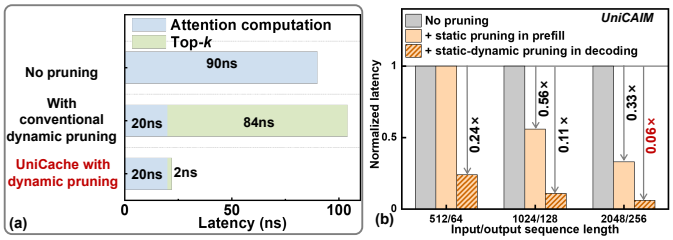

Fig. 12. (a) The impact of dynamic pruning on latency, with 20% pruning ratio, 512 input sequence length, and 64 output sequence length. (b) The comparison of latency as input and output sequence length increase with different pruning conditions.

Table II. Quantitative comparison of proposed FeFET-based UniCAIM with the state-of-the-art CIM-based LLM accelerators.

LLM accelerator		CIMFormer [15]	TranCIM [13]	Sprint [17]	UniCAIM (This work)
Technology		SRAM CIM	SRAM CIM	RRAM CIM	FeFET CAM/CIM
AEDP reduction	No pruning	1×	1×	2.5×	3~9×
	50% pruning	1×	8.9×	15×	124~372×
	80% pruning	1×	14.6×	24×	277~831×

[34] is used for all MOSFETs, and the Preisach ferroelectric switching model [35] is used for FeFETs. The parasitic wire capacitance is extracted according to [36]. The KV cache size contains 576 tokens, with 512 initial heavy tokens and 64 reserved tokens for decoding. Each token has a hidden dimension (i.e., d) of 128 with a 3-bit UniCAIM cell, and the range of attention scores is "-512" to "512", and thus a 10-bit SAR ADC is used for quantization [37].

*1) **Area**:* The static KV cache pruning during the prefill/decoding stage can reduce the KV cache size corresponding to the input/output sequence, leading to improved area efficiency, and the improvement is more significant as the input/sequence length increases due to the higher compression ratio (Fig. 10). It indicates that static KV cache pruning is the key technique for improving area efficiency. Moreover, benefiting from the proposed FeFET-based UniCAIM cell with *in-situ* multilevel expansion capability, the area efficiency can be further improved. Besides, the proposed CAM-based dynamic pruning circuit is highly compact, resulting in only a slight decrease in the improvement of area efficiency from 15× to 14.7× (Fig. 10(b)).

*2) **Energy**:* To implement dynamic pruning, conventional designs involve approximate attention computation, followed by selecting the top-k highest similar tokens with additional circuits, limiting the energy efficiency improvement. In this work, the FeFET-based CAM mode is designed for dynamic pruning, which evaluates the relative attention and selects the top-k tokens through a single SL charge-discharge process, without the need for actually calculating attention scores and ranking them. It significantly improves energy efficiency, due to reducing the energy consumption overhead associated with ADCs, and avoiding the additional power needed for top-k selection circuits (Fig. 11(a)). On the other hand, the static KV cache pruning reduces the number of tokens, thereby naturally reducing energy consumption. Moreover, the improvement of energy-efficiency is more significant from 5.3× to 27× as the input and output sequence length increase, benefiting from the static pruning during both prefill and decoding stages (Fig. 11(b) and (c)).

*3) **Delay**:* Although CIM architecture enables parallel computation in theory, the output parallelism is constrained by the maximum number of ADCs that can be accommodated within the area and power budget of the system, which further increases the compute delay. In this work, 64 SLs are sensed in parallel with 64 ADCs. As shown in Fig. 12(a), although the conventional dynamic KV cache pruning reduces the number of attention scores that need precision

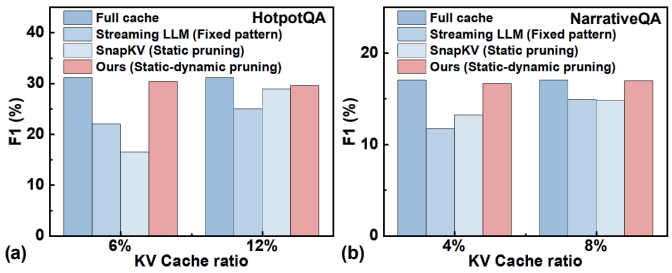

Fig. 13. Accuracy evaluation of KV cache pruning on different datasets of (a) HotpotQA and (b) NarrativeQA, where F1 is a widely adopted evaluation metric that measures the similarity of the outputs to the ground-truth answers for QA and summarization tasks.

quantization, the approximate attention computation is still limited by the number of ADCs. Additionally, the top-k selection process involves complex $\mathcal{O}(n \cdot \log n)$ time complexity, which actually increases the overall computation latency. The proposed FeFET-based UniCAIM does not require ADC quantization during dynamic pruning and can implement the top-k selection with $\mathcal{O}(1)$ time complexity, thereby further reducing computation latency. Moreover, the static KV cache pruning reduces the number of attention scores that require ADC quantization, thereby reducing computation latency. Moreover, the speed up is more significant from 4.2× to 16.7× as the input and output sequence length increase, benefiting from the static KV cache pruning during the prefill stage and static-dynamic KV cache pruning decoding stages (Fig. 12(b)).

*4) **Comparison with state-of-the-art designs**:* We use the recently reported CIM-based LLM accelerators CIMFormer [15], TranCIM [13], and Sprint [17] as the baselines for quantitative comparison, and we apply the same static/dynamic KV cache pruning ratio across different designs for a fair comparison. The proposed FeFET-based UniCAIM with static-dynamic KV cache pruning achieves a significant reduction in the AEDP (Table II). With 1-bit FeFET-based UniCAIM cell, the AEDP is reduced by 8.2×/13.9×/124× and 11.5×/19×/277× with the pruning ratio of 50% and 80% compared with Sprint/TranCIM/CIMFormer, respectively. Moreover, When further utilizing a 3-bit FeFET-based UniCAIM cell, the AEDP reduction is even more pronounced, which achieves 24.8×/41.7×/372× and 34.6×/56.9×/831×, indicating its great potential for long-context LLM acceleration at the edge.

B. Application-level Evaluation

We evaluate our proposed static-dynamic KV cache pruning algorithm on the LongChat-v1.5-7B-32k [38] model on widely used long-context tasks from LongBench [39], including HotpotQA and NarrativeQA. The prompt length of HotpotQA is 1.5k and the prompt length of NarrativeQA is 2.5k. As can be observed in Fig. 13, our proposed static-dynamic KV cache pruning algorithm does not significantly affect the accuracy of LLM and achieves comparable accuracy with full-cache attention even under low KV cache ratios. When compared with the recent KV cache pruning algorithms SnapKV [8] and StreamingLLM [19], our algorithm consistently achieves higher accuracy, indicating the effectiveness of our algorithm.

V. Conclusion

In this work, a novel FeFET-based UniCAIM architecture featuring dynamic-static KV cache pruning is proposed for sparse attention. The UniCAIM architecture can efficiently implement dynamic pruning, static pruning, and attention computation, with different CAM and CIM modes. Evaluation results at circuit and application levels show significantly reduced AEDP and high accuracy, indicating its great potential for long-context LLM acceleration at the edge.

***Abstract*—IoT protocols are essential for the communication among diverse devices. In real-world scenarios, IoT protocols utilize flexible configurations to meet various use cases. These configurations can significantly impact the protocols' execution paths, with many bugs emerging only under specific configurations. Fuzzing has become a prominent technique for uncovering vulnerabilities in IoT protocol implementations. However, traditional fuzzing approaches are typically conducted using fixed or default configurations, overlooking potential issues that might arise in different settings. This limitation can lead to missing critical bugs that appear only under alternative configurations.**

In this paper, we propose CMFuzz, a parallel fuzzing framework designed to improve fuzzing effectiveness of IoT protocols through configuration identification and scheduling. CMFuzz first constructs a generalized protocol configuration model by systematically extracting configuration items from protocol implementations. Then, based on this model, CMFuzz defines the relations among configuration items and introduces a relation-aware allocation mechanism to distribute them across parallel fuzzing instances. For evaluation, We implement CMFuzz on top of the widely-used protocol fuzzer Peach and conduct experiments on six popular IoT protocols. Compared to the original parallel mode of Peach and state-of-the-art parallel protocol fuzzer SPFuzz, CMFuzz covers an average of 34.4% and 28.5% more branches within 24 hours. Additionally, CMFuzz has detected 14 previously-unknown bugs in these real-world IoT protocols.

***Index Terms*—IoT Protocols, Parallel Fuzzing, Configuration Model Identification and Scheduling.**

I. Introduction

The Internet of Things (IoT) refers to a network of interconnected devices that communicate and exchange data using various protocols to provide advanced services. These protocols enable essential functionalities across smart homes, healthcare, and industrial systems, highlighting their significance in modern technology [1]–[4]. However, IoT protocols are also vulnerable to cyber threats, particularly in critical infrastructure systems, where disruptions can impair operations, cause financial loss, or jeopardize safety [5], [6]. Ensuring the security of IoT protocols is therefore crucial for maintaining uninterrupted services and protecting public safety.

In IoT systems, protocols are inherently configuration-sensitive, as they are designed to operate across diverse scenarios and meet a variety of operational requirements. These protocols often offer extensive and diverse configuration options, where different combinations can influence the system's execution paths and behaviors. Consequently, certain vulnerabilities may only surface under specific configurations. For example, CoAP [7] supports block-wise transfers to handle large payloads by dividing them into smaller, sequential blocks. This feature is an optional configuration that significantly impacts the protocol's execution. When enabled, the protocol introduces additional logic to manage stateful interactions by tracking individual block transfers across multiple requests and responses. This added complexity increases the likelihood of issues such as memory leaks or resource exhaustion.

✉Fuchen Ma and Yanyang Zhao are the corresponding authors.

Fuzzing is a testing technique used to detect vulnerabilities in software by feeding volumes of inputs and observing the system's behavior. It plays a crucial role in identifying security flaws in IoT protocol implementations. Existing protocol fuzzers often build data models and state models to start the fuzzing process. A data model defines the structure and format of protocol inputs. While a state model describes the sequential flow of states that the protocol follows. Protocol fuzzers like Peach [8] and SPFuzz [9] leverage these two models to guide the generation of inputs and manage transitions between protocol states. As a result, they can systematically explore protocol behaviors and uncover a range of vulnerabilities.

However, traditional fuzzers neglect the configuration model of protocols, which sets the basic environment of the protocol instance. Thus, they overlook potential behaviors under alternative configurations in IoT systems. This limitation hinders the effective exploration of deeper protocol vulnerabilities that may arise in non-default settings. Therefore, it is essential to acknowledge the multi-configuration nature of IoT systems and incorporate multiple configurations during fuzzing under the guidance of configuration models. In fact, to explore protocol execution paths under various configurations, a straightforward approach is to run parallel fuzzing instances with different configurations. However, this presents two key challenges:

The first challenge is how to generate high quality configurations for fuzzing. IoT protocols are designed with rich and complex configurations to support a wide variety of use cases and devices. The configurations span multiple domains, including security settings, network parameters, resource management, application-specific options, and so on. Each of these configurations can affect the protocol's behavior and execution path, potentially revealing vulnerabilities. Automatically constructing realistic and comprehensive configurations that reflect real-world scenarios is a difficult task. **The second challenge** is how to divide configuration item combinations between different parallel instances. Configuration items often have dependencies, synergies, or conflicts. Arbitrary assignment across instances can lead to inefficiencies or initialization failures. The challenge, therefore, is to quantify the relations among configuration items and leverage them to group the items into cohesive groups.

To address the above mentioned challenges, we propose CMFuzz. First, in addition to the traditional data model and state model, CMFuzz introduces a generalized configuration model for protocol fuzzing. Given that IoT protocols may define configurations in different forms, such as configuration files and Command-Line Interface (CLI) options, CMFuzz systematically extracts and standardizes these configuration items to build a unified model. This abstraction accommodates different configuration formats and paradigms, ensuring adaptability across diverse IoT protocols. By decomposing protocol configurations into individual items, the model enables precise exploration of parameter spaces. Then, based on

the generalized configuration model, CMFUZZ defines the pairwise relations among configuration items and introduces a relation-aware allocation mechanism to distribute them across parallel fuzzing instances. In this way, CMFUZZ can effectively explore diverse and meaningful configuration spaces with minimal redundancy.

For evaluation, we implement CMFUZZ on top of the widely-used parallel protocol fuzzer Peach. We evaluate it on six real-world IoT protocol implementations. The results show that CMFUZZ improves the total number of branches covered by 34.4% on Peach and 28.5% on SPFuzz. It also achieves a significant speedup in reaching identical code coverage compared to baseline fuzzers. Furthermore, CMFUZZ has detected 14 previously unknown bugs in real-world IoT protocols. These critical vulnerabilities could lead to security breaches, crashes, or denial of service, posing significant risks to devices operating with these protocols in real-world environments.

Our main contributions are as follows:

- We introduce the configuration model to protocol fuzzing and propose a method to construct it, enabling exploration beyond default setups to uncover additional vulnerabilities.
- We consider dependencies between configurations and design a relation-aware allocation mechanism to effectively partition configuration spaces across parallel fuzzing instances.
- We implement and evaluate CMFUZZ on six widely used IoT protocol implementations. The results demonstrate that CMFUZZ outperforms the state-of-the-art fuzzers and has exposed 14 security-critical vulnerabilities.

II. BACKGROUND

A. IoT Protocols

The Internet of Things (IoT) has rapidly expanded, connecting billions of devices across various domains, from home automation and healthcare to industrial control systems. IoT protocols are essential for facilitating communication and interoperability among these devices, with each protocol adapted to meet the distinct requirements of IoT environments. Commonly used IoT protocols, such as MQTT, CoAP, and DDS, are designed to operate efficiently in constrained environments, supporting lightweight messaging, real-time data handling, and flexible Quality of Service (QoS) controls. These protocols typically provide mechanisms to ensure data reliability, adaptability to diverse network conditions, and interoperability across devices with varying capabilities.

Generally, IoT protocols are designed with a high degree of configurability to address the diverse and dynamic nature of IoT environments. Configurations, typically applied through configuration files or command-line interface (CLI) options, allow protocols to be tailored to match specific application requirements, device capabilities, and network conditions. For instance, security settings in these protocols may include options for different authentication methods, encryption algorithms, and key management strategies to ensure data integrity and confidentiality across the network. Quality of Service (QoS) parameters may specify message delivery guarantees, balancing factors such as latency and reliability. Network configurations define addressing schemes and routing protocols that support scalability and efficient communication. Resource management configurations enable protocols to optimize power consumption, bandwidth usage, and processing load to suit devices with limited resources.

B. Protocol Fuzzing

Fuzzing is a widely used technique to identify vulnerabilities in network protocol implementations by generating and injecting unexpected or malformed packets into the protocol to observe how it responds. Based on how packets are generated, fuzzers can be categorized into two types: mutation-based and generation-based. Mutation-based fuzzers generate test cases by randomly mutating existing valid inputs from a predefined corpus, applying various transformations such as bit flipping, field truncation, or inserting unexpected values. This approach simplifies fuzzing setup, as it does not rely on protocol specifications. In contrast, generation-based fuzzers construct inputs according to the protocol's structure and rules, producing well-formed messages that can effectively target specific states or fields. This allows them to thoroughly exercise the protocol's logic and identify vulnerabilities in various scenarios, making them particularly effective for complex protocols with structured interactions.

Traditional protocol fuzzers are typically based on two models: the data model and the state model. The data model defines the structure and format of packet fields, such as field lengths, types, and value ranges, allowing the fuzzer to craft near-valid protocol messages. The state model captures interaction sequences and transitions within the protocol, simulating how states change in response to different inputs. By adhering to protocol data formats, these two models help fuzzers produce highly tailored, protocol-compliant inputs, reaching deeper, less frequently accessed protocol states. This structured approach is especially advantageous for protocols with intricate dependencies or stateful interactions, as it ensures comprehensive coverage of both common and edge-case scenarios.

III. SYSTEM DESIGN

We present an overview of CMFUZZ's design in Figure 1. CMFUZZ starts with a set of inputs comprising the protocol under test and its configurations, defined through various sources such as command-line interface (CLI) options and configuration files. The objective of CMFUZZ is to systematically extract and organize these configurations to enable efficient and diverse parallel fuzzing. The framework outputs a set of cohesive configuration groups, which are then distributed to different parallel fuzzing instances.

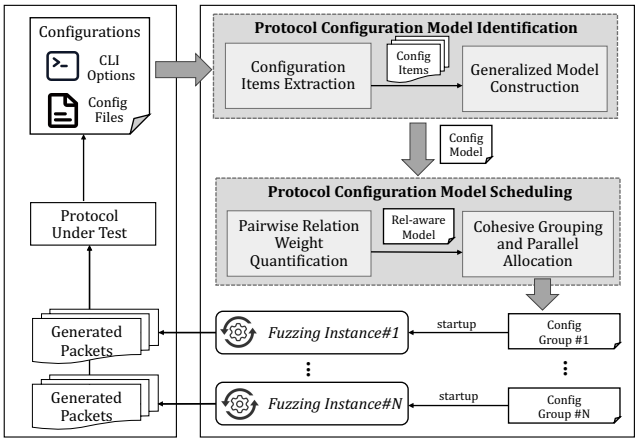

Fig. 1: CMFUZZ System Overview. It mainly consists of two components: (i) a configuration model identification module for extracting configuration items and constructing generalized model; (ii) a configuration model scheduling module for distributing configurations across parallel fuzzing instances.

CMFUZZ introduces a configuration model to explore a broader range of execution paths, supplementing the traditional data and state models used in existing protocol fuzzers. Starting with various protocol configuration formats, CMFUZZ first extracts a comprehensive list of configuration items to capture all adjustable parameters. These items are then organized into a generalized configuration

model, consisting of entities that represent each configuration item. Each entity includes the item's name, type, mutability flag, and a set of typical mutation values. With this configuration model in place, CMFUZZ then quantifies the pairwise relation weights between configuration entities by assessing their impact on startup coverage. Using these weights, CMFUZZ finally employs a cohesive grouping and allocation strategy, grouping interdependent entities together and assigning them to the same parallel fuzzing instance. This relation-aware allocation ensures that each instance explores a distinct and meaningful subset of configurations, thereby enhancing overall coverage and effectiveness in parallel protocol fuzzing.

A. Protocol Configuration Model Identification

1) Configuration Items Extraction: IoT protocol configurations are primarily found in two formats: command-line interface (CLI) options and configuration files. CLI options often follow predictable patterns, such as `--option=value` or `-flag`. To identify and extract these options, CMFUZZ uses a pattern-matching parser. For configuration files, formats vary widely, including key-value pairs (e.g., .ini files), structured hierarchies (e.g., JSON, XML), or unstandardized formats. CMFUZZ applies format-specific static analysis to handle each file structure: (i) For key-value formats, it directly parses each line to extract keys and values. (ii) For hierarchical formats, it recursively parses the structure to retrieve keys and default values based on the file's nested organization. (iii) For custom formats, CMFUZZ uses heuristics and configurable parsing rules to identify adjustable parameters based on keywords and contextual clues.

Algorithm 1: Configuration Items Extraction

Input: $\mathcal{C}_{options}$: CLI Options Configurations
Input: $\mathcal{C}_{files}$: Configuration Files
Output: Set_{CI}: The set of configuration items

1 **Algorithm**
2 $Set_{CI} \leftarrow \emptyset$
3 $Options \leftarrow$ GETCLIOPTIONS($\mathcal{C}_{options}$)
4 $Files \leftarrow$ GETCONFIGFILES($\mathcal{C}_{files}$)
5 `Extracion(` $Options, Files$)
6 **Procedure** `Extracion(` $Set_{Options}, Set_{Files}$)
7 **if** $Set_{Options} \neg \emptyset$ **then**
8 **for** $\mathcal{O}_\mathcal{C} \in Set_{Options}$ **do**
9 $Item \leftarrow$ EXTRACTCLIOPTIONS($\mathcal{O}_\mathcal{C}$)
10 $Set_{CI} \leftarrow Set_{CI} \cup Item$
11 **if** $Set_{Files} \neg \emptyset$ **then**
12 **for** $\mathcal{F}_\mathcal{C} \in Set_{Files}$ **do**
13 $Format \leftarrow$ DETECTFILEFORMAT($\mathcal{F}_\mathcal{C}$)
14 **switch** $Format$ **do**
15 **case** *KeyValue* **do**
16 $Set_{FI} \leftarrow$ EXTRACTKEYVALUE($\mathcal{F}_\mathcal{C}$)
17 **case** *Hierarchical* **do**
18 $Set_{FI} \leftarrow$ EXTRACTHIERARCHICAL($\mathcal{F}_\mathcal{C}$)
19 **otherwise do**
20 $Set_{FI} \leftarrow$ EXTRACTCUSTOMFORMAT($\mathcal{F}_\mathcal{C}$)
21 $Set_{CI} \leftarrow Set_{CI} \cup Set_{FI}$
22 **return**

Algorithm 1 illustrates the detailed workflow of CMFUZZ for extracting configuration items from various formats of IoT protocol configurations. The algorithm begins with two primary inputs: CLI Options Configurations and Configuration Files. First, we initialize an empty set Set_{CI} to store all configuration items extracted from these sources (line 2). Next, we retrieve CLI options and configuration files as structured data from the inputs (lines 3–4). Following this, we extract detailed configuration items according to their specific formats using the `Extraction` procedure. For each CLI option in $Set_{Options}$, we extract relevant details, including the configuration name, value and ranges, and add each item to Set_{CI} (lines 8–10). For each file in $Files$, we determine the format (line 13) and use format-specific extraction functions to parse the file's structure and content accordingly (lines 15–20). Items extracted from each file are then added to Set_{CI}, creating a consolidated set of configuration items for model construction (line 21).

2) Generalized Model Construction: Following the extraction of individual configuration items, CMFUZZ organizes these items into a generalized configuration model, which serves as the core structure within our framework.

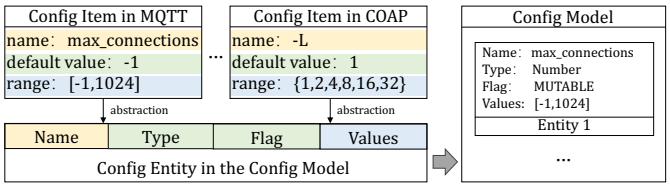

Fig. 2: Entities in the config model derived from the config item

As shown in Figure 2, this model is composed of 4-tuple entities, with each entity encapsulating essential attributes corresponding to a configuration item extracted from the protocol. The $Name$ attribute is inherited directly from the configuration item. The $Type$ attribute is inferred from the item's value patterns, for instance, numeric values are labeled as *Number*, boolean-like values as *Boolean*, and values resembling file paths or URLs as *String*. The $Flag$ attribute indicates whether a value is likely to change during typical protocol operations. Static values, such as paths or system directories, are marked as *IMMUTABLE*, while adjustable values, like numeric ranges or mode settings, are marked as *MUTABLE*. The $Values$ attribute, representing the typical set of values for each configuration, is derived from the item's defined ranges or common values using heuristic-based rules. This standardized configuration model provides a structured foundation for subsequent processes.

B. Protocol Configuration Model Scheduling

1) Pairwise Relation Weight Quantification: To leverage interdependencies among configurations and distribute the configuration model across parallel fuzzing instances, CMFUZZ enhances the original configuration model into a relation-aware configuration model, as illustrated in Figure 3. This transformation involves constructing a weighted relation graph, where each configuration entity is represented as a node, and edges with quantified weights connect pairs of entities. These weights reflect the strength of relationships between entities.

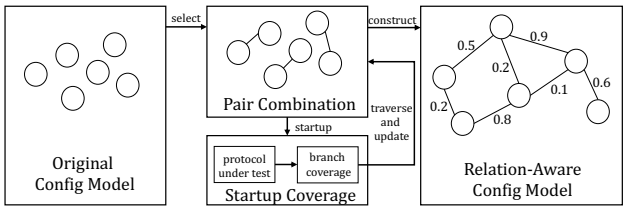

Fig. 3: Enhance an original config model into a relation-aware config model. CMFuzz achieves this by calculating the startup coverage.

When quantifying relations between configuration entities, CMFUZZ utilizes code coverage as a primary metric. Coverage serves as an effective indicator of configuration dependencies, as configurations

with synergistic relations often unlock new execution paths when used together. Conversely, configurations with conflicting relations, such as an encryption mode incompatible with a compression setting, may cause startup failures, resulting in zero code coverage. To improve efficiency, CMFuzz uses startup coverage as a lightweight proxy for overall code coverage. Because configurations are loaded and initialized during the startup phase, initial coverage provides a strong indication of the configuration's impact on later stages of execution.

By analyzing the startup coverage for each pair of configuration entities, CMFuzz then calculates the relation weight between them. Since each configuration entity may contain multiple typical values, CMFuzz explores all possible value combinations for each pair of entities and records the coverage achieved for each combination. To capture the peak interaction effect, CMFuzz selects the highest coverage across all combinations as the final relation weight between the two entities. This strategy ensures that the weight reflects the strongest potential interaction between entities, capturing critical synergies that might only emerge under specific values. Specifically, if the coverage for a pair of entities is zero across all combinations, CMFuzz does not create an edge between these entities. Finally, to ensure consistency and comparability across all relation weights, CMFuzz normalizes the calculated weights, scaling them to a standard range of [0, 1]. This normalization facilitates the grouping and clustering of configuration entities in subsequent phases.

2) Cohesive Grouping and Parallel Allocation: With the Relation-Aware Configuration Model constructed, CMFuzz proceeds to divide the graph into cohesive groups of configuration entities and allocate each group to a distinct parallel fuzzing instance.

Algorithm 2: Allocation Algorithm

Input: $RACModel$: Relation-Aware Configuration Model
Input: $\mathcal{N}_f$: The number of fuzzing instances
Output: $Groups$: The array of configuration groups allocated to each instance

1 **Algorithm**
2 $Groups \leftarrow \emptyset$, $GroupCnt \leftarrow 0$
3 $Set_{Edges} \leftarrow$ SortByWeight($RACModel$)
4 **for** $\mathcal{E}_s \in Set_{Edges}$ **do**
5 GroupNextEdge($\mathcal{E}_s$,$\mathcal{N}_f$)
6 **return** $Groups$
7 **Procedure** GroupNextEdge($\mathcal{E}$,$\mathcal{N}$)
8 $\mathcal{C}_1 \leftarrow \mathcal{E}.C_1$, $\mathcal{C}_2 \leftarrow \mathcal{E}.C_2$
9 **if** $\neg$IsSet($\mathcal{C}_1$) $\wedge$ $\neg$IsSet($\mathcal{C}_2$) **then**
10 **if** $GroupCnt < \mathcal{N}$ **then**
11 $NewGroup \leftarrow \{\mathcal{C}_1, \mathcal{C}_2\}$
12 $Groups \leftarrow Groups \cup \{NewGroup\}$
13 $GroupCnt \leftarrow GroupCnt + 1$
14 **else**
15 **for** $\mathcal{C} \in \{\mathcal{C}_1, \mathcal{C}_2\}$ **do**
16 $BestGroup \leftarrow$ FindBest($\mathcal{C}, Groups$)
17 $BestGroup \leftarrow BestGroup \cup \mathcal{C}$
18 **else if** IsSet($\mathcal{C}_1$) $\oplus$ IsSet($\mathcal{C}_2$) **then**
19 $CurGroup \leftarrow$ IsSet($\mathcal{C}_1$) ? Find($\mathcal{C}_1$) : Find($\mathcal{C}_2$)
20 $CurGroup \leftarrow CurGroup \cup$ (IsSet($\mathcal{C}_1$) ? $\mathcal{C}_2$: $\mathcal{C}_1$)
21 **return**

Algorithm 2 illustrates our allocation strategy, which aims to maximize the relation weights within groups and minimize the relation weights between groups. The algorithm starts with two inputs: the Relation-Aware Configuration Model $RACModel$ and the number of fuzzing instances N_f. First, we initialize an empty set $Groups$ to store the divided configuration groups and a counter $GroupCnt$ to track the number of groups created (line 2). Next, we sort all edges in $RACModel$ by weight in descending order, storing the sorted edges in Set_{Edges} (line 3). This sorting prioritizes edges with higher weights, promoting the formation of tightly connected groups by processing the strongest relationships first. For each edge in Set_{Edges}, we call the `GroupNextEdge` procedure, which determines how the two connected configuration entities (nodes) should be grouped (lines 4-5). In this procedure, if neither of the entities is assigned to a group (line 9), we verify whether the current number of groups $GroupCnt$ has reached the target number of instances $\mathcal{N}$ (line 10). If not, we create a new group with these two entities, add it to $Groups$, and increment $GroupCnt$ by one (lines 11-13). Once the maximum number of groups $\mathcal{N}$ has been reached, each new entity is placed into an existing group that best preserves its relations using the FindBest function (lines 15-17). Alternatively, if one entity is already part of a group, we assign another unassigned entity to the same group, thereby preserving their connection (lines 18-20).

Specifically, to identify the most appropriate existing group for an entity, the FindBest function computes a suitability score for each candidate group G_i based on the strength of the entity's connections to members of the group. The score is defined by:

$$Score(G_i, \mathcal{C}) = \frac{\left(\sum_{\mathcal{C}' \in G_i} w(\mathcal{C}, \mathcal{C}')\right)^2}{|G_i|}$$

where $w(\mathcal{C}, \mathcal{C}')$ represents the relation weight between the new entity $\mathcal{C}$ and each entity $\mathcal{C}'$ in group G_i, and $|G_i|$ denotes the number of entities in group G_i. In this formula, the numerator represents the strength of the relationship between the new node and existing nodes in G_i, while the denominator $|G_i|$ accounts for the balance in the number of entities across groups. The numerator is squared to amplify the effect of stronger connections.

Once cohesive groups have been formed, each group is assigned to a separate parallel fuzzing instance. Each instance then reassembles the configuration entities within its assigned group back into runtime-ready forms, such as configuration files or CLI options. During execution, each instance evaluates the $Flag$ attribute of each configuration entity to determine if the configuration value should be mutated. If mutation is required, it is applied based on the $Values$ attribute, which guides how the mutation should be performed. Mutations are introduced adaptively and are only applied if the current instance's coverage has reached saturation, meaning coverage has not increased over a set duration. Additionally, to prevent cross-contamination between instances, each fuzzing instance operates in an isolated network namespace. Through this structured parallel approach, each fuzzing instance is empowered to fully explore its assigned configuration subset, maximizing the chances of uncovering configuration-specific vulnerabilities.

IV. Evaluation

We have implemented CMFuzz on the state-of-the-art parallel protocol fuzzer Peach [8]. In the *Configuration Model Identification* module, we employ the Python Configuration File Parser [10] along with other specific libraries (such as `json`, `yaml`, `pyparsing`, and others) to convert configuration files into configuration items. For CLI options, we use Python Regular Expression Operations [11] to flexibly identify configuration items. In the *Configuration Model Scheduling* module, we leverage the `networkx` library to construct a weighted graph, where configuration entities serve as nodes and relations as weighted edges. For parallel fuzzing, we use Linux Network Namespaces (netns) via the `ip` networking tool to iso-

late network environments. Additionally, we use Clang to insert `trace-pc-guard` instrumentation, a feature in LLVM SanitizerCoverage [12], to collect branch coverage for pairwise relation weight quantification and parallel execution. For evaluation, we answer the following two research questions:

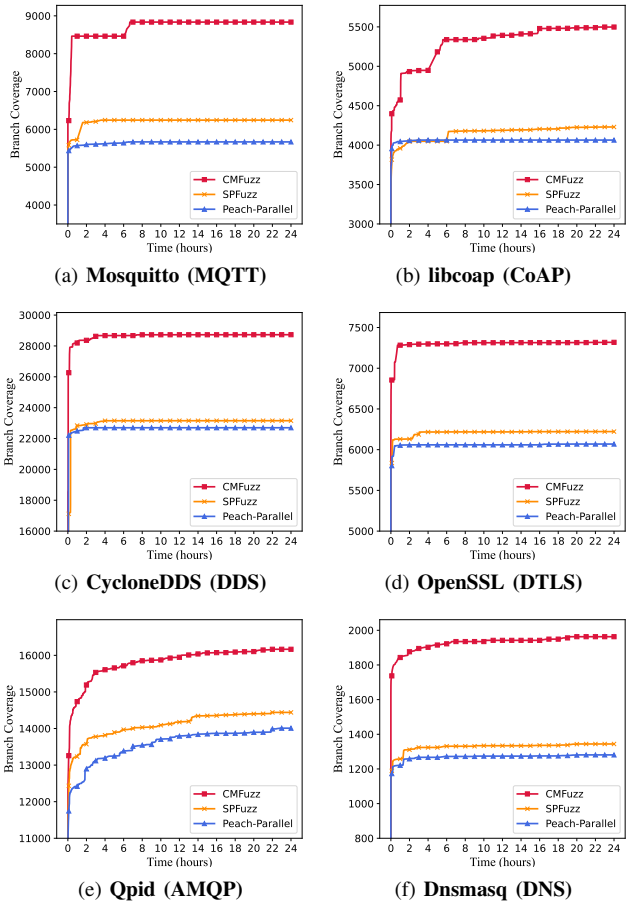
- **RQ1** Is CMFuzz more efficient than traditional parallel protocol fuzzers when applied to IoT protocols?
- **RQ2** Is CMFuzz effective in exposing previously unknown vulnerabilities in real-world IoT protocols?

A. Experiment Setup

Subjects. We selected six widely used IoT protocols: MQTT [13], CoAP [7], DDS [14], DTLS [15], AMQP [16] and DNS [17]. We use their corresponding popular open-source implementations as the test subjects, including Mosquitto [18], libcoap [19], CycloneDDS [20], OpenSSL [21], Qpid [22] and Dnsmasq [23].

Metrics. We employed three metrics for our evaluation: (i) branch coverage achieved, (ii) speedup in reaching the same coverage level as the compared fuzzers, and (iii) the number of bugs detected. The first metric is commonly used to measure the effectiveness of fuzzers, the second metric assesses the speed of parallel fuzzing, and the third metric indicates vulnerability detection capabilities.

Experiment Settings. Since the fuzzing performance fluctuates to a certain degree due to the inherent randomness, we ran each fuzzing tool on each selected project with a 24-hour time budget and repeated each 24-hour experiment five times to establish statistical significance of results [24]. For fairness, we use the same Pit files that specify the data and state models for each protocol. The experiment is executed in a Docker container with 4 CPU cores and 8 GB of RAM.



B. Coverage Analysis

To assess the efficiency of CMFuzz, we compared it to the state-of-the-art parallel-mode protocol fuzzers Peach [8] and SPFuzz [9]. Each fuzzer was run with four instances per project. We tracked and analyzed the number of branches covered by each fuzzer over 24 hours and calculated the speedup achieved by CMFuzz in reaching the same coverage level as the other fuzzers. Detailed results and improvements are summarized in Table I. The *Speedup* metric is defined as the baseline fuzzer's time to reach its final coverage divided by the time CMFuzz requires to achieve the same coverage. On average, CMFuzz improved branch coverage by 34.4% over Peach and 28.5% over SPFuzz across all tested protocol implementations. In terms of speedup, CMFuzz achieved an average acceleration of 3,544× compared to Peach and 2,746× compared to SPFuzz. These results reflect CMFuzz's significant enhancements in fuzzing efficiency for IoT protocols.

TABLE I: Average number of branches covered by each fuzzer running with four parallel instances over a 24-hour period.

Subject	CMFuzz	Peach	Improv	Speedup	SPFuzz	Improv	Speedup
Mosquitto	8,835	5,668	+55.9%	2,195×	6,244	+41.5%	30×
libcoap	5,498	4,064	+35.1%	450×	4,230	+30.0%	269×
cyclonedds	28,729	22,698	+26.6%	79×	23,155	+24.1%	146×
OpenSSL	7,318	6,069	+20.6%	8,820×	6,222	+17.6%	7,351×
Qpid	16,166	14,009	+15.4%	117×	14,440	+12.0%	41×
Dnsmasq	1,963	1,284	+52.9%	9,600×	1,348	+45.6%	8,640×
AVERAGE			+34.4%	3,544×		+28.5%	2,746×

Figure 4 illustrates that CMFuzz consistently achieves the highest branch coverage across all six projects, significantly outperforming the baseline tools Peach and SPFuzz. This underscores its effectiveness in exploring diverse execution paths. At the start of each session, all fuzzers exhibit an initial boost in coverage. CMFuzz achieves a considerable early lead because many of its extracted configuration items are loaded at startup, allowing rapid exploration of initial coverage. As time progresses, Peach and SPFuzz reach a saturation point, while CMFuzz continues to increase coverage by dynamically adjusting typical values from $Values$ field in configuration entities. This mechanism is particularly effective in protocols like CoAP, where varying block mode values allow exploration of alternative handling methods. Overall, in projects like Mosquitto and Dnsmasq, CMFuzz shows substantial improvement due to the extensive configurations in these protocols. For instance, Mosquitto supports varied QoS levels, authentication methods, and unique features like bridge connections, enabling CMFuzz to activate diverse paths by simulating different settings. In contrast, CMFuzz 's improvements on OpenSSL, CycloneDDS, and Qpid are modest due to limitations in flexibility. For instance, DTLS relies on fixed cryptographic settings, DDS's structured management restricts configuration diversity, and AMQP's predefined structure limits exploration.

(a) **Mosquitto (MQTT)** (b) **libcoap (CoAP)**

(c) **CycloneDDS (DDS)** (d) **OpenSSL (DTLS)**

(e) **Qpid (AMQP)** (f) **Dnsmasq (DNS)**

Fig. 4: Average number of branches achieved by CMFuzz and baseline parallel fuzzers within 24 hours for 5 repetitions on each IoT protocol implementation. All fuzzers are run with 4 instances.

C. Bug Detection Capability

In addition to the fuzzing efficiency improvement, CMFuzz has also uncovered 14 serious previously unknown vulnerabilities in these target protocols. These vulnerabilities pose significant security risks to devices operating with these protocols, potentially leading to device crashes, unauthorized access, or even complete system compromise. Table II summarizes the vulnerabilities discovered by CMFuzz. Each of them presents critical threats to IoT systems. Specifically, heap-use-after-free allows attackers to reuse freed memory, leading to

unpredictable behavior or remote code execution. SEGV is triggered by invalid memory accesses, and may expose sensitive information or allow code injection. Memory leaks, which cause memory to be exhausted over time, are particularly dangerous in resource-constrained IoT devices, potentially leading to system unresponsiveness and disrupted services. Allocation-size-too-big occurs when an abnormally large memory is allocated, potentially exhausting system resources or leading to denial-of-service attacks. Stack-buffer-overflow and heap-buffer-overflow involve writing data beyond allocated boundaries, potentially overwriting critical memory areas, leading to crashes or enabling attackers to execute malicious code.

TABLE II: Summary of vulnerabilities detected by CMFuzz

No.	Protocol	Vulnerability Type	Affected Function
1	MQTT	heap-use-after-free	Connection::newMessage
2		heap-use-after-free	neu_node_manager_get_addrs_all
3		heap-use-after-free	mqtt_packet_destroy
4		SEGV	loop_accepted
5		memory leaks	multiple functions
6	CoAP	SEGV	coap_clean_options
7		stack-buffer-overflow	CoapPDU::getOptionDelta
8		SEGV	coap_handle_request_put_block
9	AMQP	stack-buffer-overflow	pthread_create
10	DNS	stack-buffer-overflow	get16bits
11		heap-buffer-overflow	dns_question_parse, dns_request_parse
12		allocation-size-too-big	dns_request_parse
13		heap-buffer-overflow	printf_common
14		heap-buffer-overflow	config_parse

Case Study: Bug #8 in libcoap (CoAP). Figure 5 illustrates a SEGV vulnerability exposed by CMFuzz in the CoAP protocol. The bug occurs within `coap_handle_request_put_block` function, where `lg_srcv->body_data` is explicitly set to NULL (line 6) if `lg_srcv` is not found in the current session (line 3). However, if the block transfer process is incomplete or certain expected blocks fail to arrive, `lg_srcv->body_data` may remain NULL without being updated with valid data.

```
1  int coap_handle_request_put_block(...) {
2    ...
3    if (!lg_srcv) {
4      ...
5      // Initialize lg_srcv->body_data to NULL
6      lg_srcv->body_data = NULL;
7      LL_PREPEND(session->lg_srcv, lg_srcv);
8    }
9    ...
10 #if COAP_Q_BLOCK_SUPPORT
11   if (block_option == COAP_OPTION_Q_BLOCK1) {
12     if (check_all_blocks_in(...)) {
13       goto give_app_data;
14     }
15   }
16   ...
17 give_app_data:
18   ...
19   // Potential null dereference
20   pdu->body_data = lg_srcv->body_data->s;
21   ...
22 }
```

Fig. 5: The simplified code snippets related to the Bug#8.

When the non-default Q-Block1 configuration, which enables blockwise transfers, is activated (lines 10-11), the function checks if all blocks have been received (line 12). If they have, the code proceeds to the `give_app_data` label to reassemble and process the complete message body (line 13). At this label, `pdu->body_data` is assigned `lg_srcv->body_data->s` directly (line 20), assuming it is valid. However, if `lg_srcv->body_data` is still NULL, this assignment will cause a null pointer dereference, leading to a segmentation fault. This bug is critical as it potentially leads to server crashes and denial of service when handling blockwise transfers under specific configurations. Notably, it cannot be triggered under the default configuration, as it requires specific blockwise transfer settings to activate the vulnerable code path.

V. Related Work

Protocol Fuzzing. Numerous studies emphasize the extensive use of generation-based fuzzing for protocol implementation testing [8], [25]–[28]. Predominantly, existing research concentrates on enhancing algorithms that generate test packets. For example, Bleem [26] proposes a generation strategy focusing on packet sequences. Conversely, Logos [27] utilizes protocol server logs to conduct deep and efficient fuzzing within black-box environments. PAVFuzz [28] adopts a dynamic method to iteratively learn relationships between packet fields, aiming to improve packet generation. All these approaches focus on refining packet or sequence generation, and their effectiveness can be further bolstered by integrating CMFuzz. Our approach, CMFuzz, can autonomously determine and schedule configurations for parallel protocol fuzzing tasks and improve the effectiveness of the vulnerability detection. Thus, CMFuzz can be integrated with these existing methodologies to significantly boost fuzzing efficiency across multi-core computational resources.

Parallel Fuzzing. The enhancement of fuzzing efficiency is significantly driven by augmenting computational resources and leveraging parallel processing [29], [30]. Current research efforts concentrate on optimizing mutation-based fuzzers through information synchronization mechanisms and the strategic orchestration of fuzzing path scheduling. For example, tools such as AFL [31] and its protocol-oriented variant AFLNet [32] enable parallel fuzzing through synchronized seed sharing; AFLTeam [33] employs a dynamic task allocation model that refines task distribution, while PAFL [34] integrates a real-time synchronization framework for fuzzing status. Furthermore, SPFuzz [9] adopts a state-aware path-based method to enhance autonomous vehicle system scenarios. However, current fuzzing methodologies predominantly depend on standard configurations, neglecting the exploration of potential system behaviors under diverse configurations within IoT environments. This narrow focus restricts the ability to uncover deeper, configuration-specific protocol vulnerabilities that could emerge beyond default settings. Thus, recognizing the inherent multi-configuration complexity of IoT systems and integrating varied configurations into the fuzzing process becomes crucial for comprehensive vulnerability analysis.

VI. Conclusion

In this paper, we propose CMFuzz, a fuzzing framework that enhances parallel fuzzing for IoT protocols by dynamically identifying and scheduling configuration models. CMFuzz constructs a generalized configuration model by extracting protocol configuration items and grouping them based on inter-item relations. This approach enables parallel instances to explore diverse configuration combinations, significantly increasing coverage and the likelihood of discovering configuration-dependent bugs. Experimental results show that CMFuzz improves coverage by an average of 34.4% and 28.5% over Peach and SPFuzz, with significant speedups achieved for both baseline fuzzers. Furthermore, CMFuzz has uncovered 14 previously unknown vulnerabilities in real-world IoT protocols.

***Abstract*—*Approximate nearest neighbor search* (ANNS) is crucial in many applications to find semantically similar matches for user queries. Especially with the development of *large language models* (LLMs), ANNS is becoming increasingly important in *retrieval-augmented generation* (RAG). An in-depth analysis of ANNS reveals that its diverse operations, from extensive memory access to intensive sorting, are key performance bottlenecks, imposing significant strain on both the memory system and computing resources. Based on these observations, we present SeIM, a hierarchical in-memory architecture to accelerate ANNS. SeIM is designed to accommodate the diverse operational characteristics of ANNS. Specifically, SeIM offloads highly parallel memory-bound operations to the memory bank level and introduces a unified *execution model* to reuse hardware units, requiring only lightweight modifications to standard DRAM architecture. Additionally, SeIM places compute-bound sorting operations, which require cross-unit data access, at the memory controller level and employs an *adaptive transmission filtering* technique to reduce unnecessary data transfers and processing during sorting. Our evaluation shows that SeIM achieves 268×, 22×, and 5× higher throughput, 306×, 59×, and 4× lower latency, and 3081×, 287×, and 2× higher power efficiency than state-of-the-art CPU-, GPU-, and ASIC-based ANNS solutions.**

***Index Terms*—processing-in-memory, DIMM, ANNS.**

I. Introduction

Approximate nearest neighbor search (ANNS) is a fundamental technique for retrieving vectors similar to a query vector in vector space, widely used in deep learning [1] and information retrieval [2] systems. Traditional *large language models* (LLMs), which rely on static training data, often struggle with real-time updates, leading to contextual misunderstandings and inaccurate responses. The *retrieval-augmented generation* (RAG) [3], [4] addresses this limitation by combining ANNS-enabled vector databases with LLMs, incorporating external knowledge to improve the performance of generative models. Additionally, recommender systems like YouTube [5] and search engines like Google [6] use ANNS to improve suggestions and search results.

This work is supported by the National Key Research and Development Program of China (No. 2023YFB4503400), the National Natural Science Foundation of China and Research Grants Council (NSFC/RGC) Joint Research Scheme (No. 62461160333), and the National Research Foundation, Singapore, under its Competitive Research Programme Award NRF-CRP23-2019-0003. Dan Chen is the corresponding author.

ANNS can be classified into four main categories: quantization-based [7], graph-based [8], hash-based [9], and tree-based [10]. Among these, quantization-based ANNS has emerged as the industry's first choice [11] for large-scale search due to their high performance and low memory footprint. In quantization-based ANNS, the search process begins by filtering out the cluster centroids closest to the query vector. Next, a distance table is constructed using the codebook, and the compressed vectors within the filtered clusters are scanned. The distance to the query vector can be quickly obtained for each compressed vector by looking up the distance table. This process mainly involves three types of operation: *vector computation*, *distance sorting*, and *lookup-based computation*.

We conduct an in-depth analysis of the search process using the mainstream ANNS library FAISS [12] and identify three key findings. First, search performance is constrained by multiple phases collectively, rather than a single phase. Therefore, optimizing search performance requires comprehensive improvements across the entire process, rather than focusing on a specific phase. Second, there are significant differences in the operational intensity of various operations: *vector computation* and *lookup-based computation* are highly memory-bound and susceptible to frequent data movement between memory and processing units, whereas *distance sorting* is primarily limited by computational capacity. Lastly, these three operations exhibit a mixed computation pattern: *vector computation* and *lookup-based computation* are highly parallelizable but differ in their processing for each dimension, *distance sorting* requires sequential aggregation of the results from all subtasks, complicating parallelization efforts.

Previous studies [13]–[15] have demonstrated that *processing-in-memory* (PIM) architectures hold significant potential for accelerating memory-bound applications. However, applying existing PIM solutions to quantization-based ANNS presents several challenges. First, the search process involves both memory-bound and compute-bound operations, posing challenges for existing PIM architectures to fully support the search process. Second, while current PIM accelerators [16], [17] optimized for *general matrix-vector multiplication*

(GEMV) excel at *vector computation*, they lack optimization for *lookup-based computation*, which demands distinct hardware designs and may introduce additional overhead. Therefore, new designs are needed to accelerate quantization-based ANNS.

In this work, we present SeIM, a high-performance and energy-efficient in-memory accelerator for quantization-based ANNS. SeIM's innovation lies in its hierarchical acceleration design, which addresses the distinct characteristics of search operations and delivers full functionality at a low cost. On the one hand, we integrate computation logic into memory to support both *vector computation* and *lookup-based computation*, requiring only lightweight modifications to DIMMs based on standard DRAM technology. On the other hand, we aggregate computation results in the memory controller and efficiently handle sorting operations. With higher power and area budgets compared to DIMMs, the memory controller supports the integration of more sufficient computational capabilities. To the best of our knowledge, SeIM is the first solution to leverage PIM technique for accelerating quantization-based ANNS.

In particular, SeIM first deploys custom processing units within each DRAM bank, specifically designed to support *vector computation* and *lookup-based computation*. By employing all-bank mode, it maximizes internal bandwidth utilization and parallelism. Additionally, SeIM introduces a unified *execution model* for these offloaded-to-memory operations, enabling logical reuse and minimizing hardware resource overhead. Second, SeIM incorporates hardware priority queues within the memory controller to efficiently handle *distance sorting*. SeIM further employs an *adaptive transmission filtering* technique to reduce memory transfers caused by invalid distance values. Finally, SeIM adopts a heterogeneous computing programming model, similar to CUDA/SYCL [18], to enhance development efficiency and improve the user experience.

We list our contributions as follows:

- We perform an in-depth characterization of quantization-based ANNS, identifying key performance bottlenecks and motivating the design of in-memory acceleration.
- We introduce SeIM, the *first* in-memory accelerator for quantization-based ANNS, which addresses the diverse requirements of various operations in the search process through a hierarchical PIM architecture.
- We further propose two key optimizations: (I) a unified *execution model* to reduce hardware resource overhead for in-memory computations, and (II) an *adaptive transmission filtering* technique to decrease unnecessary data transfers for sorting.
- Experimental results show that SeIM achieves significant improvements in both performance and energy efficiency compared to existing software and hardware solutions.

II. Background and Motivation

A. Quantization-based ANNS

***Product Quantization* (PQ)**. PQ is a widely employed technique for compressing high-dimensional vectors [7]. To mitigate compression errors, this algorithm begins by splitting

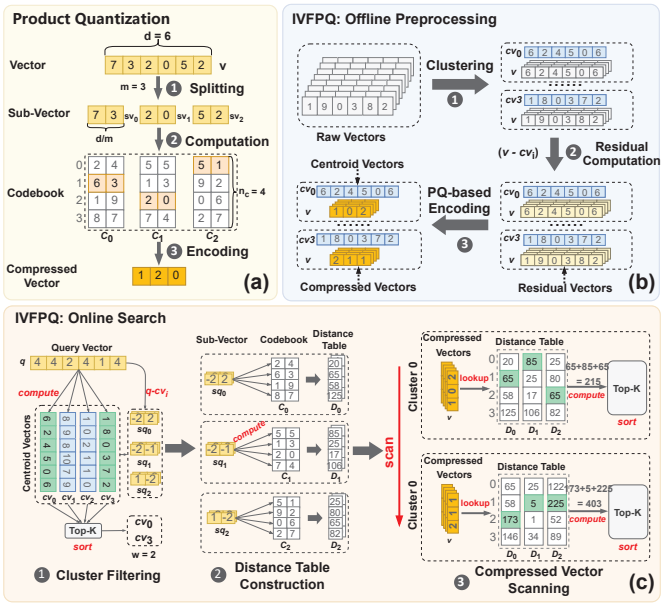

Fig. 1. An illustrative example of quantization-based ANNS (L2 distance)

the input vector v, of dimension d, into m distinct sub-vectors sv_i (where $0 \leq i < m$), each with a dimension of d/m (❶). For each sub-vector sv_i, the algorithm identifies the index of its nearest vector within the corresponding codebook C_i (❷). Consequently, the final vector v is encoded as a concatenation of m indices (❸). Fig. 1(a) illustrates an example of encoding a six-dimensional vector v with PQ. After encoding, v can be represented by three indices $\{1, 2, 0\}$.

PQ-based ANNS. Many popular ANNS libraries typically integrate the *inverted file index* (IVF) with PQ to reduce the number of compressed vectors that need to be scanned [7], a technique known as IVF-PQ. Fig. 1(b) illustrates the offline preprocessing process of IVF-PQ for database vectors. First, it clusters the database vectors (❶). Then, it computes the residuals of each vector relative to its respective cluster centroid (❷). Finally, it encodes all residual vectors utilizing product quantization (❸). After encoding is complete, the vector database will store the trained centroid vectors and compressed vectors.

Since preprocessing is an one-time operation, our primary focus is on the online search process. In ANNS, commonly used distance metrics between vectors include *euclidean distance* (L2) and *inner product distance* (IP). Fig. 1(c) shows the process of online search in IVF-PQ using the L2 distance. The initial phase is *cluster filtering* (CF). It selects the w nearest centroid vectors to the query vector q (❶). The subsequent phase is *distance table construction* (DTC). The algorithm computes the residual between the query vector q and the centroid vector of the selected cluster, then splits it into m sub-vectors and calculates the distance between each sub-vector and its corresponding codebook. Note that the computation process of IP distance is different from that of L2 distance (❷) [11]. The final phase is *compressed vector scanning* (CVS). It processes the compressed vectors within the selected w clusters. This is executed by using each dimension of a compression vector as an index to retrieve and accumulate

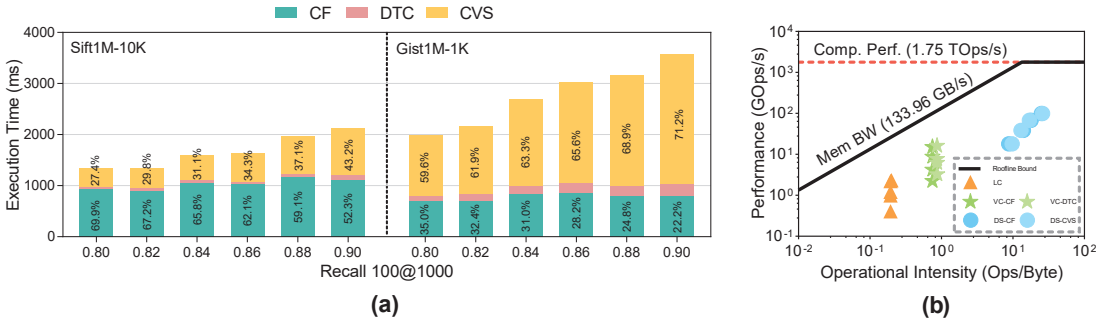

Fig. 2. (a) Search breakdown for different phases across datasets with varying recall (0.84, 0.86, 0.88, 0.90) and (b) roofline model analysis of ANNS, sweeping batch size

data from the corresponding distance table. After obtaining the distance values, the algorithm must also sort them to identify the top-k most similar vectors (❸).

B. Characterizations of Quantization-based ANNS

We characterize, FAISS [12], the popular ANNS library built by Facebook, on the CPU to identify performance bottlenecks and optimization opportunities. Experimental details are in §IV-A.

Performance Analysis. Fig. 2(a) delineates the execution time distribution across the three phases of the search process. Notably, *cluster filtering* and *compressed vector scanning* account for over 90% of the total time, indicating that optimizing these two phases is crucial to increase performance. We further analyze the key operations involved within these three phases. There are three key operations including: *vector computation* (VC), *distance sorting* (DS), and *lookup-based computation* (LC). During the *cluster filtering* phase, operations include *vector computation* and *distance sorting*; *Distance table construction* is primarily focused on *vector computation*; and *compressed vector scanning* consists of *lookup-based computation* and *distance sorting*.

Roofline Analysis. Fig. 2(b) depicts the roofline model data points for three key operations under various query conditions. The model indicates that *vector computation* and *lookup-based computation* are memory-bound, whereas *distance sorting* operation is compute-bound. Taking SIFT1M [19] as an example, the original vectors are 128-dimensional (4 bytes per element), compressed to 64-dimensional (1 byte per element), with a search for the top-100 nearest neighbors. For *vector computation*, this entails a 512-Byte DRAM read and 383 arithmetic operations (128 SUB, 128 MUL, 127 ADD), translating to an operational intensity of 0.75 operations per Byte. *Lookup-based computation* operation reads the 64-Byte compressed vector, retrieves 64 4-Byte distance values, and finally performs 63 additions with an intensity of 0.19 operations per Byte. *Distance sorting* operation, receiving a 4-Byte distance, involves updating a priority queue with up to 100 comparisons, reflecting an intensity of 25 operations per Byte.

Computation Pattern Analysis. *Vector computation* and *lookup-based computation* share similarities and key differences. Both lack dependencies between tasks, allowing them to be divided into independent subtasks for parallel processing. However, *vector computation* performs element-wise operations between two vectors followed by accumulation, while *lookup-based computation* uses vector dimensions as indices to retrieve and accumulate results from a lookup table. In contrast, *distance sorting* has a completely different pattern. It aggregates results from the other two operations to update a priority queue. Due to the dependencies in updates, distance sorting cannot be split into independent parallel subtasks.

C. Processing-in-memory Acceleration for Quantization-based ANNS

Why Choose PIM? PIM is a key technique proposed to accelerate the memory-bound operation. By integrating the compute unit in memory, PIM technique can significantly shorten the data transfer path between memory and processing units [13]–[15]. Quantization-based ANNS involves extensive memory access, making it suitable for PIM with high bandwidth and low latency capabilities. However, achieving this goal remains challenging. First, the characteristics of search operations vary, requiring more specific designs than existing PIM solutions. *Vector computation* and *lookup-based computation* are memory-bound and highly parallel, making them ideal for lower memory levels like the bank level. In contrast, *distance sorting* is compute-bound and requires aggregating results from the other two operations, making it better suited for higher memory levels. Second, while current PIM solutions [16], [17] for matrix-vector multiplications (GEMV) focus on *vector computation* at the memory bank level, they lack optimizations for *lookup-based computation*. Supporting *lookup-based computation* would require new hardware designs, potentially increasing overhead.

How to Design? To address these challenges, we propose a hierarchical PIM design. For *vector computation* and *lookup-based computation*, we deploy processing units at the memory bank level, maximizing the utilization of internal memory bandwidth. Additionally, we design a unified execution model and computation logic for these two operations, enabling resource sharing and minimizing hardware modifications, while maintaining compatibility with commercial DIMM architectures. For *distance sorting*, which requires aggregating results from the other two operations and involves computation-intensive sorting tasks, we extend the memory controller with dedicated hardware for sorting acceleration. Furthermore,

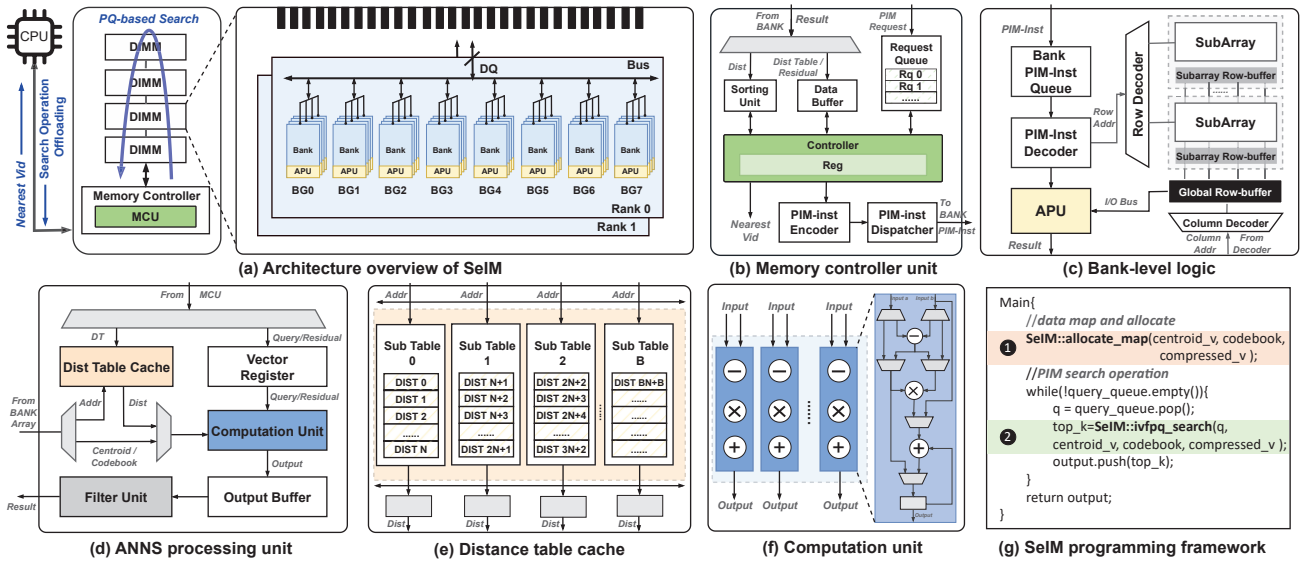

Fig. 3. The SeIM architecture

we propose an adaptive filtering mechanism to reduce the transmission and sorting of invalid results.

III. SeIM Architecture

In this section, we introduce SeIM, a DIMM-based hierarchical PIM architecture designed to accelerate quantization-based ANNS. Although SeIM is implemented using DIMM in this work, its design principles are equally applicable to HBM/HMC.

A. Architecture Overview

Fig. 3(a) depicts the overall architecture of SeIM. Unlike conventional memory systems, SeIM integrates a *memory controller unit* (MCU) within the memory controller, which manages the entire data flow and performs sorting operation. Additionally, components such as *ANNS processing unit* (APU) are deployed on each bank within the DIMMs to support diverse computing tasks. These APUs can simultaneously respond to computing instructions at the bank level, thereby exploiting DRAM's bank-level parallelism and significantly enhancing computational efficiency. Notably, SeIM maintains compatibility with conventional memory devices, as all original interfaces remain unchanged.

B. Hardware Design

***Memory Controller Unit* (MCU).** The detail of the MCU is illustrated in Fig. 3(b).The MCU comprises several components: a controller, a request queue, an encoder, a dispatcher, a data buffer, and a sorting unit. The primary function of the request queue is to temporarily store PIM requests from the host. The controller is responsible for activating either the sorting unit or the encoder based on the current progress. The encoder generates a PIM instruction for each PIM request, which is then transferred by the dispatcher to the corresponding banks within the DIMMs. To overcome C/A bandwidth limitation, SeIM utilizes the compression technique to encode all DDR commands, tags, and other relevant information in a single PIM instruction. The data buffer stores the distance table or residual vectors generated during the search process. The sorting unit is implemented as a hardware priority queue [20] based on the binary heap structure to handle all sorting tasks.

Bank-level Logic. As shown in Fig. 3(c), SeIM integrates the APU directly within each DRAM bank to enable efficient near-memory computation. In addition to the APU, SeIM incorporates an instruction queue and instruction decoder into each bank. These components are responsible for receiving and decoding PIM instructions from the memory controller. This design enables each bank to independently execute its assigned computational tasks in parallel.

***ANNS Processing Unit* (APU).** As depicted in Fig. 3(d), the core component of the APU is the computation unit. Fig. 3(f) details the design of the computation unit, which supports both *vector computation* and *lookup-based computation*. Additionally, for *vector computation*, the unit supports both IP distance and L2 distance metrics, which cover most search scenarios. The APU also includes a distance table cache for storing the distance table, a vector register for caching query and residual vectors, an output buffer for holding computation results, and a filter unit that supports the adaptive transmission filtering technique, as introduced in § III-D.

***Distance Table Cache* (DTC).** Based on the execution model described in §III-C, the APU simultaneously loads multiple compression vectors of the same dimension, which serve as addresses for lookup in the distance table. To enhance read bandwidth, the distance table cache is divided into multiple independently addressable tables, as illustrated in Fig. 3(e). In an ideal scenario, the input addresses will be distributed across different tables, allowing the distance table cache to read multiple distance values concurrently.

C. Data Layout and Execution Model

The tasks offloaded to memory (*vector computation* and *lookup-based computation*) share similar computation pattern. Therefore, we propose a unified execution model to reuse

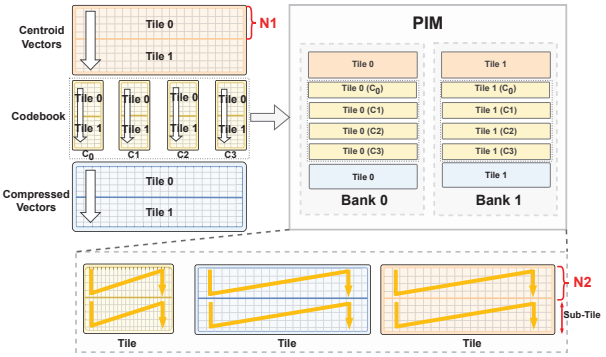

Fig. 4. Data layout and execution model

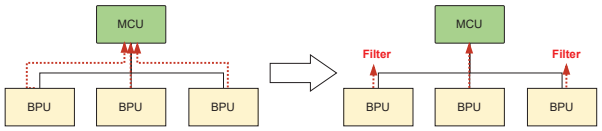

Fig. 5. Adaptive transmission filtering

hardware logic and maximize bank-level parallelism. Meanwhile, the data involved in the computations, such as the centroid vectors, codebook, and compressed vectors, all follow a consistent data layout scheme. The data layout scheme and execution model are shown in Fig. 4.

Across banks, we divide the three types of data into equally sized tiles along the row dimension, and each tile is assigned to a different bank. Each bank processes identical tasks with nearly the same amount of data, ensuring load balancing between processing units. During the search phase, memory operates in all-bank mode, where each bank processes its assigned tasks in parallel.

Within bank, for *lookup-based computation*, processing the compressed vector tiles in row-major order would require storing the entire distance table in the on-chip memory, which could result in significant area overhead. On the other hand, using column-major order would also necessitate a large buffer to store the intermediate results for all rows. To address this issue, we further subdivide the tile along the row dimension into smaller sub-tiles, with the size determined by the buffer capacity. Within each sub-tile, we store and process the compressed vectors in column-major order. To simplify hardware design, the same processing model is applied to *vector computation*.

One particular scenario is when using L2 distance for searching, where we need to compute the residuals between the query vector and each selected centroid vector. To reduce unnecessary row activations, we make a copy of the centroid tiles in each bank with an entirely row-major layout, which only consumes a few extra megabytes of memory.

D. Adaptive Transmission Filtering

The sorting unit must aggregate data from all banks, which may introduce new bottlenecks. We find that most of the distance values read into the memory controller are discarded and do not participate in the actual queue updates. To address this, we design a filtering mechanism, as shown in Fig. 5, which periodically transmits the maximum distance value from the priority queue to each APU and saves it. When the APU calculates new results, it compares them to the saved maximum distance value; if the new result exceeds this value, it is discarded directly without being transferred to the memory controller for sorting. This approach not only reduces the amount of data transmitted in memory but also saves sorting time overhead.

TABLE I

E. Programming Model and Execution Flow

SeIM adopts a heterogeneous programming model to enable PIM functionality. Fig. 3(g) illustrates the programming framework of SeIM. Before executing the search, SeIM allocates and maps data—including centroid vectors, codebooks, and compressed vectors—into corresponding memory regions, following the data layout strategy described in § III-C, while mapping indices to physical addresses. When a search operation is initiated, the host receives a batch of query requests. For each query, SeIM activates the PIM kernel to generate PIM requests that are then executed in memory. Upon completion of the search, the top-k neighbor IDs of all query requests in the batch are returned from the memory to the host through the DRAM interface.

IV. EVALUATION

A. Experimental Setup

SeIM Settings. We implement an internal cycle-accurate simulator based on Ramulator [21] for evaluating the performance of SeIM. The basic hardware configuration of SeIM is summarized in Table I. We synthesize the special hardware units using Synopsys Design Compiler [22] under a 32nm technology library at the frequency of 500MHz. The energy consumption, area, and access latency of all buffers in SeIM are estimated by CACTI [23].

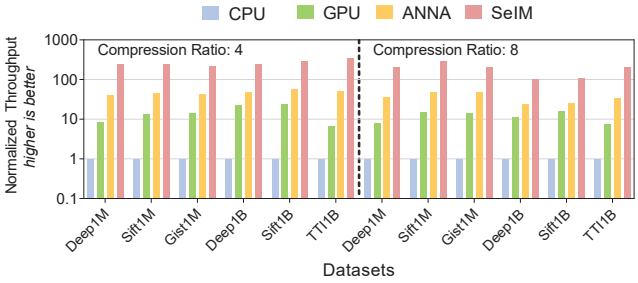

Fig. 6. Throughput comparison (recall 100@1000)

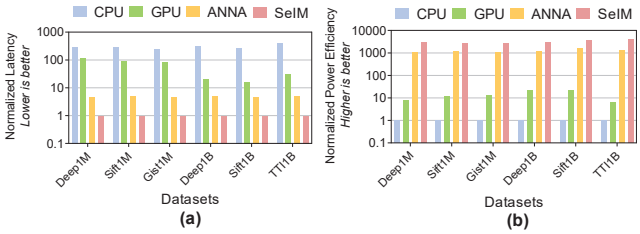

Fig. 7. (a) Latency and (b) power efficiency comparison

Datasets and Metrics. We pick four representative real-world datasets, Sift [19], Gist [19], Deep [24] , and TTI [24], with different data scales. The dataset details are shown in Table II. We compare the performance of the different solutions by measuring the *throughput* (QPS) and *latency* (ms) of the queries with the same *recall* ($R@K$), which refers to the fraction of the true R nearest neighbors included in the K search results. Additionally, we take *energy efficiency* (QPS/Watt) into account to evaluate the balance between performance and energy consumption.

Baselines. We compare SeIM to CPU, GPU, and ASIC baselines. For the CPU baseline, we choose a 14-core, dual-socket Xeon Gold 5117 CPU with 512GB of DDR4 memory, utilizing 56 threads to search in parallel during testing. The GPU baseline runs on an Nvidia V100 with 32GB of HBM2 memory. The performance and power consumption are measured by Intel RAPL and nvprof tools. We further compare SeIM with the state-of-the-art PQ-based ANNS accelerator ANNA [11]. Note that all methods are based on the most popular PQ-based ANNS library FAISS [12], and all parameters in the algorithm are identical.

B. Experimental Results

Throughput Comparison. Fig. 6 illustrates the throughput comparison of SeIM compared to CPU, GPU, and ANNA at different compression rates. Compared with CPU, GPU, and ANNA, SeIM achieves on average 188.07×, 16.99×, and 5.09× throughput improvement at compression rate of 8, and 268.76×, 22.92×, and 5.59× at compression rate of 4, respectively. The performance improvement of SeIM comes from several factors. (1) SeIM utilizes near-memory processing to fully utilize in-memory bandwidth and dramatically reduce data transfer distances. (2) SeIM customizes a highly parallelized near-memory processing unit for searching and pipelines of the data path. (3) SeIM introduces optimizations such as *adaptive Transmission Filtering*, which further reduces data transfer as well as processing.

TABLE III
SEIM HARDWARE OVERHEAD

SPU Hardware Overhead of One DIMM
Power (mW): 73.46 (CU), 320.71 (Buffer&Cache), 394.17 (Total)
Area (mm^2): 0.185 (CU), 0.262 (Buffer&Cache), 0.447 (Total)
MCU Hardware Overhead
Power (mW): 71.35 (SU), 2565.70 (Buffer), 2637.05 (Total)
Area (mm^2): 0.103 (SU), 2.098 (Buffer), 2.201 (Total)

Latency Comparison. We further evaluate the average query latency of SeIM against the baselines when the compression rate is 4. As shown in Fig. 7(a), SeIM reduces the query latency by 306.42×, 59.03×, and 4.85× compared to CPU, GPU, and ANNA. Moreover, SeIM can still process similarity searches in milliseconds for data at a billion scale, which indicates that SeIM is well suited for latency-constrained scenarios to meet strict SLA constraints.

Power and Area. Table III reports the area and power cost of SeIM. In total, SeIM adds $0.447mm^2$ for area and $0.39W$ for power consumption per DIMM. In comparison, a single commercial DIMM chip typically consumes about $10W$ of power and $3500mm^2$ of area, respectively, and the additional overhead introduced by SeIM is negligible. For the upper MCU, the area and power consumptions are $2.63W$ and $2.201mm^2$, respectively.

Power Efficiency Comparison. Fig. 7(b) provides the power efficiency comparison between SeIM and baselines. On average, SeIM is 3081.37×, 287.02×, and 2.49× more power efficient than CPU, GPU, and ANNA, respectively. This increased efficiency can be attributed to two main factors: first, minimizing the distance of data movement reduces energy consumption associated with data transfers; second, the highly parallel and customized computational architecture significantly accelerates search time.

Impact of SeIM Optimization. We compare the throughput of SeIM with and without *Adaptive Transmission Filtering*. On average, at a compression rate of 4, SeIM with *Adaptive Transmission Filtering* achieves 2.13× throughput compared to SeIM without *Adaptive Transmission Filtering*. Similarly, at a compression rate of 8, this leads to an additional speedups of 1.94×.

V. CONCLUSION

In this paper, we present SeIM, a high-performance and energy-efficient in-memory acceleration architecture for ANNS, designed to fully support the entire search process. We conduct a comprehensive analysis of mainstream ANNS tasks, identifying key performance bottlenecks and architectural requirements. Based on this, we propose a hierarchical PIM design that fully leverages internal memory bandwidth to accelerate memory-bound computations and uses controller-level hardware to accelerate compute-bound sorting. Extensive evaluations show that SeIM significantly outperforms state-of-the-art CPU-, GPU-, and ASIC-based solutions in both performance and energy efficiency.

***Abstract*—Variational quantum algorithms (VQA) based on Hamiltonian simulation represent a specialized class of quantum programs well-suited for near-term quantum computing applications due to its modest resource requirements in terms of qubits and circuit depth. Unlike the conventional single-qubit (1Q) and two-qubit (2Q) gate sequence representation, Hamiltonian simulation programs are essentially composed of disciplined subroutines known as Pauli exponentiations (Pauli strings with coefficients) that are variably arranged. To capitalize on these distinct program features, this study introduces PHOENIX, a highly effective compilation framework that primarily operates at the high-level Pauli-based intermediate representation (IR) for generic Hamiltonian simulation programs. PHOENIX exploits global program optimization opportunities to the greatest extent, compared to existing SOTA methods despite some of them also utilizing similar IRs. PHOENIX employs the binary symplectic form (BSF) to formally describe Pauli strings and reformulates IR synthesis as reducing the column weights of BSF by appropriate Clifford transformations. It comes with a heuristic BSF simplification algorithm that searches for the most appropriate 2Q Clifford operators in sequence to maximally simplify the BSF at each step, until the BSF can be directly synthesized by basic 1Q and 2Q gates. PHOENIX further performs a global ordering strategy in a Tetris-like fashion for these simplified IR groups, carefully balancing optimization opportunities for gate cancellation, minimizing circuit depth, and managing qubit routing overhead. Experimental results demonstrate that PHOENIX outperforms SOTA VQA compilers across diverse program categories, backend ISAs, and hardware topologies.**

I. INTRODUCTION

Quantum computing offers the potential to revolutionize various fields, driving decades of efforts to develop the required physical hardware. For instance, quantum algorithms can achieve exponential speedups in tasks such as integer factorization [1], solving linear equations [2], and quantum system simulation [3]. In the noisy intermediate-scale quantum (NISQ) era where we have access to dozens or hundreds of qubits susceptible to noise (e.g., qubit decoherence, gate imperfections) [4], variational quantum algorithms (VQA) is a leading class of algorithms proposed to achieve the quantum advantage (e.g., VQE for chemistry and condensed-matter simulation [5], QAOA for combinatorial optimization [6]) due to its modest resource requirements in terms of qubit number and circuit depth as well as its noise-resilience. [7].

The construction of a VQA ansatz circuit is to simulate (approximate) a desired unitary evolution under the system Hamiltonian H and the evolution duration t, through Trotterizing [7] the evolution $U(t)$ given H represented by a linear combination of Pauli strings:

$$U(t) = e^{-iHt} \simeq \left(S_k\left(\tau\right)\right)^r, \tau = \frac{t}{r}, \tag{1}$$

$$H = \sum\nolimits_{j=1}^{L} h_j P_j = \sum\nolimits_{j=1}^{L} h_j \sigma_0^{(j)} \otimes \cdots \otimes \sigma_{n-1}^{(j)}, \tag{2}$$

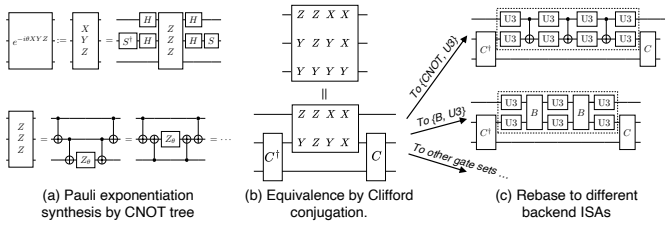

Fig. 1. Conventional Pauli exponentiation synthesis v.s. Simultaneous simplification by Clifford conjugation. (a) Pauli exponentiations are synthesized by gate set $\{H, S, S^\dagger, Z(\theta), \mathrm{CNOT}\}$, through variable CNOT-tree unrolling schemes. (b) Multiple 3Q Pauli exponentiations can be simultaneously simplified into 2Q Pauli exponentiations, through a 2Q Clifford conjugation, where $C = (H \otimes S)\,\mathrm{CNOT}\,(H \otimes S^\dagger)$ in this example. (c) The simplified Pauli exponentiations can be rebased to versatile quantum gate sets, such as CNOT-based and B-based ISAs, with significantly reduced 2Q gate count.

where k and r indicate the Trotter order and time step, respectively. Finer-grained Trotterization results in lower approximation errors. For example, the 1st-order and 2nd-order Trotterization are given by

$$S_1 = \prod\nolimits_{j=1}^{L} e^{-ih_j \tau P_j},\ S_2 = \prod\nolimits_{j=1}^{L} e^{-ih_j \frac{\tau}{2} P_j} \prod\nolimits_{j=L}^{1} e^{-ih_j \frac{\tau}{2} P_j},$$

respectively. Following Trotterization, each term S_k is expressed as a product of individual Pauli exponentiations, which can be easily synthesized using basic 1Q and 2Q gates. The arrangement of these Pauli exponentiations within each Trotter step can be freely chosen without affecting the upper bound of Trotterization (approximation) error [7], which is usually not comparable to physical noise. However, different arrangements offer varying opportunities for optimizing quantum circuits, thereby dominating the accuracy of Hamiltonian simulations on noisy hardware. Consequently, the primary challenge of compiling VQA ansatz circuits lies in synthesizing these Pauli exponentiations from a global perspective, dubbed *Pauli-based intermediate representations (IR)* throughout this paper.

Conventionally, a Pauli exponentiation is synthesized into a 1Q rotation $Z(\theta)$ sandwiched by a pair of symmetric CNOT trees, subsequently conjugated by some H and S gates, as exemplified in Fig. 1 (a). Existing state-of-the-art (SOTA) compilers primarily exploit gate cancellation opportunities exposed by the already synthesized subcircuits, whether by means of the abstract ZX diagram [8], [9], [10] representation or the variants of CNOT trees [11], [12]. Despite utilizing the Pauli-based IR, the optimization process they formulate is limited to subcircuits and local IR patterns. Furthermore, it assumes the conventional CNOT-based quantum instruction set architecture (ISA). We instead present that a set of Pauli exponentiations *can be simultaneously simplified* through appropriate Clifford

transformations. For example, Fig. 1 (b) shows that the list of weight-3 Pauli strings $[ZYY;\ ZZY;\ XYY;\ XXY]$ can be simplified into a weight-2 Pauli string list through the conjugation of a 2Q Clifford operator $C = (H \otimes S)\,\mathrm{CNOT}\,(H \otimes S^\dagger)$. This approach unlocks greater optimization opportunities *entirely at the level of Pauli-based IR* while remaining agnostic to the quantum ISA being employed.

In this work, we propose PHOENIX *(Pauli-based High-level Optimization ENgine for Instruction eXecution)*—a highly effective compilation framework for generic Hamiltonian simulation programs on near-term quantum devices. PHOENIX follows the

"IR grouping → group-wise simplification → IR group ordering"

pipeline to compile real-world VQA programs into basic quantum gates. It is ISA-independent, routing-aware, and tailored to generic VQA programs such as molecular simulation involving heterogeneous-weight Pauli strings and QAOA including only weight-2 Pauli strings. Differing from existing SOTA methods, PHOENIX utilizes an alternative formal description for Pauli-based IR and integrates heuristic optimization strategies to achieve global optimization primarily at the high-level semantic layer. We evaluate PHOENIX across diverse VQA programs, backend ISAs, and hardware topologies, demonstrating its superior performance over existing SOTA compilers. Our main contributions are as follows:

1) We utilize the *binary symplectic form* (BSF) as the formal description of Pauli-based IR and reformulate the IR synthesis process as simultaneous simplification on BSF by appropriate Clifford conjugations that simultaneously reduce the BSF's column weights, enabling global optimization to the largest extent while operating at the high-level IR.
2) We propose a heuristic *BSF simplification* algorithm as the core optimization pass in PHOENIX. It iteratively searches for the most appropriate 2Q Clifford operators to quickly lower the weight of the BSF, until the BSF can be directly synthesized by basic 1Q and 2Q gates.
3) We quantify the circuit depth overhead induced by assembling (ordering) simplified IR groups. A uniform cost function is devised to comprehensively account for circuit depth overhead, gate cancellation, and qubit routing overhead. Under the guidance of that, PHOENIX integrates a *Tetris-like IR group ordering* procedure to reliably achieve a good ordering scheme.

Overall, PHOENIX outperforms the best-known compilers (e.g., TKET [13], PAULIHEDRAL [11], TETRIS [12]), achieving significant reductions in gate count and circuit depth. For example, for logical-level compilation, PHOENIX results in 80.47% reduction in CNOT gate count and 82.72% reduction in 2Q circuit depth on average, compared to the original logical circuits. For hardware-aware compilation with heavy-hex topology, PHOENIX reduces by 36.17% (22.62%) in CNOT gate count and 43.85% (28.12%) in 2Q circuit depth on average, compared to PAULIHEDRAL (TETRIS). The reduction effect in 2Q gate count and circuit depth becomes even more impressive when targeting the newly introduced SU(4) ISA (the representative continuous ISA containing all 2Q gates) [14].

II. RELATED WORKS

Based on ZX diagram representations of Pauli gadgets. Compilers such as TKET [13], [8], PAULIOPT [9], and PCOAST [10] resynthesize quantum circuits into its ZX diagram representation. ZX diagrams are used to visually represent and simplify the commutation relations and phase interactions between Pauli operators, facilitating the reduction of circuit depth and gate count through algebraic and graphical transformations. Although it can efficiently resynthesize Pauli gadgets, the commutation rules it leverages occur locally, and it is hard to operate in a hardware-aware manner.

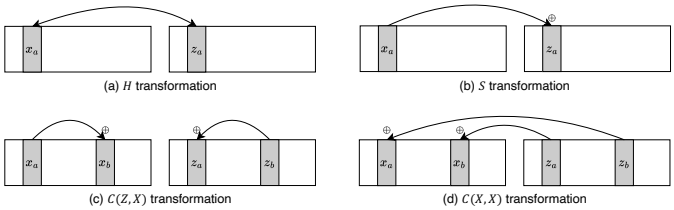

Fig. 2. Examples of Clifford transformations on BSF. Columns a and b, corresponding to qubit a and b, for X and Z blocks are indicated by x_a, x_b, z_a, z_b, respectively. (a) H gate acting on qubit a will exchanges x_a and z_a. (b) S gate acting on qubit a results in $z_a \leftarrow z_a \oplus x_a$. (c) $C(Z,X)_{a,b}$, i.e., the CNOT gate, results in $x_b \leftarrow x_b \oplus x_a$ and $z_a \leftarrow z_a \oplus z_b$. (d) $C(X,X)$ transformation is equivalent with successively applying H on a, $C(Z,X)_{a,b}$, and H on a, resulting in $x_a \leftarrow x_a \oplus z_b$ and $x_b \leftarrow x_b \oplus z_a$.

Based on synthesis variants of Pauli-based IR. Dedicated compilers like PAULIHEDRAL[11] and TETRIS [12] leverage Pauli-based IR to identify gate cancellation opportunities between nearest-neighbor IRs, exposed by the variants of their synthesis schemes based on CNOT-tree unrolling. They proposed sophisticated co-optimization techniques to minimize CNOT gate for both logical-level synthesis and SWAP-based routing achieve good performance especially on limited-topology NISQ devices. However, their optimization scope is confined to a finite set of local subcircuit patterns, and they rely solely on the CNOT-based ISA.

III. BSF AND CLIFFORD FORMALISM

We establish our synthesis scheme by representing Pauli strings in the binary symplectic form (BSF). In the BSF, each n-qubit Pauli string is represented as a row in a tableau, with columns divided into two sections: $[X \mid Z]$. Here, $[X_{i,j} \mid Z_{i,j}]$ denotes the j-th component of the i-th Pauli operator. The encoding maps X to $[1 \mid 0]$, Z to $[0 \mid 1]$, Y to $[1 \mid 1]$, and I to $[0 \mid 0]$. For instance, the Pauli string simplification shown in Fig. 1 (b) follows the formulation

$$\left[\begin{array}{ccc|ccc} 0&1&1&1&1&1\\ 0&0&1&1&1&1\\ 1&1&1&0&1&1\\ 1&0&1&0&1&1 \end{array}\right] \xrightarrow{C(X,Y)_{1,2}} \left[\begin{array}{ccc|ccc} 0&1&0&1&1&0\\ 0&0&0&1&1&0\\ 1&1&0&0&1&0\\ 1&0&0&0&1&0 \end{array}\right],$$

where $C(X,Y)_{1,2}$ is the Clifford gate in Fig. 1 (b) while written in the *universal controlled gate* representation

$$C(\sigma_0,\sigma_1) = \frac{1}{2}((I+\sigma_0)\otimes I + (I-\sigma_0)\otimes\sigma_1),\ \sigma_j \in \{X,Y,Z\}\,.$$

Any universal controlled gate is equivalent to CNOT up to local H and S conjugations. For example, $C(Z,X) = \mathrm{CNOT}$, and $C(X,Y) = (H\otimes S)\,\mathrm{CNOT}\,(H\otimes S^\dagger)$.

By definition, any operator C from the Clifford group is unitary and has the property that $CPC^\dagger$ is also a Pauli operator for any Pauli operator P. The update rules of some Clifford operators in terms of the BSF are demonstrated in Fig. 2, in which only 2Q Clifford operators (Clifford2Q) potentially have nontrivial effects of reducing the Pauli strings' weights. For any $C(\sigma_0,\sigma_1)$, its tableau update rule is a combinatorial sequence of H, S and $C(Z,X)$ (or $C(Z,Z)$) transformations. For example, $C(X,Y)_{a,b}$ exhibits the rule

$$[x_a,\ x_b \mid z_a,\ z_b] \rightarrow [x_a \oplus x_b \oplus z_b,\ z_a \oplus z_b \mid z_a,\ z_a \oplus z_b]. \quad (3)$$

Therefore, the basic approach of our synthesis scheme is to find an appropriate sequence of Clifford2Q operators to simplify the BSF[1] until it can be directly synthesized by basic 1Q and 2Q gates, i.e., the quantity "total weight"

$$w_{\text{tot.}} \coloneqq \|\vee_i (r_x^{(i)} \vee r_z^{(i)})\| \tag{4}$$

is no more than 2, where $r_{x/z}^{(i)}$ is the i-th row of X or Z block of the BSF, and the norm is the sum of all binary entries. The key lies in how to find the Clifford2Q that can reduce the weights of as many Pauli strings as possible within the BSF.

IV. Our Proposal: Phoenix

A. Overview

In the proposed framework Phoenix, Pauli-based IRs (exponentiations) are first grouped according to the same set of qubit indices non-trivially acted on. Then, the *BSF simplification* algorithm is applied to the BSF of each IR group, generating the simplified subcircuit composed of CNOT-equivalent Clifford2Q operators and Pauli exponentiations with weights no more than 2. Phoenix further selectively assemble (order) these unarranged simplified IR groups in a Tetris-like style that minimizes a uniform subcircuit assembling cost function that incorporates gate cancellation, circuit depth increase, and qubit routing overhead. By defining appropriate metric functions and heuristic algorithms, Phoenix achieves superior optimization (less 2Q gate count and circuit depth) compared to SOTA methods, efficiently handling compilation for large-scale VQA programs.

B. BSF simplification for each IR group

To search for appropriate Clifford2Q operators in BSF simplification, it suffices to just focus on a set of Clifford2Q generators of the 2Q Clifford group. We choose the six universal controlled gates

$$\{C(X,X), C(Y,Y), C(Z,Z), C(X,Y), C(Y,Z), C(Z,X)\} \tag{5}$$

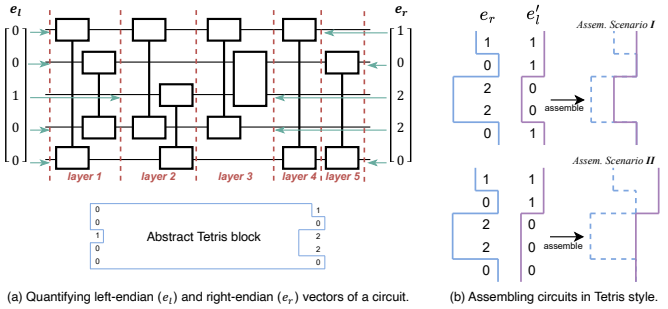
that are independent of each other and span the entire 2Q Clifford group [15]. It is a natural choice of sets of Clifford2Q generators, as each of them is Hermitian and equivalent to CNOT, and its corresponding BSF's tableau update rule can be defined as a combination of the update rules for H, S, and CNOT.

To determine which Clifford2Q operator to select from Eq. (5), we define a heuristic cost function

$$\begin{aligned}\text{cost}_{\text{bsf}} \coloneqq w_{\text{tot.}} * n_{\text{n.l.}}^2 + \sum\nolimits_{\langle i,j\rangle} \|r_x^{(i)} \vee r_z^{(i)} \vee r_x^{(j)} \vee r_z^{(j)}\| \\ + \frac{1}{2}\sum\nolimits_{\langle i,j\rangle} (\|r_x^{(i)} \vee r_x^{(j)}\| + \|r_z^{(i)} \vee r_z^{(j)}\|)\end{aligned} \tag{6}$$

to quantify the disparity of the current BSF from a desired BSF that requires no further simplification ($w_{\text{tot.}} \leq 2$). cost_{bsf} is the combined weight overlap of both X-part and Z-part among each pair of Pauli strings of a BSF, with a bias considering the impact of the number of nonlocal (n.l., that is, weight larger than 1) Pauli strings.

Algorithm 1 illustrates the BSF simplification procedure in detail. It takes set of Pauli strings as input and outputs a configuration sequence *cfg*, in which each component is either a Clifford2Q generator from Eq. (5) or a BSF with $w_{\text{tot.}}$ at most 2. Specifically, at each Clifford2Q search epoch, Crefalgo:simplification identifies the Clifford 2Q generator from Eq. (5) and qubit pair to act upon that leads to the greatest reduction in the cost function defined in Eq. (6), and the BSF is updated accordingly. This greedy process continues iteratively until the BSF's $w_{\text{tot.}}$ is no more than 2. Before each search epoch, local Pauli strings are peeled from the BSF, as they represent 1Q Pauli rotations and do not induce synthesis overhead. The output *cfg* represents a simplified IR group, while still in high-level semantics (Clifford2Q, 1Q Pauli-based IRs, and successive 2Q Pauli-based IRs), independent of any specific quantum ISA.



In theory, simplifying a BSF is always achievable, for example, we can reduce an individual Pauli string to be weight-1, peel it off, and then iterate. The efficacy of Algorithm 1 lies in its simultaneous simplification mechanism guided by the cost function in Eq. (6).

[1]The BSF that needs to simplify does not contain any weight-1 Pauli string.

(a) Quantifying left-endian (e_l) and right-endian (e_r) vectors of a circuit. (b) Assembling circuits in Tetris style.

Fig. 3. Tetris-like circuits assembling. (a) e_l and e_r examples. (b) Scenario I: $\text{cost}_{\text{depth}} = \text{SUM}(e_r + e_l')$; Scenario II: $\text{cost}_{\text{depth}} = \text{SUM}(e_r + e_l' - 1)$.

C. Ordering IR groups in a Tetris-like style

With simplified IR groups compiled via BSF simplification, Phoenix further performs a *Tetris-like IR group ordering* procedure that aims to minimize *a uniform assembling cost metric*. This is unlike [11] and [12] where the ordering is primarily determined by gate

cancellation opportunities between IR groups. We can abstract the circuit structure exhibited by each simplified IR group into something resembling a Tetris block. Then, we choose the ordering based on the circuit-depth cost function of assembling Tetris blocks, with gate cancellation opportunities and qubit routing overhead also taken into account. We primarily have three ingredients:

1) *Endian vectors of circuits and the depth cost function.* As shown in Fig. 3 (a), we define a pair of vectors e_l and e_r for each subcircuit (which would correspond to a simplified IR group in our case). The i-th entry of e_l (e_r) refers to how many layers one has to traverse starting from the left (right) side before qubit i is acted upon. The layers are defined by grouping neighboring 2Q gates that act on different qubits. See Fig. 3 (a) for an example of a generic (not necessarily simplified IR group) circuit. With this definition, the depth overhead for assembling two subcircuits—the proceeding subcircuit with left-endian vectors e_r and the succeeding subcircuit with left-endian vector e'_l is given by
$$\text{cost}_{\text{depth}} \coloneqq \begin{cases} \text{SUM}(e_r + e'_l), \text{ if } \text{ALL}(e_r[e'_l == 0] > 0) \\ \qquad\qquad\qquad \text{and } \text{ALL}(e'_l[e_r == 0] > 0) \\ \text{SUM}(e_r + e'_l - 1), \text{ otherwise} \end{cases}$$
See Fig. 3 (b) for an example.
2) *Clifford2Q cancellation.* The simplified IR group usually exposes Hermitian Clifford2Q operators at the two ends of the subcircuit. Therefore some Clifford2Q gate cancellation opportunities could be exploited, which may or may not decrease overall circuit depth, as depicted in Fig. 4 (a). We can add this consideration into $\text{cost}_{\text{depth}}$: if m pairs Clifford2Q cancelled, while (a) without decreasing subcircuit depth, $\text{cost}_{\text{depth}} \leftarrow \text{cost}_{\text{depth}} - 2m$; (b) with one side's subcircuit depth decreases, $\text{cost}_{\text{depth}} \leftarrow \text{cost}_{\text{depth}} - 2m - n$; (c) with both sides' subcircuit depths decrease, $\text{cost}_{\text{depth}} \leftarrow \text{cost}_{\text{depth}} - 2m - 2n$.
3) *Consideration of qubit routing overhead.* We try to mitigate the routing overhead for hardware-aware compilation by comparing the qubit interaction graphs of subcircuits. This approach is not limited to specific routing schemes (e.g. three-CNOT unrolling of SWAP-based routing, ancilla-based bridge gate [16]) and hardware topologies. Intuitively, two subcircuits with more "similar" qubit interaction behaviors require less mapping transition overhead between them, as demonstrated by Fig. 4 (b). Therefore, we introduce a factor characterized by the similarity between the qubit interaction graphs of two subcircuits in the cost function:
$$\text{cost}_{\text{depth}} \leftarrow \frac{1}{s} \cdot \text{cost}_{\text{depth}}, \quad s = \sum\nolimits_i \frac{\langle D_i, D'_i \rangle}{\|D_i\|_2 \|D'_i\|_2}, \quad (7)$$
where D (D') is the distance matrix of the preceding (succeeding) subcircuit's qubit interaction graph of the tail (head) part. The tail (head) is defined as starting from the right (left) of the subcircuit and incorporating more and more 2Q gates until all qubits are acted upon. $D_{i,j}$ represents the shortest path length between qubit i and qubit j. D_i is the i-th row of D.

In practice, these IR groups are first pre-arranged in descending order of their weight (subcircuit width). PHOENIX looks ahead for a certain number of subcircuits to find the one with the minimum $\text{cost}_{\text{depth}}$ with respect to the last assembled subcircuit. This process iterates until all subcircuits are assembled.

V. EVALUATION

We evaluate the effectiveness of PHOENIX across diverse Hamiltonian simulation programs, quantum ISAs, and device topologies.

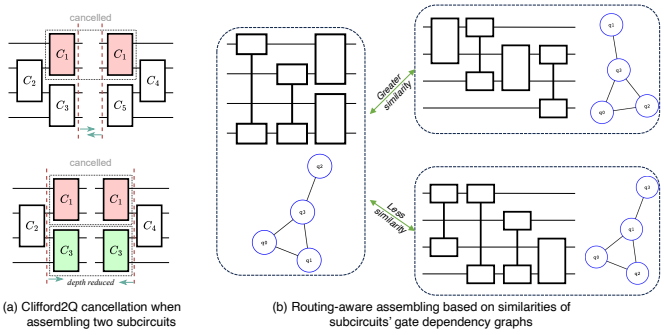

Fig. 4. Gate cancellation opportunities and routing-aware assembling. (a) Clifford2Q cancellation between the preceding and succeeding subcircuits may or may not induce circuit depth decrease. (b) The subcircuit (upper right) whose qubit interaction graph is more similar to that of the already assembled subcircuit (left) is preferred over the other (lower right).

Although PHOENIX is implemented in Python, it compiles VQA programs of thousands of Pauli strings and more than ten qubits (approximately corresponding to the program size with 10^4-10^6 CNOT gates in conventional synthesis) in dozens of seconds. Code and data are available on GitHub [17]. All experiments are executed on a laptop (Apple M3 Max, 36GB memory).

A. Experimental settings

Metrics. We evaluate PHOENIX using the following metrics: 2Q gate count, 2Q circuit depth, and the algorithmic error for VQA synthesis. Algorithmic error refers to the deviation between the synthesized circuit's unitary matrix and the ideal evolution under the original Hamiltonian, as measured by the infidelity between unitary matrices in our evaluation: $\text{infid} = 1 - \frac{1}{N}|\text{Tr}(U^\dagger V)|$. Notably, we exclude 1Q gates and their count in circuit depth, as 1Q gates are generally considered free resources due to their significantly lower error rates. Additionally, CNOT is not a native operation on most NISQ platforms, requiring extra 1Q drives before and/or after native 2Q gates (e.g., Cross-Resonance [18], Mølmer-Sørensen [19]), making 1Q gate inclusion in metrics potentially misleading.

Baselines. TKET, PAULIHEDRAL, and TETRISare primary baselines to be compared with our method. For TKET, the `PauliSimp` and `FullPeepholeOptimise` passes are adopted for logical circuit optimization. It is similar to TKET's O3 compilation in which the `PauliSimp` pass is particularly effective at optimizing Pauli gadgets. For PAULIHEDRAL, the QISKIT O2 pass is associated by default because the numerous gate cancellation opportunities exposed

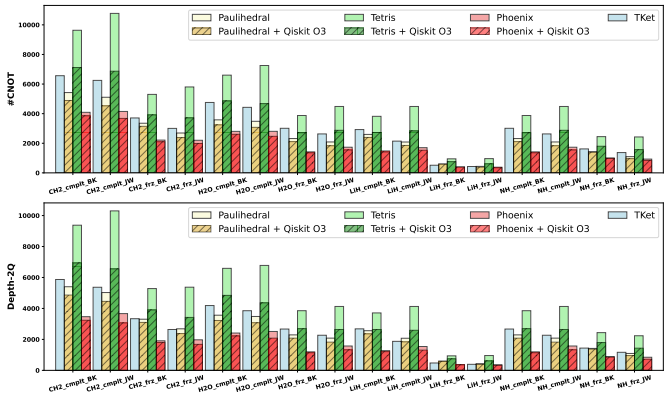

Fig. 5. Logical-level compilation (all-to-all topology).

TABLE II
AVERAGE (GEOMETRIC-MEAN) OPTIMIZATION RATES ON UCCSD.

Compiler	#CNOT opt.	Depth-2Q opt.
TKET	33.07%	30.14%
PAULIHEDRAL	28.41%	29.07%
PAULIHEDRAL + O3	25.72% (-8.54% v.s. no O3)	26.3% (-8.6% v.s. no O3)
TETRIS	53.66%	53.26%
TETRIS + O3	36.73% (-30.94% v.s. no O3)	36.37% (-31.08% v.s. no O3)
PHOENIX	**21.12%**	**19.29%**
PHOENIX + O3	**19.53%** (**-6.64%** v.s. no O3)	**17.28%** (**-8.51%** v.s. no O3)

by PAULIHEDRAL necessitate inverse and commutative cancellations. For hardware-aware compilation, all baselines and PHOENIX are followed by a QISKIT O3 pass with SABRE qubit mapping [20]. For QAOA benchmarking, 2QAN [21] is used as the SOTA baseline.

Benchmarks. We select two representative VQA benchmarks—(1) *UCCSD*: A set of UCCSD ansatzes, including CH_2, H_2O, LiH, and NH: 4 categories of molecule simulation programs. Each category is generated with STO-3G orbitals [22], encoded by Jordan-Wigner (JW) [23] and Bravyi-Kitaev (BK) [24] transformations, in turn approximated by complete or frozen-core orbitals. Details are shown in Tab. I. (2) *QAOA*: A set of 2-local Hamiltonian simulation programs corresponding to random graphs and regular graphs, for which the description and evaluation results are shown in Tab. IV.

B. Main results

Fig. 5 and Tab. II illustrates the main benchmarking results regarding logical-level compilation:

1) PHOENIX significantly outperforms baselines across all benchmarks, with an average (geometric-mean) 21.12% and 19.29% optimization rate in #CNOT and Depth-2Q, respectively, relative to original circuits.[2] That is mostly attributed to the group-wise BSF simplification mechanism, as PHOENIX adopts the same IR grouping method as PAULIHEDRAL and TETRIS.
2) TETRIS performs the worst, falling far behind TKET, PAULIHEDRAL, and PHOENIX. This is because TETRIS focuses primarily on co-optimization techniques to reduce SWAP gates during qubit routing, rather than logical-level synthesis.
3) We also compare PAULIHEDRAL/TETRIS/PHOENIX with and without QISKIT O3, to evaluate their high-level optimization capabilities. The improvement in using QISKIT O3 for PAULIHEDRAL and TETRIS is more pronounced than for PHOENIX. Therefore, PHOENIX's high-level optimization strategy is more impressive, leaving less optimization space for QISKIT O3.

[2]For example, the #CNOT optimization rate is defined as $\frac{\#\text{CNOT}_{\text{after}}}{\#\text{CNOT}_{\text{before}}}$.

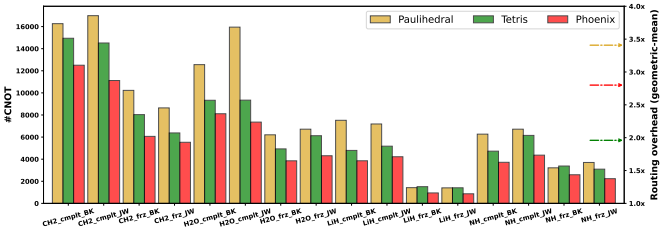

Fig. 6. Hardware-aware compilation on heavy-hex topology. Three dashed lines represent the average multiples of #CNOT within circuits after mapping relative to those after logical optimization, for PAULIHEDRAL (gold), TETRIS (green), and PHOENIX (coral), respectively.

C. Hardware-aware compilation

We use the heavy-hex topology, specifically a 64-qubit coupling graph of IBM's Manhattan processor [25], for hardware-aware compilation. Results are shown in Fig. 6, where TKET is excluded due to its significantly worse performance compared to others. Despite focusing primarily on high-level logical program optimization with humble hardware-aware co-optimization, PHOENIX still outperforms baselines, reducing CNOT gate count by 36.17% (22.62%) and 2Q circuit depth by 43.85% (28.12%) on average, compared to PAULIHEDRAL (TETRIS). Considering the qubit mapping transition overhead mitgation within its IR group ordering process, PHOENIX induces 2.8x #CNOT on average after hardware mapping. It is better than PAULIHEDRAL while worse than TETRIS, as TETRIS specializes in #CNOT cancellation for SWAP-based routing. Consequently, even on limited-topology devices, PHOENIX effectively manages routing overhead and surpasses co-design local optimization strategies.

D. Comparison in diverse ISAs

Quantum ISA, or the native gate set in a narrow sense, serves as an interface between software and hardware implementation. For a specific quantum ISA, the adopted 2Q gate dominates the accuracy and difficulty of hardware implementation, as well as the theoretical circuit synthesis capabilities. While traditional ISAs typically consist of 1Q gates and CNOT-equivalent 2Q gates, recently some works propose integrating complex and even continuous 2Q gates into the ISA design, such as the XY gate family [26], the fractional/partial ZZ and MS gates [27], [28], and the AshN gate scheme which considers all possible 2Q gates within the $\mathrm{SU}(4)$ group as the ISA [14]. Therefore, we further compare PHOENIX with baselines in different ISAs to showcase its ISA-independent compilation advantage.

The ISA-independent advantage is best shown by choosing the most expressive $\mathrm{SU}(4)$ ISA. We evaluate it with both all-to-all and heavy-hex topologies, as the same as the evaluation above for CNOT ISA. For logical-level compilation, PHOENIX directly generates $\mathrm{SU}(4)$-based circuits via its BSF simplification algorithm, while baselines (PAULIHEDRAL and TETRIS equipped with QISKIT O3 by default) require an additional "rebase" (or "transpile") step to convert CNOT-based circuits to $\mathrm{SU}(4)$-based ones. For hardware-aware compilation, all compilers include a rebase step, following the QISKIT O3 hardware-aware compilation pass. Detailed outcomes are summarized in Tab. III, highlighting the geometric-mean relative optimization rates of PHOENIX compared to the baselines' results.

TABLE III
COMPARISON FOR DIVERSE ISAS WITH ALL-TO-ALL AND LIMITED TOPOLOGY.

	CNOT ISA (all-to-all)		SU(4) ISA (all-to-all)		CNOT ISA (heavy-hex)		SU(4) ISA (heavy-hex)	
PHOENIX's opt. rate	#CNOT	Depth-2Q	#SU(4)	Depth-2Q	#CNOT	Depth-2Q	#SU(4)	Depth-2Q
PHOENIX v.s. TKET	63.87%	64.0%	**56.04%**	**54.22%**	**40.63%**	**48.32%**	44.29%	50.71%
PHOENIX v.s. PAULIHEDRAL	82.12%	73.33%	**75.57%**	**65.2%**	62.38%	54.7%	**39.84%**	**35.07%**
PHOENIX v.s. TETRIS	57.52%	53.04%	**56.54%**	**50.55%**	75.97%	71.18%	**62.23%**	**58.74%**

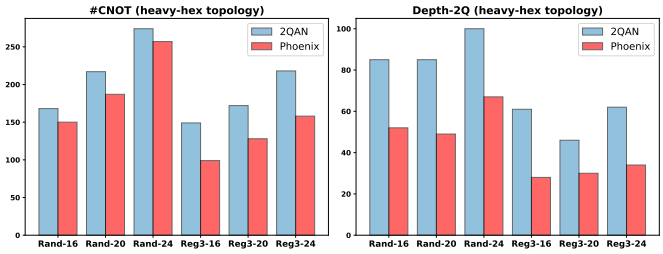

Fig. 7. QAOA benchmarking

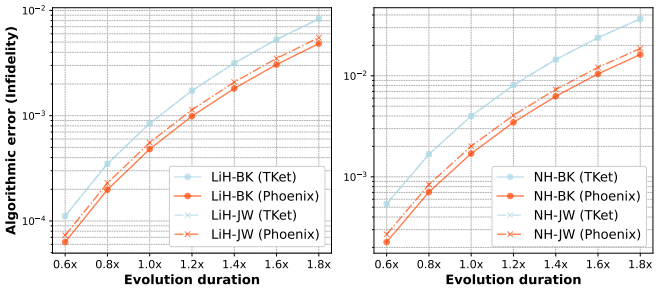

Fig. 8. Algorithmic error comparison of LiH and NH simulation.

TABLE IV
QAOA BENCHMARKING VERSUS 2QAN.

QAOA		#CNOT		Depth-2Q		#SWAP		Routing overhead	
Bench.	#Pauli	2QAN	Phoenix	2QAN	Phoenix	2QAN	Phoenix	2QAN	Phoenix
Rand-16	32	168	150	85	52	37	29	2.62x	2.34x
Rand-20	40	217	187	85	49	47	39	2.71x	2.34x
Rand-24	48	274	257	100	67	63	56	2.85x	2.68x
Reg3-16	24	149	99	61	28	44	17	3.10x	2.06x
Reg3-20	30	172	128	46	30	46	23	2.87x	2.13x
Reg3-24	36	218	158	62	34	62	30	3.03x	2.19x
Avg. improv.		-16.7%		-40.8%		-29.41%		-16.59%	

Again, PHOENIX significantly outperforms baselines when targeting SU(4) ISA. The optimization rates relative to baselines are more impressive than those in CNOT ISA, despite the baselines incorporating sophisticated optimization techniques specifically designed for the CNOT ISA. For instance, the multiple of PHOENIX's #2Q relative to PAULIHEDRAL's in CNOT ISA is 82.12% (62.38%), whereas this value decreases to 75.57% (39.84%) in SU(4) ISA for hardware-agnostic (hardware-aware) compilation. One exception is the hardware-aware compilation comparison with TKET, as TKET's hardware-aware compilation in the CNOT ISA generates circuits with much larger 2Q gate count and circuit depth than other compilers, and there are numerous 2Q subcircuit fusing opportunities such that the rebased circuits involves much fewer SU(4) gates.

E. QAOA benchmarking

For QAOA benchmarking, we focus on the performance in hardware-aware compilation, since the 2Q gate count cannot be reduced and minimizing circuit depth is easy in logical-level compilation. Both 2QAN and PHOENIX can generate depth-optimal QAOA circuits at the logical level in our field test. Fig. 7 and Tab. IV illustrate compilation results on the heavy-hex topology, across six QAOA programs corresponding to both random graphs (each node with degree 4) and regular (each node with degree 3) graphs, with qubit sizes of 16, 20, and 24. PHOENIX outperforms 2QAN across all benchmarks in all metrics (such as #CNOT, #SWAP), especially in Depth-2Q, with an average 40.8% reduction compared to 2QAN. These results further demonstrate the effectiveness of the routing-aware IR group ordering method in PHOENIX.

F. Algorithmic error analysis

We further highlight PHOENIX's advantage in reducing the algorithmic error. We select UCCSD benchmarks with qubits no more than 10 for evaluation, within the matrix computation capabilities of standard PCs. We rescale the coefficients of Pauli strings to control their algorithmic errors within 5×10^{-5} to 10^{-2}, which corresponds to different evolution durations in molecular simulation, as suggested in Fig. 8. In contrast to TKET, PHOENIX typically leads to lower algorithmic errors for both JW and BK encoding schemes. Although this improvement is program-specific, it is more significant for the Pauli string patterns of BK than those of JW, with 57% (42.7%) and 49.5% (34.1%) for NH (LiH) simulation, respectively. As they adopt the same Pauli string blocking approach, we expect the algorithmic errors resulting from PAULIHEDRAL and TETRIS to be comparable to PHOENIX, and so are not shown in Fig. 8. As a result, the impressive algorithmic error reduction effect of PHOENIX brings us closer to a possible quantum advantage on computational chemistry problems.

VI. CONCLUSION AND OUTLOOK

Mainstream circuit synthesis approaches rely on pattern rewrite rules, often restricted to small-scale, local optimizations. In contrast, we present PHOENIX, a framework leveraging high-level Pauli-based IR for Hamiltonian simulation, one of the most prominent NISQ applications. PHOENIX outperforms all SOTA VQA compilers across diverse programs and hardware platforms, showcasing its unmatched performance and versatility. This work not only bridges the gap between impactful quantum applications and physically implementable solutions but also prompts a re-evaluation of compiler optimization.

Beyond producing significantly optimized circuits, high-level IRs, as a refined abstraction layer on top of the traditional quantum ISA, create more opportunities for efficient synthesis and effective hardware mapping. Furthermore, they can act as intermediate building blocks, guiding the design of quantum processors and corresponding control schemes—potentially incorporating multi-qubit control—to implement these high-level IRs more efficiently.

***Abstract*—The Circuit Satisfiability (CSAT) problem, a variant of the Boolean Satisfiability (SAT) problem, plays a critical role in integrated circuit design and verification. However, existing SAT solvers, optimized for Conjunctive Normal Form (CNF), often struggle with the intrinsic complexity of circuit structures when directly applied to CSAT instances. To address this challenge, we propose a novel preprocessing framework that leverages advanced logic synthesis techniques and a reinforcement learning (RL) agent to optimize CSAT problem instances. The framework introduces a cost-customized Look-Up Table (LUT) mapping strategy that prioritizes solving efficiency, effectively transforming circuits into simplified forms tailored for SAT solvers. Our method achieves significant runtime reductions across diverse industrial-scale CSAT benchmarks, seamlessly integrating with state-of-the-art SAT solvers. Extensive experimental evaluations demonstrate up to 63% reduction in solving time compared to conventional approaches, highlighting the potential of EDA-driven innovations to advance SAT-solving capabilities.**

I. Introduction

The Circuit Satisfiability (CSAT) problem lies at the heart of many critical tasks in Electronic Design Automation (EDA), such as logic equivalence checking (LEC), automatic test pattern generation (ATPG), and logic synthesis (LS). It involves determining whether a Boolean circuit has an input assignment that satisfies its primary output. As a specialized variant of the Boolean Satisfiability (SAT) problem, CSAT is known to be NP-complete [1], making it both theoretically challenging and practically important in integrated circuit (IC) design and verification.

Modern SAT solvers, such as MiniSAT, Kissat, and CaDiCaL [2], [3], have been highly effective in solving problems represented in Conjunctive Normal Form (CNF). However, when applied to CSAT problems, these solvers face inefficiencies stemming from the required transformation of circuits into CNF format. This transformation often disrupts the natural structure of circuits, leading to representations that are less solver-friendly and more complex to process [4], [5]. As a result, solving CSAT instances may become unnecessarily time-consuming, particularly for large-scale, industrial circuits.

While preprocessing techniques for CNF have been extensively explored [4]–[7], similar advancements tailored specifically for circuit-based representations remain underdeveloped. Circuit-specific methods often focus on reducing circuit size or area [8], which, while useful for design optimization, do not directly address the complexity of SAT solving. This gap highlights the need for a new approach that bridges the structural strengths of circuit representations with the solving power of modern SAT solvers.

To address these limitations, we propose a novel preprocessing framework tailored to CSAT problems. Our approach integrates EDA techniques with reinforcement learning (RL) to transform CSAT instances into SAT-friendly formats. By leveraging logic synthesis tools and a cost-customized Look-Up Table (LUT) mapping strategy, our framework achieves significant reductions in solving complexity. Unlike traditional preprocessing methods, our approach explicitly prioritizes SAT-solving efficiency rather than widely-used optimization metrics like area or delay. Specifically, the main contributions of our work include:

- **EDA-Driven Preprocessing Framework**: We introduce a comprehensive preprocessing pipeline that combines logic synthesis techniques with reinforcement learning to optimize CSAT instances for efficient SAT solving. This integration bridges the gap between raw circuit structures and modern SAT solvers.
- **RL-Guided Logic Synthesis for SAT Solving**: We formulate logic synthesis as a Markov Decision Process (MDP) and train an RL agent to identify synthesis sequences that minimize solving complexity. The agent leverages circuit features inspired by [9], [10] and structural circuit embeddings from DeepGate2 [11].
- **Cost-Customized LUT Mapping for SAT Solving**: We develop a novel LUT mapping strategy that incorporates a customized cost metric reflecting branching complexity during SAT solving. This approach diverges from conventional LUT mapping methods [12], [13] by focusing on solving efficiency.

Using industrial-scale benchmarks derived from LEC and ATPG tasks, we demonstrate significant runtime reductions up to 63% compared to baseline approaches. Our method integrates seamlessly with state-of-the-art SAT solvers, such as Kissat and CaDiCaL.

II. Related Work

A. SAT and Circuit SAT Problems

SAT problem holds a pivotal position in hardware design, software verification, planning and scheduling, which seeks to identify if there exists at least one assignment that makes a given Boolean formula True. The modern SAT solvers, central in addressing SAT problems, predominantly rely on the Conflict-Driven Clause Learning (CDCL) algorithm [14]. Within the backbone CDCL algorithm, CNF has become a standard format in SAT solving, capable of representing arbitrary Boolean formulas. It is structured as a conjunction of clauses, denoted by $\phi = (C_1 \wedge C_2 \wedge \ldots)$, with each clause being a disjunction of variables or their negations, e.g., $C_i = (x_1 \vee \neg x_2 \vee \ldots)$. Over recent decades, numerous CNF-based heuristics have been developed to enhance SAT solving efficiency, including advanced clause management strategies [15] and innovative branching heuristics [16], [17].

Typically, practical CNF-modeled problems often result in redundant clauses and increased complexity. For example, a tournament scheduling problem with n teams can escalate to n^6 clauses [18]. Consequently, problem reformulation, as known as preprocessing, is essential before solving. Efforts like [4]–[6] target minimizing the CNF instances by resolution and graph transformation, resulting in faster SAT solving.

One of the most representative SAT variants in the realm of EDA is the Circuit SAT (CSAT) problem. In contrast to the general SAT problem, the CSAT problem determines the satisfiability of a Boolean circuit. Over the past decades, circuit-based SAT solvers have been developed to tackle the CSAT problems [19]–[21]. Despite these solvers conducting logic reasoning in natural formats, they still exhibit lower performance levels compared to CNF-based SAT solvers due to the inefficient circuit-based preprocessing and heuristics. For example, the previous circuit-based preprocessing approaches, such as [8], cannot promise to reduce solving time as they only scale down circuits. In this work, we introduce an efficient and effective circuit-based preprocessing framework to directly mitigate solving complexity by integrating EDA tools and reinforcement learning guidance.

B. Boolean Circuit Optimization

Boolean circuits, representable as directed acyclic graphs (DAGs) $\mathcal{G}(\mathcal{V}, \mathcal{E})$ with logic gates and wires serving as nodes $\mathcal{V}$ and edges $\mathcal{E}$, respectively, are pivotal in computational logic. In the EDA community, a wealth of efficient algorithms has been developed for circuit optimization. Logic Synthesis (LS) is a prime example, involving DAG-based transformation techniques to modify circuit's local structure for the optimization of performance, power, and area (PPA).

Besides, technology mapping, a key component in EDA flow, fine-tunes performance metrics under specific constraints [22] and maps the intermediate circuits into standard cells pre-defined in technology library. One widely used technique for technology mapping is Look-Up Table (LUT) mapping [12]. LUT mapping involves the transformation of gate combinations into k-LUTs, where each k-LUT represents a configurable memory unit capable of implementing arbitrary Boolean functions with k variables.

The advent of circuit representation learning [23] marks a progressive trend in the field, focusing on deriving neural representations of circuits to facilitate downstream tasks. The DeepGate family [11], [24], [25], for instance, integrates structural and functional aspects of circuits and has shown impressive results in testability analysis [26] and SAT solving [21]. In our research, we tailor existing EDA tools for specific requirements, utilizing DeepGate2's [11] circuit knowledge learning capabilities to inform our circuit optimization decisions.

III. Methodology

A. Overview of the Proposed Framework

Fig. 1 shows the overview of the proposed circuit-based preprocessing framework. Given a CSAT problem represented in And-Inverter Graphs (AIGs), which only contain three gate types (primary input, AND and NOT) by [27], the baseline pipeline converts it into CNF.

In our proposed framework, we first apply a predetermined sequence of AIG transformation operations to unify the distribution of input circuits [21]. Then, we utilize logic synthesis technique to reformulate SAT instance. Since the

logic synthesis process can be considered as a sequential decision-making task, we train an agent to minimize the solving complexity by reinforcement learning (RL). In the RL framework, the state comprises embeddings of the initial AIG netlist and features of intermediate circuits. Additionally, the RL agent operates within a discrete action space, where each action corresponds to executing a synthesis operation. We approximate the complexity of SAT solving based on the number of variable branching times and define the reduction in branching times as the reward for RL agent.

Finally, we employ the LUT mapping technique to hide the internal logic of circuits. To further decrease the solving time, we design a cost-customized mapping operation with the objective of minimizing the branching times during SAT solving, rather than solely focusing on reducing the problem size. After the LUT mapping, we obtain the LUT netlist with a relatively small number of cells. To ensure compatibility with modern SAT solvers, we transform the LUT netlist back into a simplified CNF.

B. Logic Synthesis Recipe Exploration

We formulate LS as a Markov Decision Process (MDP) process, with the optimization objective of reducing the solving time for a given input instance. Consequently, such sequential decision-making process entails iteratively selecting a LS operation as an action according to the current circuit state.

1) Reinforcement Learning Formulation: To explore the optimal LS sequence (i.e. LS recipe), we employ Deep Q-learning algorithm in this section to train a reinforcement learning (RL) agent. The RL agent is trained to make informed decisions to minimize solving time by learning from its interactions with the circuit environment.

As shown in Fig. 2, at each step t (where $t = 0, 1, ..., T-1$), the features of the current netlist $\mathcal{G}^t$ are extracted to form the state s^t. Subsequently, the Q-learning agent utilizes s^t as input and selects an action a^t. Then, the environment including the LS tool performs the synthesis operation based on a^t and transforms the netlist $\mathcal{G}^t$ into a new netlist $\mathcal{G}^{t+1}$. At the end of this step, the environment provides RL agent with a reward r^t. The above process is repeated for subsequent steps until $t = T - 1$. During the training process, the objective of RL agent is to maximize the cumulative sum of the reward values. As a result, the trained RL agent is able to select LS operations step by step to achieve the optimal solving time reduction.

2) State: Inspired by [9], [10], we extract the following representative features $\mathcal{E}(\mathcal{G}^t)$ of the netlist $\mathcal{G}^t$ into state s^t:

- Ratio between the area of netlist $\mathcal{G}^t$ and netlist $\mathcal{G}^0$.
- Ratio between the depth of netlist $\mathcal{G}^t$ and netlist $\mathcal{G}^0$.
- Ratio between the wire counts of netlist $\mathcal{G}^t$ and netlist $\mathcal{G}^0$.
- Proportion of AND gates in the total gates of netlist $\mathcal{G}^t$.
- Proportion of NOT gates in the total gates of netlist $\mathcal{G}^t$.
- Average balance ratio of netlist $\mathcal{G}^t$. We formally define the average balance ratio br in Eq. (1), where $\mathcal{P}_{i1}$, $\mathcal{P}_{i2}$ are predecessors of two fanin AND gate i, and d denotes the depth.

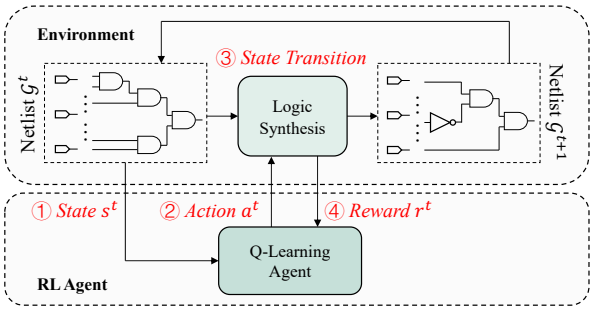

Fig. 2: RL Agent-Environment interaction

$$br = \sum_{i \in AND} \frac{abs(d_{\mathcal{P}_{i1}} - d_{\mathcal{P}_{i2}})}{max(d_{\mathcal{P}_{i1}}, d_{\mathcal{P}_{i2}})} \; / \; \#AND \tag{1}$$

The above features exhibit characteristics that can be effectively optimized by various logic synthesis operations. Consequently, the RL agent can intelligently select appropriate operations based on these features. For example, when a netlist shows a higher average balance ratio, indicating an imbalanced structure in DAG, the agent is more inclined to select the action of operation *balance*. Additionally, a large area ratio prompts the agent to opt for operations that aim to minimize the circuit area, such as *rewrite*.

Besides, the state s^t is incorporated with the primary output embeddings of the initial netlist obtained by pretrained DeepGate2 [11] (denoted as $\mathcal{D}(\mathcal{G}^0)$), which contains rich structural and functional information of the initial problem instance.

$$s^t = \text{Concatenate}(\mathcal{E}(\mathcal{G}^t), \mathcal{D}(\mathcal{G}^0)) \tag{2}$$

3) Action: The action space $\mathcal{A}$ of agent is discrete and encompasses LS operations. In this paper, we set the available operations as follows: *rewrite* [28], *refactor* [29], *balance* [30], *resub* [31] and *end* (marking the end of the LS process). The selection of these operations does not imply that the proposed framework lacks support for additional synthesis operations beyond this set. Instead, these operations are chosen due to their widespread usage and commonality. If there is a need to include additional optional operations, it can be accomplished by expanding the action space within the framework.

4) State Transition: The state transition function is implemented by the LS tool. We call the tool with a specific LS operation determined by RL agent to transform the current netlist $\mathcal{G}^t$ to another functional-equivalent but simplified netlist. More formally, we note the given netlist as $\mathcal{G}^t$ and RL action as a^t at step t. The state transition function is denoted as: $\mathcal{G}^{t+1} = \mathcal{F}(\mathcal{G}^t, a^t)$, where $\mathcal{G}^{t+1}$ is the updated netlist by tool. The updated netlist, $\mathcal{G}^{t+1}$, is then considered as the input for the subsequent decision step at time $t + 1$.

5) Reward: We consider the reduction of variable branching times during SAT solving as the reward. The reward function is shown as Eq. (3), where $\Delta\#Branching$ is the difference in branching times between the final instance and the initial instance during solving. We opt for the terminated reward, which has only one non-zero reward value at the

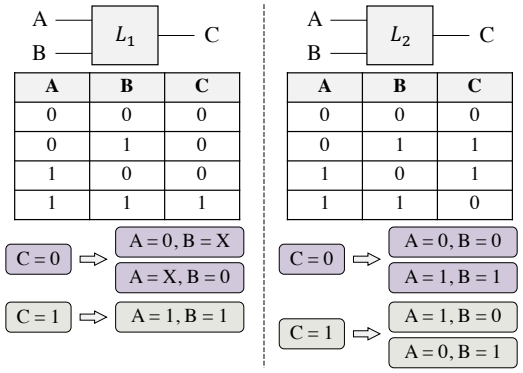
terminated step, i.e. after performing the entire sequence of synthesis operations.

$$r^t = \begin{cases} 0, t = 0, \cdots, T-2, \\ \text{-}\Delta\#Branching,\ t = T-1 \text{ or } a^t = \textit{end} \end{cases} \tag{3}$$

Prior to solving the SAT instance in circuit format, we employ the LUT mapping to convert the AIG netlist into an LUT netlist. Subsequently, the transformed netlist is converted into CNF, which will be elaborated in the following section. Additionally, we choose not to minimize the solver runtime based on two primary reasons. Firstly, determining the solver runtime for hard SAT instances is time-consuming. Secondly, the solver runtime is challenging to calculate accurately due to the fluctuating CPU status in the case of easy SAT instances. We utilize variable branching times to approximate solving time. This approach allows us to include easy cases with short solver runtime in the training dataset, thereby enhancing the efficiency of training the RL agent.

6) Policy: In the Q-learning framework [32], the policy for maximizing the total reward entails selecting the action with the highest expected value. The action value function Q uses the multilayer perceptron (MLP) to estimate the sum of future rewards after taking a certain action in the current state. The policy $\pi(s^t)$ and action-value function $Q_\theta(s^t, a)$ are shown in Eq. (4), where the θ parametrizes the function Q.

$$\begin{aligned} \pi(s^t) &= \arg\max_{a, a\in\mathcal{A}} (Q(s^t, a)) \\ Q_\theta(s^t, a) &= Index(MLP(s^t), a) \end{aligned} \tag{4}$$



We create the target function $Q_{\hat{\theta}}(s^t, a)$ to stabilize the training process. The parameter $\hat{\theta}$ is copied from θ after k steps. The parameter θ of action-value function Q is updated iteratively by loss function in Eq. (5), where γ is a hyperparameter and represents discount factor.

$$l = ||Q_\theta(s^t, a^t) - r^t - \gamma \arg\max_{a\in\mathcal{A}} Q_{\hat{\theta}}(s^{t+1}, a)||_2 \tag{5}$$

C. Cost-Customized LUT Mapping

We present a cost-customized LUT mapping approach that not only hides the internal nodes during solving, but also forms an easy-to-solve instance. Unlike conventional mapping tools that focus on constructing circuits with low area or delay, our approach aims to create circuits that are easier to solve. Specifically, we begin by defining a cost metric to quantify the branching complexity of SAT solving and compute the cost values for all 4-input LUTs. Next, we modify the cost function in the existing mapping tool to enable minimizing the overall branching complexity. Lastly, we apply the cost-customized mapper to map AIG netlist to LUT netlist and convert the LUT netlist into CNF.

1) Branching Complexity of LUT: The SAT solving process involves iteratively making variable branching decisions, where the solver selects variable assignments as either *true* or *false*. We formulate the solving process within the circuit domain. Specifically, given the logic value of a gate, the SAT solver makes decisions by selecting assignments for its fanin gates. We consider two 2-fanin LUTs, denoted as L_1 (representing an AND gate) and L_2 (representing an XOR gate), and list the truth tables for these LUTs in Fig. 3.

A	B	C
0	0	0
0	1	0
1	0	0
1	1	1

A	B	C
0	0	0
0	1	1
1	0	1
1	1	0

Fig. 3: LUTs with different branching complexity

We observe that both L_1 and L_2 have two possible combinations when the fanout pin (C) is logic-0. However, when the fanout pin is logic-1, L_2 has two possible combinations while L_1 has only one unique branch. We define the *branching complexity* C as the total number of possible fanin combinations. In this example, the LUT L_1 has $C_{L_1} = 3$ and LUT L_2 has $C_{L_2} = 4$. Therefore, L_2 is more hard to be solved than L_1.

2) Cost-Customized Mapper: Since a large number of possible branches result in an exponential search space, various heuristics [14], [33] are employed to reduce the number of potential branches and improve the efficiency of the solving process. Besides, utilizing techinque mapping tools facilitates the concealment of intermediate gates and decreases the overall number of branches [8].

In contrast to [8] that minimizes the size of the post-mapping netlist, our approach prioritizes mapping the logic into cells with lower branching complexity. Our approach is motivated by the observations that instances containing a significant proportion of XOR gates often require more time to be solved [34], [35], where the branching complexity of XOR gate (L_2 in Fig. 3) is higher than other gates.

To prioritize the LUTs during mapping process, we employ a strategy to enumerate all 4-LUTs and integrate their branching complexity into the cost function. We implement a cost-customized mapper based on mockturtle [13] by modifying the area cost to reflect the branching complexity of each LUT and fixing the delay cost as a constraint. By executing a sequence of operations aimed at minimizing the total cost, the resulting post-mapping netlists exhibit minimal overall branching complexity.Our preprocessing strategy ends with a LUT to CNF transformation [36] for compatibility.

As a result, we formally depict our overall circuit-based preprocessing framework coupled with RL-based logic synthesis exploration and cost-customized LUT mapping in Algorithm 1. The framework begins by transforming the input circuit instance $\mathcal{G}_{in}$ into AIG format, using $aigmap$ technique in ABC [37]. Then, the RL agent (elaborated in Section III-B) proceeds to select logic synthesis operations step by step through making action a^t. During this process (line 6-16),

Algorithm 1: CSAT preprocessing framework

Input: The input circuit instance $\mathcal{G}_{in}$
Output: The output simplified CNF instance ϕ_{out}
/* Initialize circuit graph $\mathcal{G}^0$ in AIG */
if *input instance is in AIG* **then**
  $\mathcal{G}^0 = \mathcal{G}_{in}$;
else
  $\mathcal{G}^0 = aigmap(\mathcal{G}_{in})$;
end
/* Explore logic synthesis recipe by RL-agent (see Section III-B) */
Define maximum step count: T;
$t = 0$;
while $t < T$ **do**
  /* Prepare the state of current circuit */
  $s^t = \text{Concatenate}(\mathcal{E}(\mathcal{G}^t), \mathcal{D}(\mathcal{G}^0))$;
  /* Make decision to choose a logic synthesis operation */
  $a^t = \pi(s^t) = \arg\max_{a, a \in \mathcal{A}}(Q(s^t, a))$;
  if a^t *is end* **then**
    break;
  end
  /* Perform logic synthesis for state transition */
  $\mathcal{G}^{t+1} = \mathcal{F}(\mathcal{G}^t, a^t)$;
  $t = t + 1$;
end
/* Perform cost-customized LUT mapping (see Section III-C) */
Define LUT costs: C ;
$\mathcal{G}_{LUT} = mapper(\mathcal{G}^t, C)$;
/* Convert to CNF */
$\phi_{out} = lut2cnf(\mathcal{G}_{LUT})$;
return ϕ_{out};

the circuit is synthesized multiple times to create a simplified circuit. Next, the framework continues to perform cost-customized LUT mapping on the AIG netlist $\mathcal{G}^t$, resulting in a compact LUT netlist $\mathcal{G}$. Finally, the LUT netlist is encoded into CNF as output ϕ_{out}. Due to these simplification approaches, ϕ_{out} has a lower solving complexity than ϕ_{in} and the subsequent SAT solving procedures can be more efficient. We will assess the effectiveness of our preprocessing by the following experiments.

IV. Experiments

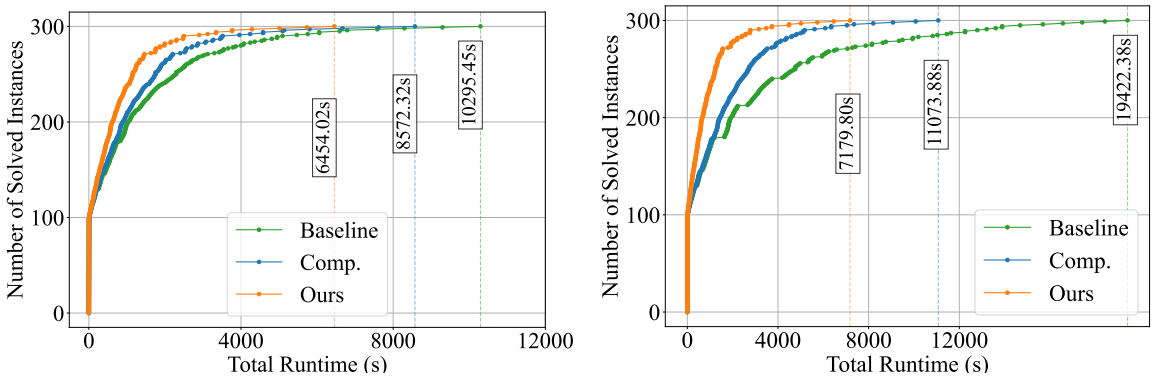
A. Experiment Settings

We collect 200 easy (solving time $0.04s - 6.68s$) instances into the RL training dataset and 300 hard instances for testing. All instances are in AIG format and derived from both industrial logic equivalence checking (LEC) and automatic test pattern generation (ATPG) problems. For LEC instances, we modify original industrial datapath circuits and connect their primary outputs (POs) through XOR gates to form CSAT instances, where satisfiability indicates non-equivalent functionality between circuits. For ATPG instances, we introduce stuck-at faults into industrial circuits and connect the POs of faulty and fault-free circuits through XOR gates, where satisfiable assignments serve as test patterns for fault detection. We construct 200 LEC instances and 100 ATPG instances in total, where 200 easy instances are selected for RL training based on their clause count after CNF transformation and solving time without preprocessing. The statistics of training instances are shown in Table I, where # Clauses shows the number of clauses after transforming AIG instances into CNFs and Time represents the solving time without any preprocessing.

TABLE I: Statistics of training dataset

	Avg.	Std.	Min.	Max.
# Gates	4,299.06	4,328.16	60	24,178
# PIs	43.66	25.17	6	102
Depth	66.43	19.98	18	138
# Clauses	10,687.28	10,801.96	131	60,294
Time (s)	2.01	1.96	0.04	6.68

In the RL setting, we assign the maximum number of steps per episode as $T = 10$ and the discount factor $\gamma = 0.98$. During each training episode, the agent randomly selects an instance and makes decisions aimed at transforming the instance to minimize the number of branching times in SAT solving. We conduct a total of $10,000$ episodes, i.e., the RL agent preprocesses instances for $10,000$ times during RL training. The batch size is 32 and learning rate is 10^{-5}.



We opt for the ABC tool [37] to synthesize the circuit and build a cost-customized mapper based on mockturtle [13] to map the circuit in LUT netlists. The solver runtime limitation is $1,000$s. Any cases that exceed this time limit are marked with TO (Time-out) and are considered to have a solving time of $1,000$ seconds ($\mathcal{T}_{solve} = 1,000s$). Each instance solving is conducted on a single core of Intel Xeon CPU E5-2630.

B. Runtime Comparison

Figure 4 illustrates the relationship between the number of instances solved and overall runtime (including RL model inference time, transformation time and solving time). The Baseline setting represents the conventional solving pipeline, encoding the circuit-based instances directly into CNFs. Our experiment evaluates the effectiveness of our proposed framework using both Kissat solver (version 4.0.0 [38]) and CaDiCaL solver (version 2.0.0 [39]), with our specific settings distinguished by the orange line (denoted as Ours).

To showcase the efficiency of our preprocessing framework, we compare the solving time with another circuit-based approach[1] [8], denoted as Comp. . To the best of our knowledge, although such approach has been around for over a decade, this is the only circuit-based SAT preprocessing technique.

[1]We do not include comparisons with CNF-based preprocessing approaches because our framework is not mutually exclusive with them and can be used in conjunction. Pratically, we keep the default CNF-based preprocessing.

(a) Kissat (c) Cadical

Fig. 4: Runtime Comparison with Baseline and Comp.

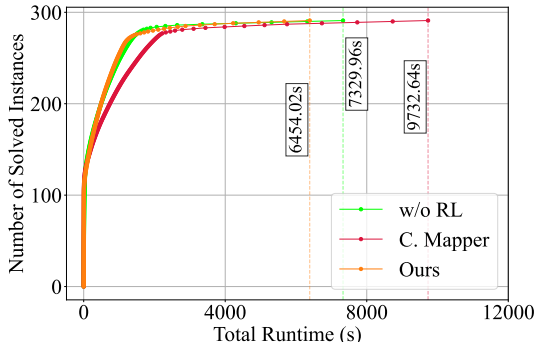


Fig. 5: Ablation Study

According to Figure 4, our proposed circuit-based proprocessing framework can significantly reduce runtime. To be specific, solving these 300 instances necessitates 19,422.38 seconds for the CaDiCaL Baseline pipeline and 11,073.88 seconds for the comparative pipeline (Comp.). In contrast, our method completes the task in a total of 7,179.80 seconds, marking a reduction of 63.03% and 35.16% in solving time compared to Baseline and Comp., respectively.

C. Ablation Studies

In the following experiments, we investigate the effectiveness of our RL-based agent and cost-customized mapper. We keep the same experiment environments and test cases above.

1) Effectiveness of Logic Synthesis Agent: To investigate the effectiveness of the RL agent, we conduct an ablation study by introducing another agent that randomly selects LS operations for $T = 10$ times (noted as w/o RL). The original setting with RL agent is noted as Ours. We test these two settings and summarized the results in Figure 5.

We observe that although the agent with a random policy is capable of employing LS operations to simplify the circuit, it still falls short in terms of achieving optimal solving time reduction. To be specific, solving these 300 instances necessitates 7329,96 seconds for the w/o RL and 6454.02 seconds for our w/ RL agent, marking a reduction of 11.95%.

2) Effectiveness of Cost-Customized Mapper: To showcase the effectiveness of our proposed cost-customized mapper, we replace our cost-customized mapper with a mapper with conventional cost metrics. We denote the new setting as C. Mapper and our original setting as Ours. It is worth noting that both settings utilize the same RL agent with same parameters, and thus, we disregard the agent runtime ($\mathcal{T}_{agent}$) in the reported results.

As shown in Figure 5, the 300 instances processed by the conventional mapper take 9732.64 seconds to solve, which is 50.80% longer than the solving time of Our Mapper. We attribute this difference to the divergent optimization objectives: the conventional mapper minimizes area and delay, while our cost-customized mapper targets solving complexity directly.

V. Conclusion and Future Work

This paper introduces a novel circuit-based preprocessing framework for circuit satisfiability problem, integrating logic synthesis with reinforcement learning to transform circuits into solver-friendly formats. Key innovations include an RL-guided logic synthesis pipeline for optimizing circuit transformations and a cost-customized LUT mapping strategy that minimizes branching complexity during SAT solving. Experiments on industrial benchmarks demonstrate significant runtime reductions—up to 63% compared to baseline approaches—while maintaining compatibility with state-of-the-art solvers. Ablation studies validate the effectiveness of both the RL agent and cost-customized mapper in improving solving efficiency.

This work highlights the potential of combining EDA innovations with machine learning to advance SAT-solving methodologies. Beyond CSAT, the proposed framework offers a promising direction for tackling other SAT variants and related combinatorial optimization problems, enabling more efficient and scalable solutions. Future work will explore extending this approach to sequential circuits and broader EDA applications.

***Abstract*—Singular value decomposition (SVD) is a matrix factorization technique widely used in signal processing and recommendation systems, etc. In general, the time complexity of SVD algorithms is cubic to the problem size, making SVD algorithms difficult to meet stringent performance requirements in real-time. However, existing FPGA and GPU solutions fall short of jointly optimizing latency, throughput, and power consumption. To settle this issue, this paper proposes HeteroSVD, a heterogeneous reconfigurable accelerator for SVD computation on the Versal ACAP platform. HeteroSVD introduces a system-level SVD decomposition mechanism and proposes an algorithm-hardware co-design method to optimize SVD ordering jointly and AI engine (AIE)-centric dataflow and placement with Versal. Furthermore, in order to improve the quality of results (QoR) and facilitate micro-architecture selection, we introduce an automatic optimization framework that performs accurate performance modeling and fast design space exploration. Experiment results demonstrate that HeteroSVD reduces the latency by 1.98× over existing FPGA accelerators and outperforms GPU solutions with an improvement of up to 7.22× in latency, 1.77× in throughput, and 13.18× in energy efficiency.**

I. Introduction

In linear algebra, singular value decomposition (SVD) is a commonly used approach for identifying singular values and constructing a set of singular vectors or matrices from a given matrix. It is widely adopted in applications such as wireless communication [1]–[3], recommendation system [4], [5], etc., where data approximation, compression, and denoising are indispensable. Despite its importance and popularity in data processing, SVD is highly computationally intensive. For example, the Hestenes-Jacobi decomposition method, one of the mainstream SVD algorithms, conducts orthogonalization transformation, namely, multiple vector multiplications, for each pair of column vectors, in a single iteration. This leads to $N \times (N-1)/2$ rounds of vector multiplication computation in an iteration for an input matrix with N columns. To make matters worse, SVD algorithms usually demand multiple iterations until results finally converge. The high computation cost of SVD makes efficient implementation extremely difficult, especially under rigorous real-time requirements.

To boost the performance of real-time SVD processing, researchers have presented SVD accelerator architectures based on field-programmable gate array (FPGA) or graphics processing unit (GPU) platforms. FPGAs [6]–[8] are featured with programmable logic and wirings that can realize any boolean function via hardware reconfiguration. As a result, using FPGAs as the substrate, researchers can take advantage of a number of flexible logic blocks and wirings to tailor the control and data paths of SVD implementation, finally achieving low latency per matrix transformation. However, the scarcity of on-chip memory hinders FPGA solutions from achieving high throughput through effective parallelism. Conversely, GPUs [9]–[13] have a large number of well-constructed computation kernels and this facilitates the simultaneous processing of a set of data. Therefore, researchers investigate batch SVD implementation on GPU and demonstrate higher throughput compared with FPGA design. Nevertheless, this is accompanied by high power consumption. Besides this, GPU solutions incur high latency in computing SVD for single and small-scale matrices since the computation kernels are mostly underutilized in this case. In summary, the existing solutions for efficient SVD implementation fail to jointly optimize latency, throughput, and power consumption due to the high computational intensity of SVD and the inherent limitations of the target platforms.

Recently, AMD/Xilinx has introduced the Versal ACAP architecture, which integrates AI engines (AIEs), programmable logic (PL), and processor systems (PS) to address the limitations of GPUs and FPGAs. The AIEs are optimized for vector and matrix multiplication, allowing for high performance and low power consumption. However, due to the complexity of Versal ACAP, there are three key challenges for efficient SVD acceleration on Versal ACAP. First, the problem size of SVD often exceeds the computational power of a single AIE kernel, necessitating careful partitioning of the input matrix for effective processing. Second, as the usage of AIEs increases with the growing design scale, the limited communication bandwidth between AIEs and PL may incur a bottleneck. Lastly, the versatility of AIEs and the flexibility of PL give rise to a vast design space, making it non-trivial to identify the optimal configurations of micro-architecture that can offer high performance and energy efficiency.

To address these challenges, in this work, we propose an acceleration paradigm of SVD on the heterogeneous computing platform Versal ACAP, which is named HeteroSVD. HeteroSVD constructs the hardware of SVD with a specific focus on the system-level optimization through effectively harnessing the AIE and PL resources. It presents the techniques of workload allocation, communication optimization, and algorithm-hardware co-design. To go one step further, HeteroSVD presents an automatic optimization framework to take into account the effect of various micro-architecture parameters, which helps to rapidly identify the optimal hardware solutions under different problem sizes. The main contributions are as follows:

- We present HeteroSVD[‡], a high-performance and scalable hardware architecture of SVD on the Versal ACAP. To the best of our knowledge, this is the first work that seeks to optimize SVD on this novel heterogeneous computing platform.
- We propose a co-design methodology that jointly optimizes the SVD ordering from an algorithm perspective and the AIE-centric dataflow and placement from a hardware perspective, which boosts the overall performance and energy efficiency.
- We introduce an automatic design optimization framework with a performance analysis model and an efficient design space exploration engine, which navigates the rapid tuning of micro-architecture parameters and ultimately leads to a fast exploration of optimal designs given different problem sizes.

II. Background

A. Block Hestenes-Jacobi Algorithm for SVD

The SVD problem can be factorized as:

$$\boldsymbol{A}_{m\times n} = \boldsymbol{U}_{m\times n}\boldsymbol{\Sigma}_{n\times n}\boldsymbol{V}^{\boldsymbol{T}}_{n\times n}, \tag{1}$$

†Corresponding author.
‡Our method is open-source at https://github.com/zhaokang-lab/HeteroSVD.

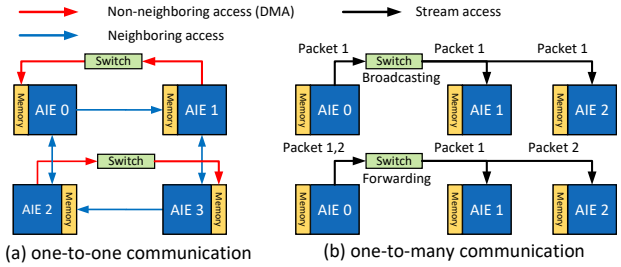

Fig. 1 Various AIE communication mechanisms.

where both U and V are unitary matrices and Σ is a diagonal matrix, and the diagonal elements of Σ are called singular value of A. The key steps of Hestenes-Jacobi [14] denoted as orthogonalization:

$$\begin{aligned} \boldsymbol{B} &= \boldsymbol{AV} = \boldsymbol{U\Sigma}, \\ \boldsymbol{V} &= \boldsymbol{J_1 J_2 J_3 J_4} \cdots . \end{aligned} \tag{2}$$

where the rotation matrix [15] $\boldsymbol{J}$ comprised of c and s is shown as:

$$[\boldsymbol{B}_i, \boldsymbol{B}_j] = [\boldsymbol{A}_i, \boldsymbol{A}_j] \cdot \begin{bmatrix} c & -s \\ s & c \end{bmatrix}, where\ \boldsymbol{B}_i^T \cdot \boldsymbol{B}_j = \boldsymbol{0}, \tag{3}$$

$$c = \frac{1}{\sqrt{1+t^2}}, \text{ and } \mathrm{s} = a_i^T a_j \frac{tc}{|a_i^T a_j|}, \tag{4}$$

$$t = \frac{\mathrm{sign}(\tau)}{|\tau| + \sqrt{1+\tau^2}}, \text{ and } \tau = \frac{a_j^T a_j - a_i^T a_i}{2|a_i^T a_j|}. \tag{5}$$

After multiple orthogonalizations for all column pairs, the convergence rate is less than the specified precision:

$$\frac{\boldsymbol{B}_i^T \boldsymbol{B}_j}{\sqrt{(\boldsymbol{B}_i^T \boldsymbol{B}_i)(\boldsymbol{B}_j^T \boldsymbol{B}_j)}} < precision. \tag{6}$$

Finally, normalization is performed to calculate Σ and U by:

$$\boldsymbol{\Sigma} = \sqrt{\boldsymbol{B^T B}}, \quad \boldsymbol{U} = \boldsymbol{B}/\boldsymbol{\Sigma}. \tag{7}$$

To solve the SVD of large matrices with limited resources, the block Jacobi algorithm is proposed. It divides a large-scale matrix into manageable sub-matrix blocks, enumerates block pairs, and further orthogonalizes all column pairs in a specific sequence such as ring [16] and round-robin [17].

B. Versal ACAP

Versal ACAP is a high-performance heterogeneous computation architecture consisting of central processing units (CPUs), PL, and AIEs, which are connected by a high-bandwidth network on chip (NoC). Each AIE comprises an AI-oriented computation core, a tile interconnect module (denoted as a switch), and a memory module with four banks of 8KB. Additionally, there are multiple interfaces called PLIO between the PL and AIEs, supporting a bandwidth of 24 GB/s from AIE to PL and 32 GB/s in the reverse direction.

Fig. 1 illustrates different mechanisms of data movement between AIEs. Fig. 1(a) depicts one-to-one communication where all AIEs are placed next to each other. The blue arrows indicate that the source AIE can access the memory of the target AIE, because the computation core and memory are adjacent, with no other computation cores or memory blocking them in between, thus considering them neighbors. In contrast, non-neighboring AIEs' communication is supported by the direct memory access (DMA) mechanism, which requires twice the memory resources and has a lower data transmission rate. Fig. 1(b) depicts two types of one-to-many communication mechanisms, including statically broadcasting packets from one AIE to several specific destinations and dynamically forwarding packets to different destinations according to the packet header. Both utilize stream access for communication, which has a speed comparable to that of DMA.

III. HeteroSVD Accelerator Design

A. Overview

SVD Decomposition. Algorithm 1 provides the SVD algorithm that is restructured for HeteroSVD. The key idea behind Algorithm 1 is to split a large-scale matrix into smaller blocks, each of which is further divided into a set of column vectors. Subsequently, column pairs are constructed by grouping any two column vectors from two blocks, which are then sent to the AIE array for result computation. The AIEs are responsible for performing two core types of operations on each pair of column vectors, namely, orthogonalization (lines 7-13) and normalization (lines 21-24).

Overall Architecture. HeteroSVD orchestrates PL and AIE to facilitate the system-level hardware optimization, as depicted in Fig. 2. To start with, the data arrangement module reads the holistic matrix $A_{m\times n}$ with the size of $m \times n$ from DDR and splits $A_{m\times n}$ into smaller ones with the size of $m \times k$. Subsequently, it reorders the incoming data from DDR or the receiver FIFOs in a round-robin manner and passes block pairs to two sender FIFOs respectively. Next, the sender module leverages the dynamic forwarding mechanism and packs each column into packets with headers to ensure correct routing to the respective AIEs. After AIEs finish processing, the receiver

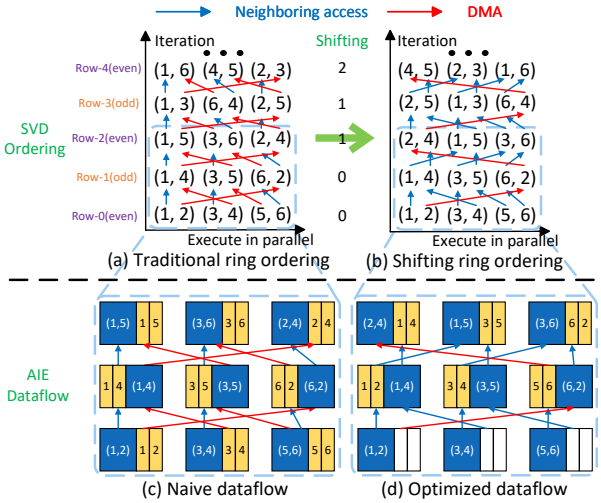

Fig. 3 The comparison of ordering and dataflow between traditional ring ordering and HeteroSVD method.

module reunites packets from AIEs, sorts them into columns, stores them in the corresponding receiver FIFOs, and then sends the deduced convergence rate to the system module. If the convergence rate is less than the user-specified precision, the system module will terminate the orthogonalization stage and proceed into the normalization stage. Finally, the data arrangement module stores the results of Σ and U into DDR and releases a signal of completion.

Note that naive SVD computation may lead to a complicated data transmission scenario between AIEs, which can severely impede communication efficiency. In light of this problem, we propose an algorithm-hardware co-design strategy to jointly optimize both the SVD ordering from an algorithm perspective and the AIE-centric dataflow from a hardware perspective. Finally, we present the method of AIE placement that instantiates the SVD on Versal ACAP.

B. Algorithm-Hardware Co-Design

SVD ordering refers to the practice of determining the processing order of orthogonalizing different column pairs. Unfortunately, the traditional SVD ordering, such as the widely used ring ordering [16], does not fit in well with AIE's inherent characteristics. Specifically, the AIEs are arranged in rows in the AIE array, with neighboring rows having different topologies: *in even rows, each computation core is located on the left side of its internal memory, whereas in odd rows, the relative position of each computation core and its memory gets reversed*. The traditional ordering of SVD algorithms maintains a monolithic data movement pattern across different iterations, which is inconsistent with the AIE alignment in different rows. This discrepancy makes it necessary to use a large number of DMA transmissions, a type of less efficient data communication between non-neighboring AIEs that leads to reduced transmission speed and increased memory usage, as discussed in Section II-B. Fig. 3 (a) and (c) illustrate this issue with matrix $A_{m\times 6}$ as an example, where the number in parentheses denotes the column index, the red arrow indicates DMA transmission and the blue represents neighboring access.

HeteroSVD proposes to co-optimize the SVD algorithm and the Versal AIE array, which can significantly reduce the number of DMA transmissions from $2k(k-1)$ to $2(k-1)$ for a matrix with the size of $m \times 2k$, as shown in Fig. 3 (b) and (d). Specifically, we propose the shifting ring ordering method to augment the SVD algorithm, and the AIE dataflow that reduces communication and memory usage.

Shifting Ring Ordering. To accommodate the AIE array's asymmetric characteristics, we propose the shifting ring ordering mecha-

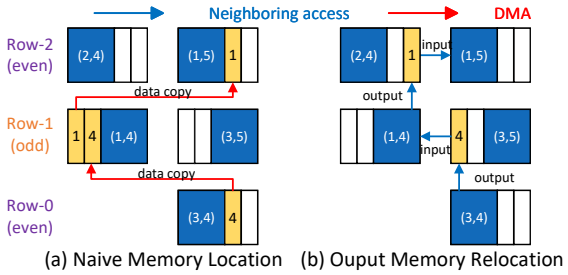

Fig. 4 Dataflow Comparison between different memory location strategies.

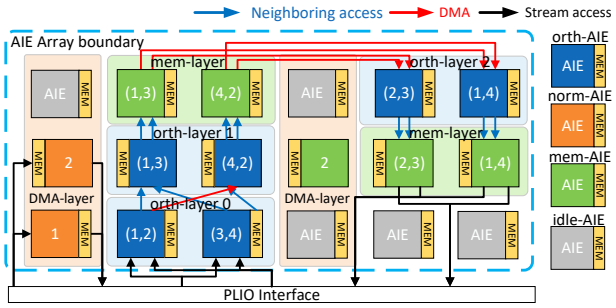

Fig. 5 AIE placement with three types of AIE.

nism for SVD. The main idea is to dynamically change the pattern of data movements in an effort to align with the topology of each AIE row, as depicted in Fig. 3 (b). For row-i, we shift the column pairs to the right by a step size of $\lfloor \frac{i}{2} \rfloor$ in a cyclic manner. For instance, in Fig. 3 (b), all the column pairs in row-2 are shifted by one step cyclically: the right-most column pair (2,4) becomes the left-most, the left-most column pair (1,5) shifts to the middle, and so on. By ordering in this way, the original straight and leftward movements from odd rows to even rows are respectively transformed into rightward and straight movements, while the movements from even rows to odd rows remain unchanged. This method synchronizes the data movement with the topologies of the AIE array.

AIE-Centric Dataflow. To optimize the inter-AIE communication, we relocate the position of output storage to convert the non-neighboring DMA transmission into direct neighboring access. As illustrated in Fig. 4 (a), using the naive memory configuration, each AIE's output is stored in its own memory, necessitating DMA to copy the data due to the lack of a direct interface between the source AIE and target AIE. This means that the orthogonalization operation requires a memory block twice the size of the result to store it, and an expensive DMA communication is engaged as well. To address this issue, we subtly assign each AIE's output to the subsequent AIE's memory in the next row as shown in Fig. 4 (b). This allows the target AIE to communicate with the source AIE through two neighboring accesses via the intermediate AIE memory. Untimately, except for the long-distance communication between the first and the last AIE columns, all data movements from the shifting ring ordering can be achieved with neighboring direct access, as shown in Fig. 3 (d).

C. AIE Placement

AIE placement means the instantiation of AIEs and the corresponding interconnect to implement the SVD algorithm on hardware. However, this problem is challenging. The complete SVD algorithm comprises two phases: orthogonalization and normalization. It is essential to wisely assign AIEs to complete both phases. In particular, the shifting ring ordering for orthogonalizing matrix $A_{m\times 2k}$ requires an array of $(2k-1)\times k$ AIEs, which is incompatible with the 8×50

size of the AIE array on our target board. To this end, we propose an AIE placement strategy, and Fig. 5 illustrate it with matrix $A_{m\times 4}$ as an example.

We define three types of AIE, namely orth-AIE, norm-AIE, and mem-AIE, which are designed for orthogonalization, normalization, and the storage of intermediate data, respectively. For the orthogonalization stage, we partition the shifting ring ordering of size of $(2k-1)\times k$ into $2k-1$ orth-layers, each consisting of k orth-AIEs. Then we place the $2k-1$ orth-layers in a row-wise manner. Notably, at the boundary of the AIE array, namely the first row and the last row, we place a mem-layer instead of an orth-layer as the maximum row limitation of the AIE array prevents a subsequent row from storing the current layer's output. Consequently, we choose another k columns to continue placing the remaining orth-layers, albeit at the expense of some unavoidable DMA transmissions. Moreover, we assign the columns on both sides of the orth-layers as DMA-layers, allocating mem-AIEs to store the copied data due to the DMA mechanism, This is necessary because the orth-AIEs with DMA have already stored data from the previous orth-layers and lack sufficient memory to accommodate the additional copied data. For the normalization stage, we allocate the norm-AIE within the remaining idle-AIE.

We further establish a dynamic forwarding rule to ensure that the block pair from PL is correctly routed to the placed AIEs. Specifically, we designate that odd and even columns are sourced from different blocks within the block pair, utilizing four PLIOs for their respective transmission. Different columns from a single block are routed to different AIEs as shown in Fig. 5. For the norm-AIE, we only use two PLIOs, as the two blocks in the block pair are transmitted sequentially between the PL and AIE.

IV. Automatic Design Optimization Framework

In this section, we first describe the micro-architecture parameters derived from two levels of parallelism. After that, we discuss our performance modeling and design space exploration (DSE) methods.

A. Micro-Architecture Parameters

HeteroSVD has two levels of parallelism that expand its design space, as shown in Fig. 6. The first parallelism is AIE-level parallelism (denoted as P_{eng}), which determines the number of AIEs used in parallel to execute the SVD computation for a single task. The second parallelism is task-level parallelism (denoted as P_{task}), which represents the number of tasks processed simultaneously in the computing system. These two parallelism factors, together with the given operating frequency of PL, determine the system-level performance and guide the selection of parameters in the HeteroSVD design, making them first-order micro-architecture parameters, as listed in TABLE I. Additionally, second-order micro-architecture parameters include the number of PLIOs and the counts of AIEs designated as orth-AIE, norm-AIE, and mem-AIE.

In summary, by specifying P_{eng}, P_{task}, and PL frequency, we can determine the architecture of HeteroSVD. However, searching for the optimal and feasible HeteroSVD architecture by enumerating all possible micro-architecture parameters requires the full invocation of the EDA front-end, back-end, and cycle-accurate simulation flow, which is extremely time-consuming. For instance, running a single design point for an SVD of a 128×128 matrix would take more than seven hours. Considering a design space of (P_{eng}, P_{task}) that leads to 286 design points, the cost of searching for optimal architecture is unaffordable. Therefore, HeteroSVD proposes an automation design approach with a performance model and a design space exploration flow to construct the optimal HeteroSVD structure of a given problem size within minutes.

TABLE I HeteroSVD architecture parameters at different hierarchies.

Hierarchy	Parameter	Range or Value
First order	P_{eng}	$n \in [1, 11]$
	P_{task}	$k \in [1, 26]$
	PL frequency (MHz)	-
Second order	the number of orth-AIE	$n(2n-1)k$
	the number of norm-AIE	nk
	the number of mem-AIE	-
	the number of PLIO	$6k$

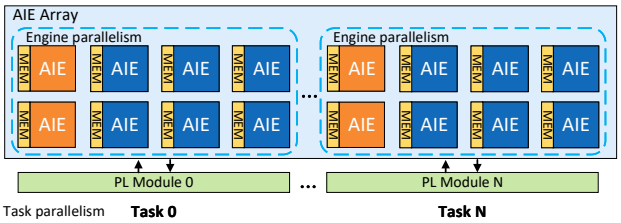

Fig. 6 Engine parallelism and task parallelism.

B. Performance Model

To efficiently evaluate the performance with different AIE-level and task-level parallelisms, we first present a performance model to estimate the latency and throughput of the overall computing system. The complete pipeline of the orthogonalization is shown in Fig. 7. This pipeline can be further decomposed into data sending (Tx) from PL to AIE, data receiving (Rx) of PL from AIE, and execution of orthogonalization (orth-AIEs). And since orth-AIEs have two inputs and output, we use left(L) and right(R) to distinguish them.

The execution time of Tx and Rx is determined by PL frequency and PL bandwidth:

$$t_{Tx,Rx} = \frac{databits}{bandwidth \cdot frequency}, \tag{8}$$

and the AIE time is estimated by the AIE simulator in advance. Besides, there are three main types of latency.

AIE-wait latency ($t_{AIEwait}$) arises from the imbalance between the execution time of AIE and the time taken for data transmission:

$$t_{AIEwait} = max(t_{orth} - P_{eng} \cdot t_{Tx}, 0). \tag{9}$$

Specifically, when multiple packets are transmitted serially to different AIEs through a single PLIO, the incoming data must wait for the completion of AIE's last execution.

Algorithm latency (t_{algo}) results from the data dependency between the second Rx-R and the first Tx-R in the round-robin algorithm:

$$t_{algo} = t_{Tx} + t_{AIEwait}. \tag{10}$$

The lack of sending data causes data-wait latency ($t_{datawait}$):

$$\begin{aligned} t_{datawait} = max(-(num-1)\cdot(t_2 + t_{Tx}) \\ + t_{AIEs} + t_{Rx} + t_{algo}, 0), \end{aligned} \tag{11}$$

where num and t_{AIEs} represent the number of block data pairs and the total AIEs time between Tx and Rx.

Beyond these latencies, there is also latency caused by HLS (t_{hls}) and DDR (t_{DDR}). HLS [18] incurs additional cycles when switching between loops, thus, t_{hls} can be calculated based on the loop structure in the code. The inability to load block pairs from DDR simultaneously results in significant latency during the first iteration:

$$t_{DDR} = num \cdot t_{Tx}. \tag{12}$$

Then we can calculate the time required for one iteration:

$$\begin{aligned} t_{blocks} &= num \cdot (t_{Tx} + t_{AIEwait}) + t_{algo} + t_{datawait}, \\ t_{iter} &= (num-1)\cdot t_{blocks} + AIE_{total} + t_{Rx}. \end{aligned} \tag{13}$$

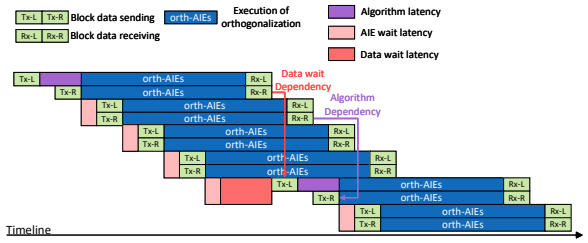

Fig. 7 HeteroSVD pipeline model at orthogonalization stage

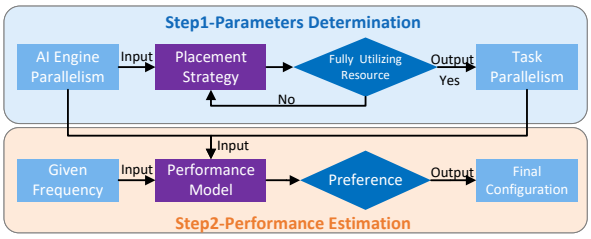

Fig. 8 DSE flow with two stages.

Norm-AIE's pipeline resembles orth-AIE's but with single input/output and no algorithm latency. We define the normalization time as t_{norm}. The task time can be computed by summing the execution times of orthogonalization, normalization, and additional latency. The system time can then be derived using:

$$\begin{aligned} t_{task} &= t_{DDR} + ITER \cdot t_{iter} + t_{norm} + t_{hls}, \\ t_{sys} &= \lceil \frac{num_{task}}{P_{task}} \rceil \cdot t_{task}, \end{aligned} \tag{14}$$

where ITER represents the specified iterations and num_{task} represents the number of tasks.

C. Design Space Exploration (DSE)

Problem Formulation. In general, the goal of our architecture optimization framework is to increase the performance of the SVD computing system. Specifically, given the size of the matrix ($M \times N$) and batch size (B), we need to properly select the first-order parameters listed in TABLE I, i.e., the parallelism factor of AIEs (P_{eng}) and tasks (P_{task}), and the practical frequency ($Freq$) of PL, while keeping all types of resources, including AIE kernel, PLIO, BRAM and URAM, under their budgets. To this end, we formally define our problem of design space exploration as follows:
