$$\begin{aligned} \min \quad & runtime(P_{eng}, P_{task}, Freq), \\ \text{s.t.} \quad & Resource_i(P_{eng}, P_{task}), \leq C_i \\ & i \in \{AIE,\ PLIO, BRAM, URAM\}. \end{aligned} \tag{15}$$

DSE Flow. Fig. 8 illustrates the design exploration flow to search for the optimal HeteroSVD architecture. In the first stage, we enumerate the engine parallelism and maximize task parallelism by fully utilizing resource according to our placement strategy. Equation (16) summarized all constraints C_i, where $i \in \{AIE, PLIO, BRAM, URAM\}$, represent the number of hardware resource limits. The actual usage of AIE resource, num_{orth}, num_{norm}, num_{mem}, and num_{PLIO}, can be determined after placement while the resource usage of PL memory, including num_{BRAM} and num_{URAM} can be estimated by the array size of PL design. In the second stage, with engine parallelism, task parallelism, and the user-specified frequency as input, we utilize our performance model to estimate the overall computing system's performance. Furthermore, We determine the optimal HeteroSVD architecture based on the demand of latency or throughput.

$$\begin{aligned} num_{orth} + num_{norm} + num_{mem} &\leq C_{AIE}, \\ num_{PLIO} &\leq C_{PLIO}, \\ num_{BRAM} &\leq C_{BRAM}, \\ num_{URAM} &\leq C_{URAM}. \end{aligned} \tag{16}$$

V. Experiment Results

A. Experimental Setup

Our experiments are conducted on AMD/Xilinx Versal AI Core Series VCK190 [19] evaluation board. We use the Vitis 2023.2 toolkit to build up the whole HeteroSVD acceleration system. The AIEs operate at 1.25 GHz, while the frequency of the PL design depends on the specific system configurations. We use the AMD BEAM tool [20], to measure the exact power of the system while running on the VCK190 board. We compare our SVD acceleration system with the SOTA SVD accelerators implemented on AMD/Xilinx XC7V690T FPGA and GeForce RTX 3090 GPU.

B. Performance and Energy Efficiency

We compare HeteroSVD, with the state-of-the-art high-performance hardware implementations on FPGA [6] and GPU [11], both of which offer better latency or throughput compared to other implementations on the same platform. To enable a fair comparison, we perform six iterations per matrix and configure the FPGA accelerator to its maximum task parallelism at an achievable peak frequency of 200 MHz. Generally speaking, the GPUs perform better with large-scale data, while the FPGAs are featured with low-latency data processing. TABLE II presents the latency comparison and resource utilization between HeteroSVD and FPGA. The experimental results show that the HeteroSVD solution supports more flexible architecture and significantly outperforms the FPGA solution regarding latency in all matrix sizes, achieving 1.27× – 1.98× speedup over FPGA. Meanwhile, HeteroSVD consumes fewer computational resources than FPGA, indicating that HeteroSVD has greater potential for parallelism in handling multiple tasks.

Furthermore, we evaluate the latency, throughput, and energy efficiency for batch data processing of SVD between HeteroSVD and GPU as listed in TABLE III. We obtain the optimal micro-architecture configuration from HeteroSVD's DSE flow. In addition, we perform multiple iterations of SVD until the results converge at a rate of 10^{-6} for both HeteroSVD and GPU solution. HeteroSVD achieves 1.15× – 7.22× latency speedup over GPU for small matrix. Regarding throughput, HeteroSVD shows up to 1.77× speedup with a small matrix size. However, as the matrix size increases, the GPU solution outperforms our HeteroSVD solution in throughput. Fig. 9 illustrates the underlying mechanism. As the design size increases, the GPU solution exhibits higher utilization of its computation cores and memory, significantly boosting its performance. In contrast, due to limitations in PL memory, HeteroSVD experiences reduced task parallelism, leading to lower overall utilization. Moreover, larger design sizes increase the complexity of the PL, which reduces the maximum achievable frequency and further diminishes HeteroSVD's latency and throughput. Therefore, with adequate RAM resources and optimized operating frequency, we believe that HeteroSVD has the potential to outperform GPU solutions with similar core utilization.

As for energy efficiency, HeteroSVD demonstrates 4.36× – 13.18× improvement over GPU solutions. In summary, the tremendous gains justify that HeteroSVD is a highly competitive alternative to both FPGA and GPU in achieving high-performance yet energy-efficient SVD accelerators.

TABLE II Latency comparison and resource utilization between HeteroSVD and FPGA.

Matrix Size	FPGA [6]				HeteroSVD				HeteroSVD
	Latency(s)	LUT	BRAM	DSP	Latency(s)	LUT	URAM	AIE	Speedup

C. Effectiveness of DSE

Accuracy of Performance Model. The accuracy of the performance model is key to developing a high-quality design space exploration approach. Therefore, in this experiment, we first evaluate the effectiveness of our performance model. We apply different factors of engine parallelism and the input matrix size and examine the processing time of HeteroSVD in terms of a single iteration. The frequency of the PL side is fixed at 208.3 MHz. TABLE IV shows the results of the HeteroSVD performance model and the on-board measurement. We can observe that the maximum error of our model is 3.03% and the average error is 1.78%, which shows the efficacy of our performance model in the evaluation of latency.

To further validate the generalization ability of the performance model across different application scenarios, we use the HeteroSVD DSE approach to identify the optimal configuration with minimum execution time. Then, we get the latency of processing a single matrix and the throughput of processing 100 matrices from both the model and on-board measurement. As shown in TABLE V, our performance model demonstrates a maximum error of 7.52% and an average error of 4.33%. This highly accurate performance model ensures the effectiveness of our DSE flow with design point enumeration.

TABLE VI Latency(ms), throughput(task/s) and power(W) comparison between different design points. The matrix size is 256×256 and the PL frequency is reported in 208.3MHz

P_{eng}	P_{task}	AIE	URAM	Latency	Throughput	Power
2	26	293(73.25%)	416(89.85%)	35.689	707.501	44.16
4	9	357(89.25%)	144(31.10%)	19.303	508.436	34.63
6	4	366(91.50%)	120(25.92%)	13.117	306.876	30.79
8	2	322(80.50%)	32(6.91%)	9.247	219.257	26.06

Discussion on DSE Results. TABLE VI evaluates how micro-architecture parameters influence latency, throughput, and power consumption of SVD implementation, with each design point executing six iterations. Increasing P_{eng} allows for more AIEs to be allocated to a single SVD, effectively reducing latency. However, a design point with high P_{eng} is not suitable for scenarios with strict throughput requirements, as it restricts task parallelism. Conversely, higher task parallelism (P_{task}) improves throughput but increases URAM usage, leading to significant power consumption. In summary, we favor lower P_{eng} and higher P_{task} for high throughput, while the opposite configuration is preferable for minimizing latency. Moreover, a comprehensive consideration of micro-architecture parameters is essential for effectively managing power consumption.

VI. Conclusion

In this paper, we propose HeteroSVD, an optimized hardware accelerator of block-Jacobi SVD based on the novel heterogeneous computing platform, Versal ACAP. For HeteroSVD accelerator design, we decompose the computation of SVD and propose the algorithm-hardware co-design for SVD ordering, AIE dataflow, and AIE placement. To further optimize the design with a set of micro-architecture parameters, we introduce a design space exploration flow to expedite the search for the best hardware solutions at different problem sizes.

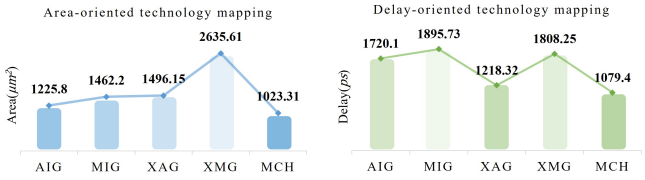
***Abstract*—The independence of logic optimization and technology mapping poses a significant challenge in achieving high-quality synthesis results. Recent studies have improved optimization outcomes through collaborative optimization of multiple logic representations and have improved structural bias through structural choices. However, these methods still rely on technology-independent optimization and fail to truly resolve structural bias issues. This paper proposes a scalable and efficient framework based on *Mixed Structural Choices* (MCH). This is a novel heterogeneous mapping method that combines multiple logic representations with technology-aware optimization. MCH flexibly integrates different logic representations and stores candidates for various optimization strategies. By comprehensively evaluating the technology costs of these candidates, it enhances technology mapping and addresses structural bias issues in logic synthesis.**

Notably, the MCH-based lookup table (LUT) mapping algorithm set new records in the *EPFL Best Results Challenge* by combining the structural strengths of both And-Inverter Graph (AIG) and XOR-Majority Graph (XMG) logic representations. Additionally, MCH-based ASIC technology mapping achieves a 3.73% area and 8.94% delay reduction (balanced), 20.35% delay reduction (delay-oriented), and 21.02% area reduction (area-oriented), outperforming traditional structural choice methods. Furthermore, MCH-based logic optimization utilizes diverse structures to surpass local optima and achieve better results.



***Index Terms*—logic synthesis, technology mapping, structural bias, structural choices, heterogeneous representations.**

I. Introduction

Logic synthesis is one of the key steps in the *electronic design automation* (EDA) workflow. The process of logic synthesis mainly includes translation, technology-independent logic optimization, and technology mapping, aiming to convert RTL designs into mapped netlists with optimized power, performance, and area (PPA). Achieving high-quality synthesis results is a significant and challenging scientific task.

During the logic synthesis phase, the design representation evolves from truth tables, *sum of products* (SOPs), *binary decision diagrams* (BDDs), to *directed acyclic graphs* (DAGs), while the scale of the design gradually expands. Currently, mainstream logic representations in the logic synthesis process include *AND-Inverter graph* (AIG), *Majority-Inverter graph* (MIG) [1], *XOR-AND graph* (XAG) [2], and *XOR-Majority graph* (XMG) [3]. For different types of circuits, each representation has its unique advantages. For example, some novel logic representations perform better in arithmetic-intensive circuits [4]. In recent years, some studies have focused on exploring optimization methods and application for different logic representations [5–8]. Modern IC designs consist of complex functional modules that can be specifically optimized using different logic representations.

Recent studies have achieved better optimization results by combining different logic representations [9–12]. For example, the LSOracle framework [10, 11] introduces a heterogeneous synthesis approach. It partitions the circuit into segments optimized using different logic representations, which are later unified into a single representation for mapping. However, these methods are often limited by ***structural bias***, a well-known issue in logic synthesis [13]. They convert all representations into a single form for mapping, which compromises the structural advantages of other representations.

(a) Mapping area information (b) Mapping delay information

Fig. 1: Technology mapping for different logic representations

As design types and requirements become increasingly complex, the limitations of relying on a single logic representation are becoming more apparent. Fig. 1 illustrates the conversion of the "Max" circuit from the *EPFL benchmark suite* [14] into various logic representations, along with information on technology mapping using the *Arizona State Predictive PDK 7nm* (ASAP7) library [15]. Results indicate that, for delay-oriented mapping, using XAG yields better performance for this circuit, while for area-oriented mapping, AIG achieves superior results. The mapping results are strongly influenced by the circuit's structure. Therefore, an effective technology mapping method should be able to jointly evaluate different logic representations, enhancing adaptability across different synthesis scenarios to achieve superior mapped netlists. In fact, our method achieves this by utilizing *Mixed Structural Choices* (MCH) to effectively overcome the *structural limitations* of single logic representations, resulting in more competitive outcomes.

The issue of structural bias permeates all stages of logic synthesis. The root cause lies in the independence between logic optimization and technology mapping. This causes logic optimization may misalign with mapping, wasting resources and missing optimal structures. Some studies employ machine learning and heuristic approaches to explore better mapping structures [16–18]. Another promising approach is structural choices, which preserve different structural candidates during logic optimization to address structural bias [13, 19–21]. However, these methods are limited to searching for optimal mapping structures within the optimized graph. It is difficult to cope with the structural limitations of the graph when the optimization is close to a local optimum. On the other hand, existing structural choice methods rely on equivalence checks between technology-independent optimized networks, significantly limiting the diversity of candidates and reducing the efficiency of constructing choice networks. In recent studies, E-Syn utilize e-graphs to explore optimal structures [22]. However, its efficiency is relatively low when handling large-scale designs.

Fig. 2 illustrates the limitations of the traditional synthesis flow through a simple example. The original network is an AIG with 11 nodes. After technology-independent optimization, the number of AIG nodes is reduced to 8, but the mapping cost increases instead.

This work was supported in part by the NSFC under Grant No. 62274100, in part by the Key R&D Program of Zhejiang Province under Grant No. 2024C01111 and Ningbo City under Grant No. 2023Z071, and in part by the Zhejiang Provincial NSFC under Grant Nos. LDT23F0402 and LDT23F04021F04.

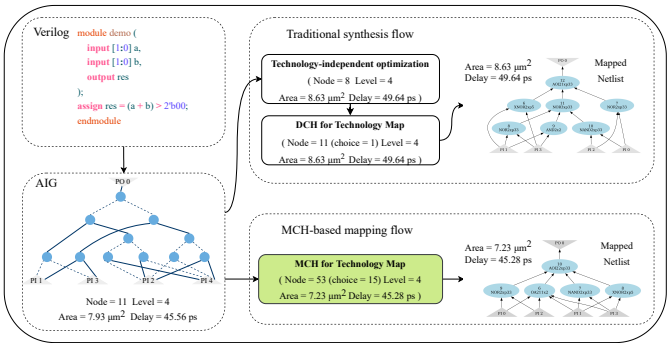


Fig. 2: Comparison of the MCH-based mapping flow with the traditional synthesis flow

Subsequently, traditional structural choice algorithms [13] (denoted as DCH in ABC [23]) still fail to effectively address the impact of structural limitations. This issue is particularly common in large-scale designs. Thus, achieving synergy between logic optimization and technology mapping remains a significant technical challenge.

Based on existing issues, this paper introduces the *Mixed Structural Choices* (MCH) operator. They are mixed networks incorporating heterogeneous logic representations, eliminating the constraints of relying on a single logic representation during logic synthesis. Unlike existing heterogeneous synthesis methods, MCH preserves the original logic structure through structural choices while incorporating new logic representations as candidates. Furthermore, to obtain diversified candidate structures, MCH introduces a multi-strategy structural choices algorithm. It combines node path classification with synthesis strategies targeting different objectives, preserving equivalence rather than performing local replacements before optimization, thereby retaining diverse optimization candidates. Finally, MCH integrates with technology mapping, using technology information to evaluate candidate logic representations and structures, thereby enhancing technology mapping.

The main contributions of this paper are as follows:

- The concept of MCH is proposed, enabling the simultaneous evaluation of different logic representations through choice networks.
- Multi-strategy structural choices differentiate critical paths and apply diverse optimization strategies, preserving varied logic representations and optimization candidates.
- Forms an MCH-based technology mapping method, which evaluates candidate logic representations and optimizations using technology information.
- In tests based on the EPFL benchmark suite, MCH-based *application specific integrated circuits* (ASIC) technology mapping achieved improvements across multiple metrics. MCH-based *field programmable gate array* (FPGA) technology mapping set new records in the *EPFL Best Results Challenge*. MCH-based graph mapping overcomes local optima, improving logic optimization and post-mapping results.

II. Background

A. Boolean Network

In logic synthesis, Boolean networks are typically represented as directed acyclic graphs. DAGs consist of logic nodes representing Boolean functions, *primary inputs* (PI), *primary outputs* (PO), and directed edges connecting these nodes. The level of node n is defined as the length of the longest path from any PI to node n. The level of a Boolean network is determined by the maximum level of its internal nodes. The output of a node n can connect to other nodes, known as the node's fanout, and the set of all fanout nodes forms the *transitive fanout* (TFO) cone. The *transitive fanin* (TFI) cone of a node n includes all nodes reachable through its fanin connections. A cut C for a node n in a DAG is a set of nodes that represent a portion of the logic function, where the nodes in C, known as leaf nodes, ensure that every path from the PI to n passes through at least one leaf node. The cut enumeration algorithm [24] can compute the set of cuts for all nodes in a Boolean network for further analysis. The *maximum fanout-free cone* (MFFC) of a node n is a subset of its TFI, where all paths to any PO pass through n.

B. Technology Mapping

Technology mapping is the process of converting a logic network represented as a DAG into a netlist composed of actual technology library cells. Technology mapping is typically divided into standard cell mapping for ASICs and *K-input lookup table* (K-LUT) mapping for FPGAs. This process involves steps such as cut enumeration, Boolean matching, and iterative mapping, using gates from the library that implement the same Boolean functions to cover the nodes in the network. The quality of technology mapping is usually evaluated in terms of area, delay, and power consumption. A delay-oriented mapping focuses on reducing the delay along the longest path in the cover, while an area-oriented mapping seeks to minimize the total area of the cover [25].

The quality of the mapped netlist depends on the matching possibility between the technology library cells and the DAGs to be mapped. Therefore, the quality of the mapped netlist is influenced by the DAGs to be mapped, and two DAGs representing the same Boolean function but with different structures may lead to significantly different results [26].

C. Structural Choices

Structural choice networks retain different structures that are functionally equivalent or complementary within a Boolean network. Fig. 3 illustrates an example of a choice network. A cut-based technology mapper can consider different options to decide which of the two equivalent structures to cover, which often helps alleviate structural bias, resulting in higher-quality outcomes [27]. The concept of lossless logic synthesis was introduced in [13], applying choice networks to address structural bias issues. However, the creation of choice networks relies on technology-independent optimization, leading to structural limitations. LCH effectively addresses the inefficiency of traditional structural choice algorithms but does not resolve the inherent structural limitations [21]. A novel structural choice method based on logic optimization candidates is used to address structural bias issues; however, its support for large-scale circuits remains limited [28].

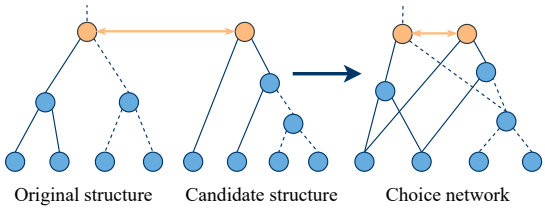

Fig. 3: Combine networks to generate a choice network

III. Our Approach

This chapter provides an overview of the workflow for the *Mixed Structural Choices for Technology Mapping* framework. The framework is a heterogeneous mapping approach that integrates mixed

choice networks, technology-aware evaluation, and mapping-base optimization methods. The algorithms have been open-sourced as the `mch` command in the open-source logic synthesis tool *also*[1]. As shown in the Fig. 4, the main innovations of this work consist of three parts:

(a) *Mixed Structural Choice*: This section explains the concept and creation of mixed structural networks. It preserves the structural characteristics of different logic representations through mixed structural networks and obtains candidate structures based on a path-classification multi-strategy synthesis approach.
(b) *Technology Mapping with MCH*: This section introduces the technology mapping algorithm based on MCH, which evaluates candidates in MCH using technology mapping costs to enhance the mapping process.
(c) *Extending Applications*: This section presents the application of MCH in mapping-based logic optimization, demonstrating its excellent scalability.

A. Mixed Structural Choices

This section introduces the mixed structural choices, a heterogeneous logic representation approach based on structural choices, capable of integrating structural characteristics from different logic representations. MCH retains the original structure while storing other logic representations as candidates, enabling simultaneous evaluation of different logic representations during mapping. This enables the technology mapping phase to select the most suitable logic form, yielding higher-quality mapping results.

AIG, as one of the most popular logic representations, is structurally compatible with XAG, MIG, and XMG. Therefore, we can create mixed choice networks based on AIG combined with any logic representation. Fig. 4 (a) illustrates an example of an mixed choice network, where the original network is an AIG network with a simple structure, while its choice nodes are in MIG, a form with more compact logic expressions. Through MCH, both structural characteristics are simultaneously available, allowing technology mapping to overcome the limitations of single logic representations and achieve an optimized logic network structure with enhanced mapping quality.

The MCH construction algorithm flow is shown in Algorithm 1. The algorithm takes a Boolean network $\mathbb{N}$, a maximum cut size parameter k, a maximum number of cuts for each node parameter l, a maximum number of PIs in the MFFC parameter K, a constant parameter r that controls the proportion of critical path nodes and the synthesis strategies library lib as inputs. The output of the algorithm is the mixed choice network G.

When creating MCH, the first step involves storing the input network within a different logic representation format (line 1). For instance, the input AIG network is one-to-one mapped into the MIG data structure. This process traverses the input AIG nodes and creates corresponding AND nodes, constants, PIs, and POs within the MIG structure, ensuring that the original AIG characteristics are fully retained.

Algorithm 1: Mixed Structural Choices

Subsequently, MCH uses a hash table to collect critical path nodes, forming the critical path node set f. These nodes include PO nodes with logic depths greater than or equal to the network logic depth * r, along with all nodes on paths from these POs to the PIs (line 2). Next, MCH runs a cut enumeration algorithm to calculate cut information, which is saved according to cut size k and cut number limit l (line 3).

After completing the above steps, MCH uses a *multi-strategy structural choice algorithm* to obtain diversified candidate information, as shown in Algorithm 2. *Mixed structural choices information* (*info.*) refers to the equivalence information between the obtained logic representations and optimization candidates and the original network nodes. The algorithm traverses all nodes. For nodes in the critical path node set f, the focus is on obtaining structures with level advantages. Therefore, the cuts for these nodes are processed using level-oriented synthesis strategies, such as the 4-input NPN library [29], to generate a diverse set of candidate options (lines 2-6). For non-critical path nodes, their MFFCs are computed (line 8). Area-oriented synthesis strategies, such as SOP and DSD, are then applied to generate candidate options with area advantages (lines 9-13). It is worth noting that these synthesized subcircuits do not replace the original network but are retained alongside it as structurally different but functionally equivalent options. After synthesis and restructuring, the obtained candidates will be preserved with new logic representation structures. The *multi-strategy structural choice algorithm* further enriches the diversity of structural choices by combining path classification with multi-objective logic optimization strategies.

Finally, the mixed choice network G is constructed based on MCH information (line 5). Nodes in the original network are defined as `representative nodes`, and their equivalent candidates are added to the network as `choice nodes`. This MCH creation approach achieves a balance between depth and area, and MCH can also create networks optimized for area or delay by adjusting parameter r and synthesis strategies to meet different design goals.

B. Technology Mapping with MCH

Thanks to the characteristics of MCH, we can achieve synergy between logic optimization and technology mapping. This section will explore how to combine MCH with technology mapping algorithms to utilize technology information for technology-aware evaluation.

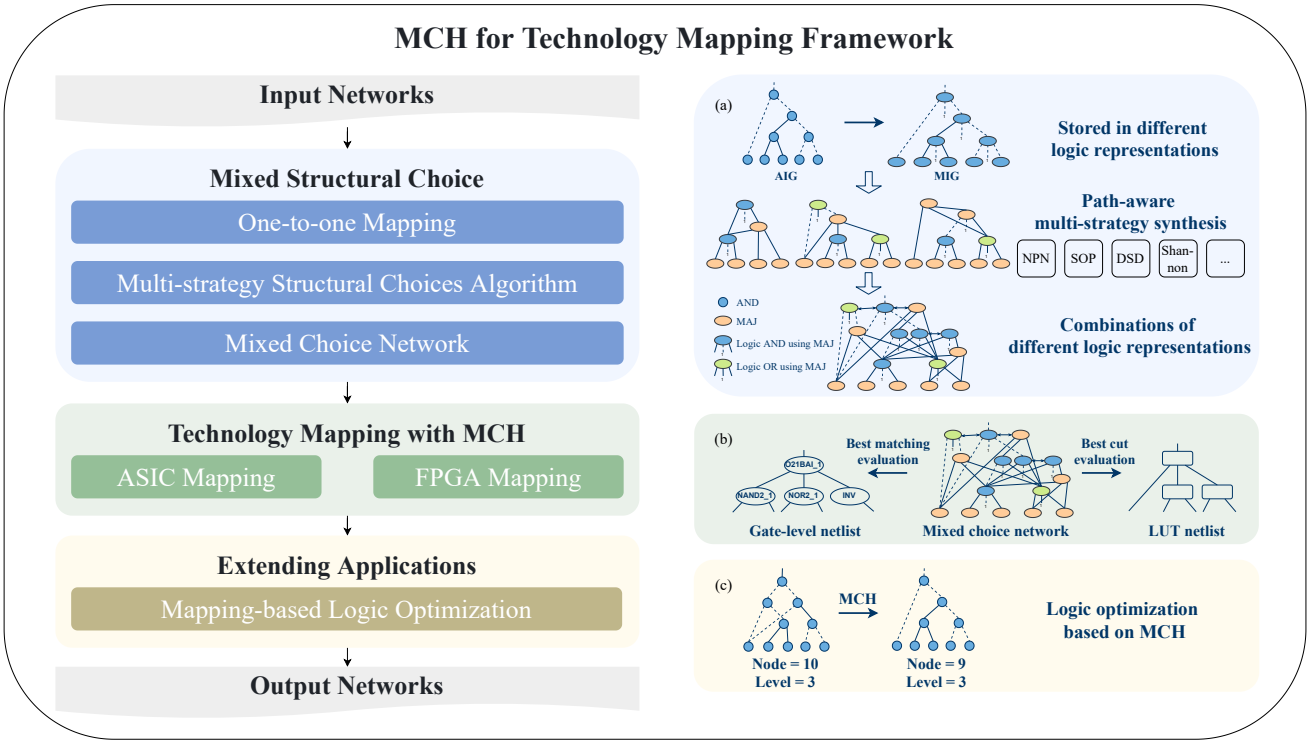

Fig. 4: Mixed Structural Choices for Technology Mapping Framework

MCH-based technology mapping integrates the evaluation and selection of candidate structures from the choice network into existing mapping steps, guiding the mapper to choose the optimal structure for mapping. The process pseudocode for the MCH-based technology mapping algorithm is shown in Algorithm 3. The input of this algorithm is the mixed choice network G obtained from subsection A, and the output is the mapping netlist $\mathbb{M}$. Thanks to the high flexibility of MCH, our method supports technology mapping for both ASIC and FPGA.

First, the mixed choice network is traversed to compute and save each node's cuts (line 1). Next, MCH transfers the candidate structural information from choice nodes to their representative nodes. This process involves iterating through the cut sets of choice nodes and integrating their cuts into the cut sets of the corresponding representative nodes. Finally, a simple sorting is performed to remove cuts exceeding the cut set limit (lines 2-8). When the graph to be mapped contains some structurally different nodes marked as equivalent, cut-based technology mappers need to evaluate different covering options to select the optimal structure for coverage. Therefore, sharing the cut sets of choice nodes is essential.

During technology mapping, the mapper sorts the cut sets based on mapping objectives, selects the optimal cut, and determines the best cell by combining required time and Boolean matching. Since the candidate structures for logic representation and optimization have been successfully stored in the mixed choice networks, the mapper can select the structure with the lowest technology cost based on mapping requirements and technology information. Mapping is a dynamic programming process, for ASIC mapping, the MCH-based mapper continuously updates and selects the cut and matching cell with the lowest cost from numerous candidates. For FPGA mapping, the best cut is dynamically selected in each iteration based on the mapping target (lines 9-13). Finally, the mapped netlist is generated and output, completing the mapping process (lines 14-15).

MCH-based technology mapping achieves a seamless integration of logic optimization and technology mapping. The heterogeneous logic representations and optimization candidates stored in MCH are directly utilized by the mapper, which selects structures with lower technology costs from the candidates. This approach addresses the limitations of the original network structure and directly improves the QoR of technology mapping.

Algorithm 3: MCH-based technology mapping

Input: Mixed choice network G, cut limit l, tech library $tech_lib$
Output: Mapping netlist $\mathbb{M}$

```
1  cuts set C ← Cut enumeration (G, l);
2  for each gate n ∈ G do
3  |  n' ← n's choice node;
4  |  while n' have choice node do
5  |  |  for each cut c ∈ C(n') do
6  |  |  |  insert cut c to C(n);
7  |  |  n' ← n''s choice node;
8  |  limit C(n)'s size <= l;
9  for compute mapping do
10 |  for each gate n ∈ G do
11 |  |  sort C(n) (delay / area);
12 |  |  compute required time;
13 |  |  compute delay-oriented / area-oriented mapping (G, C,
   |  |    tech_lib);
14 M ← generate mapping netlist;
15 return M;
```

C. Extending Applications

Structural bias partly arises from the limitations of logic optimization, which are related to the logic optimization operators applied. Due to constraints imposed by graph structures or the optimization algorithms themselves, logic optimization algorithms often fall into local optima, thereby limiting the discovery of global optimal solutions. This phenomenon has been confirmed in recent *IWLS Programming Contests*[2], where many participating teams have

[2]https://www.iwls.org/iwls2024/

focused on addressing this issue.

MCH offers a new approach to addressing such issues. MCH can be easily extended to mapping-based logic optimization algorithms. MCH-based logic optimization leverages its unique features, combining different logic representations to help the original algorithms overcome local optima. MCH inherently provides a broader range of optimization candidates, and when integrated with logic optimization, it further expands the solution space, making it possible to achieve better optimization results.

Graph mapping is a mapping-based method that remaps the original network to achieve the conversion between logic representations or to optimize logic networks [25]. Fig. 5 illustrates the MCH-based graph mapping algorithm. The newly added work is marked in green in the figure. Our method uses MCH as an intermediate representation for graph mapping, performing cut enumeration and Boolean matching based on the mixed choice network. As shown in the figure, the algorithm can select the most advantageous structure for matching and mapping from three candidate structures. It then completes subsequent mapping and ultimately produces an optimized logic network. At this point, the output network corresponds to the new logic representation selected from the MCH candidates. Therefore, when implementing logic optimization, the output network can be mapped one-to-one to the target logic representation again. And then MCH-based graph mapping is performed to obtain the final optimized network. Through iterative cycles, the structural characteristics of multiple logic representations are combined to achieve higher-quality graph mapping optimization.

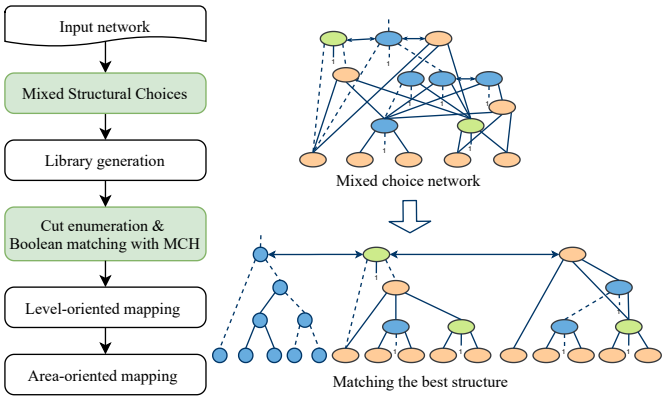

Fig. 5: MCH-based graph mapping

IV. Experimental Results

In this section, we conducted experiments and evaluations of the technology mapping and logic optimization based on MCH. The experiments include technology mapping based on MCH, an evaluation of structural choice effects (comparing MCH and DCH), and an assessment of logic optimization results with MCH. We developed algorithms related to MCH based on the open-source logic synthesis framework *Mockturtle* [30] and conducted experiments. All experiments were performed on a 3.70 GHz AMD(R) Ryzen 5(R) 7500F CPU with 32GB of main memory. Our test cases come from the EPFL benchmark suite [14] which includes arithmetic and random_control benchmark circuits. All results have been formally verified with ABC's `cec` command.

A. MCH for Technology Mapping

1) ASIC Technology Mapping: In the ASIC technology mapping experiment, we evaluated the effectiveness of technology mapping based on MCH. The experiment first used ABC's `compress2rs` flow for iterative optimization to simulate the logic optimization process. Then, the mapping quality is evaluated using the ASAP7 technology library. The experimental results are presented in Table I, which summarizes the area (μm^2) and delay (ps) information reported from the mapped netlist. The CPU runtime (Time) is recorded in seconds. The geometric mean (Geomean) and gain (Improvements) of each data point are also presented.

The experiment primarily compares mapping and structural choices algorithms in ABC. We use the netlist results obtained from the command combinations for different mapping objectives in ABC as the baseline. In contrast, *MCH Balanced* creates the choice network based solely on the input AIG, with candidate structures generated through a strategy that combines critical path and non-critical path node classification. Finally, achieving a balanced improvement in the mapping results. *MCH Delay-oriented* adopts a more aggressive strategy. First, it transforms the input AIG into an XAG. Then, it retains the structural advantages of XAG and creates mixed choice networks of XAG and AIG. During the creation of candidate structures, the range of collected critical path nodes is also expanded. Finally, a delay-oriented mapping is performed. *MCH Area-oriented* combines AIG and XMG to create mixed choice networks and performs area-oriented mapping based on MCH.

The results show that *MCH Balanced* achieves a 3.73% area reduction and a 8.94% delay optimization compared to the baseline. In the experiments for delay-oriented and area-oriented mapping scenarios, DCH yields very limited optimization benefits due to structural bias. In comparison, MCH leverages the structural advantages of XAG and XMG, achieving superior mapping results. Specifically, *MCH Delay-oriented* achieves a 20.35% delay improvement while sacrificing only 9.75% of the area. On the other hand, *MCH Area-oriented* achieves a similar area gain to ABC but significantly reduces the delay. This is because MCH utilizes heterogeneous representations to offer more possibilities for mapping. Additionally, although the computation and evaluation of candidate structures slightly increase mapping time. But for the larger circuits such as "Hypotenuse", MCH can achieve more competitive results in a shorter time. This highlights the significant advantage of MCH for large-scale designs.

2) FPGA Technology Mapping: The *EPFL Combinational Benchmark Suite*'s *Best Results Challenge* focuses on obtaining 6-LUT networks with the minimal LUT count. We use this challenge to evaluate the LUT mapping with MCH. Many studies have demonstrated its effectiveness through this challenge[3].

The experiment first converts the existing results into AIG networks using ABC's `strash` command. Note that the AIGs obtained through this conversion contain many redundant structures, and direct mapping of these AIGs yields poorer LUT netlists compared to the original results. We use the converted AIG networks as inputs to create the mixed choice networks. These mixed choice networks retain the original AIG structures while creating equivalent XMG candidate structures. Finally, we perform area-focused LUT mapping on the mixed choice networks.

Table II presents the results of the test cases in which MCH achieved new records. We set new records for the minimum 6-LUT count in four test cases compared to the *best 6-LUT count results of 2023* (Best (2023)) and in three test cases compared to those of 2024 (Best (2024)). Notably, this experiment directly evaluated the effectiveness of the MCH-based mapper without any logic optimization or post-mapping optimization steps.

In this experiment, our method dynamically evaluates the structural features of both XMG and AIG. MCH stores them as selectable substructures, rather than simplifying the entire circuit into a single

B. MCH for Logic Optimization

This section conducts tests on the MCH-based logic optimization algorithm. The experiment selected the graph mapping algorithm from [25] (*Graph Map*) for comparison. The experiment evaluated the logic optimization effect on the XMG network and the LUT mapping results (*LUT Map*) of the optimized network. This experiment is conducted based on the mixed choice networks composed of MIG and XMG. The experiment performed iterative optimization on the logic network until no further improvement could be achieved, assessing the node count and logic level of the optimized XMG network. Subsequently, the optimized network was mapped to 6-LUT network, and the node count and logic level of the LUT network were evaluated.

The experimental results are presented in Fig. 6. Test cases also come from the *EPFL Combinational Benchmark Suite*. The experiments use the results of the original algorithm iterated to a local optimum as the baseline (Baseline). The horizontal and vertical axes represent the improvements in level and node count achieved by our method for the test cases. The blue squares in the figure represent the improvements in graph mapping optimization for each case under the influence of MCH (*MCH for Graph Map*). The red circles represent the improvements for each case brought by the 6-LUT network generated from the optimized XMG using MCH-based LUT mapping (*MCH for LUT Map*). The blue and red star markers represent the geometric mean of MCH's gains for *Graph Map* and *LUT Map*, respectively. It is evident that with the assistance of MCH, most cases exhibit significant improvements. In some cases, after breaking through local optima, certain metrics improve by as much as 30% or more. For some test cases, such as "Round-robin arbiter" and "Square-root", both the node count and level count were reduced by approximately 50%. For *Graph Map*, our method reduced the XMG level count by an average of 18.59% and the node count by 11.56%. After LUT mapping, the 6-LUT level count and node count were further reduced by 4.71% and 7.31%, respectively.

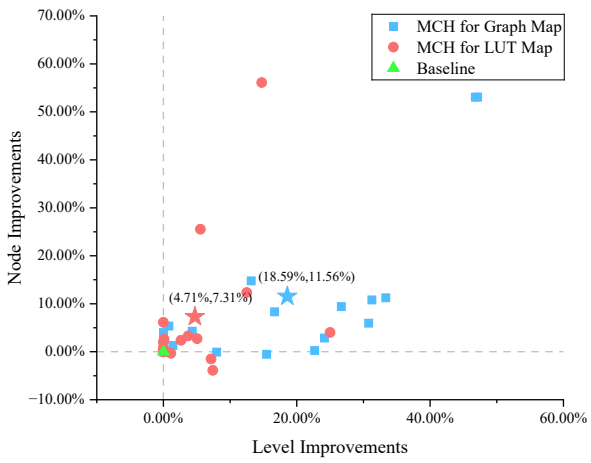

Fig. 6: Experimental results of Graph Map Optimization

V. Conclusion

This paper presents a technology mapping framework based on mixed structural choices operator. The framework introduces mixed structural choices to retain multiple logic representations simultaneously and provides a rich set of candidates through an extensible multi-strategy structural choice method. MCH-based technology mapping effectively combines MCH with technology mapping algorithms, enabling dynamic evaluation of different logic representations and logic optimization candidates based on technology information. Additionally, the framework supports extension to various mapping-based optimization algorithms, helping to overcome the limitations of local optima. The method proposed in this paper is not only of reference value in heterogeneous synthesis and mapping of multi-logic domain, but also in structural bias problems based on structure choices.

***Abstract*—Sparse general matrix-matrix multiplication (SpGEMM) serves as a fundamental operation in real-world applications such as deep learning. Different from general matrix multiplication, matrices in SpGEMM are highly sparse and therefore require a compact representation. This places an additional burden on data preprocessing and exchanging and also causes irregular memory access patterns, which can in turn lead to communication and computation bottlenecks. To break these bottlenecks, we present VSpGEMM, a hardware accelerator for SpGEMM that is tailored and optimized on Versal ACAP. Firstly, a new storage format called BCSX is proposed in VSpGEMM, which offers a unified and block-wise compression strategy to deal with both row-major and column-major representation of non-zero data, enabling fixed-pattern memory accesses and effective data preloading. Secondly, a multi-level tiling mechanism is introduced to decompose the holistic SpGEMM into multiple computation granularities that fit into the AI Engines (AIEs) on Versal in a hierarchical manner, enhancing data reuse. Thirdly, a hybrid partitioning scheme is presented to orchestrate both the AIEs and programmable logic (PL) for intermediate product merging, which together resolve the issues of high memory utilization and communication demand. Experimental results demonstrate a 2.65× speedup over state-of-the-art (SOTA) GEMM design on Versal and an average 33.62× improvement in energy efficiency compared to cuSPARSE on RTX 4090 GPU, showing the efficacy of VSpGEMM.**

I. Introduction

General matrix-matrix multiplication (GEMM) is a widely used operation defined as $A \times B = C$, characterized by accessing matrices A and B in a fixed pattern. However, in many real-world applications, matrices usually have high sparsity, meaning most elements are zeros. In these cases, the conventional GEMM solution becomes inefficient due to the large number of redundant computations performed on zero elements. This inefficiency highlights the need for SpGEMM, where the matrices involved in the computation are sparse. SpGEMM must handle non-zero elements with random spatial locations, which poses challenges including the increased communication overhead of transferring intermediate products and the limited computational intensity with unpredictable memory access to index the non-zero elements from compressed matrix elements, which can severely slow down the applications.

In academia, some methods have been proposed to accelerate SpGEMM on different hardware platforms, including CPUs [1], [2], GPUs [3]–[6], and FPGAs [7], [8]. These solutions mainly focus on the optimization of three aspects, namely, storage formats for storing and indexing sparse matrices [9], algorithms to perform matrix multiplication [10], and workload distribution methods [11]. CPUs and GPUs offer flexible control units and parallelized computation cores to optimize SpGEMM in all computation phases, but they incur high power consumption, which undermines energy efficiency. FPGAs enable customized operations for indexing elements from storage formats but they are limited by on-chip resources when the problems become complicated. Recently, AMD/Xilinx introduced the Versal Adaptive Compute Acceleration Platform (ACAP) [12], a heterogeneous system composed of AI Engines (AIEs), programmable logic (PL), and a processing system (PS). This platform excels in delivering flexible customization for hardware implementation, with computationally intensive multiplications handled by high-performance AIEs and complex control logic managed by PL, which is a promising substrate for efficient SpGEMM implementation.

Despite the high computational power provided by Versal, accelerating SpGEMM on Versal is non-trivial. The recent work CHARM [13] has proposed an efficient method to accelerate GEMM on Versal, which leverages the regular data access patterns of GEMM to achieve efficient pipelining. Nevertheless, new challenges arise when the matrices become sparse. The first challenge lies in excessive memory access to the local memory of AIEs, where the predominant row-wise computation pattern under compressed sparse row (CSR) or compressed sparse column (CSC) format contributes to irregular and unpredictable data accesses, leading to poor data reuse and avoiding data preloading when indexing in the AIE memories. Second, the limited bandwidth in Versal and the high communication demand of transferring intermediate products of SpGEMM can trigger a communication bottleneck, severely hampering overall performance.

To fully unleash the computational power of Versal for SpGEMM acceleration, we propose three innovative optimization strategies: a new compressed storage format for efficient data processing, a multi-level tiling scheme for scalable matrix decomposition, and a hybrid workload partitioning scheme to coordinate different computation resources. These strategies collectively facilitate parallelism of computation, enhance memory management, and reduce communication overhead, finally delivering salient gains in performance and energy efficiency over existing SpGEMM implementation on mainstream computation platforms. The contributions of this paper are summarized as follows:

†Corresponding author

- We introduce a new compressed storage format, BCSX, unifying the representation of CSR and CSC in blocks. This storage format enables fixed-pattern data accesses, preserves high data locality, and supports data preloading.
- We propose a multi-level tiling scheme to hierarchically distribute the computation of SpGEMM to multiple AIEs while enhancing data reuse during computation.
- We develop a hybrid workload partitioning method that efficiently allocates the intermediate product merging operations to AIEs and PL, ensuring minimal communication overhead.
- To the best of our knowledge, we present the first attempt to optimize SpGEMM on Versal ACAP, finally achieving a 2.65× speedup over CHARM on Versal and a 33.62× energy efficiency gain against cuSPARSE on the RTX 4090 GPU.

II. Related Work

Previous works on accelerating SpGEMM using GPUs, CPUs, and FPGAs have proposed various optimizations, including hash tables and the ESC method. However, these approaches often suffer from poor data locality or high communication overhead. For instance, the work [5] on NVIDIA Pascal GPUs reduces scratchpad memory by grouping matrix multiplication (MM) computation tasks and predicting memory size for output matrices. However, it incurs significant overheads from probing hash tables and repeatedly accessing discontinuous memory under the CSR format. The ESC method [14] enhances the parallelism of GPU cores by merging the sorted, index-adjacent MM results, but it faces substantial communication overhead due to the transfer of intermedia products generated during the expansion stage of ESC. FSpGEMM [8] improves data reuse in Gustavson's method [15] with row-wised computation pattern by introducing the compressed sparse vector (CSV) format and a row reordering strategy, maximizing on-chip resource utilization on FPGAs. Nonetheless, the CSV format does not fundamentally eliminate the overheads brought by the row-wised computation pattern, and the row reordering strategy introduces additional computational overhead. HASpGEMM [16] improves workload balance concerning computation and memory access through a micro-benchmarking scheme on asymmetric CPUs but remains constrained by the overheads inherent in the row-wise pattern. In summary, existing methods on SpGEMM acceleration still do not effectively address the problems of high communication costs and random memory access during computation.

On the Versal platform, CHARM [13] is the SOTA work on accelerating GEMM across all heterogenous conponents of Versal, whereas it still struggles with sparse matrix processing. This is because the inherent strategies to process the dense matrices are incompatible with sparse matrix operations that primarily involve compact data representations with non-zero elements. In contrast, our approach seeks to establish fixed memory access patterns and reduce communication overhead for exchanging intermediate products in SpGEMM, which are essential for efficiently processing sparse matrices.

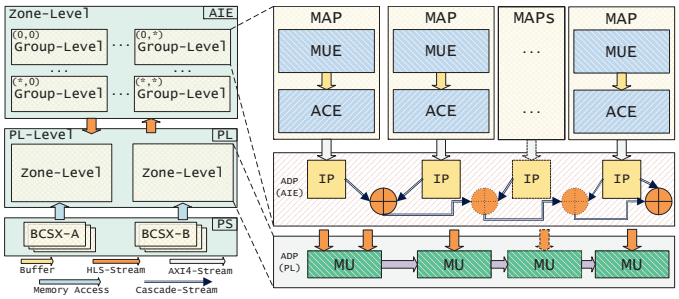

Fig. 1 Architecture of VSpGEMM

III. Versal ACAP Architecture

The Versal ACAP is a heterogeneous platform that integrates AIEs, PL, and PS with a Network on Chip (NoC). The AIEs consist of very-long instruction word (VLIW) processors equipped with single instruction multiple data (SIMD) vector units, operating at a maximum frequency of 1.25 GHz, enabling high parallelism for computation-intensive applications. Each processor in the AIEs is denoted as an AIE tile, which comprises an AIE core for computation, a data memory for program storage and caching, and an AXI4-Stream switch [17] for stream access to the data memory.

Communications within the AIEs are categorized into two types: buffer-based access and stream-based access. The local data memory inside the AIE tile is composed of eight memory banks, allowing for horizontal or vertical data access to neighboring tiles. This configuration provides a four-way memory access which exposes four data memories to one AIE tile. The AXI4-Stream switches divide stream-based access into two modes: cascade-stream for horizontally adjacent tiles and normal streams for all tiles. Notably, the cascade-stream offers a 384-bit data width to transfer large data in one single clock cycle, while normal streams merely support a 32-bit data width per cycle. The PLIO interfaces are responsible for the communication between AIE and PL, each of which offers eight 64-bit output channels and six 64-bit input channels operating at the PL clock frequency, totaling 1.2 TB/s for VCK190 with 39 PLIOs. Data transmission between the PS and PL should use DDR memory as an intermediate buffer and the bandwidth is 100 GB/s. Consequently, a communication gap arises between the high performance of AIE tiles and the limited PLIO and DDR bandwidth, which could become a bottleneck to deploying applications on Versal.

IV. Design Methodology

In this section, we introduce the acceleration paradigm, VSpGEMM, whose overall architecture is depicted in Fig. 1. It decomposes the holistic computation process of SpGEMM into two types of partitions: the MAC-Partition (MAP) and the hybrid ADD-Partition (ADP).

The MAP conducts MMs at a fine-grained level, while the ADP merges the intermediate products to form the final results at a coarse-grained level. Based on this, the MAP can be further divided into a multiplication engine (MUE) and an accumulation engine (AUE) to perform the outer product for SpGEMM, which constitutes the main part of MM. The

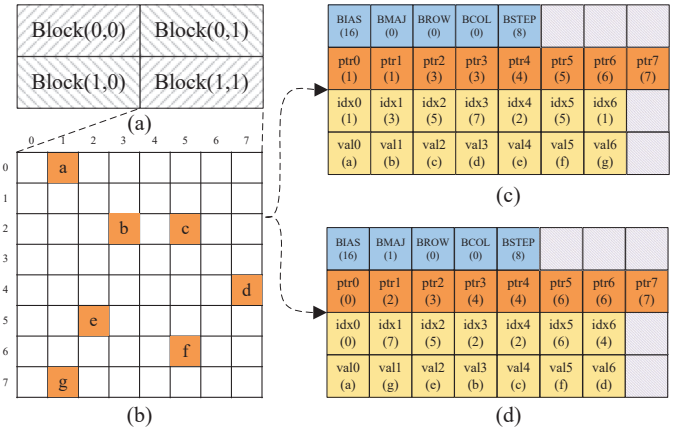

Fig. 2 BCSX Storage Format: (a) The structure of block-wise matrices in BCSX format in memory. (b) The matrix Block(1,1) in 2D dense form. (c) The BCSX format of Block(1,1) in row-major. (d) The BCSX format of Block(1,1) in column-major. Attribute descriptors in BCSX are marked in blue, pointers in red, and indices and values in yellow.

hybrid ADP is designed to be conducted partially in AIEs and PL to minimize the transmission of intermediate products generated by MAPs. The complete architecture of VSpGEMM is supported by the proposed BCSX storage format, multi-level tiling scheme, and hybrid workload partitioning strategy.

A. BCSX Storage Format

The commonly used storage formats like CSR and CSC form the foundation of various works on SpGEMM since they preserve row-wise and column-wise data locality, respectively. The prior arts attempt to use a single storage format to construct the two input matrices (denoted as A and B), and adopt Gustavson's algorithm for SpGEMM. In such cases, although matrix A exhibits high data locality, matrix B usually experiences irregular and unpredictable memory accesses, preventing effective memory optimizations such as data preloading and reuse. Moreover, CSR and CSC are monolithic representation methods that compress the entire matrix at once, making it difficult to partition and distribute computation workloads to hardware resources at a fine-grained level. To address these issues, in this paper, we propose a new storage format called Blocked Compressed Sparse eXtension (BCSX). This storage format aims to merge the strengths of these conventional storage formats, offer a consistent storage method for both row- and column-major representations, and facilitate data access in a regular and block-wise pattern. In the rest of this section, we illustrate the details of the BCSX format, the implementation of BCSX on AIE, and the memory access patterns supported by BCSX.

Construction of BCSX Format. BCSX utilizes five descriptors named BIAS, BMAJ, BROW, BCOL, BSTEP, and three arrays named idx*, ptr*, and val* to capture the structural information and non-zero elements in a per-block manner. Fig. 2 demonstrates BCSX with an 8×8 matrix as an instance.

The five descriptors identify the arrays in matrix blocks from memory and facilitate vectorized loading. The BIAS serves as a relative offset of the idx* array to the memory address of the current block. The BMAJ is a binary value that specifies whether the matrix is constructed in row-major (0) or column-major (1) order. When both the input matrices A and B are constructed in row-major order with BMAJs set to 0, a row-wise computation pattern is enabled. If the two BMAJs are set to 1 and 0 respectively, an inner product method can be applied. Conversely, when the BMAJs are set to 0 and 1, the outer product can be conducted, which is the adopted algorithm in this paper. With BMAJ to indicate the order, all computation patterns can be flexibly supported. The BROW and BCOL reveal the spatial coordinates of the current block within the entire sparse matrix, aiding both AIE and PL in organizing matrix blocks for multiplication and merging. The BSTEP determines the vector length of AIEs to fetch data from data memory, which could be adjusted in light of matrix sparsity and workload for a single AIE tile, thus enabling a dynamic load step for AIE tiles working on various matrix blocks.

TABLE I Features of BCSX compared to CSR and CSC

Storage Format \ Memory Access	Row Major	Column Major	Block-wise Structrue	Vectorized Loading
CSR	✓	×	×	×
CSC	×	✓	×	×
BCSX	✓	✓	✓	✓

The ptr* array records the number of non-zero elements in each line of the current block. Specifically, each element of ptr* records the cumulative number of non-zeros for the current and preceding rows or columns. The idx* and val* arrays store all the non-zeros of the current block in BMAJ order, with each element in these two arrays corresponding one-to-one.

Vectorized Loading on AIE. Different from CSR and CSC, BCSX skips the prefix 0 and captures the exact number of rows or columns in blocks to facilitate vectorized loading in AIE kernels. Within each AIE tile, memory access to BCSX for blocks in B is vectorized, which loads data in vectors of length BSTEP, which is a power of two. However, the prefix 0 in conventional formats impedes data alignment because the length of ptr* becomes non-divisible by a vector step, requiring an extra load to fetch the last few ptr* entries. In an AIE tile, the iterator for vector can only iterate at an entire vector step, causing misalignment when loading ptr* and leading to incorrect vector iterator for the idx* and val* arrays. To enable efficient vectorized loading in AIE tiles, BCSX eliminates the prefix 0, records the vector step in descriptor BSTEP, and utilizes the BIAS descriptor to mark the relative starting address of the idx* array, ensuring an aliquot length of ptr* for efficient vectorized loading. In general, BCSX facilitates MMs on AIEs with the features shown in TABLE I.

Memory Access Patterns with BCSX. Suppose the input matrices are in square with non-zeros uniformly distributed across rows and columns, and let NNZ denote the average number of non-zeros per row. In row-wise production, as illustrated in Fig. 3(a), to calculate row $C_{(0,*)}$ of matrix C, the non-zeros $A_{(0,0)}$ and $A_{(0,2)}$ in row $A_{(0,*)}$ are loaded. For each non-zero in row $A_{(0,*)}$, the corressponding rows $B_{(0,*)}$ and

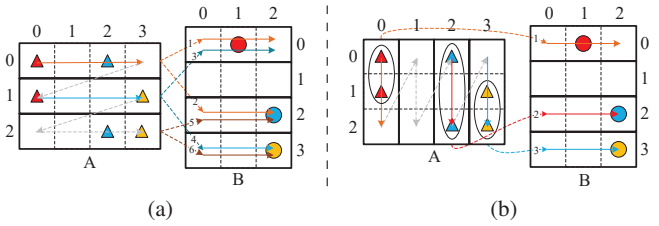

Fig. 3 Memory access patterns of two representative SpGEMM algorithms: (a) Gustavson's method; (b) Outer product. Gustavson's method involves six irregular memory accesses to matrix B, while the outer product has only three accesses in a fixed pattern with data locality.

$B_{(2,*)}$ are loaded as multipliers. Similarly, while calculating row $C_{(1,*)}$, row $B_{(0,*)}$ and $B_{(3,*)}$ are loaded, resulting in worse performance due to the random and discontinuous accesses to the same row $B_{(0,*)}$, preventing data preloading in AIE kernels, since the indexing of those non-zeros in matrix A is non-prior knowledge to AIEs. In contrast, the memory access becomes regular by using BCSX, as illustrated in Fig. 3(b), with each column $A_{(*,k)}$ and corresponding row $B_{(k,*)}$ loaded simultaneously for calculating the output matrix C. This allows non-zero $A_{(0,k)}$ and $A_{(1,k)}$ from $A_{(*,k)}$ to get multiplied by vector $B_{(k,*)}$, creating fixed memory access patterns to column $A_{(*,k)}$ and row $B_{(k,*)}$ due to the prior knowledge of k that is considered in design, which enables data preloading for columns in A and rows in B, thus opening up new opportunities for performance improvement.

B. Multi-Level Tiling Scheme

We propose a multi-level tiling scheme that distributes the computation workload of SpGEMM to PL and AIEs. The key idea is to fully utilize the computation power of AIEs to perform multiplication and addition operations at a fine-grained level while taking advantage of the abundant memory resources of PL to accomplish the merging of intermediate results at a coarse-grained level. This tiling scheme can significantly reduce the *reuse distance* [18] of matrix elements from a matrix scale to a block scale, thereby enhancing performance by minimizing redundant data transfers. It is worth noting that the proposed tiling process is performed hierarchically, progressively breaking down the SpGEMM computation from the PL level to the zone level, then to the group level, block level, and finally, the kernel level, as shown in Fig. 4.

PL- and Zone-Level Tiling. Originally, matrix A with the size of $M \times K$ and matrix B with the size of $K \times N$ are stored in DDR in the BCSX format at a PL level. Matrix A and B are then divided into $PX \times PZ$ and $PZ \times PY$ zones, respectively, where each zone is transferred from DDR to on-chip BRAMs of PL and then mapped to the AIEs. As shown in Section III, the bandwidth of DDR is much smaller than that of the PLIOs. Hence, we allocate ping-pong BRAMs to store the zone data for both of the input matrices, as shown in Fig. 5. Specifically, one BRAM acts as a ping buffer to receive a zone from DDR, while the other functions as a pong buffer to produce a zone for AIEs, allowing parallel communication between DDR and PL, as well as between PL and AIEs.

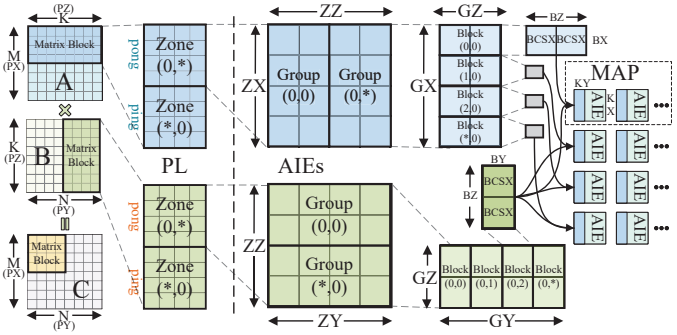

Fig. 4 Multi-Level Tiling Scheme across AIEs and PL

Group-Level Tiling. We further divide the zones into smaller groups to enhance the parallel execution of AIEs. We note that the size of a zone may exceed the capacity of the AIE array. Therefore, the zones of matrix A and B are subdivided into $\frac{ZX}{GX} \times \frac{ZK}{GK}$ and $\frac{ZK}{GK} \times \frac{ZZ}{GZ}$ groups, respectively, where each group corresponds to a group-level region on AIEs. To obtain the result $Group_{(0,0)}$ for zone C, all groups from A and $ZZ \times Group_{(*,0)}$ from B must be sent to the AIEs. Consequently, these groups from zone B need to be transferred ZZ times to get multiplied with all the groups from zone A. Hence, using the on-chip BRAMs to store all groups of zone B, the entire ZZ times of accesses could be reused, avoiding repetitively loading data from the DDR in the monolithic methods. Furthermore, these groups of zone B need to get transferred to AIEs ZZ times as well, which heavily increases the communication burdens. Therefore, on the zone level, we utilize circuit switches to broadcast the $Group_{(*,0)}$ to group-level tiles on AIEs simultaneously, achieving an ZZ-fold data reuse ratio compared to non-titling scenes.

Block- and Kernel-Level Tiling. Matrices A and B at the group level are further divided into $GX \times GZ$ and $GZ \times GY$ blocks, respectively, where data accesses to A are column-wise and to B are row-wise at the block level. Finally, the blocks are then divided into kernel-level tiles, and the outer product method is performed at this fine-grained level. To be more specific, the outer product at the kernel level can be reduced to the scalar-vector multiplications using elements in columns from A and corresponding rows from B in a predetermined execution order. This approach boosts the computation efficiency of AIE cores by facilitating data reuse in a fixed pattern.

Again using Fig. 3(b) as an example, to complete the outer product, matrix A follows a per-column data fetching pattern. Both the two elements in the first column of A are fetched and multiplied with the element in the first row of B (marked as red triangles for A and circles for B, respectively). Since the access pattern is determined beforehand, the first row of B only needs to be fetched once, whereas the Gustavson's computation pattern shown in Fig. 3(a) necessitates fetching the same row of B multiple times. For instance, the first row of B should be multiplied with both the first element in the two rows of A. However, this is a random way of fetching the rows in B due to the inherent irregularity of the spatial distribution of non-zeros from rows of A in Fig. 3(a), thus impeding data reuse. In summary, our method subtly leverages

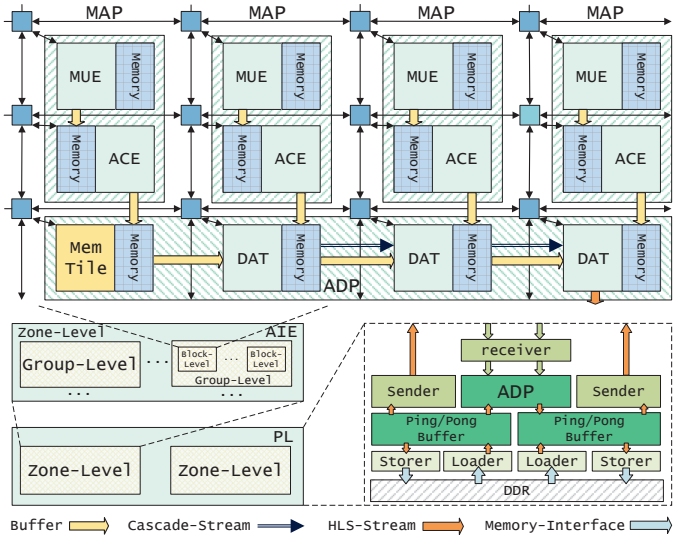

Fig. 5 Hybrid ADD-Partition on AIEs and PL

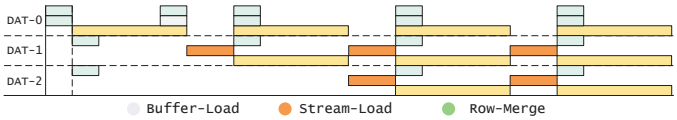

Fig. 6 Pipeline model of DATs

both the fixed memory access pattern enabled by BCSX and the outer product method of MM to maximize the data reuse during the data fetching of matrices A and B at the kernel-level.

C. MAC-Partition and Hybrid ADD-Partition

The MM of $A_{M\times K} \times B_{K\times N}$ generates K batches of intermediate products (IP), which are sent to adders to be merged into the final results. We design MAPs on AIEs to perform detailed MMs using the outer product method with the support of BCSX. Nonetheless, merging all IPs to standalone adders within AIEs is impractical due to limited data memory and communication bandwidth for non-neighboring AIEs. The situation gets exacerbated when performing all the merges with frequent data transfers via the PLIOs between AIEs and PL. To address these issues, we propose the hybrid ADP to perform partial merges at fine-grained levels within AIEs to reduce the size of IP locally. The remaining merge operations are completed on PL to leverage the large on-chip memory, thereby further reducing the communication burden.

MAC-Partition on AIEs. The MUE at the kernel level produces sparse vectors, composing at most K batches of IPs with the size of $M \times N$ when both the column from A and the corresponding row of B contain non-zeros. Once a batch of IP is produced, it is transferred to the ACE through AXI-Stream. The ACE accumulates the IPs to the data memory on the local AIE tile to form the first-stage IPs. Since the MUE and ACE are physically adjacent to AIEs, compared to transferring IPs entirely to PL through PLIOs or accumulating entirely on AIEs, the adjacent AXI-Swithes enable fewer cycles for moving IPs to accumulators, significantly reducing communications latency. Besides merging operations in the accumulating stage, combining corresponding blocks for a result matrix requires additional transfers and data memory as well. Therefore, we propose the hybrid ADP to address this.

ADD-Partition on AIEs. As illustrated in Fig. 5, each ADP is positioned vertically above or below a MAP, where the MAP shares the same memory bank with the ADP to achieve maximum bandwidth in AIEs. Inside each ADP, dense accumulation tiles (DAT) are connected in cascade-stream to combine rows of each matrix simultaneously. Specifically, the first-stage IPs in the output from the first two MAPs are input into the first DAT through a single cycle load via buffer-based communication manner. Subsequent DATs receive one IP stored in a shared memory bank from MAP and accept rows for accumulation from the cascaded proceeding DATs, providing high communication bandwidth. The first DAT queries two IPs for merging and utilizes an additional neighboring AIE tile as shared memory storage, allowing parallel operation of these chained DATs. Consequently, the pipeline of this IP merging scheme at the kernel level is presented in Fig. 6. For each block level in AIEs, the ADP merges BZ blocks with $(BZ-1)$ DATs and outputs one block as the second-stage IP to PL, reducing the communication amount of IPs at a fine-grained level.

ADD-Partition on PL. On the PL side, ADPs are instantiated in multiple Merging Units (MU). For each zone-level second-stage IPs produced from AIEs, MUs in ADPs of PL receive $(ZX \times ZZ \times ZY) \times (GZ \times GY)$ block-level IPs for merging, which operate sequentially with ping-pong buffers as illustrated in Section IV-B. The MUs are chained in a dataflow manner, with the header MU merging two IPs in row order, simultaneously forwarding the sum of each row to the next MU as an augend. This enables ADP on PL with the initiation interval (II) = 1, which allows for a minimum number of clock cycles between successive loop iterations, facilitating continuous data processing without stalls. Under the cooperation of ADPs across AIEs and PL, we achieve low latency with reduced communication burdens in merging IPs.

V. EXPERIMENTS

We evaluate the performance, power consumption, energy efficiency, and latency of VSpGEMM. To demonstrate the effectiveness of VSpGEMM, we compare our results with the SOTA work CHARM on Versal ACAP and the cuSPARSE library on NVIDIA GPUs.

A. Experimental Setup

For experiments on the Versal ACAP, we use the VCK190 toolkit to evaluate VSpGEMM and CHARM. These experiments are built with Vitis 2024.1, and results are collected from an onboard testbench. We set the PL running at 250 MHz and the AIEs at 1.25 GHz, and use BEAM Tool [20] and xbutil [21] to evaluate the onboard power of VCK190. For comparisons with cuSPARSE, the experiments are conducted on an NVIDIA RTX 4090 GPU with CUDA 12.6 and an Intel Xeon Platinum 8375C CPU with 128 cores at 3.5 GHz for the host-side program. We use nvidia-smi [22] to evaluate the power of the RTX 4090. Additionally, iterations for all of these experiments are configured for more than one minute to obtain a stable performance at runtime.

We utilize datasets with sparse matrices from the SuiteSparse Matrix Collection [23], and we assume that matrices are pre-stored in the BCSX format, similar to the work on GPU [24]. The CHARM implementation was initially based on Vitis 2021.1, where some AIE APIs are deprecated, and the AIE clock operates at a maximum of 1.0 GHz, different from Vitis 2024.1, which operates at 1.25 GHz. Therefore, we port CHARM to Vitis 2024.1 to ensure a fair comparison.

B. Evaluation of Performance

In this experiment, we evaluate the performance of VSpGEMM and compare our results with the SOTA GEMM implementation on Versal, the CHARM [13] framework. The AIE kernels in VSpGEMM are currently implemented using the INT16 datatype, so we limit the values in datasets to the range of 16-bit integer for both input and output while maintaining the original spatial distribution of non-zeros. VSpGEMM schedules the number of MAPs based on the size of input matrices to efficiently utilize AIE tiles while maintaining high communication efficiency within MAPs. In current settings, the zone on AIEs performs SpGEMM with two maximum matrix dimensions of 256 or 384 per iteration, which are mapped to 176 or 264 AIE tiles respectively. VSpGEMM determines the usage of AIE tiles according to the input matrix size that is closest to the multiples of these two maximum dimensions, ultimately achieving optimal tile utilization. The experimental results are shown in TABLE II. As can be seen, for smaller matrices, VSpGEMM utilizes fewer AIE tiles because the dimensions of each level in tiling are small, which can fit into one single MAP. As the problem size increases, a large number of MAPs are mapped into AIEs and a higher level of parallelism is achieved, resulting in a performance boost. We can observe that VSpGEMM consistently outperforms CHARM on different problem sizes, achieving an average speedup of 2.65×.

C. Evaluation of Energy Efficiency

We investigate the latency, power, and energy efficiency of VSpGEMM, with a comparison to cuSPARSE [19] and CHARM [13]. Given that cuSPARSE does not support INT16 datatype, we set the datatype of cuSPARSE to FP32 to perform the calculation. The latencies of VSpGEMM and CHARM both increase as the matrix scale increases, while the latency of cuSPARSE decreases due to the low utilization of SMs on GPU at small matrix scales. For all problem sizes, VSpGEMM achieves the lowest latency and outperforms the CHARM on Versal and the cuSPARSE on GPU, which fully justifies the capability of the Versal platform on SpGEMM acceleration.

The power consumption of VSpGEMM is primarily composed of AIE cores, the PL domain, and the PS domain [25]. Among all the platforms, VSpGEMM achieves the lowest power consumption of 15.45W on the problem size of 115×115. Moreover, VSpGEMM demonstrates the highest energy efficiency among all the problem sizes, with an average energy efficiency gain of 33.62× and 2.74× compared to cuSPARSE and CHARM, respectively. Therefore, the experimental results show that VSpGEMM can achieve high performance and high energy efficiency at the same time, which is an ideal solution for real-world applications, especially on edge devices that have a stringent requirement for energy efficiency.

VI. Conclusion

In this work, we design VSpGEMM, an accelerator framework for SpGEMM on Versal ACAP. We introduce the BCSX format, a unified compressed storage format for storing sparse matrices in a block-wise row or column-major order, facilitating efficient memory access patterns with efficient data preload. We also propose a multi-level scheme under BCSX to enhance data reuse across AIEs and PL hierarchically. Additionally, the hybrid ADD-partition method is developed to reduce communication overhead for intermediate products. As a result, our approach achieves an average speedup of 2.65× compared to CHARM and a 33.62× energy efficiency gain compared to cuSPARSE.

3D-Flow: Flow-based Standard Cell Legalization for 3D ICs

Yuxuan Zhao, Peiyu Liao, Bei Yu
Department of Computer Science and Engineering
The Chinese University of Hong Kong

***Abstract*—The standard-cell placement legalization is a critical step in the physical design. The emerging 3D ICs have brought challenges to traditional legalizers on efficiency and effectiveness. In this work, we present a fast flow-based legalization algorithm, 3D-Flow, that minimizes cell displacement in a 3D solution space. Our legalizer resolves overflowed bins by finding the shortest augmenting path on a 3D grid graph, utilizing an effective branch-and-bound algorithm. Moreover, a post-optimization with a cycle-canceling algorithm is proposed to minimize the maximum displacement. Our approach leverages the global perspective inherent in network flow methods, considering multiple dies in 3D ICs to minimize cell displacement. Experimental results on ICCAD 2022 and 2023 contest benchmarks demonstrate our proposed algorithm achieves up to 13% and 43% less average and maximum cell displacement compared to state-of-the-art legalizers in a similar runtime.**

I. Introduction

Placement legalization is a critical step in the physical synthesis flow. It is typically invoked after global placement and timing optimization, such as gate sizing and buffer insertion, which may compromise the legality of a placement. An ideal legalization algorithm removes all overlap of instances while preserving the quality of the given placement. As technology scaling approaches its physical limits, 3D integrated circuits (3D ICs) [1] have emerged as a viable solution for extending Moore's Law. The vertical stacking of multiple dies in 3D ICs introduces new challenges and optimization opportunities for legalization algorithms.

Existing legalization algorithms can be broadly categorized into two types: *greedy search* and *formal optimization*. Most legalizers [2]–[5] fall into the former category, sequentially moving cells to the nearest free locations. Typically, the sequence of movement is determined by the cells' x-position, arranged in either ascending or descending order. A notable example of this approach is Tetris [2], which has been widely adopted in modern placement tools [6], [7]. Abacus [4] follows a similar procedure as Tetris, but moves the cells already legalized in a row by dynamic programming to minimize the total movement. While the greedy approaches are fast and flexible, they can result in excessive cell displacement, especially in designs with high utilization or blockages caused by macros.

In contrast, formal optimization approaches model placement legalization through mathematical formulations such as network flow [8]–[12] or diffusion [13]. Specifically, the diffusion model [13] employs force-directed methods to globally reposition cells. In flow-based methods, legalization is modeled as a minimum-cost flow problem, where cells are moved from source bins to sink bins, resolving overflow with minimal cell movement. If all cells are of uniform size, the problem can be efficiently solved in polynomial time [8]. However, real-world designs have cells with different sizes, necessitating a flow realization step in these approaches. Cho *et al.* [9] introduce a history-based legalization algorithm that incorporates history data into the cost formulation to avoid unfeasible flows. Inspired by the successive shortest path algorithm [14], BonnPlaceLegal [10] ensures that only flow augmentations, which can be realized exactly by cell movement, are considered. The algorithm iteratively computes the shortest paths from source bins to sink bins using Dijkstra's algorithm. While this approach achieves satisfactory cell displacement results, the iterative calls to Dijkstra's algorithm make it unscalable for large designs. To improve efficiency, Darav *et al.* [11] propose utilizing the breadth-first search (BFS) algorithm to identify multiple candidate paths. Although this algorithm is robust and efficient, it may result in large total cell displacement as it does not consider the cost when selecting the augmenting paths. Innovations are needed to balance the trade-off between solution quality and efficiency in formal optimization approaches.

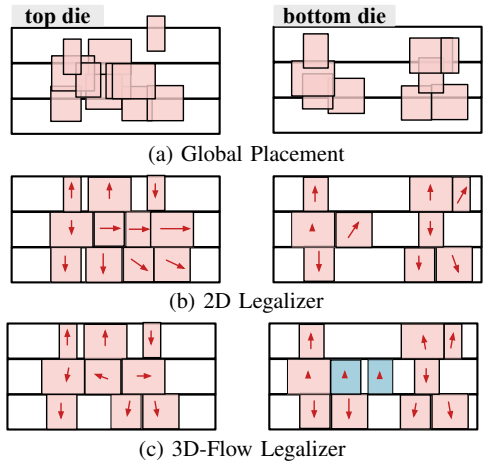

Fig. 1 Motivation for 3D-Flow legalizer. Global placement (a) is given for a 3D IC with two dies. (b) and (c) show legal placements, with red arrows indicating the cell displacement between global and legal placements. By moving two **blue**-colored cells (c) from the top to the bottom die, our 3D-Flow legalizer achieves reduced displacement.

In the context of 3D placement, placers need to determine both cell positions and cell partitioning to optimize design objectives. Pseudo-3D placers [15], [16] separate the partitioning and placement phases. They utilize 2D placement tools to determine cell positions while employing either partitioning-first [15] or partitioning-last [16] flows to perform the die assignment. In contrast, true-3D placers [17]–[20] relax discrete die partitioning constraints and adopt analytical approaches to simultaneously optimize cell partitioning and positions in a 3D solution space. Recent studies demonstrate the superiority of true-3D placers, as they explore a larger solution space. However, legalization algorithms are overlooked in existing true-3D placers. The state-of-the-art (SOTA) true-3D placers [18], [19] greedily assign cells to the nearest die after global placement and then legalize the placement with fixed die assignments using traditional 2D legalizers [2], [4]. However, legalizing the placement in a 3D solution space will produce results with higher quality. Fig. 1 shows an example that by moving cells across the dies, the total displacement and maximum displacement can be significantly reduced at the legalization stage for 3D ICs.

In this work, we present a fast flow-based legalization algorithm for 3D ICs. Our approach leverages the global perspective inherent

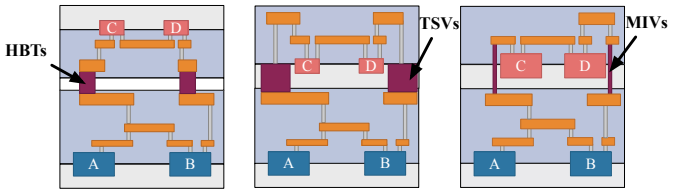

Fig. 2 The typical types of 3D ICs. (a) F2F bonded 3D ICs enable heterogeneous technology integration without space crowding on the silicon layer. (b) TSVs occupy large silicon area, resulting in low integration density. (c) Monolithic 3D ICs require sequential fabrication with low yield.

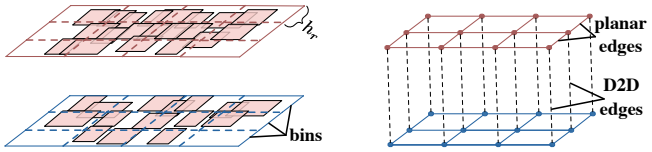
in network flow methods, considering multiple dies in a 3D solution space to minimize cell movement. Our contributions are summarized as follows.

- We propose the first 3D legalizer, 3D-Flow, to minimize cell displacement in a 3D solution space for 3D ICs using network flow methods.
- We resolve overflowed bins by finding the shortest augmenting path on a 3D grid graph, utilizing an effective branch-and-bound algorithm. A post-optimization with cycle-canceling is proposed to reduce maximum displacement.
- Experimental results on ICCAD 2022 and 2023 contest benchmarks demonstrate 3D-Flow achieves up to 13% and 43% less average and maximum displacement compared to SOTA 2D legalizers in a similar runtime.

II. Preliminaries



A. 3D ICs

3D integration enables higher transistor density on the silicon and replaces the long 2D interconnects with shorter inter-die connections. There are mainly three types of 3D ICs: through-silicon-via (TSV) based, monolithic, and face-to-face (F2F) bonding. Fig. 2 illustrates the 3D stacking for typical 3D ICs.

TSVs [21] occupy a significant amount of silicon area and introduce large parasitics, limiting TSV-based 3D ICs to a few inter-die connections. While monolithic inter-tier vias (MIVs) exhibit nanoscale sizes and enable fine-grain 3D interconnects, monolithic 3D ICs [22] require sequential fabrication of multiple dies, resulting in low yield and high cost. F2F bonded 3D ICs [23], [24] consist of two prefabricated dies, where the top die is flipped and stacked on top of the bottom die using hybrid bonding terminals on the topmost metal layers. The ease of fabrication and small size of bonding terminals enable a high integration density at a low cost. Additionally, prefabricated dies can adopt different technology nodes to achieve cost-effective performance, making F2F bonding a preferred approach. Recent ICCAD contests [25], [26] have addressed 3D placement for F2F bonded 3D ICs with heterogeneous technology integration. Therefore, we evaluate our 3D-Flow legalizer in F2F bonded settings, but our legalization algorithm is sufficiently general to apply to other types of 3D ICs with more than two dies.

B. Flow-based Legalization Formulation

We focus on standard cell legalization after global placement for true-3D placers, where cells are positioned in a continuous 3D space with their die assignments yet to be determined. The macros have been placed on their corresponding dies without any overlap. Specifically, we adopt the F2F bonded stacking specified in the ICCAD 2022 and 2023 contests [25], [26]. The cells must be placed on either the top or bottom die, aligned to placement rows and sites, and without any overlap.

(a) Initial Bin Assignment (b) 3D Grid Graph

Fig. 3 Flow network construction. (a) Cells are assigned to their nearest bins based on global placement. (b) Each bin is modeled as a vertex. Adjacent bins on the same die are connected by planar edges. And the bins on different dies with planar overlap are connected by die-to-die (D2D) edges.

TABLE I The main notations used in this paper.

Notations	Descriptions
C	the set of standard cells (indexed by c)
(x'_c, y'_c)	initial low-left corner of cell c
(x_c, y_c)	current low-left corner of cell c
w_c	width of cell c (w_c^+ for top die, w_c^- for bottom die)
V	the set of bins (indexed by v)
(x_v, y_v)	low-left corner of bin v
w_v	width of bin v
$\Gamma(v)$	the set of (fractional) cells assigned to bin v
$D_c(v)$	displacement of cell c assigned to bin v

The main notations used in this paper are listed in TABLE I. The top and bottom dies are divided into horizontal placement rows with a row height denoted as h_r. Note that if heterogeneous technology integration is adopted, the row heights may differ for the top die (h_r^+) and the bottom die (h_r^-). For simplicity, we will omit the superscript when there is no ambiguity. The height of a standard cell is equal to the height of a row on its corresponding die. We treat the macros as blockages, hence each row may be segregated into several segments. And each segment is divided into uniform bins with a bin width denoted as w_v. Initially, all the movable cells C are assigned to their nearest dies and then to their nearest bins based on the global placement, as illustrated in Fig. 3(a). Cells are allowed to be fractionally assigned to two bins if the bins are on the same die and horizontally adjacent. Hence, the objects that we move are fractional cells $\gamma = (c_\gamma, \rho_\gamma)$, where $c_\gamma = c$ and $\rho_\gamma \in (0, 1]$, and we have $\sum_{\gamma: c_\gamma = c} \rho_\gamma = 1$ for any cell c. We denote the bin set as V. Adjacent bins on the same die are connected by planar edges, while bins on different dies with planar overlap are connected by die-to-die (D2D) edges. Thus, we construct a 3D grid graph $G(V, E)$, as illustrated in Fig. 3(b).

For a bin v, let $\text{cap}(v) = w_v$ represent the free capacity that can be used by standard cells. Based on the initial bin assignment, let $\Gamma(v)$ be the set of fractional cells assigned to bin v. We can compute the total width of fractional cells as $w_{\Gamma(v)} = \sum_{\gamma \in \Gamma(v)} w_{c_\gamma} \times \rho_\gamma$, where w_{c_γ} represents the width for cell c_γ. Then we can define the supply value for a bin v:

$$\text{sup}(v) = \max\{0, w_{\Gamma(v)} - w_v\}, \tag{1}$$

similarly, we define the demand value for a bin v:

$$\text{dem}(v) = \max\{0, w_v - w_{\Gamma(v)}\}. \tag{2}$$

If $\text{sup}(v) > 0$, the bin v is overflowed and is treated as a source bin. If $\text{dem}(v) > 0$, the bin v is treated as a sink bin. The goal is to find an assignment of cells to bins such that no bin is overflowed while minimizing the average and maximum cell displacement.

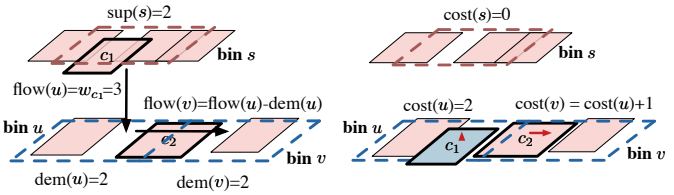
III. Proposed 3D-Flow Legalizer

The overall legalization flow of our 3D-Flow legalizer is shown at the end of this section (Algorithm 2). We first give the mathematical model for flow-based legalization in Section III-A. The core part of our legalizer involves finding the shortest augmenting path on the 3D grid graph using a branch-and-bound algorithm (Section III-B). Our legalizer iteratively augments flows along these paths (Section III-C) to resolve overflowed bins. Once we have determined an assignment of cells to bins, we can legalize all cells within their respective rows (Section III-D). Additionally, our legalizer adopts an incremental legalization step with a cycle-canceling algorithm (Section III-E) to reduce the maximum cell displacement.

A. Legalization as a Minimum-Cost Flow Problem

Based on the flow network $G(V, E)$, we can model the legalization as an assignment problem. The goal is to resolve all overflowed bins while minimizing the total cell displacement. Note that fractional cells are not applicable in this discrete assignment formulation. We should assign the complete cells to their nearest bins. Thus, we use $c \in \Gamma(v)$ to denote a cell c in a bin v instead of fractional cells. Let $S = \{v \mid v \in V, \text{sup}(v) > 0\}$ represent the source bins, and $T = \{v \mid v \in V, \text{dem}(v) > 0\}$ represent the sink bins. Let $R = V - S - T$ denote the remaining bins. We can have the following integer linear programming (ILP) formulation:

$$
\begin{aligned}
\min \quad & \sum_{(u,v)\in E} \sum_{c\in\Gamma(u)} \text{cost}_{u,v,c} a_{u,v,c} \\
\text{s.t.} \quad & \sum_{u\in V} \sum_{c\in\Gamma(v)} w_c a_{v,u,c} - \sum_{u\in V} \sum_{c\in\Gamma(u)} w_c a_{u,v,c} \geq \text{sup}(v), \quad \forall v \in S \\
& \sum_{u\in V} \sum_{c\in\Gamma(u)} w_c a_{u,v,c} - \sum_{u\in V} \sum_{c\in\Gamma(v)} w_c a_{v,u,c} \leq \text{dem}(v), \quad \forall v \in T \\
& \sum_{u\in V} \sum_{c\in\Gamma(u)} w_c a_{u,v,c} - \sum_{u\in V} \sum_{c\in\Gamma(v)} w_c a_{v,u,c} = 0, \quad \forall v \in R \\
& a_{u,v,c} \in \{0,1\}, \quad \forall (u,v) \in E, \forall c \in \Gamma(u),
\end{aligned}
\tag{3}
$$



where $a_{u,v,c} = 1$ indicates the cell $c \in \Gamma(u)$ is moved from bin u to bin v; otherwise, the cell remains in bin u. The cost for such movement is calculated as:

$$D_c(v) = |x_c - x'_c| + |y_c - y'_c|, \tag{4}$$

$$\text{cost}_{u,v,c} = D_c(v) - D_c(u). \tag{5}$$

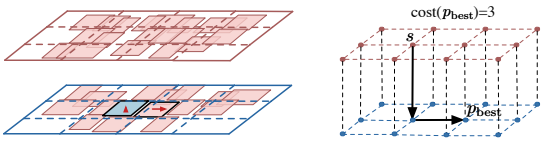
$D_c(v)$ is the estimated displacement when cell c is assigned to bin v. Since bins are aligned to placement rows, we have $y_c = y_v$, y-coordinate of bin v. And x_c is set as the nearest horizontal position within bin v based on the x-coordinate of global placement x'_c. For example, if $x'_c < x_v$, then we have $x_c = x_v$.

According to Equation (3), if w_c is constant for all cells, the optimization problem is a minimum-cost flow problem, which can be solved in $O(|V|\log|V|(|E|+|V|\log|V|))$. However, in practice, we have different cell sizes, resulting in an NP-hard problem. Given the sheer number of cells in modern designs, solving the ILP problem directly is impractical for legalization. One approach is to divide each cell into partial cells with unit width to enable a minimum-cost flow formulation. However, the resulting flow may be unattainable and even misleading [9]. The successive shortest path algorithm for solving minimum-cost flow [14] is appropriate for our application, as we can modify it to ensure that only augmentations that can be exactly realized by cell movements are considered, avoiding the flow realization issue.

(a) Candidate Path (b) Cell Movement

Fig. 4 Path augmentation. (a) Candidate path with corresponding flow. (b) Cell movement with corresponding cost. A candidate path $s-u-v$ for solving the overflow in source bin s is shown in (a). At each step, the cells with minimal cost are selected to move. Since s and u belong to different dies, cell c_1 is moved completely. And u and v are horizontally adjacent, cell c_2 is moved partially to minimize displacement cost.

Algorithm 1 Augmentation with Branch and Bound



Input: Flow network $G(V, E)$, a supply bin s.
Output: The shortest augmenting path p_{best} resolving overflow.

```
1: flow(s) = sup(s); cost(s) = 0; parent(s) = nullptr;
2: visited(s) = true;
3: Q.insert(s)                          ▷ priority queue Q sorted by cost(·);
4: while Q ≠ ∅ do
5:     u = Q.pop()                      ▷ bin u as source bin;
6:     for each bin v connected to bin u do   ▷ bin v as sink bin
7:         if visited(v) then           ▷ visit more than once
8:             continue;
9:         end if
10:        outFlow, cost = computeFlow(u, v);   ▷ Equation (6)
11:        flow(v) = outFlow; cost(v) = cost(u) + cost;
12:        parent(v) = u; visited(v) = true;
13:        if cost(v) < (1 + α)cost(p_best) then;   ▷ set the bound
14:            if flow(v) ≤ dem(v) then;   ▷ a candidate path
15:                if cost(v) < cost(p_best) then
16:                    p_best = v;      ▷ update the shortest path
17:                end if
18:            else
19:                Q.insert(v);         ▷ insert intermediate path
20:            end if

B. Augmentation with Branch-and-Bound

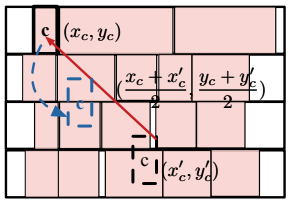
The traditional successive shortest path algorithm [14] begins with a zero flow and iteratively employs Dijkstra's algorithm to identify shortest paths between supply node u and demand node v in the residual graph. However, this approach faces two significant limitations in our application. First, the repeated call of Dijkstra's algorithm becomes computationally expensive for large-scale designs. Second, during iterative optimization, the cost function eq. (5) can yield negative values, indicating that we can move cells toward their initial positions. But Dijkstra's algorithm requires non-negative edge costs. To address these limitations, we propose an enhanced algorithm that combines a modified breadth-first search (BFS) with branch-and-bound techniques to find the shortest augmenting path in the 3D grid graph, achieving high solution quality with better efficiency.

Algorithm 1 presents our path augmentation algorithm. Since our algorithm ensures that each bin is traversed only once (line 7), an n-ary search tree rooted at the supply bin s is constructed during the

(a) Shortest Augmenting Path

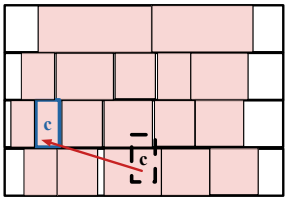
(b) Eliminated Branch

Fig. 5 Augmentation with branch and bound. (a) Augmenting path p_{best} with the smallest cost. (b) Eliminated branch with large cost. Moved cells are highlighted with red arrows indicating displacement. The **blue**-colored cell in (a) is from top die. The intermediate paths with large cost are stopped from being explored.



search process. Each branch of the tree represents a candidate path for moving cells to resolve overflow. For each bin v in the search tree, we define parent(v) as the predecessor of v, flow(v) as the required flow that needs to be moved from bin parent(v) to bin v, and cost(v) as the total displacement cost for the path from root s to bin v. For the root bin s, the required flow is set as the supply value sup(s). Unlike the typical BFS algorithm, we prioritize bins with lower displacement costs when extending the search path (line 5).

A step that is critical for the algorithm is the selection of the set $C(u, v)$ of fractional cells to be moved from u to v in line 10, which should resolve overflow with minimal displacement cost. To ensure that no new overflowed bin is created, we compute the $outFlow$ as follows:



$$outFlow = w_{C(u,v)} \geq \text{flow}(u) - \text{dem}(u), \tag{6}$$

where dem(u) represents the flow that can be sunk by bin u. Thus, $outFlow$ in Equation (6) is the flow that needs to be moved out when flow(u) is moved into bin u. If bins u and v are horizontally adjacent in the same die, we can choose the fractional cell $\gamma \in \Gamma(u)$ with $\rho_\gamma < 1$ to ensure that $w_{C(u,v)} = \text{flow}(u) - \text{dem}(u)$. Specifically, we sort the fractional cells in $\Gamma(u)$ by the cost in Equation (5), which reflects the displacement cost for such movement. The cheapest fractional cells are then selected to reduce their ρ_γ and the path cost is updated accordingly (line 11). On the other hand, if u and v belong to different rows or dies, we can only move cells completely because no cell can be distributed across different segments. Hence, moving γ from u to v means removing all parts of c_γ from their bins (which must be in the same segment as u) and assigning them to v. In these cases, we select the cells such that $w_{C(u,v)} \geq \text{flow}(u) - \text{dem}(u)$ with the lowest displacement cost. If the flow(v) can be completely sunk by bin v, a candidate path for resolving the overflow is found (line 14). An example of one candidate path is illustrated in Fig. 4.

We keep track of the path p_{best} with the smallest cost (line 16). During the search process, any branch with a cost greater than $(1 + \alpha) \times \text{cost}(p_{\text{best}})$ will be eliminated (line 13), where $\alpha \geq 0$, controlling the solution space that our algorithm explores. When $\alpha = 0$, the algorithm becomes a greedy search, including only intermediate paths with costs smaller than the current best cost. Conversely, a large α will cause the algorithm to traverse the entire search tree. Although there are edges with negative costs, such edges are few. Thus, a small $\alpha = 0.1$ can help our algorithm find the shortest augmenting path with great efficiency in practice. Fig. 5 shows an example that a branch with large cost is eliminated.

(a) Negative Cycle

(b) Reduced Displacement

Fig. 6 Post-optimization with cycle-canceling. (a) Negative cycle. (b) Reduced maximum displacement. The black dashed box indicates the initial position. Our algorithm only selects cells with displacement larger than the predifined threshold to move toward their initial positions. Our incremental legalization will reduce the maximum displacement while making minimal perturbation to other cells.

Note that BonnPlaceLegal [10] also adopts a flow-based methodology. However, it utilizes vanilla Dijkstra's algorithm to find the augmenting path on a 2D grid graph, which is not applicable for negative-cost movements. Based on the 3D flow network, our algorithm can move cells freely both intra-die and inter-die to minimize the total displacement with improved computational efficiency.

C. Moving Cells Along Augmenting Path

Once the shortest augmenting path is found by Algorithm 1, the set of fractional cells $C(u, v)$ are moved between the adjacent bins along the path to resolve the overflow. The cell movement is performed by backtracking the path from the leaf bin p_{best} to the root supply bin s. For each current bin v, we apply the same method as in Algorithm 1 to select the set of fractional cells $C(u, v)$ from the parent bin $u = \text{parent}(v)$ with the minimal cost, where $w_{C(u,v)} = \text{flow}(v)$. The procedure repeats until reaching the root supply bin s, thereby resolving the overflow in bin s.

D. Legalization Within a Row

After the flow-based legalization, cells are assigned to bins aligned with placement rows. However, the overlap between cells within a bin may still exist. Many well-known row-based placement algorithms [4], [27], [28] can be used to remove the overlap between cells within a row. We use the `PlaceRow` algorithm in Abacus [4], which efficiently minimizes quadratic cell movement in linear time.

E. Post-Optimization with Cycle-Canceling

At the final step, we propose a post-optimization technique inspired by the cycle-canceling algorithm [29] to minimize maximum displacement. The cycle-canceling algorithm improves the objective function by finding negative cost cycles in the residual graph and augmenting the flow on these cycles. In our application, we construct such negative cycles by moving cells with large displacement toward their initial positions. Specifically, we select the cells with displacement $D_c > threshold$, where $threshold = \max\{5h_r, \frac{D_{\max}}{2}\}$, h_r is the row height and $D_{\max}$ is the current maximum displacement. For each selected cell c, we reposition it at the midpoint between its current and initial positions $(\frac{x_c + x'_c}{2}, \frac{y_c + y'_c}{2})$. This movement may introduce a few overflowed bins, and we perform the flow-based legalization again and remove all the cell overlap. Fig. 6 shows an example of the proposed cycle-canceling algorithm. Our flow-based legalizer enables incremental legalization inherently, therefore, the post-optimization can significantly reduce maximum displacement with minimal perturbation to other cells.

Algorithm 2 3D-Flow Legalizer

```

F. Overall Algorithm

Algorithm 2 provides an overview of the proposed 3D-Flow legalizer. We process all supply bins in descending order based on their supply values. For each supply bin s, we identify the augmenting path with minimal cost using Algorithm 1 and adjust cell positions accordingly to resolve overflow. This process iterates until all overflow is eliminated.

The choice of bin width w_v involves a trade-off between result quality and efficiency. For the flow-based legalization, we set the bin width $w_v = 10\bar{w}_c$ to enhance efficiency, where $\bar{w}_c$ is the average width of all cells. During post-optimization, w_v is reduced to $5\bar{w}_c$ for more precise cost estimation, given the limited number of overflowed bins. Our algorithm is flexible enough to handle various constraints. In heterogeneous technology integration, cell movement across die-to-die edges requires updating cell widths. We manage different widths w_c^+ on the top die and w_c^- on the bottom die, ensuring the utilization rate of each die is not exceeded.

$$\text{cost}_{u,v,c} = D_c(v) - D_c(u) + \text{sup}(v) - \text{dem}(v). \tag{7}$$

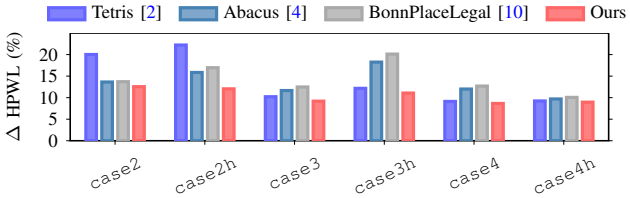
We set the die-to-die edge cost as shown in Equation (7) to encourage cells to move from the congested die while penalizing unnecessary cross-die movements.

IV. Experimental Results

A. Experimental Setup

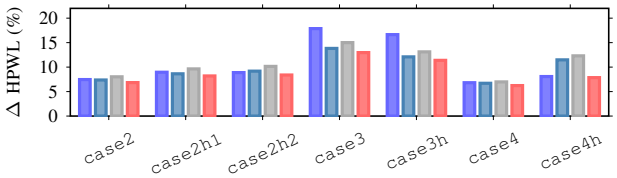
To validate our proposed 3D legalizer, we conducted experiments on ICCAD 2022 [25] and 2023 [26] contest benchmarks, which address standard-cell placement and mixed-size placement for F2F bonded 3D ICs, respectively. The detailed benchmark statistics are shown in TABLE II. The global placements for ICCAD 2022 and 2023 contest benchmarks were generated by SOTA true-3D placers [18] and [19], respectively. We implemented the proposed 3D legalizer in C++. All the experiments were performed on a Linux machine with 20-core Intel Xeon Silver 4210R CPU (2.40GHz) and 24GB RAM.

B. Comparison with SOTA Legalizers



We compared 3D-Flow legalizer with existing SOTA 2D legalizers including Tetris [2], Abacus [4], and BonnPlaceLegal [10]. Tetris and Abacus are the most popular legalization algorithms based on greedy search, which are extensively used in modern global placers [6], [7], [18]–[20]. And BonnPlaceLegal is a competitive flow-based legalizer.

The experimental results are shown in TABLE III and TABLE IV. For ICCAD 2022 contest benchmarks, which contain only standard cells, legalizers have more flexibility to reposition cells without large macros as blockages. Our 3D-Flow legalizer consistently obtained the best results for all the cases, as shown in TABLE III. Compared to Tetris, it achieved 1.61× less average displacement and 2.31× less maximum displacement. Tetris places cells sequentially based on their x-position, resulting in larger displacement for cells placed later. And our legalizer reduced average displacement by 13% and maximum displacement by 54% compared to Abacus. Although Abacus allows movement of already placed cells, they remain on a fixed row, causing significant displacement for later placements. Moreover, 3D-Flow outperformed BonnPlaceLegal by 15% and 43% less average and maximum displacement. While BonnPlaceLegal uses a flow-based method, it limits edge costs to positive values, missing further optimization opportunities. In contrast, our 3D-Flow repositions cells in a 3D solution space, fully utilizing the vertical stacking of 3D ICs. Leveraging the global view in the network flow method, our legalizer allows simultaneous movement of multiple cells across rows and dies to minimize displacement. The post-optimization with cycle-canceling further reduces maximum displacement while maintaining quality.



For ICCAD 2023 contest benchmarks, large macros divide placement rows into segments, posing challenges in finding available space near macro boundaries. Despite this, our 3D-Flow legalizer outperformed all SOTA legalizers, as demonstrated in TABLE IV. It achieved 1.46×, 1.08×, and 1.13× less average displacement, and 2.97×, 1.40×, and 1.34× less maximum displacement compared to Tetris, Abacus, and BonnPlaceLegal, respectively.

The HPWL increase results for ICCAD 2022 and 2023 contest benchmarks are shown in Fig. 7. Although HPWL increase may not always align with displacement results, our 3D-Flow consistently achieved the best outcomes, with 1.29×, 1.30×, and 1.38× less increase for ICCAD 2022 contest benchmarks, and 1.17×, 1.13×, and 1.22× less increase for ICCAD 2023 contest benchmarks, compared to Tetris, Abacus, and BonnPlaceLegal, respectively.

Regarding runtime, Tetris is the fastest due to its simple procedure, being 1.32× and 1.45× faster than our method on ICCAD 2022 and 2023 contest benchmarks. And 3D-Flow achieved better results with similar runtime compared to Abacus. However, BonnPlaceLegal showed poor scalability in large cases. Leveraging our efficient branch-and-bound algorithm, 3D-Flow achieved 3.34× and 8.89× speedup over BonnPlaceLegal on ICCAD 2022 and 2023 contest benchmarks, respectively.

C. Ablation Study on Die-to-Die Cell Movement

To validate the effectiveness of die-to-die movement in our 3D legalizer, we performed experiments on ICCAD 2023 contest benchmarks for our 3D-Flow legalizer with and without die-to-die cell movement. The experimental results are shown TABLE V. In the last column, we list the number of cells moved across dies. By moving only a few cells vertically, our legalizer finds white space for other cells to minimize displacement in a global view. Our 3D-Flow legalizer outperformed its 2D counterpart by 6.8% and 19% less average and maximum displacement. The displacement of different settings for case3 is visualized in Fig. 8.

(a) w/o. D2D cell movement (b) Our 3D-Flow Legalizer

The gray block represents the macro. The **blue**-colored cells in (b) are from the bottom die. Black lines indicate cell displacement.

V. Conclusion

This paper introduces 3D-Flow, the first 3D legalizer designed to minimize cell displacement for 3D ICs using network flow methods. Leveraging a novel branch-and-bound algorithm, 3D-Flow efficiently identifies the shortest augmenting path on a 3D grid graph to iteratively resolve overflowed bins. By fully utilizing the vertical stacking of 3D ICs, our legalizer finds legal positions for cells with minimal displacement in a global view. Additionally, a post-optimization with a cycle-canceling algorithm further reduces maximum displacement while preserving result quality. Experimental results on ICCAD 2022 and 2023 benchmarks show that our 3D legalizer achieves up to 13% and 43% less average and maximum displacement, respectively, compared to state-of-the-art legalizers, within a similar runtime.

***Abstract*—High-Level Synthesis (HLS) offers various optimization directives that enable designers to flexibly adjust hardware microarchitecture. However, existing HLS performance prediction methods typically rely on control data flow graphs generated (CDFG) from original HLS C/C++, which struggle to capture the complex interactions between directives and the resulting hardware resource reuse issues. To address these issues, this paper proposes a post-implementation performance prediction method tailored for directive-optimized circuits design, which utilizes a Graph Builder to integrate directive optimization and resource reuse information into the graph representation. In addition, the performance prediction model, which integrates a TransformerConv-based graph neural network (GNN) and an aggregation pool module, effectively captures key features related to post-implementation performance. Experimental results show that our method can reduce the prediction error of critical path delay (CP), power, and resource utilization to 3.87%∼8.08%, significantly outperforming existing state-of-the-art methods. It also demonstrates excellent generalization on unseen kernels, providing a more effective and accurate performance prediction tool for HLS.**

***Index Terms*—High-Level Synthesis, Directive-Optimized, Resource Reuse, Performance Prediction Model.**

I. Introduction

With the rapid development of 5G, autonomous driving, and large model technologies, hardware accelerator are playing a crucial role in enhancing computational performance and efficiency [1]. However, hardware programming typically requires extensive hardware knowledge and expert experience, along with significant effort to write Register-transfer-level(RTL) code, making the process both time-consuming and error-prone. To improve hardware development efficiency, High-Level Synthesis (HLS) technology has emerged as a solution.

HLS enables designers to create RTL hardware designs at a higher level of abstraction using programming languages such as C/C++, and to optimize micro-architecture configurations through various optimization directives [2]. However, the interactions between optimization directives are complex, and simply increasing the number of directives does not necessarily lead to better design outcomes. As a result, designers must carefully balance and select the optimal combination of directives from a vast design space, which introduces new challenges to design optimization. **First**, as the number of optimization directives increases, the design space expands exponentially, making it increasingly difficult to find the optimal design. **Second**, using HLS tools to evaluate the performance of hardware implementations is highly time-consuming, as the process involves layout, routing, and other post-implementation steps. This time-consuming evaluation process further slows down the progress of design space exploration. Hence, the introduction of a fast and accurate performance prediction proxy model as a substitute for HLS tools becomes crucial.

Existing performance prediction models can be categorized into analytical models and learning-based models. Analysis models such as Lin-analyzer [3] and Comba [4] rely on extensive hardware knowledge and an understanding of regularized data flow designs. However, traditional analysis models often require substantial time to obtain necessary parameters, such as instruction latency, and fails to capture the heuristic optimization rules within HLS tools.

To address these limitations, researchers in [5] proposed a learning-based model for performance prediction. Recent work [6] has further advanced this direction by using control data flow graphs (CDFG) in combination with GNNs to predict design quality. GNN-DS [7] and HARP [8] directly insert directive nodes into the graph representation to improve performance prediction. However, this coarse-grained insertion approach has limitations: when applying the unroll directive, it may treat all expanded operations as a single node, making it challenging to capture the fine-grained impacts on execution order and resource utilization. In contrast, they [9] directly incorporates directive effects within a single for loop and uses a hierarchical GNN network to predict overall quality.

Nevertheless, existing methods, whether analysis or learning models, have yet to fully capture the complex effects of directive interactions and resulting resource reuse. Specifically, when *unroll* and *array partition* directives are applied together, parallelism and memory bandwidth are expected to improve. However, when multiple operations share the same hardware resource, this reuse can alter the intended scheduling order, impacting overall performance. Therefore, effectively incorporating directive interaction effects and resource reuse information into the graph representation, a more accurate reflection of operation scheduling and resource allocation in circuit design can be achieved, providing GNN models with richer design information and significantly enhancing the accuracy and reliability of performance prediction.

To address the above issues, this paper proposes a post-implementation performance prediction method tailored for directive-optimized circuit design. This approach not only

*Corresponding author.

achieves precise performance prediction but also demonstrates excellent generalization capability. Our main contributions are as follows:

1) We propose a Graph Builder that constructs a directive-optimized graph by consider the effects of directives and hardware resource reuse, aligning more closely with the actual operation scheduling and resource allocation in hardware circuits. To our knowledge, this is the first approach in HLS performance prediction that introduces hardware resource reuse to simulate circuit characteristics, enabling more accurate performance prediction.
2) Based on the constructed directive-optimized graph, we propose a post-implementation performance prediction model that fully considers the impact of edge features on node information. This model integrates TransformerConv and aggregation pool modules to capture graph-level features related to performance metrics, while incorporating global information to enhance prediction accuracy and generalization capability.
3) Experimental results demonstrate that the proposed method outperforms state-of-the-art models across five performance prediction metrics; Specifically, the MAPE for LUT, FF, CP, and Power, and the MAE for DSP, are reduced to 8.08%, 3.87%, 4.34%, 6.49%, and 0.11%, respectively. Furthermore, it exhibits strong generalization capabilities on unseen kernels. Ablation studies further indicate that incorporating hardware resource reuse dependencies reduces prediction error.

The remainder of this paper is organized as follows: Section 2 introduces some preliminary concepts. Section 3 details the proposed method, including the directive-optimized graph construction, node and edge feature encoding, and the prediction model. Section 4 presents an extensive experimental analysis. Section 5 presents the conclusions.

II. PRELIMINARIES

This section introduces the core foundational knowledge involved in this study, focusing on how programs are transformed into graph representations and the role of directives in HLS hardware design optimization. Additionally, we will discuss the principles of Graph Neural Networks and their application in hardware performance prediction. These concepts form the basis for the subsequent our approach and experiments.

A. Program-to-Graph and Directives

In HLS tools, such as Vitis HLS, the source program is first compiled by an LLVM-based [10] front-end to generate an intermediate representation (IR), and then a Control Data Flow Graph (CDFG) is constructed based on the relationships between nodes and blocks. This graph clearly represents the dependencies and execution order of various operations within the program. The graph structure based on LLVM IR makes the transformation from high-level languages to hardware designs more efficient, enabling designers to intuitively understand the execution logic of the program and analyze its hardware implementation details.

Furthermore, hardware design optimization involves the application of optimization directives (e.g., unroll, pipeline, array partition), which directly impact resource allocation and scheduling. To accurately capture the effects of these directives, they must be integrated into the graph structure to reflect actual resource allocation and scheduling. The directives involved in this paper are shown in Table I.

TABLE I: Configuration of directives.

Pragma	**Configuration**
Loop unrolling	Unrolling factors
Loop pipelining	Enabled/Disabled
Loop flattening	Yes/No
Array partitioning-type	Block/Cyclic/Complete
Array partitioning-factor	Partitioning factors
Function inlining	Yes/No

B. Graph Neural Networks

Graph Neural Networks [11] are a class of deep learning models specifically designed to process graph-structured data. By iterative propagation and aggregation of node information, GNNs learn feature representations of nodes and edges within the graph. Unlike traditional neural networks, GNNs can capture the topological structure of the graph and complex dependencies between nodes, making them well-suited for graph-related tasks. In the context of HLS, where the CDFG is generated from the intermediate representation, GNNs can effectively learn the dependencies between control flow and data flow, capturing the interactions between operations. Additionally, GNNs exhibit strong generalization capabilities, maintaining high accuracy in performance prediction across various design choices and optimization strategies. This is crucial for Design Space Exploration (DSE), as GNNs enable designers to quickly evaluate the performance of a large number of design points, accelerating the iterative optimization process and providing robust support for hardware microarchitecture optimization.

In summary, the application of GNNs can address the challenges of optimization directives in complex hardware designs, enhancing the accuracy and efficiency of design quality prediction and offering advanced solutions for hardware design optimization.

III. METHODOLOGY

Fig. 1 illustrates the overall framework of our proposed post-implementation performance prediction method, which is divided into three stages: dataset generation, model training, and inference.

In the dataset generation stage, we randomly sample candidate optimization directives to determine the specific optimization strategy applied to the designs. Based on the IR generated by the HLS front end, the Graph Builder constructs a directive-optimized graph that incorporates resource reuse and directive

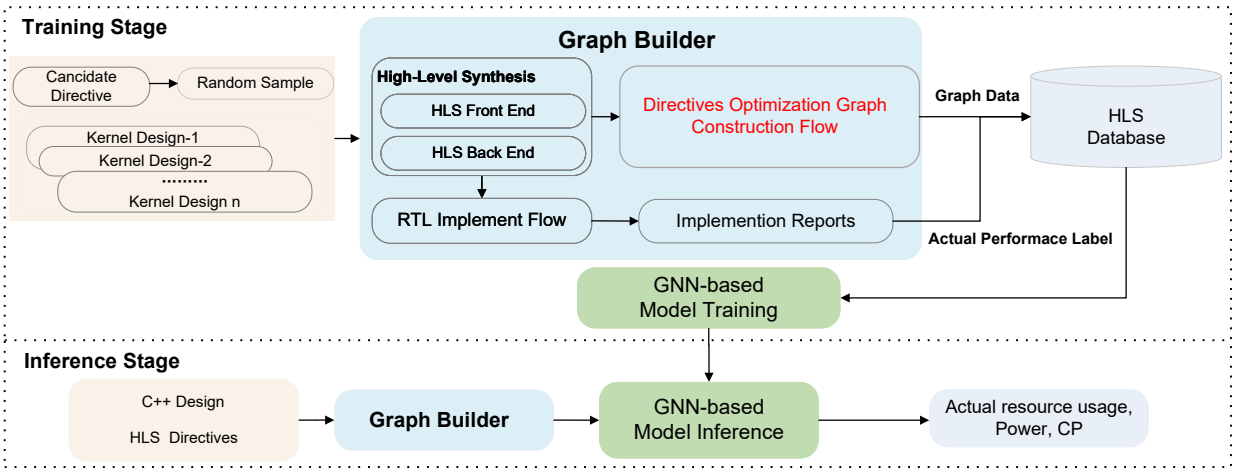

Fig. 1: Framework overview of the proposed method.

optimization effects, providing a more accurate simulation of resource allocation and operation scheduling in hardware circuits. This setup facilitates the use of GNN's powerful graph information learning capabilities for performance prediction. Subsequently, the C-to-bitstream design flow is completed to extract post-implementation performance metrics (LUT, FF, CP, Power, DSP). Using this information, we generate a directive-optimized graph representation corresponding to the optimization directives, along with true performance labels, to build a HLS performance prediction database.

During the training stage, we use the generated HLS database to train a model that integrates GNN and aggregation pool modules. Finally, in the inference stage, for a given test design, the directive-optimized graph representation generated by the Graph Builder is input into the trained model, enabling the prediction of post-implementation performance results without complete the post-implementation process.

A. *Directives Optimization Graph Construction Flow*

We use the Graph Builder to construct a graph representation of the design, which simulates the actual behavior of the hardware circuit. This graph representation incorporates control data flow information, the effects of various optimization directives, and hardware resource reuse details. Fig 2 illustrates our graph construction flow.

1) **Explicit Representation of Directive Optimization**
The CDFG generated from LLVM IR (as shown in Fig.2(a)) provides a clear representation of the program's control structures and data dependencies, aiding designers in analyzing program behavior. However, optimization directives provided by HLS tools can alter the microarchitecture of the hardware circuit design. Specifically, applying the unroll directive duplicates the execution logic within loops to enhance parallelism, while the array partition directive increases memory bandwidth to improve throughput, thereby impacting the overall performance. Consequently, the interactions between directives can significantly change the data flow execution patterns of the program, making accurate performance prediction essential.
To intuitively reflect the impact of directives on hardware design, we constructed a graph representation based on the frontend IR generated by HLS tools and the design principles of optimization directives. This graph representation effectively illustrates the effects of optimization directives on the source program, providing a clear graph structure for GNN-based performance prediction and facilitating the learning of directive interaction features (as shown in Fig.2(b)).
2) **Impact of hardware resource reuse**
The optimized data flow graph effectively captures the execution characteristics of the program but often overlooks the impact of resource reuse caused by directive interactions. To more accurately model the resource allocation and operation scheduling in hardware circuits, we extend the optimization graph representation constructed in step (1) by incorporating resource dependency information derived from the backend of HLS tools. This enhancement improves the reliability of post-implementation performance prediction (as shown in Fig.2(c)).
More specifically, in Fig.2(c), the application of the unroll and array partition directives duplicates the execution logic and partitions array B into two segments, thereby improving parallelism and memory bandwidth. However, due to hardware resource reuse constraints, the two multiplication operations (mul1 and mul2) must share a single DSP resource. Consequently, mul2 must wait for mul1 to release the multiplier resource (e.g., DSP) before execution. To address this, a resource reuse dependency is introduced between these two multiplication operations, ensuring that mul1 and mul2 share the same DSP resource and that mul2 is scheduled to execute after mul1. This optimized graph representation more accurately reflects the resource allocation and operation scheduling in hardware circuits, enabling a more realistic simulation of hardware execution behavior.

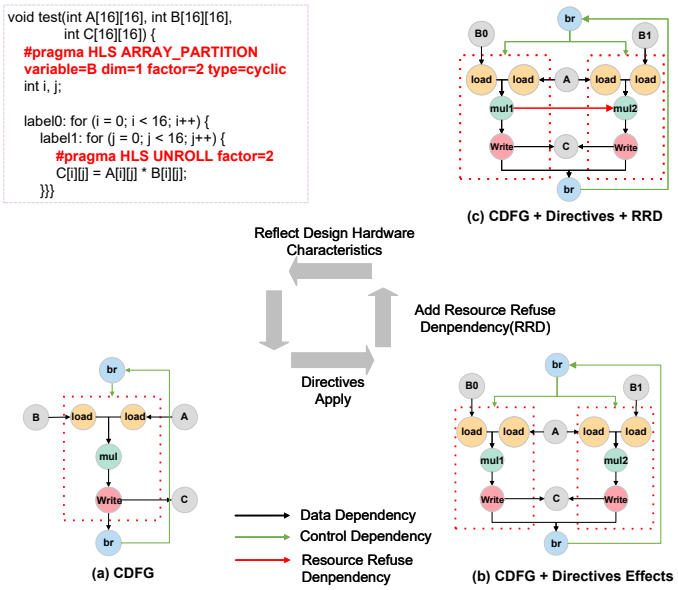

Fig. 2: Directive-optimization Graph Representation.

B. *Graph Feature Extraction and Annotation*

The extraction of node and edge features from the directives optimization graph constructed by Graph Builder is crucial for model training (see Table II).

Firstly, node features are derived from the front-end of the HLS tool, extracting key information related to performance prediction, including node type, opcode type, latency, and resource usage (such as LUT, DSP, FF, etc.). Additionally, each node includes a "Reuse" flag, indicating whether the node reuses hardware resources. Node type and opcode type are encoded using one-hot vectors, while other features (such as latency and resource usage) are represented using numerical values. These features assist the GNN model in understanding the function and resource requirements of each node.

Edge features primarily describe the dependencies between nodes, including data dependencies, control dependencies, and resource reuse dependencies. In particular, resource reuse dependencies describe the operation scheduling and resource sharing in circuit design, aligning more closely with the characteristics of actual hardware execution. Comprehensive feature extraction and precise encoding enable the GNN model to gain deeper insights into the details of hardware design, helping it more effectively analyze and predict the performance of designs optimized by directives.

TABLE II: Node and edge features.

Category	Description	Values
Node Features	Type	Instruction, Variable, etc.
	Opcode Type	Load, Mul, etc.
	Delay	Float values
	LUT	Integer values
	DSP	Integer values
	FF	Integer values
	Reuse	0, 1
Edge Feature	Type	Control, Data, Call, Resource Reuse

C. *GNN-Based Prediction Approach*

Mainstream GNN models (such as GAT [12] and GraphSAGE [13]) typically focus on aggregating node features while often overlooking edge feature learning. However, in the directive-optimized graph constructed by Graph Builder, edge relationships contain rich circuit characteristics, including hardware resource reuse and the interactions between directive. To address this limitation, our performance prediction model (as shown in Fig.3) employs TransformerConv [14] as a foundational module for node information aggregation. TransformerConv introduces a self-attention mechanism similar to that in Transformers, enabling dynamic fusion of edge features between nodes, which allows for more effective handling of the graph data generated by Graph Builder. While learning node features, TransformerConv can also fully capture data dependencies, directive interactions, and resource reuse, thus extracting critical features related to performance metrics.

The learning of node features is illustrated by Equation (1),

$$\mathbf{x}_i' = \mathbf{W}_1\mathbf{x}_i + \sum_{j\in\mathcal{N}(i)} \alpha_{i,j}(\mathbf{W}_2\mathbf{x}_j + \mathbf{W}_5\mathbf{e}_{ij}) \tag{1}$$

where the attention coefficient $\alpha_{i,j}$ is calculated as follows:

$$\alpha_{i,j} = \text{softmax}\left(\frac{(\mathbf{W}_3\mathbf{x}_i)^\top(\mathbf{W}_4\mathbf{x}_j + \mathbf{W}_5\mathbf{e}_{ij})}{\sqrt{d}}\right) \tag{2}$$

where $\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3, \mathbf{W}_4, W_5, \mathbf{W}_5$ are learnable weight parameters, and $\mathbf{x}_i$ and $\mathbf{e}_{ij}$ represent the feature embeddings of node i and the edge between nodes i and j, respectively. To further enhance the model's ability to learn graph-level features, we introduce an aggregation pool module [15] after three layers of TransformerConv to obtain a graph-level representation. Additionally, global information is incorporated into the graph-level representation, further enriching the information expression for circuit design and significantly improving the model's prediction accuracy and generalization capability. Finally, the graph-level and global features are concatenated and fed into a multi-layer perceptron (MLP) layer to predict performance metrics.

In summary, by integrating the TransformerConv model and aggregation pool, incorporating global information, we capture critical features related to performance prediction, thereby enhancing the performance prediction capability for circuit designs. Our prediction model framework is shown in Fig.3.

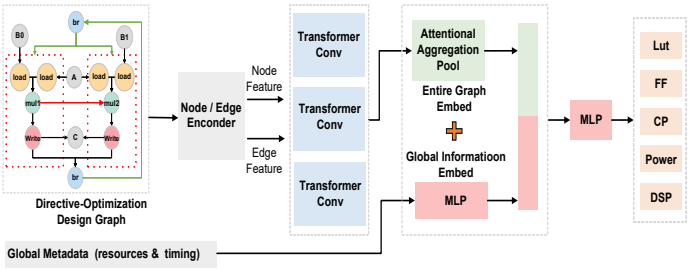

Fig. 3: The architecture of predictive model.

IV. EXPERIMENT

A. *Experimental Setup*

Dataset. We selected 19 representative kernel designs from the commonly used MachSuite [16] and PolyBench [17] benchmark suites. These kernels cover various types of computational complexity, including typical algorithms such as matrix multiplication, triangular solving, dynamic programming, and Jacobi iteration.

For each kernel design, we randomly generated 1,000 different directive configuration combinations, synthesized using Vitis HLS 2023.2 and implemented with Vivado to obtain actual hardware performance metrics, including resource usage (e.g., LUT, DSP, FF), critical path delay (CP), and power consumption. Finally, we combined each HLS kernel's generated directive-optimization graph representation with corresponding performance labels, constructing an HLS dataset to comprehensively evaluate the effectiveness of our method.

More specifically, these 19 kernels generate a total of 19,000 design points. Among them, design points from 15 kernels are used for training and testing, while the remaining 4 kernels are reserved to evaluate the model's generalization capability on unseen kernel designs. The specific details of the constructed HLS dataset are shown in Table III.

TABLE III: Statistics of databases which consist of 19 kernels.

Version	Kernels	Range	LUT	FF	CP	Power	DSP
Vitis HLS 2023.2	19	min	19	26	1.48	0.24	0
		max	138942	246368	10	2.97	1428

Baseline. To validate the effectiveness of our method, we compared it with four baseline methods: PNA [18], IronMan-Pro [6], GNN-DSE [7], and HGP [19] represent kernel characteristics through data flow graphs, while GNN-DSE directly inserts directive nodes into the graph representation. In our experiments, we primarily focus on prediction accuracy and generalization capability, using Mean Absolute Percentage Error (MAPE) to evaluate LUT, FF, CP, and Power metrics, and Mean Absolute Error (MAE) for the DSP metric. Additionally, we implemented the Graph Builder in Python to construct the directive-optimized graph representation and perform feature extraction and encoding. Both our method and the baseline GNN methods were implemented using Python and PyTorch Geometric.

B. *Model Evaluation*

In the above experimental setup, we selected 15,000 design points (from 15 kernel designs), with 80% used for training and 20% for testing, to evaluate the performance of all models.

The performance of all models is shown in Fig. 4, the proposed model outperforms baseline models (PNA, IronMan-Pro, GNN-DSE, and HGP) across five evaluation metrics, achieving the lowest MAPE (MAE) values. Compared to PNA and IronMan-Pro, the proposed approach demonstrates significant improvements in all performance prediction metrics, primarily due to its effective capture of node features and edge dependencies in the directive optimization graph. Although GNN-DSE and HGP reduce performance prediction errors to some extent, the proposed method still surpasses them, further demonstrating its ability to effectively learn hardware resource reuse, directive interaction information, and correlations between performance metrics.

Overall, our model reduces the prediction errors for LUT, FF, CP, and Power to 8.08%, 3,87%, 4.34%, and 6.49%, respectively. And achieves an MAE of 0.11 for DSP, which is significantly lower than that of other models, this low error indicates a high consistency between predicted and actual values, further validating the model's high accuracy and stability.

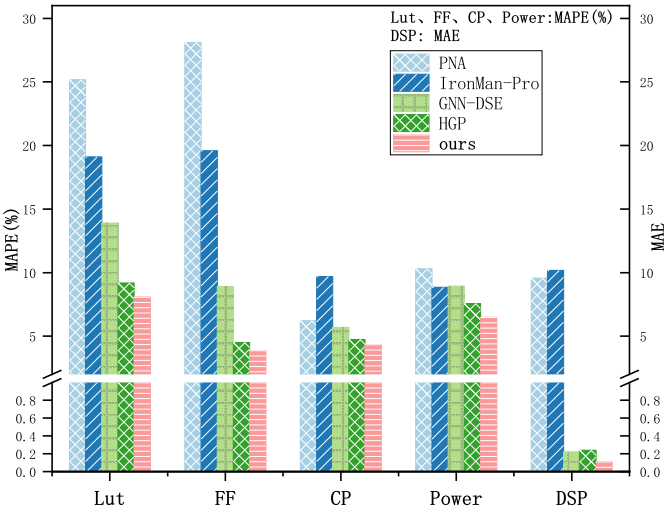

Fig. 4: Performance comparison.

C. *Effectiveness of Resource Reuse*

In actual RTL circuits, resource reuse is closely related to operation scheduling and resource allocation, making it essential to consider resource reuse information for reducing model prediction errors. To assess the impact of resource reuse information, we compared the model's performance with (W/) and without (W/O) this information. As shown in TableIV, incorporating resource reuse information significantly reduces prediction errors across five metrics. Specifically, the MAPE for LUT, FF, CP, and Power decreased from 9.41%, 4.52%, 4.54%, and 7.25% to 8.08%, 3.87%, 4.34%, and 6.49%, respectively, while the MAE for DSP dropped from 0.20 to 0.11. These results indicate that incorporating resource reuse information enables the model to more accurately capture the operation scheduling and resource allocation characteristics of hardware circuits, effectively reducing prediction errors.

TABLE IV: Performance comparison of resource reuse.

Method	Configuration	MAPE (%)				MAE
		Lut	FF	CP	Power	DSP
Ours	W/O Resource Reuse	9.41	4.52	4.54	7.25	0.20
	W/ Resource Reuse	8.08	3.87	4.34	6.49	0.11

TABLE V: Generalization performance comparison of different models on unseen Kernels. GNN-DSE is abbreviated as GD in the table.

D. Generalization on Unseen Kernel

To evaluate the model's generalization capability, we conducted experiments on four unseen kernel designs (viterbi, trmm, syrk, and 2mm). As shown in TableV, the proposed model outperforms other baseline models (PNA, GNN-DSE, and HGP) on unseen kernel designs, achieving lower MAPE (MAE) across five metrics. Specifically, the average MAPE of our model for LUT, FF, CP, and Power decreased to 17.45%, 7.23%, 7.21%, and 9.40%, respectively, while the MAE for DSP was significantly reduced to 0.85, much lower than other models. The experimental results validate the strong generalization capability of the proposed method on unseen kernel designs, further demonstrating the effectiveness of combining the directive optimization graph representation with the performance prediction model architecture. This approach enables a more comprehensive modeling of the commonalities and differences across various designs, highlighting its robustness and adaptability.

V. Conclusion

In this paper, we propose a novel post-implementation performance prediction method for directive-optimized designs. This approach involves the development of a Graph Builder, which constructs a directive optimization graph that integrates both directive optimization effects and resource reuse information. By combining an ensemble GNN model with an aggregation module, we extract key features relevant to performance prediction, such as resource allocation and operation scheduling, to achieve precise performance estimation. Experimental results demonstrate that our method significantly outperforms the baseline approaches across five metrics and exhibits strong generalization ability on unseen kernels.

***Abstract*—Transformers have delivered exceptional performance and are widely used across various natural language processing (NLP) tasks, owing to their powerful attention mechanism. However, the high computational complexity and substantial memory usage pose significant challenges to inference efficiency. Numerous quantization and value-level sparsification methods have been proposed to overcome these challenges. Since higher sparsity leads to greater acceleration efficiency, leveraging both value-level and bit-level sparsity (hybrid sparsity) can effectively exploit the acceleration potential of the attention mechanism. However, increased sparsity exacerbates load imbalance across compute units, potentially limiting the extent of acceleration benefits. To fully exploit the acceleration potential of hybrid sparsity, we propose Libra, an attention accelerator developed through algorithm-hardware co-design. At the algorithm level, we design the bit-group-based algorithm consisting of filtered bit-group sparsification (FBS) and dynamic bit-group quantization (DBQ) to maximize the utilization of sparsity in attention. FBS imposes structured sparsity on weights, while DBQ introduces dynamic sparsification during the computation of activations. At the hardware level, we design task pool to achieve multi-level workload balance, effectively mitigating the load imbalance among compute units induced by hybrid sparsity. Additionally, different stages in DBQ can be executed in parallel, with each stage operating at distinct bit-widths. To support this, we design an adaptive bit-width architecture that enables simultaneous computations at varying bit-widths. Our experiments demonstrate that, compared to state-of-the-art (SOTA) attention accelerators, Libra achieves up to $1.49\times \sim 5.89\times$ speedup and $2.65\times \sim 10.82\times$ enhancement in energy efficiency.**

I. Introduction

In recent years, Transformers [3] have exhibited remarkable performance in Natural Language Processing (NLP) [4, 10, 6, 7, 8, 5, 15], establishing themselves as the prevailing architecture for various tasks. This success is largely attributable to their innovative attention mechanism. The emergence of large pre-trained language models, such as GPT [8, 10], has further entrenched the dominance of Transformer architectures in the field. However, as these models grow in size and complexity, Transformers face increasingly significant computational challenges. The attention mechanism, in particular, imposes substantial computational costs and results in considerable memory footprints, thereby restricting the deployment of Transformer models in resource-constrained devices and real-time applications.

Attention mechanism analyzes the relationships between all tokens in input sequence to evaluate their relative significance through attention scores. However, as the input sequence length grows, the computational complexity and memory cost of attention scores increase quadratically. As a result, attention computation becomes the primary bottleneck in deploying Transformers. To address the high computational redundancy inherent in attention calculation, sparse attention is an appealing approach. Sparse attention reduces the computational cost of dense attention by skipping attention calculation for tokens with low scores, thereby eliminating redundancy in the process. Sanger [14] mitigates some of this redundancy through threshold filtering, setting low-relevance scores to zero. However, it focuses solely on activation computation, neglecting the significant redundancy present in weights. By leveraging sparsity in both weights and activations, the overall redundancy in attention computation can be more effectively reduced.

†Corresponding author

Existing Transformer accelerators [14, 17, 20] leverage value-level sparsity to skip computations involving zero-value correlations, effectively reducing the computational load and achieving acceleration. However, as shown in Fig. 1, even among non-zero values, numerous zero bits remain. This naturally suggests leveraging bit-level sparsity to further reduce inference latency. Computing an N bits data element by only one multiplier unit requires N cycles without accounting for bit-level sparsity. However, with bit-serial architecture (BSA), the number of required cycles matches the number of significant bits, which is always less than or equal to N. However, previous attempts to accelerate using BSA were tailored for Convolutional Neural Networks (CNNs) and are not hardware-friendly for Transformers, making direct adaptation infeasible. This poses significant challenges to our efforts to implement both value-level and bit-level sparsity (hybrid-sparsity) in attention.

In bit-serial computation, workload distribution across compute units is often imbalanced due to the uneven distribution of bit sparsity. As stated in Fig. 1, compute units with lighter workloads may experience extended stalling, waiting for those with heavier workloads to complete. This issue is particularly evident when employing bit-level sparsity in activations. The root of the problem lies in fact that data channels remain unchanged after initial scheduling until all computations are complete, leading to stalled computational resources without further rescheduling. By employing structured sparsity to control distribution of effective bits, bit-level sparsity in weights can mitigate workload imbalance.

To tackle the insufficient utilization of sparsity in attention computation and the workload imbalance caused by hybrid sparsity, we propose Libra, a hybrid-sparse attention accelerator that achieves workload balance through bit-group, offering a solution to make Transformer acceleration more efficient. Our main contributions can be summarized as follows:

- We propose the bit-group-based algorithm consisting of filtered bit-group sparsification (FBS) and dynamic bit-group quantization (DBQ), applying structured sparsity to weights and dynamic sparsity to activations, thereby maximally eliminating redundancy in attention computation.
- An adaptive bit-width hardware architecture is developed to leverage the structural characteristics of the bit-group-based algorithm, allowing different bit-width computation stages to execute in parallel and improving hardware utilization.
- A multi-level workload balance scheme centered around the task pool for workload distribution is introduced. By decomposing workloads into fine-grained tasks and dynamically scheduling them, the scheme achieves near-optimal performance when exploiting hybrid-sparsity.
- Extensive experiments are conducted to evaluate the performance of our accelerator. Libra achieves up to $1.49\times \sim 5.89\times$ speedup and $2.65\times \sim 10.82\times$ enhancement energy efficiency compared to SOTA attention accelerators with negligible accuracy loss.

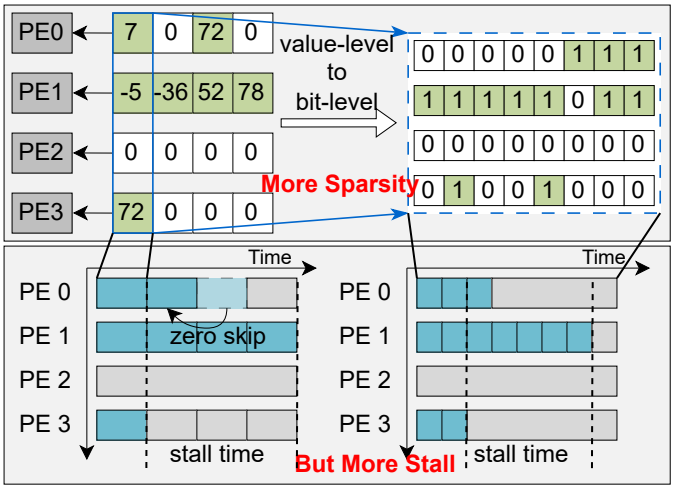

Fig. 1: Increased workload imbalance issue when leveraging bit-level sparsity.

II. BACKGROUND AND MOTIVATION

A. Attention Mechanism

The attention mechanism is the core operation within the Transformer models. During the computation of attention, the embedded input sequence is initially processed through linear layer to generate the Query (Q), Key (K), and Value (V) matrices. After that, the score matrix is derived by computing the dot product between Q and the K^T. Subsequently, the generated score matrix is normalized using non-linear functions to produce the probability matrix P which is then multiplied with the V. The result matrix is applied to linear functions and derived through residual connection. After the final layer normalization, we can get the attention result.

B. Sparse Accelerator

Various sparsity and quantization methods have been employed to accelerate attention computations. Sanger [14] leverages redundancy in the attention mechanism to enhance value-level sparsity. DTQAtten [17] and DTATrans [16] implement token-wise mixed-precision quantization. DEQ [20] further advances this by introducing element-wise mixed-precision quantization. These methods have achieved remarkable performance. However, they only optimize at the value level, neglecting the huge potential for acceleration at the bit level.

Existing researches on bit sparsity focus on accelerating CNNs using BSA. Laconic [9] processes both weights and activations as bit sequences, while Adas [18] dynamically selects the side with fewer effective Booth terms for sequence expansion. However, the irregular distribution of bit sparsity in weights and activation can result in load imbalance during computation, where some processing elements (PEs) are active while others remain idle. While Adas uses inner-join units to alleviate this issue, it does not fully resolve the problem for the entire PE array. To address the issue of load imbalance, Bit-Balance [19] proposes a channel-wise bit-sparse quantization method and uses clustering techniques to balance workloads across PEs.

Despite these advances, the aforementioned bit-sparsity methods primarily rely on patterned distributions of significant bits in weights, which are less applicable to the dynamically generated activations in Transformers. BSViT [21] introduces a dense-sparse hybrid dataflow method to achieve workload balance in PEs but primarily leverages dynamic patch quantization in Vision Transformers (ViT) [11] and lacks a comprehensive focus on the unique characteristics and requirements of the attention mechanism in Transformers.

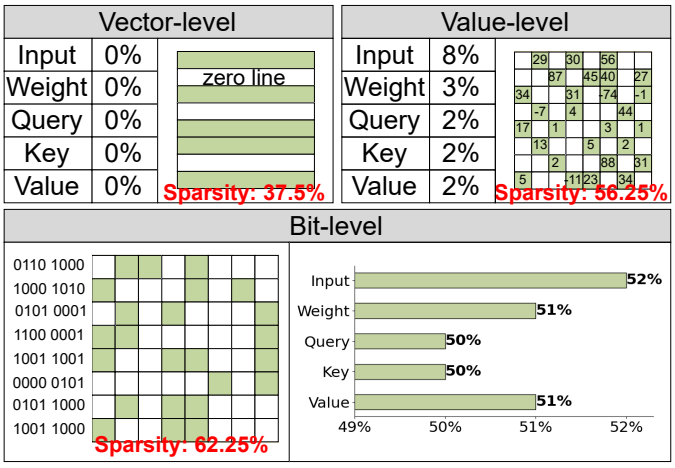

Fig. 2: Preliminary experimental results on the vector-level, value-level and bit-level sparsity in the BERT model and GLUE dataset.

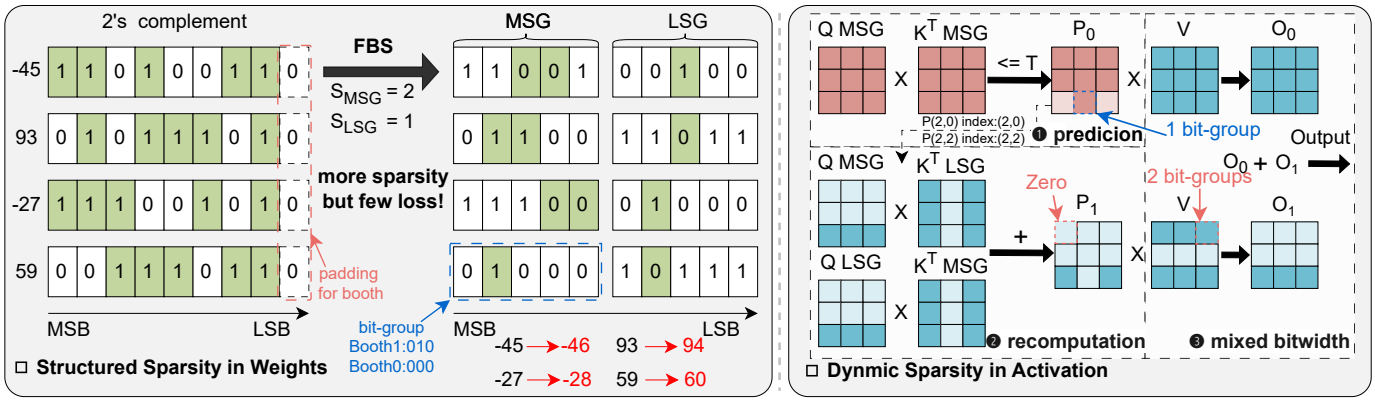
C. Motivation

The primary motivation for our work is based on two key observations. On the one hand, as shown in the Fig. 2, Transformers exhibit extremely high bit-level sparsity, approximately 25× greater than value-level sparsity without applying quantization or sparsity techniques. In particular, the bit-level sparsity in P can reach as high as 96%. Therefore, leveraging hybrid sparsity will further enhance the acceleration effects by adding bit-level sparsity on top of value sparsity. Additionally, due to the redundant nature of the attention mechanism, combining hybrid sparsity with attention features holds significant potential for further acceleration.



On the other hand, as illustrated in Fig. 1, the irregular distribution patterns of zero values and zero bits increase the likelihood of compute units idling, which further exacerbates workload imbalance. The acceleration benefits brought by increased sparsity may not always offset the losses caused by load imbalance. Therefore, maintaining balanced workloads while leveraging hybrid sparsity remains an unavoidable challenge. For instance, Bit-Balance [19] uses a clustering method to group workloads with similar characteristics into the same channels, facilitating inter-channel load balance through scheduling. Adas [18] achieves load balance within PEs through inner-join units. However, when leveraging hybrid sparsity, single-level load balance methods are insufficient to address these challenges. This motivates the design of our multi-level workload balance strategy.

III. BIT-GROUP-BASED ALGORITHM

In this section, we introduce our algorithmic optimizations based on bit-group, extending from weight FBS to activation DBQ. BSA performs a significant amount of unnecessary computations due to the presence of negative numbers [9]. To eliminate these redundancies, we incorporate Booth encoding into our bit-level operations. Furthermore, to fully leverage the advantages of Booth encoding, our algorithm is structured around bit-group, each containing 5 bits that can be encoded into two Booth codes.

A. Filtered Bit-group Sparsification

We propose the FBS scheme to reduce redundancy in weight representations and decrease hardware computational overhead. For integers encoded with Booth encoding, only bit sequences of '000' and '111' are encoded as '0'. Therefore, increasing the continuity of bit positions in the weights can enhance the sparsity of weights after Booth encoding.

(a) Filtered Bit-group Sparsification (b) Dynamic Bit-group Quantization

Fig. 3: An overview of bit-group-based algorithm. (a) Libra takes filtered bit-group sparsification (FBS) to balance weight distribution with negligibe accuracy loss. (b) Libra employs dynamic bit-group quantization (DBQ) to introduce dynamic sparsity in activations.

Algorithm 1: Filtered Bit-Group Sparsification

Input: Weight tensor $\mathbf{W}$, error threshold ϵ
Output: Compensated sparsified weight tensor $\mathbf{W}_{\text{comp}}$
$\mathbf{W}_q \leftarrow \text{Quantize}(\mathbf{W},\ 8\ \text{bits})$ ▷ Step 1
  Extract high bits (**MSG**) and low bits (**LSG**):
  MSG $\leftarrow$ high 5 bits of $\mathbf{W}_q$;
  LSG $\leftarrow$ low 4 bits of $\mathbf{W}_q$;
  LSG $\leftarrow$ left-shift **LSG** by 1 bit;
Sparsify **MSG** and **LSG** under constraints: ▷ Step 2
  $\text{MSG}_{\text{sparse}} \leftarrow \text{Sparsify}(\textbf{MSG},\ S = 2)$;
  $\text{LSG}_{\text{sparse}} \leftarrow \text{Sparsify}(\textbf{LSG},\ S = 1)$;
Reconstruct sparsified weights: ▷ Step 3
  $\mathbf{W}_{\text{sparse}} \leftarrow \text{Combine}(\text{MSG}_{\text{sparse}},\ \text{LSG}_{\text{sparse}})$;
Compute error: $\Delta\mathbf{W} \leftarrow \mathbf{W}_q - \mathbf{W}_{\text{sparse}}$ ▷ Step 4
while $\|\Delta\mathbf{W}\|_2 > \epsilon$ **do**
  Adjust $\text{MSG}_{\text{sparse}}$, $\text{LSG}_{\text{sparse}}$ to minimize $\|\Delta\mathbf{W}\|_2$ under constraints;
  Reconstruct $\mathbf{W}_{\text{sparse}}$;
  $\Delta\mathbf{W} \leftarrow \mathbf{W}_q - \mathbf{W}_{\text{sparse}}$;
$\mathbf{W}_{\text{comp}} \leftarrow \mathbf{W}_{\text{sparse}} + \text{CompensateError}(\Delta\mathbf{W})$;

To better preserve the numerical value of the weights, each quantized weight can be represented as $B = -B_{n-1}2^{n-1} + \sum_{i=0}^{n-2} B_i * 2^i$. Numerical values are composed of the sum of multiple powers of two. Therefore, the weights can be denoted as follows,

$$B = \begin{cases} \sum_{i=m}^{M} B_i * 2^i, & B \geq 0 \\ -\sum_{i=m}^{M} B_i * 2^i - 1, & B < 0 \end{cases}, \quad (1)$$

where $M = \min(N-1, m+s-1)$, s represents the length of the continuous range of effective bits, and $m \in \{0, 1, 2, \ldots, N-1\}$. As shown in Fig. 3 and Algorithm 1, the quantized weights are first divided into two groups. The first group, called Most Significant Group (MSG), includes bits from the 7th to the 3rd position. The second group, called Least Significant Group (LSG), includes bits from the 3rd to the 0th position, with an additional zero appended at the end according to Booth encoding rules.

Next, we assign a fixed maximum number of significant bits, S, to each bit group. For example, $S = 2$ for MSG and $S = 1$ for LSG. For positive integers, the significant bits are the non-zero bits, but for negative integers, the significant bits are the zero bits. Finally, we optimize the weights of the current layer according to the constraints defined by our scheme. If the difference between the sparsified weights and the original weights exceeds a given threshold ϵ, we introduce appropriate compensations and re-sparsify them iteratively until the specified constraints are satisfied.

B. Dynamic Bit-group Quantization

In Transformers, the correlation between each pair of tokens is initially calculated as $P = Q \cdot K^T$. Due to the softmax function, less significant correlations P approach zero, making them irrelevant in the subsequent $P \cdot V$ computations. Therefore, we can predict the value of P using lower-cost computations, assign lower bit-width precision to less important values, and perform high-precision recalculations for important values. This approach minimizes computational complexity while maintaining accuracy.

In our design, we introduce a Dynamic Bit-group Quantization (DBQ) scheme, which can dynamically allocate data bit-widths without requiring a redesign of the network architecture. Since i-BERT [13] can maintain accuracy comparable to full precision using Int8, our design also adopts Int8 as the base precision. As shown in Fig. 3, the DBS scheme consists of two main stages.

The first stage is the prediction stage. To be compatible with the DBQ scheme, the MSG of Q and K are multiplied to generate a prediction result P, which is represented by a single bit-group. Each element of P is then compared to a predefined threshold T. The threshold T is determined by a ratio parameter r and the specific task. If $P_{i,j} \leq T$, the corresponding correlation is considered unimportant and can be represented with a single bit-group. Otherwise, a high-precision recalculation is required to avoid accuracy loss. To facilitate locating important elements, we retain the row and column indices for future use.

The second stage is the recomputation stage. Using the previously stored indices, we can locate the important elements $P_{i,j}$, retrieve the ith token of Q and the jth token of K, read their MSG and LSG, and then perform vector-vector multiplication to obtain $P_{i,j}$. This recalculation process is repeated for all important elements. Now, we have a matrix P with two different precision, which needs to be multiplied by the value matrix V. Considering hardware implementation specifics, we split this into two groups of computations: one for the full-precision p multiplied by V, producing a partial output matrix O_0. The other group, based on the previously stored indices, retrieves the high-precision $P_{i,j}$ and the jth token of V, multiplying them to produce another part of the output matrix O_1. The final output O is obtained by summing the two matrices.

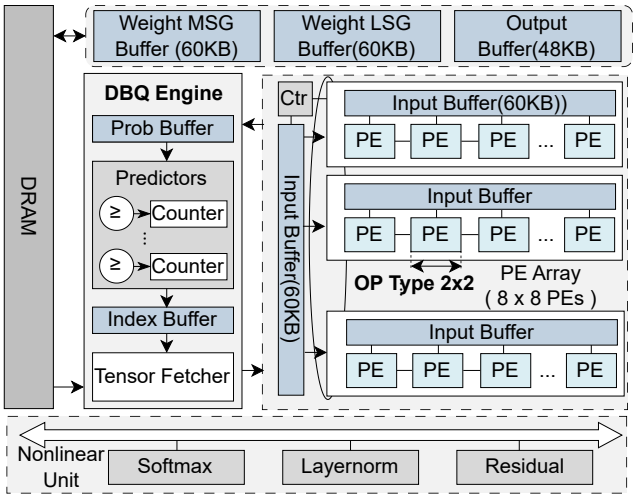


Fig. 4: Overview of Libra hardware architecture.

IV. LIBRA HARDWARE ARCHITECTURE

A. Architecture Overview

To fully leverage the advantages of FBS and DBQ, we designed Libra, a hybrid-sparse attention accelerator closely tailored to the algorithm. The key architectural highlights include: 1) an adaptive bit-width PE based on the bit-group multiplier unit (BMU), which accommodates the varying bit-width requirements at different computation stages. 2) a task pool, which maximizes bit sparsity utilization, effectively balances workloads across multi-levels. In this section, we first present the overall architecture of Libra. Then we discuss how the task pool within the BMU reduces unnecessary computations by exploiting bit sparsity. Finally, we detail the PE constructed from BMU, highlighting its ability to leverage hybrid sparsity and implement multi-level workload balance strategies. The overall architecture of Libra, as shown in Fig. 4, includes input buffers, weight buffers, an output buffer, an 8×8 decoupled PE array composed of adaptive bit-width PEs, a global accumulator, nonlinear units, a DBQ engine, and a top-level controller.

B. Bit-group Multiplier Unit

As shown in Fig. 6, a single PE unit consists of four BMU. Each BMU is composed of an encoder, a task pool, four bit-group compute cores, and decoder. The input to each BMU is bit-groups. As shown in Fig .5, after being encoded by the encoder, tasks are generated and stored in the task pool for computation, with the output handled by the accumulation unit. In the task generation phase, our hardware unit eliminates unnecessary 0-Booth computations, taking advantage of bit sparsity.

1) **Encoder**. We ensure that each BMU receives data represented by a single bit-group, which allows us to implement our encoder with very low overhead. The encoder receives bit-group in each cycle, producing necessary task pairs that are sent to the task pool. The bit-group can be encoded into two Booth-encoded values according to the following formulas: $Booth_1 = 4 * (-2b_4 + b_3 + b_2)$, $Booth_0 = 1 * (-2b_2 + b_1 + b_0)$. The values of b_i range from {2, 1, 0, -1, -2}, so $Booth_i$ has a range of $[-8, 8]$, and can be shown as $[-2^3, 2^3]$. So we can decode these into a sign bit, a valid bit and a 3-bit shift term. When performing multiplication, only the exponent terms need to be added. Finally, the decoder produces the final output.

During the task generation stage, we use valid bit to compress unnecessary computations. For example, as shown in Fig. 5, for A and B, with valid bits of [1, 0] and [1, 1], respectively, if the Booth_0

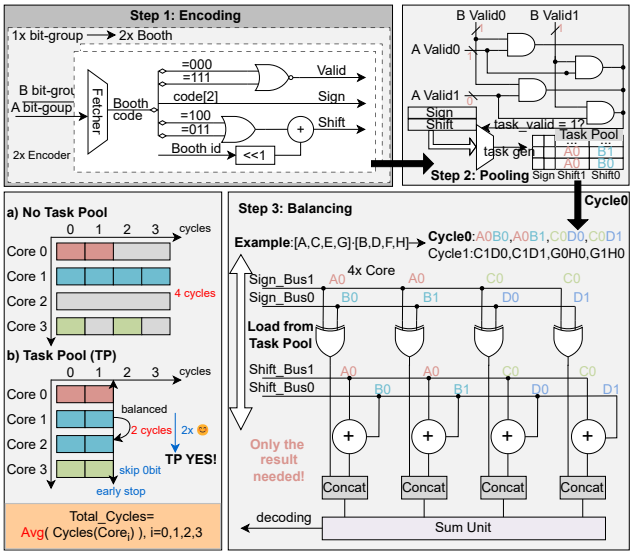

Fig. 5: Illustration of workload balancing in BMU via task pool.

of A is 1, two tasks $[A_0, B_1]$ and $[A_0, B_0]$ will be generated. This reduces the required tasks by 50% compared to the original four tasks.

2) **Task Pool**. The task pool is primarily used to temporarily store tasks, enabling fine-grained scheduling both within and between BMU to fully utilize sparsity. Since each BMU contains four compute cores, the task pool must maintain enough tasks to ensure all cores remaining active, to prevent idle periods. Simultaneously, since up to 4 tasks can be generated in a single decode cycle, we designed the task pool of each BMU to have a depth of 8, striking a balance between functionality and minimizing overhead.

For each BMU, the computation involves multiplying and summing two vectors. As we only need the correct final result rather than element-wise result, we can use the task pool to issue tasks out-of-order, dynamically assigning them to compute cores that have finished their previous tasks. This avoids load imbalance caused by the irregular distribution of bit sparsity within the BMU.

3) **Compute Core**. The input to the compute core is a task. Due to the decoder design, we can use an adder to achieve the same functionality as a multiplier. We perform an XOR on the sign bits to obtain the sign of the partial product, while the exponent terms are added to determine the final shift amount. Since we only need the sum of all partial products, there is no need for immediate decoding. The sum unit accumulates the results from all cores based on the sign bits, and once all computations are complete, the decoder provides the final output.

C. BMU-based Adaptive PE

In the computation process, we encounter three different bit-width operations: 2×2, 2×1, and 1×1, where '1' represents a single bit-group (3 bits) and '2' represents 2 bit-groups (5 bits). To avoid wasting area by designing separate PE units for each bit-width, we designed an adaptive bit-width PE unit based on BMU. By combining BMUs in different configurations, we support three different bit-width operations required by our algorithm.

As shown in the Fig. 6, we can combine 2 BMU into one 2×1 PE. Similarly, 4 BMU can be further combined into a 2×2 PE. Taking 2×2 computation as an example, there is some sparsity at the value level. Thus, before feeding data into the PE, we perform bit-mask preprocessing to eliminate unnecessary computations at the value level. Bit-level sparsity utilization is handled by the task pool,

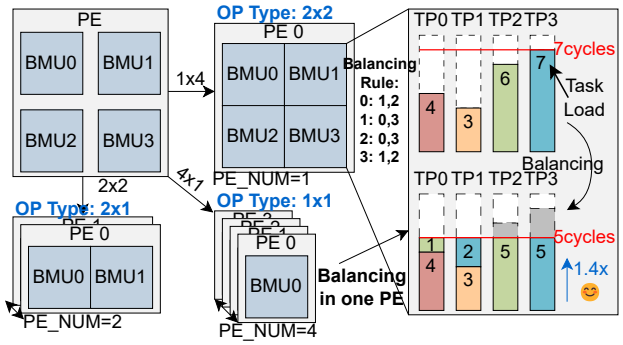

Fig. 6: Cases of adaptive bit-width in PE. Workload balancing within PE for 2x2 OP type.

as described in the previous section. Due to the irregularity of the hybrid sparsity distribution, we found that maintaining workload balance among BMUs within a PE and across different PEs is difficult through pre-allocation alone. Therefore, we implement a multi-level workload balance strategy using the task pool from the BMUs. Each PE contains 4 task pools, which are arranged in a loop to enable data sharing between 4 BMUs. To further reduce the overhead caused by task scheduling, tasks are prioritized within the same PE. As shown in Fig. 6, when BMU0 completes its computation, it loads task from the task pool of the adjacent BMU at the tail end, performs the calculation, and temporarily stores the accumulated result in a dynamic register. Once all computations are completed, the result is returned to the corresponding BMU for summation, allowing for any subsequent operations such as shifting.

Similarly, load imbalance can occur across PEs. We set up a stack in each PE's input channel to temporarily store input data loaded onto the chip. A monitor is added to stack to track the number of value pairs expected to be computed by each PE in real time. Within the same PE group, stacks are shared. When one PE finishes its computation, it will prioritize reading from the stack of the PE with the most remaining tasks, thereby balancing the workload within the same PE group. Considering that in the $P \cdot V$ computation stage, different PE groups handle different types of computations, and cross-PE group scheduling would incur significant overhead, outweighing the potential benefits. Therefore, we do not consider scheduling across PE groups.

V. EVALUATION

A. Experimental Setup

Benchmarks. To validate the computing performance of Libra, we select the Bert-base model and fine-tuned it on eight GLUE text classification tasks. Our evaluation criteria encompass F1 scores for MRPC and QQP, Pearson correlation for STS-B, and Matthews correlation for CoLA. Accuracy on the validation set is reported for remaining tasks. Subsequently, we evaluate the model's inference capabilities, building them with the open-source Huggingface [12] and PyTorch [2] libraries. For all models, we perform five rounds of fine-tuning using the AdamW optimizer with a learning rate of 2e-6 and cosine scheduling.

Hardware implementation. We implement the Libra architecture in Verilog HDL and synthesize it by Synopsys Design Compiler at 500MHz under TSMC 28nm HPC+ technology. The power consumption of SRAM-based on-chip systems is obtained by CACTI 7 [1].

B. Evaluation on Libra Algorithm

1) Weight FBS. To evaluate the effectiveness of the proposed FBS for weights, we test the Booth sparsity of weights after applying FBS and compare the results with a baseline without FBS. Fig. 7 shows the Booth sparsity across different datasets. We apply '2' and '1' constraints to MSG and LSG, respectively. Compared to the baseline, Booth sparsity in weights after FBS increase by an average of 15.92%. Given that, without FBS, the computational reduction in Bit-Serial Architecture depends on bit sparsity, we compare the Booth sparsity of weights after FBS with the bit sparsity of baseline weights, observing an average increase of 13.41%. While significantly enhancing sparsity, the accuracy loss due to the FBS algorithm remains negligible. This is because FBS leverages the characteristics of Booth encoding to filter out a large number of redundant consecutive '1's in negative values. Additionally, the introduction of bit-group reduces the impact on larger values and allows for more aggressive sparsification of less influential values.

TABLE I Accuracy Results of Different Approaches on Different Tasks

TASK	QNLI	MRPC	MNLI	QQP
Baseline	91.1	89.8	84.7	87.9
Sanger	91.0	88.7	84.8	87.9
DTQAtten	90.5	89.7	85.0	75.5
DEQ	90.8	89.6	85.2	87.7
Libra	**91.1**	**88.6**	**83.6**	**88.1**
TASK	**SST-2**	**CoLA**	**RTE**	**STS-B**

DEQ	92.5	58.3	62.4	88.4
Libra	**91.9**	**57.8**	**65.7**	**88.7**

TABLE II Area and Power of Different Modules

Module	Area[mm^2]	Power[mW]
PE Array	0.247	62.53
DBQ Engine	0.004	0.102
Nonlinear - Softmax	0.13	5.63
Nonlinear - Others	0.072	1.085
SRAM Buffer	0.478	268.9
Others	0.199	38.41
Total	**1.13**	**376.66**

2) Activation DBQ. To investigate the effective utilization of activation sparsity potential by DBQ, we evaluate the impact of the ratio parameter r on accuracy loss and the associated reduction in computation across multiple datasets. Fig. 8 illustrates the percentage of computations for $Q \cdot K^T$ that can directly leverage the predicted results under different values of r. And Table III illustrates the accuracy loss. Notably, for QQP at r = 0.8, the proportion of computations that directly used predicted results reached 93.3%, with no accuracy loss. This observation underscores that within attention computation, a substantial portion of calculations are redundant, indicating that only a small subset of token pairs exhibiting high correlation significantly affect accuracy.

Sanger and DTQAtten directly eliminate computations related to token pairs with low correlation, resulting in wasted computational overhead for prediction. We argue that for token pairs with low correlation, the information provided by the prediction is sufficient to replace the result from full-precision computation without causing significant accuracy loss. When the dynamic sparsity ratio is sufficiently high, even the eliminated small values still contain a substantial amount of information. Furthermore, the computational overhead of predicting correlation increases with the input length. Therefore, DBQ reuses the predicted results, allowing fewer high-precision calculations while maintaining the same accuracy loss as Sanger and DTQAtten.

3) Put it Together. Using the optimal configuration, we integrate FBS and DBQ, presenting the final accuracy and corresponding

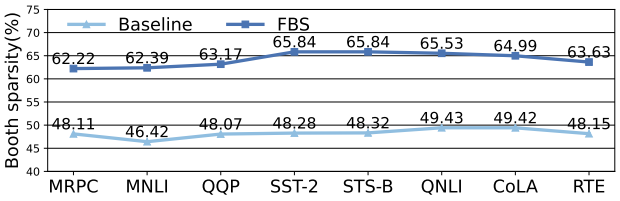

Fig. 7: Average Booth sparsity of linear layer weights across different tasks on Glue.

speed-up for each dataset in the Table I. The average accuracy loss for the Libra sparse scheme remains under 1%.

C. Evaluation on Libra Hardware

Libra is implemented in TSMC 28nm technology, operating at 500MHz. The detailed area and power breakdown of Libra are shown in Table II. Our accelerator features an 8×8 processing array, with 408 KB of SRAM allocated for weights, inputs, temporary buffers, and their corresponding buffers. Our accelerator have a total area of $1.13mm^2$ and total power of $376.66mW$.

We contact extensive experiments on glue datasets to compare our accelerator with SOTA Transformer accelerators in terms of speedup and energy efficiency. A cycle-accurate simulator is developed to collect performance statistics. Fig. 10 presents the normalized performance with other accelerators. Experimental results show that comparing with Sanger, DTQAtten, DEQ, Libra has achieved $5.89\times$, $3.35\times$, $1.49\times$ normalized performance gain, respectively. As shown in Fig. 11, our accelerator achieves $10.82\times$, $7.41\times$, and $2.65\times$ enhancement in energy efficiency compared with Sanger, DTQAtten, and DEQ, respectively. The improvements are driven by three key factors. First, our algorithm exploits hybrid sparsity, reducing redundant computations caused by zero values and bits. And then, Libra significantly decreases the computational load in the $Q \cdot K^T$ operation, a critical step in attention mechanisms, resulting in enhanced overall efficiency. Lastly, the multi-level workload balance strategy improves the utilization of computational resources and reduces energy consumption.

Fig. 9 illustrates the performance under different task pool depths (0, 4, 8, and 16) across various tasks. We observe that as the depth increases, performance also improves. This trend can be attributed to the enhanced capacity of the task pool to manage workloads, thereby reducing the likelihood of load imbalance. However, increasing the depth also results in greater area and power consumption, as well as increased complexity in scheduling logic. Considering the trade-offs between performance and additional overhead, we set the task pool depth to 8 for optimal balance.

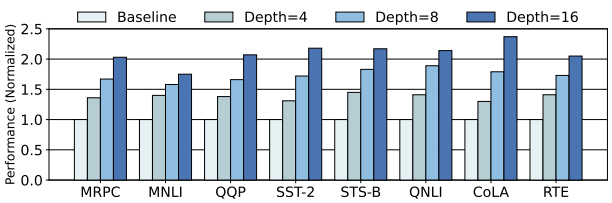

Fig. 9: Performance analysis with different task pool depths. All results are normalized to Baseline (depth=0).

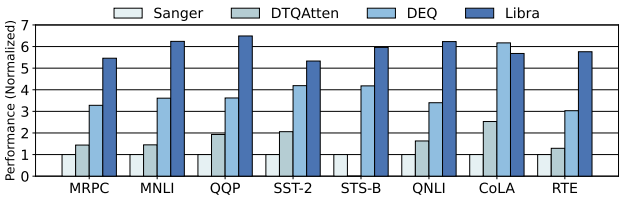

Fig. 10: Comparison of performance between Libra and other accelerators. All results are normalized to Sanger.

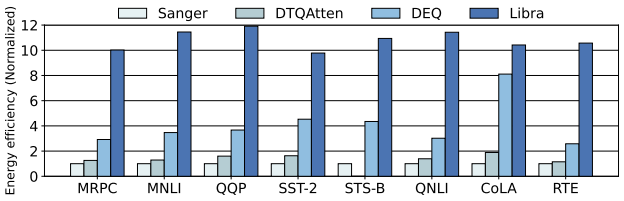

Fig. 11: Comparison of energy efficiency between Libra and other accelerators. All results are normalized to Sanger.

To validate the effectiveness of our multi-level workload balance strategy, we evaluated Libra's performance under same conditions without enabling the multi-level load balance strategy across various tasks. When the task pool depth is 0, the multi-level workload balancing strategy is not enabled. As shown in the Fig. 9, without multi-level workload balance, Libra's performance decreased by an average of $1.73\times$, indicating the strategy's effectiveness. The multi-level workload balance strategy allows Libra to achieve local workload balance within BMUs and between PEs, thereby reducing the stalling of compute units.

VI. CONCLUSION

This paper presents Libra, a software-hardware co-design that leverages hybrid sparsity to accelerate attention-based models. The bit-group-based algorithm applies sparsification to weights, and dynamically adjusting the number of bit-groups for different elements by exploiting the redundancy in the attention mechanism, resulting in a significant reduction in computation. To fully harness the potential of the hybrid sparsity and algorithm, we design a matching adaptive bit-width architecture, with multi-level optimizations to address load imbalance caused by hybrid sparsity. Experimental results demonstrate that Libra can achieve up to $1.49\times \sim 5.89\times$ speedup and $2.65\times \sim 10.82\times$ enhancement in energy efficiency.

***Abstract*—The introduction of multiple transform types in the Versatile Video Coding (VVC) standard has yielded notable encoding gains but also imposed considerable computational burdens. Existing transform circuits of different types are typically implemented separately due to their independence, leading to substantial hardware overhead. To address this, we explore the relationship between Discrete Cosine Transform Type-2 (DCT2) and Discrete Sine Transform Type-7 (DST7) matrices and reveal a prominent diagonal aggregation phenomenon in their transfer matrix. Based on this insight, the least-squares method is applied to optimize the transfer matrix sparsity, achieving a high-precision, low-cost approximate conversion from DCT2 to DST7. Furthermore, we optimize DCT2 computation by proposing an elaborate matrix decomposition approach that allows a lightweight shift-adder unit to efficiently generate all required product terms across varying sizes. Leveraging these algorithmic optimizations, we implement a highly reusable and area-efficient approximate transform accelerator that supports sizes from 4 to 32 points and accommodates three types in VVC. Experimental results demonstrate that the proposed accelerator achieves over 44% reduction in circuit resource consumption with negligible BD-BR performance loss of just 0.53%, maintaining processing capabilities up to 8K@57 fps.**

***Index Terms*—Video coding, transform accelerator, approximate architecture, sparsity optimization, area-efficient**

I. Introduction

Transform coding has been widely integrated in video coding due to its efficient spatial decorrelation capability. Cooperating with quantization and entropy coding, it significantly improves compression rates while maintaining slight quality loss. It was proved in [1] that the Discrete Cosine Transform Type-2 (DCT2) can optimally approximate the Karhunen-Loève (K-L) transform and is also more computationally efficient, resulting in its widespread adoption in H.264 and H.265. Later, Han et al. [2] demonstrated that for images modeled by a first-order Gaussian-Markov process, the Discrete Sine Transform Type-7 (DST7) provides better decorrelation than DCT2. Therefore, the latest coding standards have introduced DST7 alongside DCT2 for more comprehensive decorrelation.

The introduction of multiple transform types provides significant coding benefits, yielding a 2.10% coding gain, but it also substantially increases computational complexity. In terms of hardware resource consumption, supporting multiple transform types requires instantiating additional transform circuits, which incurs high hardware costs. To mitigate these costs, several approaches have been proposed, grouped into three main categories. The first category focuses on **independent optimizations for DCT2**. Early studies include the Butterfly algorithm, which reduces multipliers by leveraging symmetry. Ahmed et al. [3] further reduced multiplications by decomposing DCT matrices into sparse sub-matrices. Additionally, multiplier-less techniques [4]–[6] have been developed to optimize multiplication. Recent DCT2 hardware optimizations focus on improving reusability. Hao et al. [7] proposed using smaller transform matrices as subsets of larger ones to improve reusability. Zheng et al. [8] and Hao et al. [9] introduced data rearrangement schemes that allow even-odd decomposition circuits to be reused across different transform sizes.

The second category focuses on the **independent optimization of DST7**. Notably, Discrete Cosine Transform Type-8 (DCT8), another transform type used in VVC, exhibits significant symmetry with DST7, allowing the optimization of both transformations to be reduced to the optimization of DST7. Garrido et al. [10]–[15] explored various approaches for designing efficient DST architectures on FPGA, including utilizing DSP resources for multiplication and replacing multiplication with shift-add operations. Fan et al. [16], [17] applied the RAG-n algorithm to minimize adder count, significantly reducing resource usage.

The third category focuses on the **joint optimization of both types**. These methods typically employ approximate computation strategies to reduce resource overhead. In [18], the matrix elements are modified to multiples of 2^3 to reduce multiplier size, though suffering unneglectable performance loss. Ahmed et al. [19] proposed a method to convert results of inverse DCT2 to DST7 with good coding performance. However, it requires an inverse transform in the forward transform pipeline, making it impractical for hardware implementation.

Previous studies have predominantly focused on optimizing DCT2 or DST7 architectures in isolation, or on joint optimization strategies that are impractical for real-world applications, often failing to effectively balance performance retention with hardware constraints. In this paper, we achieve a high-precision and low-cost approximate transform accelerator designed through algorithm-hardware co-optimizations. The main contributions are summarized as follows:

- **High-precision and low-cost approximate scheme for DST7.** Our analysis reveals an efficient transfer relationship between DST7 and DCT2. Leveraging this insight,

we define a transfer matrix and further optimize its sparsity with the least squares method, facilitating a high-precision result conversion from DCT2 to DST7. Notably, 79.3% multipliers can be saved for the 32-point case.

- **Matrix decomposition-based calculation scheme for DCT2.** Building upon the butterfly algorithm, we further reduce the remaining complexity by proposing an improved computation scheme for DCT2, enabling a lightweight shift-adder unit (SAU) to generate all product terms across varying size.
- **Highly-pipelined and area-efficient approximate transform architecture.** With above algorithmic optimizations, we develop a pipelined architecture that integrates multiple resource-reuse and data-parallelism strategies. Compared to related works, the proposed architecture achieves a reduction of over 44% in resource costs and delivers the highest throughput.

II. Background and Motivation

A. Background of transform

The transform scheme employed in VVC integrates three primary transform types: DCT2, DST7, and DCT8. By exploiting the separability, the two-dimensional (2D) transform is decomposed into two sequential 1D transforms, effectively reducing both storage and computational costs. Therefore, optimization efforts for transform architectures mainly focus on 1D transforms. The 1D DCT2 is defined as (1),

$$Y(k) = \sqrt{\frac{2}{N}}\varepsilon_k \sum_{n=0}^{N-1} x(n) cos\left[\frac{k(2n+1)\pi}{2N}\right],\ \varepsilon_k = \begin{cases} \sqrt{\frac{2}{N}}, k=0 \\ 1 \quad\quad , k\neq 0 \end{cases} \tag{1}$$

where k is the index of transform coefficients. $Y(k)$ is the transformed outputs, $x(n)$ is the input data, and N is the transform size. It can be expressed in matrix form as follows:

$$Y = A \times X^T, \tag{2}$$

where A is the transform matrix. In practical video coding, by scaling and rounding the A matrix while preserving its orthogonality, the integer transform matrix T can be obtained. Therefore, the integer 1D transform can be conducted as (3):

$$Y = T \times X^T. \tag{3}$$

The transformation process is inherently a computation-intensive matrix multiplication. The T varies with transform types. Thus, the optimization of the transform architecture relies on refining the corresponding matrix multiplications.

B. Motivation

The integration of multiple transform types intensifies the industry's desire for a unified architecture that supports all three transform types with the resource cost of a single type. However, the independence of DCT2 and DST7 matrices poses a huge challenge as the general multipliers-based architecture leads to heavy resource overhead. While DST7 and DCT8 share the same circuit, an efficient solution for merging DCT2 and DST7 into a joint design remains unresolved. Previous works targeting joint optimization are not efficient enough to balance coding performance with hardware friendliness, rendering them impractical for most real-world applications.

For optimizing DCT2 and DST7 jointly, we conduct an in-depth analysis of their computation processes and observe a prominent diagonal aggregation feature in the transfer matrix, motivating us to explore its sparse optimization for high-precision and cost-effective result conversion from DCT2 to DST7. Besides, we observe that after applying the butterfly transform to DCT2, the remaining matrix multiplications exhibit a beneficial feature, providing further opportunities to reduce the computational resource requirements for DCT2.

III. Hardware-Oriented Algorithmic Optimizations

A. Algorithmic Optimizations for DST7

To establish the relationship between the DCT2 and DST7, we begin with their corresponding transform processes:

$$Y_2 = T_2 \times X^T, \qquad Y_7 = T_7 \times X^T, \tag{4}$$

By transposing both sides of these equations, we obtain:

$$Y_2^T = X \times T_2^T, \qquad Y_7^T = X \times T_7^T. \tag{5}$$

Further, a transfer matrix TF is defined to reflect the conversion between the results of DCT2 and DST7:

$$Y_2^T \times TF = Y_7^T \iff X \times T_2^T \times TF = X \times T_7^T, \tag{6}$$

simplifying it as:

$$T_2^T \times TF = T_7^T. \tag{7}$$

Considering that T_2 is an orthogonal matrix, we have $T_2^{-1} = \frac{T_2^T}{2^n}$, where 2^n is introduced for integer transform. Besides, the inverse matrix of T_2^T is $\frac{T_2}{2^n}$. Substitute it into (7) and TF can be derived as (9):

$$\frac{1}{2^n} \times T_2 \times T_2^T \times TF = \frac{1}{2^n} \times T_2 \times T_7^T, \tag{8}$$

$$TF = \frac{1}{2^n} \times T_2 \times T_7^T. \tag{9}$$

Fig. 1a presents the scaling and rounding case of the transfer matrix TF, which converts the transform results from DCT2 to DST7. It is evident that the elements of TF exhibit a pronounced aggregation pattern, with the larger magnitudes concentrated along the diagonal and values farther from the diagonal approaching zero. Smaller values, representing lower significance, can be discarded to reduce computational costs while preserving transfer accuracy.

The previous observation inspires the sparse optimization of TF. This optimization problem can be formulated as a constrained optimization problem, where the objective is to minimize the error defined in (10) between the original DST7 matrix T_7 and its approximation $\widetilde{T_7}$ (11) computed from the sparse transfer matrix $\widetilde{TF}$, subject to the constraint of limiting the number of non-zero values in each column of $\widetilde{TF}$. This can be expressed mathematically as follows:

$$E(\widetilde{TF}) = \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} (T_7(i,j) - \widetilde{T_7}(i,j))^2 \tag{10}$$

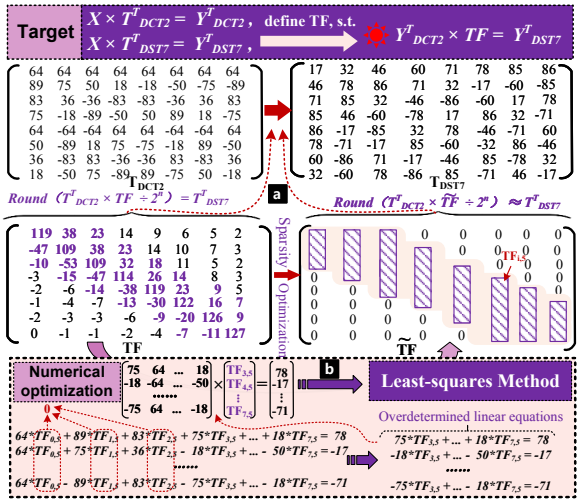

Fig. 1. The algorithmic optimizations for DST7. (a) The introduction of transfer matrix and the motivation of sparsity optimization. (b) Sparsity optimization of $TF_{i,5}$ with the least-squares method

$$\widetilde{T_7^T} = round\ (T_2^T \times \widetilde{TF} \div 2^n); \tag{11}$$

$$\begin{aligned} &\textbf{minimize}\ E(\widetilde{TF}), \\ &\textbf{subject to}\ \widetilde{TF}_{i,j} = 0,\ |i-j| > (r-1)/2, \\ &\qquad \widetilde{TF}_{i,j} \in \mathbb{Z} \cap [-2^n+1, 2^n], \end{aligned} \tag{12}$$

where r is the number of retained elements in each column of $\widetilde{TF}$. For example, when $r = 5$, as illustrated in Fig. 1a, only the diagonal and two neighboring elements on each side are preserved. Besides, note that the error $E(\widetilde{TF})$ is accumulated independently from every column, therefore, the optimization problem can be further decomposed into individual column-wise optimization tasks, which effectively reduces the optimization complexity. In this paper, we employ the least squares method to solve the constraint optimization for each column. Fig. 1b presents the optimization process for the sixth column $TF_{i,5}$. It is evident that, for $r = 5$, the system of equations becomes overdetermined. By formulating this system of equations as a matrix equation, it can be efficiently solved using MATLAB to obtain the least squares solution.

Following that, we conduct a group of experiments to determine the optimal variable r and the results are illustrated in Fig. 2. **For performance evaluation**, five video sequences with varying resolutions were randomly selected as test vectors, and the results of $r = 5$, $r = 7$, and $r = 9$ are depicted in Fig. 2a. As r increases, the Bjøntegaard Delta-Bit Rate (BD-BR) [20] loss decreases across all sequences. It is worth noting that the loss reduction between $r = 7$ and $r = 9$ is less significant than that between $r = 5$ and $r = 7$. Specifically, For *basketballDrill*, the performance loss decreases by 0.24% when r increases from 5 to 7, while the reduction from 7 to 9 is only 0.06%. Additionally, **the multiplier usage ratio** for the approximation to the exact transform is presented in Fig. 2b, where the multiplier usage increases approximately linearly with r. Taking performance and multiplier usage into consideration, $r = 7$ is selected as the optimal parameter.

Fig. 2c depicts the approximation of the first eight basis vectors of the 16-point DST7 when $r = 7$. The results clearly

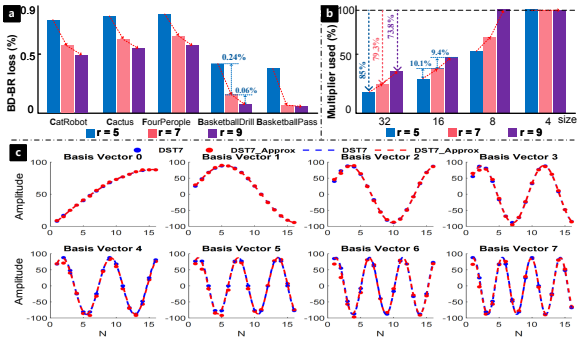

Fig. 2. (a) The Bd-BR loss of five sequences under different r. (b) The multiplier usage ratio of four sizes under different r. (c) Performance of approximation when $r = 7$.

indicate that the $\widetilde{T_7}$ derived from (11) closely matches the original matrix, underscoring the efficacy of the proposed method in balancing precision and computational complexity.

B. Algorithmic Optimizations for DCT2

The algorithmic optimizations for DCT2 are inspired by an efficient hardware design of DST7. The DST7 transform matrix exhibits a beneficial feature: its row/column coefficients are derived from a unified set, differing only in position and sign. This feature enables an efficient SAU-based matrix multiplication, where N identical SAUs generate all product terms, which are then accumulated through an adder tree, significantly reducing computational resources, as shown in Fig. 3a. However, Fig. 3b reflects that this feature doesn't appear in the DCT2 transform matrix, making direct optimization impractical. Encouragingly, after applying the classic butterfly algorithm to DCT2, its sub-matrices possess this desirable feature. As shown in Fig. 3b, the 8-point DCT2 with the butterfly algorithm is presented, which merges inputs with matching coefficients to produce the E and O vectors. These vectors are subsequently processed by sub-matrices to derive the final transformed outputs. The presence of this mentioned feature in the sub-matrices allows for further optimization of the remaining calculations.

It is worth noting that directly optimizing the sub-matrix computations with SAU-based matrix multiplication still results in substantial resource consumption. This stems from the diversity in sub-matrix elements across various sizes, requiring distinct SAUs to be instantiated for each size. To enhance SAU reuse across multiple sizes, we introduce a matrix decomposition-based calculation scheme for DCT2, as depicted in Fig. 3.c, defined as follows:

$$T = Q \times s + R, \tag{13}$$

here, s represents a scaling factor with a power-of-two value (2^n), determined by balancing the complexities of Q and R. As the s increases, the complexity of Q decreases and that of R increases. For each entry in $T(i,j)$, its decomposition equation is given by (14):

$$\begin{cases} T(i,j) = & Q(i,j) * s + R(i,j), \\ |R(i,j)| \leq & s/2. \end{cases} \tag{14}$$

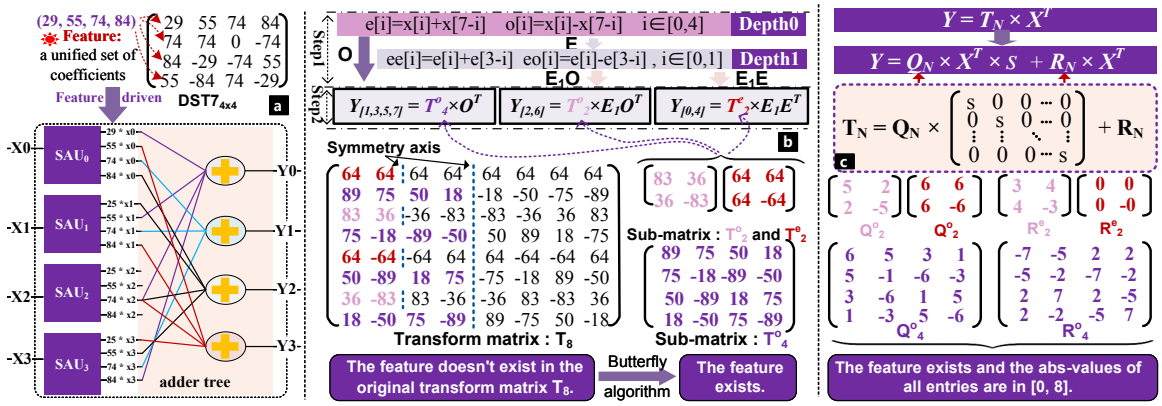

Fig. 3. (a) The beneficial feature and the SAU-based matrix multiplication. (b) The butterfly algorithm and sub-matrix of DCT2. (c) The proposed calculation scheme based on matrix decomposition.

Given that the maximum entry of the DST7 and DCT2 matrix is 90. We can acquire the range of absolute value in Q and R matrices presented in Table I. Clearly, when s is equal to 16, these two matrices share a similar level of complexity. In this case, the optimized calculation scheme for DCT2 can be described as (15):

$$Y^T = Q \times X^T \times s + R \times X^T, \tag{15}$$

where the X is the inputs, and the computationally intensive matrix operation is carried out by two simpler matrix multiplications and shift operations. The limited range of Q and R enables a lightweight SAU circuit with output $\{1x, 2x, 3x, 4x, 5x, 6x, 7x, 8x\}$ to generate all required product terms, improving the reusability dramatically.

IV. The Hardware Transform Accelerator Implementation

A. Overall Architecture Design

We implement a highly parallel, extensively reusable, and deeply pipelined transform accelerator in Fig. 4, capable of processing 32 samples per cycle. For transform sizes below 32 points, multiple input sets are combined to create a 32-point input. This approach processes 8 groups of 4-point inputs, 4 groups of 8-point inputs, 2 groups of 16-point inputs, or a single group of 32-point inputs in each cycle. Such parallel processing achieves the highest level of concurrency among existing research.

The proposed accelerator features a deeply pipelined architecture with six stages: even-odd decomposition, lightweight SAU calculation, selector tree, adder tree, DCT2 result integration, and transfer calculation. The initial five stages focus on DCT2, whereas the last stage handles DST7. The following sections provide a detailed description of the data flow within each pipeline stage, highlighting the strategies for parallelism and reusability.

TABLE I
The Range of Absolute Value in Q and R Matrices

Scale factor s	4	8	16	32	64
abs Q range	[0,23]	[0,11]	[0,6]	[0,3]	[0,1]
abs R range	[0,2]	[0,4]	[0,8]	[0,16]	[0,32]

B. Even-Odd Decomposition Stage

Stage0 is the even-odd decomposition stage, breaking down inputs into E and O vectors via the butterfly algorithm, as shown in Fig. 3b. For this purpose, a custom decomposition circuit was designed, specifically for processing 8 groups of 4-point inputs, as illustrated in Fig. 4b.

Reusability. Applying this decomposition circuit to other input sizes directly leads to data mismatches. For instance, with a set of 32-point input, the correct $e[0]$ should be derived by adding X_1 and X_{31}, but the circuit would erroneously compute it as the sum of X_1 and X_3, leading to a malfunction. To ensure functional correctness and enable reuse of the decomposition circuit across varying input sizes, we propose a data rearrangement scheme depicted in Fig. 5, where X_{31} is repositioned to the location of X_3 accordingly. This strategy eliminates data mismatches and allows a single decomposition circuit to support four input sizes, effectively reducing the adder resource consumption by 75%.

C. Lightweight SAU Calculation Stage

Stage1 is the SAU computation stage, generating all the product terms involved in the matrix multiplications.

Reusability. As shown in Table I, the absolute value range of all matrix elements is confined within [0, 8]. Therefore, we design a lightweight SAU embedding with only three adders to efficiently generate the product terms, as shown in Fig. 4a. The reuse strategy of this pipeline stage is twofold: first, the SAU can be reused across different transform sizes; second, there is no need to instantiate separate SAU circuits for the Q and R sub-matrices, as they share a similar value range.

Parallelism. The accelerator instantiates 32 lightweight SAUs in total, which operate in parallel to generate the product terms corresponding to the 32 inputs.

D. Selector Tree

Stage2 is the selector tree stage, which routes the product terms produced by the SAUs. The appropriate SAU outputs are selected based on the matrix elements and forwarded to the next stage via Adder-tree Selectors (ATS), as depicted in Fig. 4c. Each ATS includes multiple selectors, controlled by the *size* signal.

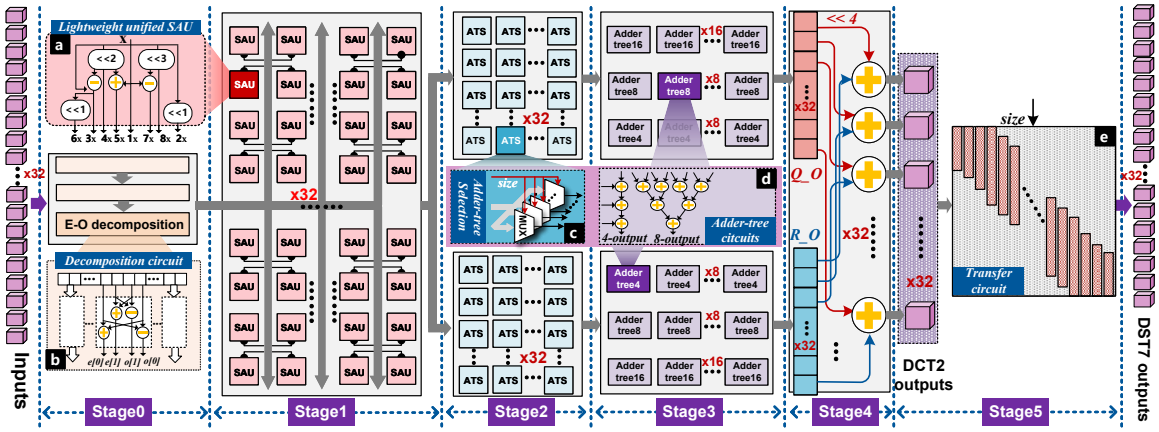

Fig. 4. The proposed architecture. (a) Lightweight unified SAU. (b) Decomposition circuit. (c) Adder tree selection. (d) Adder-tree circuit. (e) Transfer circuit.

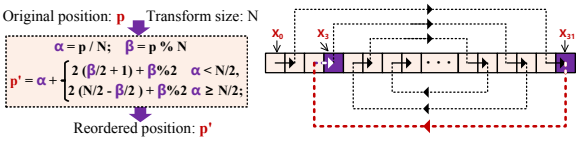

Fig. 5. The proposed data rearrangement scheme.

Parallelism. In this stage, the selection process for the sub-matrices Q and R is performed in parallel. Each of them requires 32 ATS units, resulting in a total of 64 ATS units working concurrently.

E. Adder Tree and DCT2 Result Integration Stages

Stage3 is the adder tree stage, where the selected product terms are accumulated.

Parallelism. This stage employs three types of adder trees: adder-tree4, adder-tree8, and adder-tree16, as depicted in Fig. 4d for efficiently accumulating 4, 8, and 16 inputs, respectively. In the original DCT2, each output is obtained by accumulating 32 product terms, which would typically demanding 32 adder-tree32. However, the butterfly algorithm reduces the number of multiplications significantly. For the 32-point case, after the even-odd decomposition, the actual sub-matrices involved in the computation are O, EO, EEO, and EEE, with dimensions of 16×16, 8×8, 4×4 and 4×4, respectively. Consequently, instead of 32 adder-tree32, only 16 adder-tree16, 8 adder-tree8, and 8 adder-tree4 are needed. Meanwhile, the sub-matrices Q and R are processed concurrently, the number of adder-tree circuits is doubled. Thus, the proposed accelerator requires 32 adder-tree16, 16 adder-tree8, and 16 adder-tree4 for parallel accumulation.

Stage4 is the DCT2 result integration stage, where the final DCT2 results are computed using the outputs of sub-matrices Q and R, as defined in (15).

F. Transfer Calculation Stage

Stage5 is the transfer calculation stage,where the DCT2 results are approximated to DST7 results through sparse matrix multiplication, as defined in (6). This stage employs 212 multipliers, significantly fewer than $32 \times 32 = 1024$ multipliers needed for precise DST7 calculation. This approximation strategy achieves a 79.3% reduction in multiplier consumption.

TABLE II
COMPARISON OF THE ALGORITHMS

	DCT2	TCSVT [19]	ICIP [21]	ISCAS [18]	Ours
Performance	Evaluating metric: **BD-BR (%)**				
Hardware Friendly	✓	×	✓	✓	✓
A1 & A2	1.36	0.20	1.13	1.79	0.69
B	1.54	0.14	1.32	1.16	0.74
C	2.97	0.06	0.96	0.93	0.23
D	2.37	-	0.99	0.96	0.35
E	2.24	0.18	0.95	1.25	0.65
Average	**2.10**	**0.15**	**1.07**	**1.22**	**0.53**

V. EVALUATION

A. Experimental Setup

Performance evaluations were carried out using the VVC reference software VTM17.0 under all-intra configurations, employing BD-BR as the evaluation metric. The accelerator was designed in Verilog HDL and synthesized using Global Foundry's 28nm standard cell library to measure area, frequency, and power consumption metrics.

B. Coding performance comparison

To validate the effectiveness of the proposed algorithm, a comparison with other approximate transformation algorithms was conducted, as shown in Table II. When the transformation type in VVC is restricted to DCT2, coding performance drops by 2.10% relative to the use of multiple transform types. Significantly, applying the proposed approximation method within the multiple transform framework minimizes this loss, reducing it to just 0.53%. This ensures that most of the coding benefits of the original approach are maintained.

Approximation algorithms in existing research can be divided into two types. **Neglecting hardware constraints** and **Hardware-friendly algorithms**. The first type often overlooks practical hardware limitations in algorithm design. For example, [19] proposes a high-precision private approximation architecture. Despite its high accuracy, it necessitates embedding an inverse transform circuit in the forward pipeline and modifying the decoder, which doubles the circuit area and renders it unsuitable for most embedded applications. The second type, including [18], [21], and the proposed algorithm, is tailored to be hardware-friendly, allowing easy

integration into the forward transform pipeline without decoder modifications.While [18] and [21] are hardware-efficient, they result in coding performance losses of over 1%. In comparison, our method cuts this loss in half, highlighting its enhanced approximation accuracy.

C. Hardware Implementation Comparison

To demonstrate the hardware superiority of the proposed accelerator, a comparison with existing works is presented in Table III, highlighting resource requirements, throughput, and power metrics.

Resource. With a parallelism of 32 samples per cycle and a gate count of 184.4K, the proposed accelerator significantly outperforms existing designs. Compared to [8], which requires 329K gates for the same parallelism, our design reduces resource usage by 44%. Moreover, while [16] supports only two transform types at the same throughput with 275.4K gates, our accelerator achieves a 33% reduction in gate count despite supporting more transform types, thanks to advanced algorithmic optimizations.

Since different designs have varying specifications, the level of data parallelism they support may differ. To facilitate a fairer comparison, we introduce the Normalized equivalent Gate Count (NGC), defined in (16), as a metric for evaluating design efficiency. Then, we provide a comparison of the NGC for DCT2 and DST7/DCT8 across various works.

$$NGC = Gate\ Count\ /\ Parallelism\ . \tag{16}$$

For DCT2, our accelerator achieves a 32-point data parallelism with only 132.5K equivalent gates, resulting in the NGC of 4.125. The NGC of works [22] and [23] in the comparison list are 20.375 and 5.5, respectively. Compared to them, our accelerator reduces the normalized resources for DCT2 by **77.9%** and **25%**, respectively.

For DST7/DCT8, the computational resources in our work are primarily allocated to the transfer calculation stage, requiring 51.9K gates with an NGC of 1.628. Two designs, [16] and [18], are compared. The design in [16] achieves an NGC of 8.61 with 275.4K gates for 32-point parallelism. Compared to this, our design reduces normalized resources by 81.1%. For work [18], which supports variable throughput with a maximum parallelism of 8 points and an NGC ranging from 3.838 to 15.35, our accelerator achieves a normalized resource reduction of **57.6%** to **89.4%.**

The designs in [24], [8], and [25] support three transform types in VVC, with NGC values of 17.05, 10.281, and 48.4, respectively. The proposed design, which also supports three transform types with a constant and maximum parallelism of 32-point, achieves an NGC of 5.763. This represents a reduction in normalized resources of **66.2%**, **44%**, and **88%** compared to these works.

Throughput. Beyond area efficiency, the proposed architecture also delivers the highest processing speed among all designs. It achieves superior parallelism and operating frequency compared to existing works, making it capable of supporting real-time encoding for **8K@57fps.**

Power. The power efficiency of the proposed accelerator is evaluated using frequency-normalized dynamic power (NP) as defined in [22]. Table III indicates that, compared to the works reporting power consumption, the proposed accelerator achieves NP savings of over **40.7%**, **88.3%**, and **62%** for DCT2, DST7, and three types, respectively.

VI. CONCLUSION

This paper presents a high-precision, cost-effective approximate transform accelerator, supporting three transform types and sizes ranging from 4 to 32 points. Following the principle of algorithm-hardware co-optimization, an approximate algorithm based on a sparse transfer matrix is proposed for DST7, and a matrix decomposition-based algorithm is proposed for DCT2. Furthermore, based on these two algorithms, a deeply pipelined, area-efficient, and highly parallel accelerator is designed. Evaluation results demonstrate that the proposed design offers significant advantages in resource, throughput, and power consumption.

***Abstract*—Intermittent systems require software support to execute tasks amid frequent power failures. In designing such techniques, software designers rely on execution models that abstract hardware-level operations. In this paper, we propose an execution model that more accurately describes emerging intermittent systems with small energy storage. Our evaluation shows show that systems designed based on the traditional models can be up to 5.62x less power-efficient than expected and may result in unsafe checkpoint operations. Our design guidelines enhance the performance of existing static and dynamic checkpoint techniques by 3.04x and 2.85x on average, respectively.**

***Index Terms*—Intermittent Computing, Batteryless System.**

I. Introduction

Batteryless systems are emerging as a promising future platform of Internet-of-Things (IoT) devices. These systems adopt a small capacitor as an energy storage and operate by harvesting power from environmental sources. This setup effectively addresses challenges associated with traditional battery-based systems, such as need for human intervention for recharging or replacement [1] and harmful environmental impacts [2]. They are also known as intermittent systems, since the computation happens intermittently during short periods only when there exist sufficient power to compute.

Intermittent systems require software supports to sustain long-running executions across power failures. During operation, volatile data (e.g., registers or SRAM data) must be saved to Non-Volatile Memory (NVM) through a process called checkpointing. When power is restored, this saved state is recovered to allow operations to resume the execution from the last checkpoint (recovery). In designing these state retention techniques, software designers rely on an *execution model* that abstracts hardware-level operations and represents behavior of intermittent systems necessary for software design.

Fig. 1 illustrates such execution model commonly adopted in the literature [3]–[10]. As energy accumulates, the voltage of the capacitor gradually increases. Once the voltage reaches the power-on threshold V_h, the collected power is supplied to the system. The system begins operation at this point, and execution is halted when the capacitor voltage reaches the power-off threshold V_l. Software designers aim to leverage this execution model to implement intermittent systems at minimal cost (e.g., by executing checkpoints just before reaching the power-off threshold [4], [5], [11]–[13]).

This work was supported by IITP grant funded by the Korea government (MSIT) (No.2021-0-00360 and RS-2024-00438551).

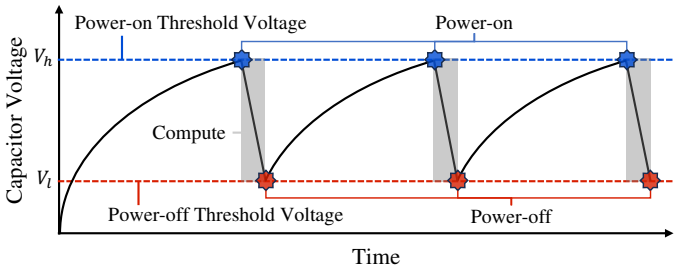

Fig. 1: Traditional execution model of intermittent systems.

In the meantime, recent research on intermittent systems is increasingly exploring shorter operation times by using smaller capacitors. Operating on small capacitors is generally desirable, as it reduces device volume and enhances the responsiveness by enabling the system to wake up more frequently [5], [14], [15]. As a result, recent studies have targeted operation times in the range of tens of milliseconds [1], [13], [16]–[20] or even microseconds [16], [17]. However, as energy storage sizes decrease, the traditional execution model is failing to provide an accurate abstraction of actual execution behavior. The major source of this discrepancy is the buffering effects of the system's inherent capacitance, mostly coming from its decoupling capacitors. This factor has been overlooked in the traditional model, as the inherent capacitance was considered negligible compared to the main energy storage.

Decoupling capacitors are on-board capacitors that act as energy buffers. They are mandatory since the buffered energy prevent transient voltage drop when the system suddenly draws a large current, such as during checkpointing (Sec. II-A). However, their buffering effects also introduce discrepancies between the execution model and actual behavior. For example, during power-on, they rapidly charge from the energy storage, making capacitor voltage an unreliable estimate of available energy. This buffered energy also allows the system operate for a while at sub-normal voltages after the power supply is stopped. Additionally, between power cycles, decoupling capacitors discharge due to the resistance of the system, considerably lowering the power efficiency. In systems with smaller capacitors, these effects dominate the behaviors that are modeled in the traditional execution model. Consequently, highly efficient checkpoint techniques according to the traditional model may introduce substantial power overhead and even correctness issues in small-scale systems.

In this paper, we propose a new execution model for

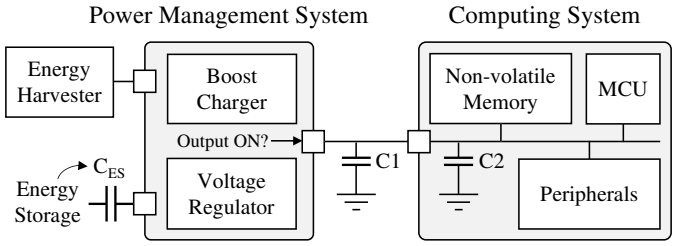

Fig. 2: A typical hardware setup of intermittent systems.

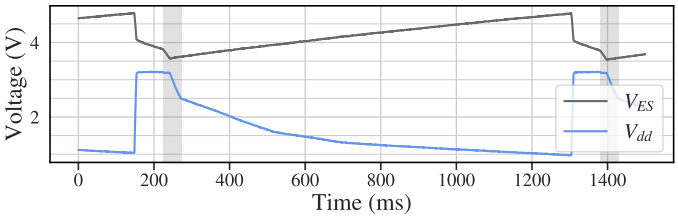
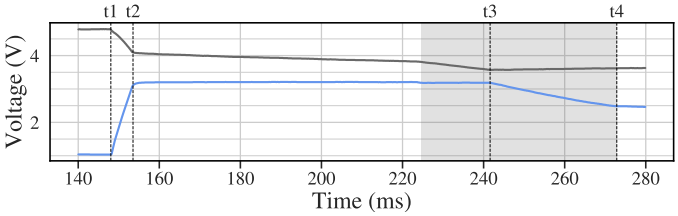
intermittent systems which accounts for the buffering effects of decoupling capacitors. In Sec. II, we demonstrate that understanding this model is critical for software designers: intermittent systems designed upon the traditional model can be up to 5.62x more energy-inefficient than expected and may fail to predict power-off timings accurately, leading to unsafe checkpointing. In Sec. III, we present design guidelines to implement efficient intermittent systems with small energy storages, leveraging insights from our model. Our guidelines include designs which improve end-to-end execution latencies by 3.04x in static and 2.86x in dynamic checkpointing schemes on average, without incurring additional overhead.

II. Detailed Intermittent Execution Model



In this section, we describe our execution model and its implications for software design. Sec. II-A introduces the target architecture and the reference system used for evaluations. Sec. II-B presents our execution model, derived from key observations obtained through experimental results. In the following three sections, we discuss how this model affects both the power efficiency and correctness of software design. Finally, in Sec. II-F, we evaluate the effectiveness of our model across systems with various architectural configurations.

A. Target Architecture and Reference System



A typical intermittent system consists of two main components: a power management system and a computing system, as shown in Fig. 2. The power management system collects incoming energy into storage (C_{ES}) and supplies a stable-voltage current to the computing system. The computing system equips NVMs along with an MCU and peripherals, and utilize the NVMs for state retention between power failures.

This setup includes two notable decoupling capacitors that affect the execution model of intermittent systems. The first one (C1) is located in the power management system, required by voltage regulators to ensure stable operation. The second capacitor (C2) is part of the computing system and used to stabilize the operating voltage against sudden current draw.

Recent studies have increasingly explored 32-bit architectures for computing systems [17], [19], [21]–[29], as emerging applications on intermittent systems, such as Deep Neural Networks (DNNs) [7], [27]–[36], demand greater computational capabilities [14], [37]. In this context, we employ a custom-built board featuring a 32-bit ARM Cortex-M33 processor (STM32L5, operating at 16Mhz) with 512KB of Ferroelectric RAM (FRAM, Infineon FM22L16) as our reference system.

(a) Voltage traces for one power cycle.

(b) Voltage traces of the first execution cycle.

Fig. 3: Voltages trace of energy storage (V_{ES}) and V_{dd}.

For the power management system, we use a TI BQ25570-based board configured with V_h = 4.9V and V_l = 3.4V. We empirically select 22uF and 220uF capacitors for C1 and C2, respectively, as smaller capacitors fail to provide a reliable voltage for checkpoint and recovery. Sec. II-F evaluates the generality of our model across different architectures, such as systems with different NVM (e.g., Magnetic RAM, MRAM) and a 16-bit core (e.g., MSP430).

B. Execution Model

To derive a general execution model with the effects of decoupling capacitors, we first present a sample measurement from our reference system. In this paper, we denote the voltage of the energy storage C_{ES} as V_{ES} and the MCU operating voltage as V_{dd}. To achieve an operation time of 50 ms under 1.5mA current supply, we use a 470uF capacitor for C_{ES}. Fig. 3a illustrates the voltage traces of V_{ES} and V_{dd} over a single power cycle. Note that V_{dd} is maintained by decoupling capacitors once the power supply from the power management system stops. The shaded areas represent the periods that system executes the application code.

Fig. 3b presents the first execution cycle in more detail. It reveals several differences between the traditional execution model and the actual operation. Among them, we highlight three key observations that affect software design decisions:

- **O1**: The capacitor voltage (V_{ES}) drops rapidly to charge decoupling capacitors when the system wakes up ($t1$–$t2$).
- **O2**: System operates at sub-normal voltage using decoupling capacitors, even after power supply stops ($t3$–$t4$).
- **O3**: Decoupling capacitors discharge while the system is powered off (after $t4$, as shown in Fig. 3a).

Fig. 4 illustrates our detailed execution model, incorporating these key observations. When V_{ES} reaches V_h, the voltage experience a rapid drop due to the buffering effects (①), instead of gradual decline. After initialization (②), the system begins execution at normal operating voltage (③), 3.3V for example. When the voltage hits V_l, the power supply stops

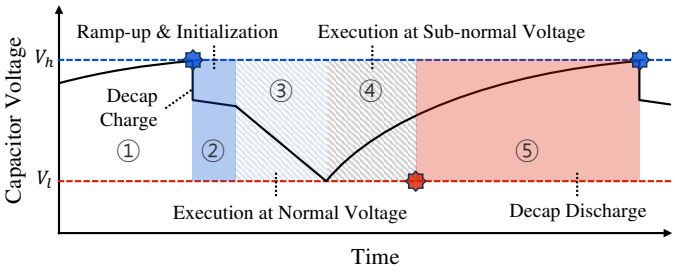


Fig. 4: Detailed execution model of intermittent systems.

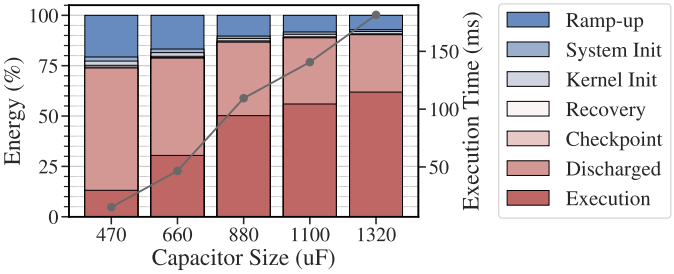

Fig. 5: Distribution of energy consumed in a power cycle.

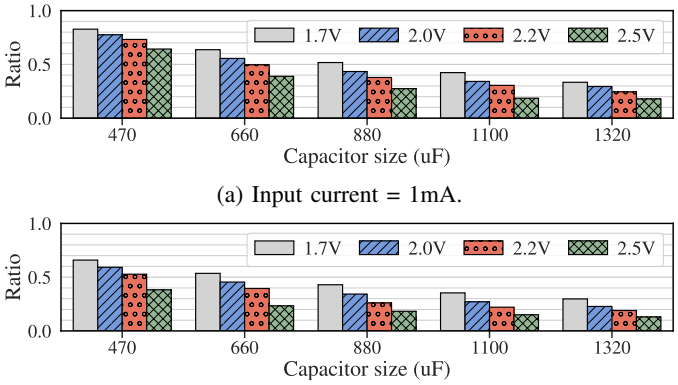
but system now starts to operate using the buffered energy (④). Since the voltage of the decoupling capacitors decreases as they discharge, the system executes at sub-normal voltage until it reaches the voltage level it cannot operate (e.g., 2.5V in Fig. 3). Finally, until the next power-on event, the remaining energy in decoupling capacitors continues to discharge (⑤).



When designing intermittent systems, particularly those utilizing small capacitors, understanding the effects described by this model is critical. In the following sections, we discuss impacts of our model to software design in more detail.

C. Impact on Power Efficiency

The traditional model implies that the energy consumed between V_h and V_l is entirely used in the computing system. However, our model reveals that considerable energy is used for charging the decoupling capacitors (**O1**) and dissipated during power-off durations (**O3**). This indicates that much smaller energy may be used for the useful computation compared to the designer's expectation.

Fig. 5 shows the distribution of the energy consumption for each stage of operation within one power cycle, averaged over 50 executions, where 1mA of input current is provided at 1.9V. The x-axis represents the size of C_{ES} and the line in the secondary axis represents the average operation times for application code. The checkpoint is executed by the interrupt from the power management system [4], [11], [20], [38], [39], which is generated when V_{ES} reaches V_l (3.4V). Note that this is the most efficient point for checkpoint execution according to the traditional model (i.e., just before the poweroff).

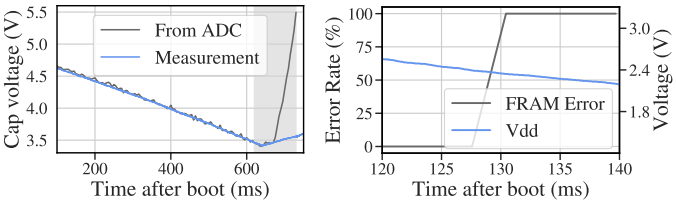
The results shows that significant energy is wasted in the decoupling capacitors. For example, in 470uF case, 60.7% of the energy is lost during the power-off duration (denoted as *Discharged*), leaving only 13.1% of the energy for computation. While the ratio of *Discharged* decreases with larger C_{ES},

(a) Input current = 1mA.

(b) Input current = 3mA.

Fig. 6: Ratio of sub-voltage operations in total execution time.

it remains substantial; for example, in the 1320uF case, 28.5% of energy is discharged, which is still non-negligible.



This is because the discharging behavior can be modeled as an RC-discharging circuit (i.e., $q = CVe^{-\frac{t}{RC}}$), which exhibits an exponential discharge rate. Indeed, 50% of the energy is discharged within the first 161 ms in our measurements. Since recharging C_{ES} takes 2.13 secs even in 470uF configuration, most of the buffered energy is lost before the next power-on, regardless of the size of C_{ES}. As a result, the energy loss ratio due to discharging is larger with smaller capacitors.

Another important observation is the error introduced by the traditional model. The traditional model expects both the energies, *Execution* and *Discharged*, are used for computation. This introduces huge errors, up to 5.62x in 470uF setup, for example. In the same context, the traditional model predicts that using a 470uF capacitor for C_{ES} instead of a 1320uF would result in only 1.22x overhead in energy efficiency, while the actual difference is 4.71x. This can significantly mislead system designers when they select capacitor sizes by considering tradeoffs between overall efficiency and reactiveness. In Sec. III, we explore strategies to minimize the inefficiencies caused by discharging when designing software techniques.

D. Impact on Predicting Power Failures

According to the traditional model, system states should be saved to NVM before V_{ES} reaches V_l, as the system is expected to halt at this point. On the other hand, our model shows that the system may continue operating using the energy stored in the decoupling capacitors (**O2**). Since modern MCUs can operate across a wide range of supply voltages (e.g., 1.7V to 3.6V in STM32L5 and MSP430), the computing system operates until the voltage of decoupling capacitors drops to the minimum operating level. This makes V_{ES} not a reliable indicator for the imminent power-off.

Fig. 6 presents the ratio of the times executed under sub-normal voltages to the total execution times, averaged over 30 measurements. The x-axis represents the sizes of C_{ES} and the colors indicate the voltage levels at which the system stops operation. We evaluate a range of stop voltages from 1.7V to 2.5V since not all components in the computing system

(a) Analog-Digital Converter. (b) External FRAM.

Fig. 7: Incorrect operations at sub-normal voltages.

may function at the lowest voltage level (Sec. II-E). Also, we examine two cases with input currents of 1mA (Fig. 6a) and 3mA (Fig. 6b), to assess the impact of input power.

The figure shows that a significant portion of MCU operation occurs at sub-normal voltages. For example, when 470uF capacitor is used at 1mA input current (Fig. 6a), 82.8% of computation takes place *after* the power-off threshold. This ratio decreases as the system stops earlier (reducing sub-voltage operation time) or the input current increases (extending operation time at normal voltage). However, at least 13.0% of computations are operated at sub-normal voltages even in highly optimistic configurations (1320uF in Fig. 6b).

These values can be directly translated to the inefficiencies of the systems based on the traditional model. For example, in the case of 470uF with a input current of 1mA, systems executing checkpoint at V_l may operate 16.3 ms. However, the system could operate for an additional 29.4 ms if the checkpoint can be delayed until 2.5V. At the next power-on, the decoupling capacitors discharge to similar voltage levels in both cases, as discussed in Sec. II-C. As a result, failing to utilize the buffered energy at sub-normal voltages introduces significant power inefficiency. In Sec. III-B, we validate this aspect and propose methods to fully utilize the buffered energy.

E. Impact of Sub-normal Voltage Execution

The traditional model leads software designers to assume that the system is executed under a stable voltage. However, a significant portion of execution may happen after the power-off threshold at sub-normal voltages (**O3**), as discussed in Sec. II-D. Being aware of this is crucial to software designers since analog components and peripherals may function differently at sub-normal voltages. Two relevant examples are Analog-Digital Converters (ADCs) and external NVMs.

ADCs are commonly used to determine when to execute a checkpoint by reading V_{ES}. It quantizes the input analog voltage into discrete 2^n values, ranging from 0 to the given reference voltage, where n is a resolution. Using smaller reference voltage increases sensitivity of ADC at the cost of reduced representation range.

Fig. 7a shows the behavior of ADCs, where the execution in sub-normal voltages are depicted in gray. Because STM32L5 uses V_{dd} as a reference voltage, accessing the ADC under sub-normal voltages produces inconsistent results. As shown in the figure, the ADC returns values higher than the actual measurements since its representation range decreases as V_{dd} drops. Consequently, ADC may mislead the system into overestimating the energy in C_{ES} during sub-normal voltage executions, potentially leading to checkpoint miss and a loss of progress for the entire power cycle.

TABLE I: Architectures for generality evaluation

	Core	Core Freq.	Capacitance (uF)			Current	Memory
			C1	C2	C_{ES}		
A1	STM32L5	16MHz	22	220	1,320	3mA	MRAM (off-chip)
A2	MSP430FR5994	8MHz	22	10	40	100uA	FRAM (on-chip)

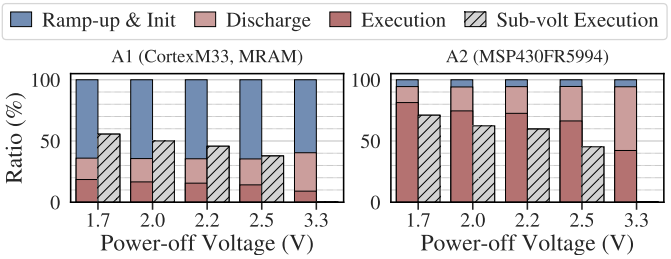


Fig. 8: Energy breakdown and the ratio of sub-voltage operations in different architectures.

Also, intermittent systems typically designed to operate with peripherals such as sensors [5], [40]–[42], wireless communication modules [6], [43], [44] or external NVMs [6], [23]–[25], which have their own minimum operating voltage requirements. Fig. 7b illustrates the error rate of FRAM in the reference system at different voltages, showing FRAM cannot operate reliably below 2.4V. Since the system continues operating until it reaches the lowest MCU operation voltage (e.g., 1.7V), software designers must ensure that peripherals are accessed only at safe voltage levels. Failing to do so can result in corrupted sensor data or unsafe checkpointing.

F. Sensitivity to Architectural Designs

To evaluate the generality of the proposed model, we assess it across two additional architectural setups. Table I shows the detailed parameters of the target architectures. A1 shares the same configuration as the reference system but equips MRAM (Everspin MR5A16ACYS35), which is gaining attention as a next generation NVM [6], [14], [17], [23], instead of FRAM. Second target is MSP430 equipped with on-chip FRAM, a widely adopted 16-bit platform in intermittent system research. For both systems, the architectural parameters are configured to achieve an operation time of approximately 50 ms.

Fig. 8 shows the results for different power-off voltages. The bars on the left illustrate the energy breakdown in a single power cycle, and the bars on the right represent the ratio of the sub-normal voltage executions. The most noticeable difference is ratio of energy consumed during the *Ramp-up & Init* stage. While A1 consumes 63.4% power at this stage on average, only 5.6% of energy is consumed in A2. This is because A1 is configured with an external MRAM, which exhibits significantly higher leakage current, even compared to the FRAM used in the reference system. In contrast, A2 is equipped with on-chip FRAM, which has much lower leakage.

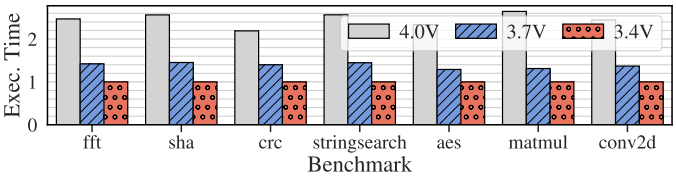

Fig. 9: Execution times across various checkpoint voltages, normalized to the 3.4V configuration.

Despite these differences, both architectures exhibit high sub-normal voltage execution rates, up to 55.5% in A1 and 70.1% in A2. In addition, discharged energy takes considerable portion in both A1 (31.4%) and A2 (52.0%) at 3.3V power-off voltage configuration, which represents the techniques based on the traditional model that halt immediately at V_{ES}. In summary, the evaluation demonstrates that the modeled buffering effects are general and their impacts are significant across different system architectures.

III. Design Guidelines

Based on the insights from our model, we propose design guidelines to implement efficient intermittent systems. The effectiveness of these guidelines is evaluated using seven benchmarks on the reference system used in Sec. II. We ported five benchmarks from miBench [45] benchmark suite and implemented two computation kernels (*matmul* and *conv2d*) commonly used in the evaluation of intermittent systems in the literature [11], [23], [24], [46], [47].

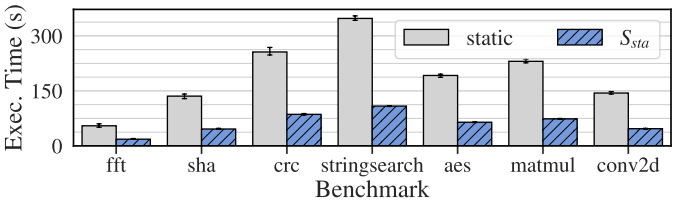
We evaluate two popular existing checkpointing schemes: *static* and *dynamic*. In *static*, checkpoint triggers are inserted at the back-edge of every loop in the program during compilation [3], [24], [25], [48]. At runtime, checkpoint triggers examine V_{ES} and execute checkpoint only when it is below a predefined threshold. In contrast, *dynamic* [4], [11], [20], [38], [39] does not modify the original program code. Instead, it executes checkpoints via interrupts from the power management system, generated when V_{ES} reaches V_l. These schemes are considered since most checkpoint techniques utilize V_{ES} either by actively polling it (as in *static*) or by receiving external signals generated based on V_{ES} levels (as in *dynamic*). All the evaluations are conducted with 470uF energy storage and 1mA of input current at 1.9V, unless otherwise stated.

A. Delaying Checkpoint Executions

The first design practice we propose is to delay checkpoint executions until the last possible moment. While this practice is generally regarded as desirable in existing works [3], [49], it has not been recognized as a critical property. Under the traditional execution model, early checkpoint execution is often considered acceptable as it makes the system wake up sooner, incurring only minor costs for initialization and recovery. For example, some approaches have explored proactive power-offs based on the program's worst-case execution time [1], [16], [50]. In contrast, our model reveals that significant energy is wasted each time the system powers off (Sec. II-C).

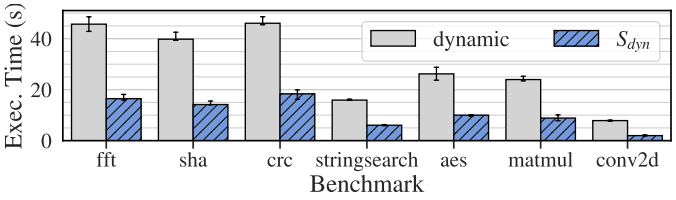
We evaluate the impact of delaying checkpoint executions in *dynamic*, by varying the interrupt voltage. A 1100uF capacitor is used for C_{ES}. Fig. 9 presents the average execution times of the benchmarks over 30 runs, normalized to the 3.4V configuration. The results show that executing checkpoints earlier is significantly inefficient as opposed to existing expectations: by 1.38x in 3.7V, and 2.45x in 4.0V setups, on average. Moreover, the overhead is consistent across all benchmarks since early checkpoint executions directly reduce the energy available for the computing system. Consequently, for maximum power efficiency, checkpoint techniques should be able to minimize the margin between the checkpoint execution and the power-off. Achieving this fundamentally depends on accurately predicting imminent power failures, which is the focus of the next section.

B. Using V_{dd} with a Reference Voltage for Checkpoint Signals



Sec. II-D demonstrates that V_{ES} is not a reliable estimate for the system's remaining execution time and that low V_{dd} is the direct cause of power-off. Based on this insight, we propose using V_{dd} to more accurately detect the imminent power failures, as in works without power management system (Sec. IV). We present two efficient implementations, S_{sta} and S_{dyn}, to accurately detect the imminent power-off events in approaches similar to *static* and *dynamic*, respectively.

Meanwhile, when designing techniques using V_{dd}, designers should account for the behaviors of analog components at sub-normal voltages (Sec. II-E). For consistent operation of ADCs, we adopt a voltage source with a known value of V_{ref}. In STM32L5 and MSP430, an internal reference voltage source of 1.2V is available; alternatively, an external voltage reference (e.g., TI LVM431 [51]) can be used. Note that V_{ref} should be lower than the minimal operating voltage of MCU (e.g., 1.7V) as V_{ref} is generated by regulating V_{dd}.



S_{sta} is designed for techniques similar to *static*, which query whether to execute a checkpoint at checkpoint triggers. Since directly reading V_{dd} is infeasible (i.e., V_{dd} itself is a reference voltage), S_{sta} reads V_{ref} instead. This results in the same value of $\lfloor V_{ref}/V_{dd} \cdot 2^n \rfloor$ when operating on normal voltage, where n is the ADC resolution. On the other hand, during sub-normal voltage executions, this value increases as V_{dd} decreases, as discussed in Sec. II-E. As a result, given that the target threshold voltage for checkpoint execution is V_{th}, software designers can compare the ADC value against $\lfloor V_{ref}/V_{th} \cdot 2^n \rfloor$ to determine whether to execute a checkpoint.

On the other hand, S_{dyn} utilizes an on-chip comparator, which is available in most modern MCUs including STM32L5 and MSP430. As V_{ref} is always lower than V_{dd}, we use a voltage divider consisting of two resistors, $R1$ and $R2$, to scale V_{dd} and compare it with V_{ref}. Specifically, we configure $R1$ and $R2$ to satisfy $\frac{R2}{R1+R2} \cdot V_{th} = V_{ref}$, so the comparator generates an interrupt when V_{dd} reaches the threshold V_{th}.

Fig. 10 compares the average execution times of the benchmarks over 30 iterations between traditional systems and the proposed setups. Fig. 10a and Fig. 10b illustrates the results of S_{sta} and S_{dyn}, respectively. The whiskers indicate the minimum and maximum execution times for each benchmark. The results show significant improvements in execution times for both systems, with average gain of 3.04x in S_{sta} and 2.85x

(a) Static checkpointing with S_{sta}.

(b) Dynamic checkpointing with S_{dyn}.

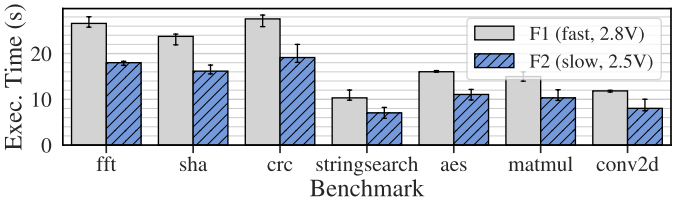

Fig. 11: Impact of peripheral operating voltage.

in S_{dyn}. While the effectiveness of checkpoint schemes varies depending on application characteristics, our setups evenly enhance performance across all benchmarks. This underscores the importance of accurately detecting power-off events for efficient intermittent system operation.

Another advantage of the proposed setups is their simplicity and practical applicability. Since the both setups only modify the method to detect imminent power failures and leave the checkpoint algorithms unchanged, it is straightforward to apply them in existing techniques. Furthermore, the proposed setups can reduce the system complexity, as they eliminate the need for communication between the energy storage system and the computing system (e.g., interrupt or access to V_{ES}).

C. On Selecting Hardware Components

Our model also helps designers in selecting efficient hardware components across various parameters. For example, it reveals that operating voltage of peripherals (e.g., external NVMs) is a critical design consideration (Sec. II-E), often more important than other factors such as latency.

To evaluate this tradeoff, we simulate two FRAM configurations, F1 and F2, in our reference system. F1 represents a slower setup capable of operating down to 2.5V. This is achieved by doubling the software-configurable wait time for FRAM accesses. F2 is set to have the lowest access latency but requires the system stop operating at 2.8V.

Fig. 11 presents the execution times of the benchmarks for the two configurations in S_{dyn}, averaged over 30 runs. Despite its doubled latency, F1 completes the workloads 1.46x faster on average, with consistent improvements across all benchmarks. These results imply that using slower FRAM that operates until 1.8V (e.g., [52]) could considerably improve the performance of our reference system. This example highlights that operating voltage, often overlooked in the traditional model, should be considered a critical design parameter.

Finally, our model highlights advantages of using smaller decoupling capacitors. Larger buffers not only increases the ratio of sub-normal voltage operations but also raise the amount of discharged energy during power-offs. Indeed, in our reference system with C_{ES} = 1100uF, we observe that completing benchmarks takes 1.18x and 1.36x longer on average, when 440uF and 660uF capacitors are used as C2, respectively, compared to our setup with a 220uF capacitor.

IV. Related Work

This work can be compared to existing modeling-based approaches that estimate the timing or efficiency of intermittent systems [7]–[10], [22], [53]. The primary focus of these works is identifying the most efficient design configurations (e.g., capacitor size, input power or checkpoint techniques [22]) for a given application. Zhan et al. [54] especially examined the trade-offs between capacitor sizes and forward progress. However, these works assume that the entire energy discharged from the capacitor is utilized by computing system, overlooking the buffering effects addressed in this work. Furthermore, our work proposes several practical guidelines to improve the efficiency of existing techniques with minimal efforts.

In some works that do not have a dedicated power management system and directly supply unregulated power to the computing system [13], [38], [39], [55], [56], V_{dd} has been used as a checkpoint signal. This is natural in these works since the voltage of the energy storage is always identical to V_{dd}. In contrast, our work demonstrates that accounting for sub-normal voltage operations is also critical in systems with regulated power supplies, which represent the majority of intermittent system setups. Also, we address the impacts of sub-normal voltage executions on the correctness and efficiency of software designs, along with suggestions to exploit such impacts for improved system performance.

V. Conclusion

As recent intermittent systems target smaller energy storages and shorter operation times, the traditional execution model for intermittent systems is failing to accurately represent actual system behaviors. In this paper, we propose a new execution model that incorporates the buffering effects from the system's inherent capacitance, which is a primary source of the discrepancies of the traditional model. Our model reveals that systems designed upon the traditional model can be up to 5.62x power-inefficient than expected and may result in unsafe checkpoint executions. Based on the insights from our model, we propose several design guidelines, including setups to improve performance of existing static and dynamic checkpoint techniques by 3.04x and 2.85x on average, respectively.

***Abstract*—This paper focuses on optimizing the Matrix-Power Kernel (MPK), which relies on a series of Sparse Matrix-Vector multiplications (SpMVs) using the same sparse matrix. MPK is a crucial component of Krylov subspace methods for solving large sparse linear systems in various fields, including circuit simulations. MPK offers a potential for matrix reuse in cache, which can accelerate memory-bound sparse solvers. Additionally, many sparse matrices encountered in applications are symmetric, allowing us to reduce the memory footprint for SpMVs by half. However, reusing the matrix introduces data dependencies between subsequent SpMVs, and symmetric SpMVs can result in data conflicts during shared-memory parallelization. Previous research has often focused on either matrix reuse or symmetry, failing to leverage both aspects effectively.**

This paper proposes a unified, memory-efficient approach called *Me-MPK* that takes advantage of both cache reuse and matrix symmetry for MPK on shared-memory multi-core systems. We first introduce a *unified dependency graph* for a sparse matrix, which represents all potential data dependencies and conflicts. Next, we perform architecture-aware recursive partitioning on this graph to create subgraphs and formulate a separating subgraph that decouples all dependencies and conflicts among the subgraphs. These independent subgraphs are then scheduled for parallel execution of SpMV or symmetric SpMV in a specified order to optimize cache reuse. We apply Me-MPK in two s-Step Krylov subspace solvers, and our evaluations show that Me-MPK significantly outperforms the current state-of-the-art solutions, delivering an average speedup of up to 2.00X and 1.86X on X86 and ARM CPUs, respectively. As a result, we achieve overall speedup in the sparse solvers of up to 1.65X and 1.58X.

***Index Terms*—SpMV, matrix power kernel, cache reuse, matrix symmetry, Krylov subspace solvers**

I. Introduction and Related Work

The Matrix-Power Kernel (MPK) involves a sequence of Sparse Matrix-Vector multiplications (SpMVs) to compute $\mathbf{Ax}$, $\mathbf{A^2x}$,..., $\mathbf{A^sx}$ for a matrix $\mathbf{A}$, a vector $\mathbf{x}$, and a constant s [1]–[3]. MPK is a crucial and time-consuming step in solving large-scale sparse linear systems, eigenvalue problems, and similar tasks [4]. Optimizing MPK is vital to enhance simulation efficiency across various fields, including circuit simulation and power grid analysis.

Given that SpMV is heavily constrained by memory, numerous efforts have been made to optimize memory efficiency for an individual SpMV invocation [5]–[8]. MPK offers a potential to exploit temporal locality for a sequence of SpMVs by reusing the matrix elements in cache, instead of repeatedly loading them from main memory. Meanwhile, the sparse matrices in many scientific applications are often symmetric [9]–[11]. Exploiting symmetric SpMV can significantly reduce memory usage by only storing either the upper or lower triangular part of the sparse matrix. Therefore, by taking advantage of both matrix reuse and symmetry, there is a significant opportunity to develop memory-efficient MPK, which can help mitigate the 'memory wall' problem that often challenges sparse solvers.

However, reusing the matrix in cache creates data dependencies between successive SpMV invocations. In the case of symmetric SpMV, there are data conflicts when multiple threads attempt to update the output vector simultaneously. These data dependencies and conflicts complicate the efficient and scalable implementation of multi-threaded processing on shared-memory multi-core systems.

Previous implementations of MPK have primarily focused on reusing matrices to minimize the frequency of distributed communications and synchronizations for communication-avoiding or s-Step algorithms [12]–[15]. The motivation behind exploiting cache reuse in MPK is largely rooted in classic blocking strategies used in stencil computations [16]–[19]. These methods typically involve identifying the neighboring blocks necessary for MPK concerning a specific matrix power s. This often leads to performance bottlenecks due to either

This work was funded by the National Natural Science Foundation of China under Grant No. 62272474. Co-first author: Chuanfu Xu. Corresponding authors: Chuanfu Xu, Jianbin Fang, Shengguo Li and Yonggang Che

redundant computations or irregular matrix accesses. A recent level-based cache blocking approach for MPK [2], based on the Recursive Algebraic Coloring Engine (RACE) [10], organizes matrix rows into levels using a distance-k coloring. This method maintains dependencies for cache reuse but limits parallelism, allowing only one level to be executed in parallel at a time. Therefore, it relies on point-to-point synchronization and level coarsening strategies to improve scalability, but its performance still degrades severely for large power. Zhang *et al.* partition a sparse matrix and create a computation pipeline for fine-grained cache reuse by reusing a matrix row rather than a row block in MPK [1]. Although the approach is easy to implement, it requires graph coloring for parallelization, which can result in high synchronization overhead and poor spatial locality [20]. To summarize, all MPK implementations overlook the symmetry of the matrix. Thus, our work aims to leverage both cache reuse and matrix symmetry to further enhance MPK performance.

There has been some work in implementing symmetric SpMV, primarily focused on efficiently managing data conflicts at the shared-memory level. For instance, a reduction-based approach [21], [22] mitigates conflicts by using thread-local vectors to store temporary results, followed by a reduction loop to accumulate these results into the output vector. However, this method increases memory usage and traffic, which grows linearly with the number of threads, thereby limiting its overall scalability. Recently, researchers have introduced graph coloring algorithms to identify independent row sets from the graph representation of the symmetric matrix for parallel execution [9], [10]. While coloring-based approaches demonstrate impressive performance for low-bandwidth symmetric matrices, they struggle to scale effectively with large, irregular, high-bandwidth matrices. Furthermore, existing implementations of symmetric SpMV typically focus on a single invocation and do not leverage cache reuse for MPK. In summary, prior work has not fully exploited on the advantages of both matrix reuse and matrix symmetry; they tend to address only one aspect or the other.

This paper optimizes MPK by introducing a new, unified and memory-efficient approach called *Me-MPK*, which takes advantage of both cache reuse and matrix symmetry for MPK on multi-cores. We present the *unified dependency graph* for a sparse matrix, where each vertex represents a row of the matrix, and each edge denotes potential data dependencies or conflicts between rows. We then apply architecture-aware recursive partitioning to this graph to create subgraphs. In each recursion, we formulate a separate subgraph, known as the *separator*, to eliminate all dependencies and conflicts among the subgraphs. All subgraphs are then reordered to enhance data locality. Finally, we schedule these independent subgraphs in a specific order for parallel execution, ensuring that the same subgraph can be reused in the cache at least twice for subsequent calls to SpMV or symmetric SpMV.

We apply Me-MPK in two *s*-Step Krylov subspace methods, i.e., the Conjugate Gradient (CG) method and the Biconjugate Gradient Stabilized (BiCGStab). Our work was evaluated on a 28-core Intel Xeon X86 CPU and a 32-core Kunpeng 920 ARMv8 CPU [23] with 214 sparse matrices from the SuiteSparse Matrix Collection [24]. We compare Me-MPK to the MPKs based on SpMV and symmetric SpMV from the vendor-tuned Intel oneMKL library [25] and the RACE approach [2]. On X86, Me-MPK outperforms the MPKs based on the oneMKL SpMV and symmetric SpMV by an average speedup of 1.95X and 1.56X for *s*=4, 2.00X and 1.59X for *s*=8. Compared to the RACE-based MPK, Me-MPK yields an average speedup of 1.32X and 1.20X for *s*=4, 1.42X and 1.26X for *s*=8 on X86 and ARM. As a consequence, Me-MPK accelerates the sparse solvers by an average speedup of up to 1.59X and 1.51X for *s*=4, 1.65X and 1.58X for *s*=8 on X86 and ARM, respectively.

II. Background

This section first introduces the background of SpMV and symmetric SpMV. Then we introduce the Matrix-Power Kernel (MPK) and its application in *s*-Step Krylov subspace solvers.

A. SpMV and Symmetric SpMV

The SpMV operation involves multiplying a sparse matrix $\mathbf{A}$ by a dense input vector $\mathbf{x}$ to produce a dense output vector $\mathbf{b}$. Sparse matrices are typically stored in a compressed format to conserve space, which involves only retaining their nonzero elements and their corresponding locations. The top of Fig.1(b) illustrates the popular Compressed Sparse Row (CSR) format for a symmetric sparse matrix $\mathbf{A}$, as shown in Fig.1(a). The CSR format uses two arrays: one for storing the nonzero values and another for their corresponding column indices. Additionally, a row pointer array indicates the number of nonzero elements in each row. Algorithm 1 (lines 1-8) presents the pseudo-code for the serial SpMV in CSR.

The most common storage format for symmetric sparse matrices is the Sparse Symmetric Skyline (SSS) format [4], which is a variant of CSR with an additional array to store the matrix's main diagonal. The bottom of Fig.1(b) shows the SSS format storing the upper triangular part of the matrix $\mathbf{A}$. Algorithm 1 (lines 9-18) shows the pseudo-code of serial symmetric SpMV in SSS. Shared-memory parallelization of the outer loop (line 10) will introduce race conditions due to concurrently writing the output vector $\mathbf{b}$ ($b[col]$ in line 15 and $b[i]$ in line 17). Fig.1(d) illustrates this problem for the symmetric matrix $\mathbf{A}$ using two threads. In this example, thread 0 not only updates entries b_0 to b_3 but also affects b_4 to b_6, leading to write conflicts between the two threads.

B. MPK and Its Application in Krylov Subspace Solvers

MPK calculates a sequence of SpMVs to obtain $\mathbf{Ax}$, $\mathbf{A^2x}$,... $\mathbf{A^sx}$ or their linear combination such as $\mathbf{Ax} + \mathbf{A^2x}$, for the same matrix $\mathbf{A}$. Algorithm 1 (lines 19-22) shows the pseudo-code for a traditional MPK implementation, which performs s consecutive calls to the SpMV function. If the caches are too small to hold the entire matrix, it will need to be loaded s times from the main memory.

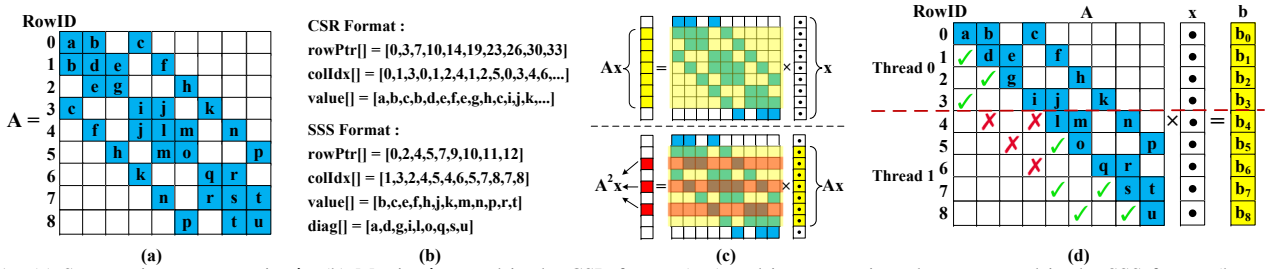

Fig. 1. (a) Symmetric sparse matrix $\mathbf{A}$; (b) Matrix $\mathbf{A}$ stored in the CSR format (top) and its upper triangular part stored in the SSS format (bottom); (c) Data reuse between $\mathbf{Ax}$ and $\mathbf{A^2x}$; (d) Data conflicts (red $\times$) between two threads using the upper triangular part of $\mathbf{A}$ in symmetric SpMV.

Algorithm 1: SpMV, symmetric SpMV and MPK

```
1  function SpMV(A, x, b)
2  for i ← 0 to N do
3      sum ← 0
4      for j ← A.rowPtr[i] to A.rowPtr[i + 1] do
5          sum = sum + A.value[j] · x[A.colIdx[j]]
6      end
7      b[i] = b[i] + sum
8  end
9  function SymmSpMV(A, x, b)
10 for i ← 0 to N do
11     sum ← A.diag[i] · x[i]
12     for j ← A.rowPtr[i] to A.rowPtr[i + 1] do
13         col = A.colIdx[j]
14         sum = sum + A.value[j] · x[col]
15         b[col] = b[col] + A.value[j] · x[i]
16     end
17     b[i] = b[i] + sum
18 end

MPK is a crucial component in many applications, such as Krylov subspace methods, multigrid methods, polynomial preconditioners, and eigenvalue problems. This work applies our MPK within two s-Step (or communication-avoiding) Krylov subspace methods: the Conjugate Gradient (CG) method for solving Symmetric Positive Definite (SPD) linear systems, and the Biconjugate Gradient Stabilized (BiCGStab) method for addressing non-SPD linear systems. Algorithm 2 provides the pseudo-code for the s-Step CG method [26][1]. These Krylov subspace solvers are widely used to solve large-scale sparse linear systems of transistor-level SPICE-like circuit simulations.

The s-step Krylov solvers generate s Krylov basis vectors at a time using MPK (line 4 in Algorithm 2), potentially reducing the communication cost of standard Krylov solvers by s. MPK also offers an opportunity to reuse the matrix elements in the cache. However, reusing cache data incurs dependencies between multiple SpMV invocations. Fig.1(c) illustrates this problem with $s = 2$. Suppose the submatrix (yellow rows) has been loaded into cache for $\mathbf{Ax}$, it is possible to reuse a subset (red rows) of this submatrix for $\mathbf{A^2x}$. However, this data reuse must fulfill the dependencies between successive SpMVs, i.e., the column indices of the subset must be in the range of the row indices of the original submatrix.

[1]For the pseudo-code of the s-Step BiCGStab method, please refer to [26]

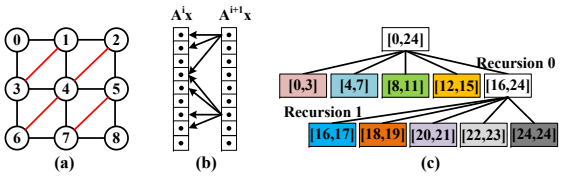

Fig. 2. (a) The unified dependency graph for the matrix in Fig.1(a); (b) Data dependencies between $\mathbf{A^ix}$ and $\mathbf{A^{i+1}x}$ for two vector elements; (c) The tree data structure corresponds to Fig.3(b). Numbers in the brackets indicate the starting and ending indices for matrix rows. [16,24] and [24,24] are the separators for the first and second recursions, respectively.

III. The Memory-efficient Matrix-Power Kernel

This section presents our unified approach to design memory-efficient MPK and its shared-memory parallelization.

A. Unified Dependency Graph

We propose *Unified Dependency Graph* (UDG), which is an undirected graph to represent all potential data dependencies and data conflicts in exploiting cache reuse and matrix symmetry for Me-MPK. Fig.2(a) shows the graph for the matrix $\mathbf{A}$ in Fig.1(a). Each vertex represents a matrix row. Each black edge indicates that a nonzero element of row i, which has a column index equal to j (or vice versa). These black edges correspond to all potential data dependencies among subsequent SpMV invocations. Fig.2(b) illustrates dependencies between two subsequent SpMVs for two vector elements: calculation of $\mathbf{A^{i+1}x}[0]$ and $\mathbf{A^{i+1}x}[6]$ depends on specific elements in $\mathbf{A^ix}$. When symmetric SpMV is employed in MPK, we introduce red edges in the graph, indicating that two rows have nonzero

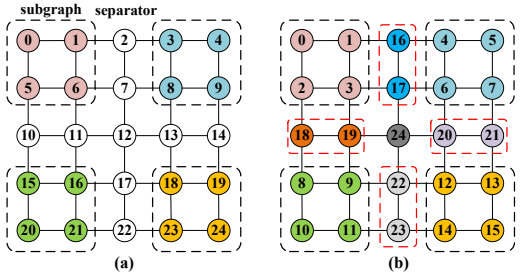

Fig. 3. (a) A graph partitioned into four subgraphs and one separator (without reordering); (b) After two recursive partitions (with reordering).

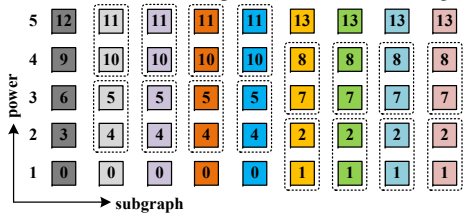

Fig. 4. Diagram illustrating the execution of Fig.3(b) in Me-MPK with the power *s=5*. Numbers in boxes indicate the execution order. Subgraphs with the same numbers are executed concurrently. Boxes in the same dotted rectangles indicate that subgraphs are reused in cache. For simplicity, this diagram assumes the sparse matrix is non-symmetric.

elements with the same column index. These black and red edges correspond to all potential data conflicts that may appear in a single invocation of shared-memory symmetric SpMV.

B. Architecture-aware Recursive Partitioning

For a given unified dependency graph of a sparse matrix, we propose an architecture-aware recursive approach to partition the graph. We start by partitioning the graph into *numPart* subgraphs. This can be implemented using existing graph partitioning tools like Metis [27]. For a CSR-based sparse matrix with 8-byte double values and 4-byte int indices, each subgraph contains no more than $partSize = \frac{cacheSize/8}{1.5*avg_nnz_per_row}$ rows, where $avg_nnz_per_row$ is the average number of nonzero elements per row, and *cacheSize* is the L2 cache size in bytes for the processor. This ensures that each subgraph can fit into the L2 cache. $numPart$ is set to $(\lfloor \frac{N/partSize}{numCore} \rfloor + 1) * numCore$, where N is the total number of matrix rows, allowing all subgraphs be evenly distributed among the *numCore* processor cores.

Then we formulate a special subgraph called *separator* by figuring out all vertices which have neighbors in other subgraphs. Next, we reorder vertices for each subgraph and the separator to ensure that each subgraph contains consecutive vertices, and the separator is indexed after the other subgraphs. This can improve the data locality when accessing the input/output vectors in SpMV. Fig.3 shows a graph after two recursive partitions (*numPart=4*). We use a tree pointer *treePtr* to save the result of recursive partitioning, used in the following parallel implementation. Fig.2(c) shows the tree data structure for Fig.3(b).

For invocations of standard SpMV in Me-MPK, we partition the separator one more time. For symmetric SpMV invocations, we recursively partition the separator multiple times. The optimal number of recursive partitions depends on the specific sparse symmetric matrices and the architectures used. This will be discussed further in the experiments.

Algorithm 3: Memory-efficient parallel MPK

```
1  function uSpMV(A, x, b, treePtr)
2  for i ← treePtr->st to treePtr->ed do
3      if A is symmetric then
4          line 11-17 in Algorithm 1
5      else
6          line 3-7 in Algorithm 1
7      end
8  end
9  function SymmSpMV_Recursive(A, x, b, treePtr)
10 if treePtr->separator == nullptr then
11     uSpMV(A, x, b, treePtr)
12     return
13 end
14 for i ← 0 to treePtr->numPatrs do in parallel
15     uSpMV(A, x, b, treePtr->son[i])
16 end
17 SymmSpMV_Recursive(A, x, b, treePtr->separator)
18 function puSpMV(A, x, b, treePtr)
19 if A is symmetric then
20     SymmSpMV_Recursive(A, x, b, treePtr)
21 else
22     for i ← treePtr->st to treePtr->ed do in parallel
23         line 3-7 in Algorithm 1
24     end
25 end
26 function Me_MPK(A, x, s, treeRoot)
27 if s==1 then
28     puSpMV(A, x[:,0], x[:,1], treeRoot)
29     return
30 end
31 i ← 0
32 separator ← treeRoot->separator
33 puSpMV(A, x[:,0], x[:,1], separator)
34 while i < s do
35     for j ← 0 to treeRoot->numParts do in parallel
36         uSpMV(A, x[:,i], x[:,i+1], treeRoot->son[j])
37         if i + 1 < s then
38             uSpMV(A, x[:,i+1], x[:,i+2], treeRoot->son[j])
39         else stop; end
40     end
41     i ← i+2
42     if i < s then
43         puSpMV(A, x[:,i-1], x[:,i], separator->separator)
44         for j ← 0 to separator->numParts do in parallel
45             uSpMV(A, x[:,i-1], x[:,i], separator->son[j])
46             uSpMV(A, x[:,i], x[:,i+1], separator->son[j])
47         end
48         puSpMV(A, x[:,i], x[:,i+1], separator->separator)
49     end
50     else
51         puSpMV(A, x[:,i-1], x[:,i], separator)
52     end
53 end
```

C. Parallel Implementation

After recursive partitioning of the graph for a sparse matrix, we obtain independent subgraphs (i.e., submatrices) at each recursion, because all edges (i.e., data dependencies and data conflicts) among subgraphs have been removed via separators. These submatrices, represented by the starting and ending row indices in the tree data structure, can be scheduled for parallel execution in a specified order to achieve cache reuse in MPK.

Algorithm 3 presents the pseudo-code of Me-MPK. To facilitate the implementation of Me-MPK for both symmetric and non-symmetric sparse matrices, the serial SpMV and symmetric SpMV for a submatrix (row index between `treePtr->st` and `treePtr->ed`) are encapsulated in a

TABLE I

L3 cache	39 MiB	32 MiB
Main memory	128 GiB	128 GiB

unified kernel `uSpMV` (lines 1-8). Accordingly, the parallel version is encapsulated in another unified kernel `puSpMV` (lines 18-25). Note that for standard SpMV, shared-memory parallelization can be directly implemented at the row loop (line 22); for symmetric SpMV, we implement a recursive kernel `SymmSpMV_Recursive` (lines 9-17) to parallelize it at the subgraph loop (line 14). This can avoid data conflicts for shared-memory parallelization of symmetric SpMV.

Me-MPK is implemented using two kernels: `uSpMV` and `puSpMV`. Fig.4 shows the execution order for different subgraphs shown in Fig.3(b). Since each subgraph or submatrix can fit into the L2 cache and all data dependencies or conflicts have been addressed, we can immediately schedule SpMVs or symmetric SpMVs for subsequent powers to use the entire submatrix that has been loaded into L2 from the previous power. For example, the subgraphs marked with an execution order of 1 and those marked with an execution order of 2 are reused in L2, as indicated by the dotted rectangles. Fig.4 shows that most subgraphs, except the separator at the second recursion, can be reused successfully.

IV. PERFORMANCE EVALUATION

This section begins by introducing our experimental setup, which includes the hardware, software, and tested matrices. We then present and analyze the performance results.

A. Experiment Setup

Hardware and software. We perform experiments on two multi-core CPUs: one Intel Xeon Gold 6258R X86 CPU@2.4GHz and one HUAWEI Kunpeng 920 ARMv8 CPU@2.6GHz [23]. Table I shows the detailed configurations for each CPU. All codes are compiled in double precision with '-O3' using Intel oneAPI 2022.1 for the X86 architecture and GCC 8.4.1 for the ARM architecture, respectively.

We set thread affinity for all tests, binding each software thread to an individual physical core (without hyperthreading). We run different implementations 100 times for each matrix and measure the average GFLOPS.

Sparse matrices. We select 214 large matrices from the SuiteSparse Matrix Collection [24] for our tests, where each matrix has more than 100,000 rows and more than 200,000 non-zero elements. Out of these, 162 sparse matrices are numerically symmetric. Additionally, we chose 12 circuit matrices (Table II) for a detailed comparison of our approach with existing methods. For non-symmetric matrices, we perform two rounds of partitioning. For symmetric matrices, we profile each matrix across two CPUs and conduct no more than four rounds of partitioning for most of them. The preprocessing cost associated with recursive partitioning for a sparse matrix is generally less than the time taken for one solver iteration.

TABLE II

TABLE III
AVERAGE SPEEDUPS OF VARIOUS MPKS USING MKL ON X86 AND CSR ON ARM AS BASELINES.

	Intel 6258			Kunpeng 920		
	s=1	*s=4*	*s=8*	*s=1*	*s=4*	*s=8*
MKL-symm	1.27	1.23	1.23	-	-	-
RACE	1.10	1.43	1.35	1.07	1.52	1.47
Me-MPK(*reuse*)	1.17	1.53	1.59	1.21	1.51	1.54
Me-MPK(*reuse+symm*)	1.69	1.95	2.00	1.60	1.84	1.87

B. Performance Results

1) Overall Performance: On the X86 CPU, we evaluate the following MPK implementations: ❶ MKL. This version calls the Intel oneMKL SpMV in MPK, without exploiting cache reuse and matrix symmetry; ❷ MKL-symm. This version calls the Intel oneMKL symmetric SpMV to exploit matrix symmetry in MPK; ❸ RACE. This version is implemented by [2], which exploits cache reuse in MPK using the Recursive Algebraic Coloring Engine (RACE) approach [10]; ❹ Me-MPK(*reuse*). This version calls the standard CSR-based SpMV, but implements our strategy of cache reuse in MPK; ❺ Me-MPK(*reuse+symm*). This version implements our strategy of cache reuse, and it also calls our symmetric SpMV to exploit matrix symmetry in MPK. On the ARM CPU, we compare our work with MPK based on the standard SpMV using CSR format (referred to as CSR) and MPK based on RACE (referred to as RACE).

Fig.5 and Fig.6 show the overall performance for different MPK versions on the two CPU processors. Table III lists the average speedups of various MPKs using MKL on X86 and CSR on ARM as baselines. Compared to other MPKs, our two MPK versions, i.e., Me-MPK(*reuse*) and Me-MPK(*reuse+symm*), achieve higher speedups on both CPU platforms. Among all MPKs, Me-MPK(*reuse+symm*) performs best: On X86, it improves the performance by 1.95X and 2.00X, 1.56X and 1.60X, 1.32X and 1.42X, compared to MPKs based on oneMKL SpMV, oneMKL symmetric SpMV and RACE, for *s*=4 and *s*=8; On ARM, it improves the performance by 1.84X and 1.87X, 1.20X and 1.26X, compared to MPKs based on CSR and RACE, for *s*=4 and *s*=8. Compared to Me-MPK(*reuse*), Me-MPK(*reuse+symm*) enhances the performance by 1.32X and 1.21X, 1.14X and 1.19X on X86 and ARM for *s*=4 and *s*=8. These results

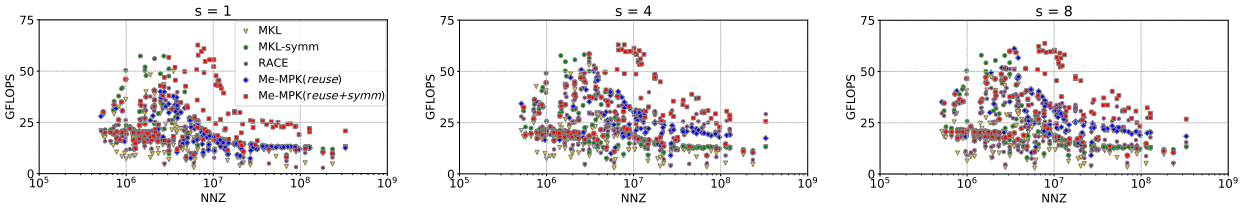

Fig. 5. Performance in GFLOPS for different MPK implementations using 214 sparse matrices on the Intel 6258R CPU. Note that MKL-symm and Me-MPK(*reuse+symm*) are evaluated using 162 symmetric matrices.

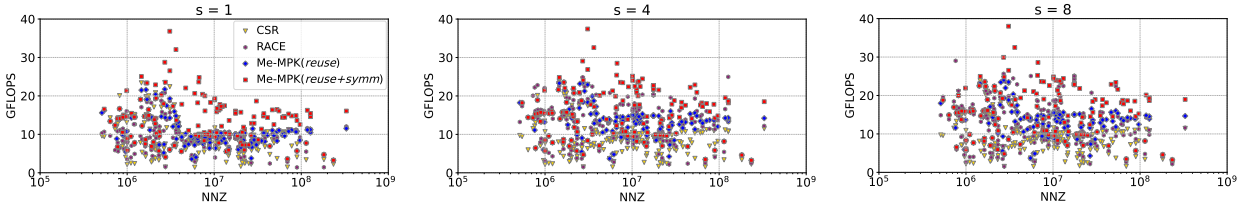

Fig. 6. Performance in GFLOPS for different MPK implementations using 214 sparse matrices on the Kunpeng 920 CPU. Note that Me-MPK(*reuse+symm*) is evaluated using 162 symmetric matrices.

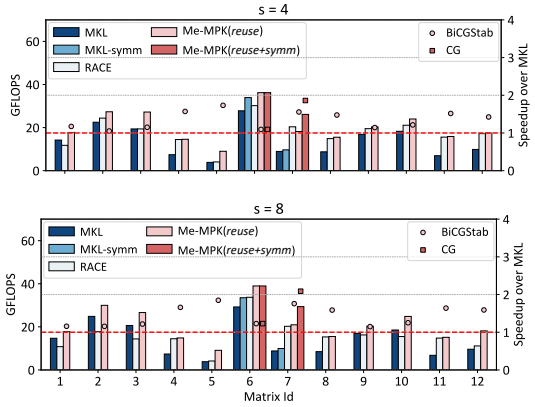

Fig. 7. Performance in GFLOPS for different MPK implementations using the 12 circuit matrices on the Intel 6258R CPU. The right Y-axis indicates the speedup for solvers compared to MKL-based baseline.

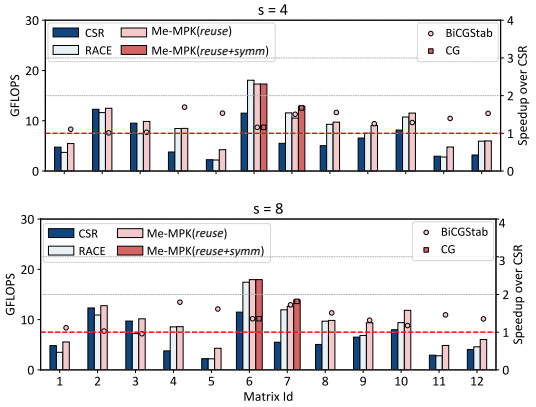

Fig. 8. Performance in GFLOPS for different MPK implementations using the 12 circuit matrices on the Kunpeng 920 CPU. The right Y-axis indicates the speedup for solvers compared to CSR-based baseline.

demonstrate the advantage of exploiting both matrix reuse and matrix symmetry in MPK. Note that the performance of RACE-based MPK drops for large power s. This is mainly because RACE reuses matrix elements in the L3 cache where s is the reuse distance, and increasing s will probably exceed the cache capacity, making it unable to reuse the data [2]. On the contrary, our approach always reuses data in the L2 cache for two successive SpMVs (i,e., $\mathbf{A^i x}$ and $\mathbf{A^{i+1}x}$), and the number of total cache reuse will increase with s because we reuse data (s-*1*) times for a given power s.

We also evaluate Me-MPK in two s-Step Krylov subspace solvers (i.e., CG and BiCGStab). Compared to MKL-based solvers on X86 and CSR-based solvers on ARM, Me-MPK accelerates the performance for a single solver iteration by an average speedup of 1.76X and 1.60X (s=4), 1.81X and 1.62X(s=8) for CG. The average speedup for BiCGStab is 1.34X and 1.33X (s=4), 1.40X and 1.38X (s=8) on X86 and ARM, respectively. Note that our approach fulfills all data dependencies and conflicts when exploiting matrix reuse and symmetry in MPK, therefore it has no negative effect on the solver convergence.

2) Performance on Circuit Matrices: Fig.7 and Fig.8 show the performance for the 12 circuit matrices. For 10 non-SPD matrices, Me-MPK(*reuse*) yields an average speedup of 1.57X and 1.61X, 1.18X and 1.38X, compared to MKL and RACE for s=4 and s=8 on X86; On ARM, the average speedup is 1.53X and 1.56X, 1.19X and 1.30X, compared to CSR and RACE for s=4 and s=8. For 2 SPD matrices, MPK(*reuse+symm*) delivers an average speedup of 1.95X and 2.11X, 1.70X and 1.85X, 1.24X and 1.30X, 1.17X and 1.18X, compared to MKL, MKL-symm, RACE and MPK(*reuse*)for s=4 and s=8 on X86; On ARM, the average speedup is 1.87X and 1.99X, 1.03X and 1.09X, 1.11X and 1.12X, compared to CSR, RACE and Me-MPK(*reuse*) for s=4 and s=8. Taking MKL-based solvers on X86 as baselines, we accelerate the s-Step CG and BiCGStab solvers by 1.63X and 1.40X (s=4), 1.65X and 1.41X (s=8) for circuit simulations. Taking CSR-based solvers on ARM as baselines, the average speedup is 1.49X and 1.38X, 1.59X and 1.40X for s=4 and s=8.

V. Conclusion

We have proposed Me-MPK, a memory-efficient Matrix-Power Kernel (MPK) designed for shared-memory multi-core systems. Me-MPK effectively leverages both cache reuse and matrix symmetry, significantly enhancing the performance of memory-bound sparse matrix solvers, such as the s-Step CG and BiCGStab methods that use MPK.

***Abstract*—Large language model (LLM) inference poses dual challenges, demanding substantial memory bandwidth and computing resources. Recent advancements in near-memory accelerators leveraging 3D DRAM-to-logic hybrid-bonding (HB) interconnects have gained attention due to their highly parallel data transfer capabilities. We address limitations in previous HB-DRAM accelerators, such as those stemming from distributed controller designs, by introducing an architecture with a centralized controller and dual-IO scheme. This approach not only reduces the chip area overhead but also enables reconfigurable GEMV/GEMM operations, boosting the performance. Simulations for the OPT 66B model show that our proposed accelerator achieves 2.9X, 3.5X, and 2.5X higher performance compared to NPU, DRAM-PIM, and heterogeneous designs (DRAM-PIM + NPU), respectively.**

I. Introduction

Transformer-based large language models (LLMs) [1]–[3] have emerged as pivotal components in various language processing applications, ranging from chatbots to machine translations [4]–[6]. Moreover, these models are extending their influence into other domains such as vision applications and the integration of multiple domains [7]–[10]. LLMs demand substantial external memory due to their vast number of parameters, placing a strain on memory data bandwidth. Consequently, state-of-the-art deep learning platforms, including graphic processing units (GPUs) and neural processing units (NPUs), lean towards utilizing high bandwidth memory (HBM) as the primary memory source.

DRAM processing-in-memory (PIM)-based architectures [11]–[13] have been proposed to significantly boost data bandwidth, leveraging bank-level parallelism. However, DRAM-PIMs face challenges in achieving high performance for end-to-end LLM processing. The advent of multi-batching techniques [14]–[16] underscores a growing need to enhance LLM inference throughput by increasing the proportion of compute-intensive matrix-matrix multiplications (GEMM), which can lead to a degradation in the effectiveness of DRAM-PIM system optimized for memory-bound matrix-vector multiplications (GEMV). To overcome the challenge, heterogeneous systems which employ both NPU and DRAM-PIM together have been recently proposed [17], [18]. While the systems show performance improvement over NPU-only or DRAM-PIM-only system by selectively assigning GEMV and GEMM operations to DRAM-PIM and NPU, achieving equal load balancing between PIM and NPU is challenging, making it difficult to increase resource utilization. Furthermore, Tall-and-Skinny GEMM (TS-GEMM) appearing in multi-batch LLM inference shows both memory-intensive and compute-intensive traits, making both NPU and DRAM-PIM suffer.

To address these multifaceted challenges, we focus on the potential of Hybrid Bonding (HB) technology which provides high-density vertical interconnect between stacked silicon chips, enabling high performance and efficiency [19]. Recently, several accelerators based on 3D DRAM-to-Logic HB interconnect have been reported to demonstrate outstanding performance by exploiting the high compute density and high memory bandwidth which HB technology offers [20]–[22]. However, we observe that several design challenges still remain for efficient accelerator architecture based on HB, especially for LLM applications. First, previous works on near-memory processors based on logic-to-DRAM HB technology [20]–[22] placed a DRAM controller for each DRAM bank to handle data at the bank level to transfer control signals via the bank level 3D HB interconnect. However, assigning a controller for each bank incurs significant area overhead [21]. Second, operating frequency of processing elements is limited to the HB-DRAM bank-level data rate which lowers the performance of the compute-bound GEMM in LLM inference.

To address these challenges, we propose a centralized controller based on a dual I/O scheme, which exploits both conventional DRAM I/O structure and bank-level I/O. The conventional structure I/O for external access in HB-DRAM does not utilize the benefit from bank-level parallelism of HB. However, we notice that its bus structure connects to multiple banks so that the control signals can be broadcast to the banks from the centralized memory controller. Therefore we make the centralized controller send the control signals to banks and the banks just *drop* the data to logic die. Replacing the distributed controller with the centralized controller saves significant area, enabling higher compute density. The proposed dual I/O enables reconfigurable GEMM/GEMV operations with variable operating frequency. Our design demonstrates higher frequency GEMM operations by transferring data at higher per-pin data rate using conventional DRAM I/O as well as lower frequency yet massively parallel GEMV operations using bank-level HB-interconnect.

Our main contributions can be summarized as follows:

- We present the dual I/O scheme and a centralized DRAM controller. The schemes provides significant area savings over previous designs that employed distributed DRAM controller. The dual I/O scheme enables reconfigurable GEMM/GEMV operations with variable operating frequency of processing elements: higher frequency GEMM operations as well as lower frequency yet massively parallel GEMV operations.
- Based on the proposed concepts, we present HB-NPU, a 3D DRAM-to-logic HB technology-based processing-near-memory (PNM) LLM inference accelerator architecture that can support both GEMM and GEMV operations efficiently.
- We demonstrate that HB-NPU exhibits 2.9X, 3.5X, and 2.5X higher performance than NPU, DRAM-PIM, and the heterogeneous system respectively, on OPT-66B using the custom simulator based on DRAMSim3 simulator [23].

II. Background

A. Memory bottleneck in LLM inference

LLM [1]–[3] inference is divided into two phases: prefill and decoding. These phases exhibit significantly different operation intensities (OI). Prefill, characterized by parallel processing of multiple tokens, is dominated by compute-bound GEMM operations, whereas decoding, processing only one token at a time, is dominated by memory-bound GEMV operations. Batching [14]–[16] allows concatenation of tokens from multiple client requests that share the same weight matrix, enabling the conversion of GEMV operations

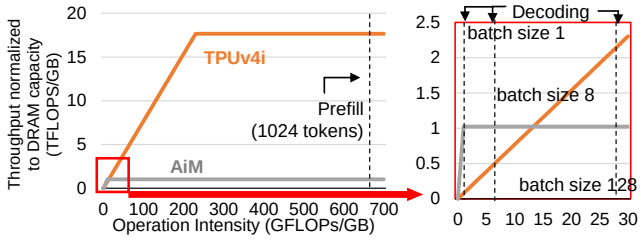

Fig. 1: Roofline model of representative NPU and DRAM-PIM; Google TPUv4i [24], and SK Hynix AiM [11]. Operation intensities for OPT-13B [3] inference with BF16 format and context length of 1024 are used. In the Y-axis, throughput with the same DRAM capacity is shown to compare TPUv4i and AiM which have different DRAM capacities.

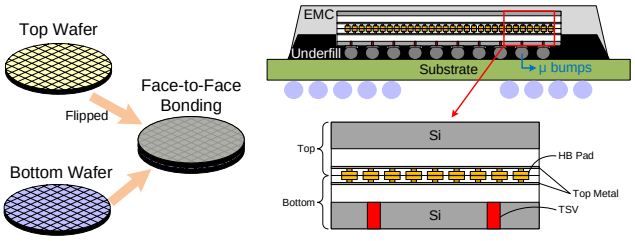
in decoding phase to GEMM operations. However, the activation-activation multiplication in attention layer still need to be done with memory-bound GEMV operations even in the multi-batching scenario. Fig. 1 shows the roofline model of state-of-the-art accelerators for OPT-13B model [3]. While TPUv4i [24], a representative NPU, has abundant compute resources, AiM [11], a DRAM-PIM, has extremely high memory bandwidth thanks to its high bank-level parallelism. Given the same DRAM capacity, NPU outperforms the DRAM-PIM in prefill phase with high operation intensity because DRAM-PIM has a much lower compute density than NPU. On the other hand, decoding phase shows extremely low operation density, resulting in substantial memory bottlenecks in NPU. As a result, an efficient GEMV unit as well as an efficient GEMM unit is desired for an efficient LLM inference. With multi-batching, NPU can outperform DRAM-PIM even in decoding phase. Nevertheless, the performance is still much lower than its maximum throughput. This is because attention layers still depend on memory-bound GEMV operations, and it is hard to increase the batch size due to the strain on the memory capacity by memory parameters and KV cache, making input matrix shape tall and skinny (i.e. called Tall-and-Skinny GEMM or TS-GEMM). The size of KV cache increases with the batch size linearly so that the batch size is typically limited to less than 64 in real LLM inference servings [25]. Consequently, it is also desired to develop hardware optimized for TS-GEMM acceleration as well as reconfigurable GEMM/GEMV.

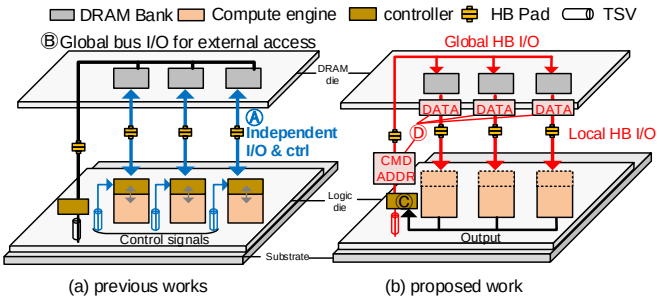
B. Hybrid Bonding (HB) Technology



Hybrid bonding (HB) has emerged as a promising alternative to traditional solder bumps, driven by the limitations in scaling solder bump pitch. In 3D System-in-Package (SiP) designs, where efficient chip-to-chip connections are essential, growing data transfer demands can lead to increased power consumption, causing communication inefficiencies. HB technology, with its exceptionally small sub-10μm pitch and low electrical loading, addresses these challenges by enabling more connections, higher bandwidth, and reduced power consumption for data transfer.

Fig. 2 illustrates the wafer-to-wafer HB stacking process in a face-to-face configuration, showcasing the cross-section of the stacked wafers. The top wafer is flipped to align face-down with the bottom wafer, allowing direct contact between HB pads on the top metal layer. This configuration significantly reduces connection thickness, leading to lower parasitic capacitance and resistance and achieving a connection quality similar to on-chip interconnects [19]. TSVs on the bottom die provide off-chip interfaces and power delivery.

III. Proposed Centralized Controller and Dual-I/O



A. Distributed I/O Channels in Previous HB DRAM

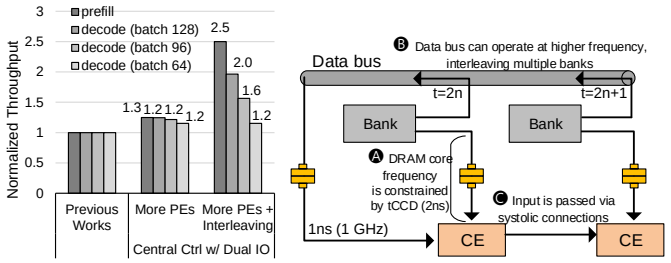
The I/O configuration of previous HB DRAM shows a distinct structure compared to conventional DRAM, as depicted in Fig. 3a.

(a) Wafer-to-wafer bond (b) Cross section view

Fig. 2: Illustration of 3D-stacked chip using hybrid bonding

(a) previous works (b) proposed work

Fig. 3: (a) Distributed memory controllers in previous HB DRAM [20]–[22] and (b) the proposed centralized memory controller in our design Note that extra TSVs for power delivery are omitted here.



HB DRAM supports independent I/O and controllers for each bank [20]–[22] enabling higher bandwidth through multiple connections between the DRAM die and logic die (Ⓐ). This configuration provides significant advantages in data transfer rates over conventional DRAM systems. However, this distributed memory controller design incurs significant area overhead. Each bank requires dedicated components, including individual control paths, address decoder, timing controls, and Built-In-Self-Test (BIST) units, of which area consumes approximately 17% of a bank area, as reported in [21].

Additionally, the structure requires HB connections not only between memory banks and compute engines but also for off-chip communication via a conventional DRAM I/O global bus shared among multiple banks (Ⓑ). Since the substrate is attached to the logic die, the off-chip datapath from the DRAM banks must pass through HB connections to interface with the TSVs on the backside of the logic die. We leverage this unused I/O with low data bandwidth in previous PNMs to enhance performance and efficiency.

B. Proposed Centralized controller and Dual-I/O

To overcome the limitations in the distributed memory controller-based designs, we propose a centralized controller and dual HB I/O between DRAM and NPU: Local bank-to-engine HB I/O and Global HB I/O (Fig. 3b). We eliminate local memory controllers for each compute engine, and instead use a centralized memory controller for global bus I/O to broadcast the control signals to banks (Ⓒ). In our design, local HB I/O is used to read the data from multiple DRAM banks to corresponding logic in parallel, and global HB I/O is used to read and write the data with lower bandwidth. Data from multiple banks are read in parallel via local HB I/O once each DRAM bank receives command/address through global HB I/O, so each bank does not need a dedicated controller (Ⓓ).

A previous work [21] claimed that distributed controllers were preferred in their vision AI accelerator design since centralized controllers require large area overhead to route and gather the distributed I/Os from different banks to the centralized controller. However, one of our key findings is that the centralized controller

(a) Speedup by Dual-I/O (b) Bank interleaving for high frequency

Fig. 4: (a) Analysis of speedup of the proposed design for OPT-13B with context length 1024 and various batch sizes. We can allocate more processing engines (PEs) by removing local memory controllers [21] and boost PE frequency by bank interleaving. (b) Bank interleaving using Global HB I/O.

is the better option for LLM accelerations. Firstly, the output traffic in matrix multiplication is smaller than the input traffic, so write operations require much lower bandwidth compared to read operations. Therefore, by using shared I/O instead of aggregating all distributed I/O, the number of I/O can be significantly reduced in write operation. Secondly, centralized control is more effective for DRAM access. Although the distributed controllers allow execution of different addresses for each bank in parallel, most operations in LLM, particularly Matrix Multiplication, exhibit regular memory access patterns, thus enabling to broadcast the same address to the banks simultaneously. For instance, in AiM [11], a PIM command is sent to all banks simultaneously with the same bank row and column addresses for executing matrix-vector multiplication.

By employing a centralized DRAM controller that handles both normal access and massively-parallel data access, the area overhead due to distributed controllers can be eliminated and the area can be used for extra compute resources. It enhances the compute density and throughput for compute-intensive layers in LLM. Replacing the distributed controller area with more computing resources results in approximately 1.2x-1.3x improvement in throughput for the OPT-13B model, as shown in Fig. 4a (labeled as *More PEs*).

Additionally, Global HB *data* I/O is useful for input data read in compute-bound operations since it can achieve a higher per-pin data rate than Local HB I/O for the same number of I/Os. By activating multiple banks in parallel and reading them in an interleaved manner, we can circumvent DRAM timing constraints and enhance per-pin data rate, thereby supporting higher logic frequencies. In our HB-NPU design example shown in Fig. 4b, processing engines (PEs) operate at 500MHz due to the 2ns of column-to-column delay (tCCD) timing constraint between each column-read command, when the input data directly come from DRAM banks via Local HB I/O (Ⓐ). On the other hand, Global HB I/O can provide the higher 1GHz frequency by activating two banks in parallel and reading one of them alternately (Ⓑ). To supply inputs from global I/O to all PEs, we organized all PEs connected via systolic connections to efficiently pass the inputs to neighboring PEs (Ⓒ). Utilizing this bank interleaving technique, we use Global HB I/O to feed input data into the PE array during compute-bound GEMM operations, which do not require the high memory bandwidth provided by Local HB I/Os. Such variable frequency operations using the proposed dual I/O further improve the throughput as shown in Fig. 4a, particularly in prefill and larger batches with high operation intensities.

IV. HB-NPU: Architecture and Dataflow

Based on the aforementioned centralized controller and dual-I/O, we develop a prototype for an LLM inference accelerator, *HB-NPU*.

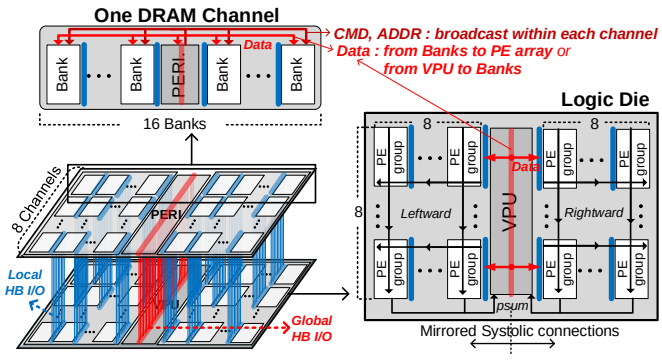


Fig. 5: Organization of the proposed HB-NPU.

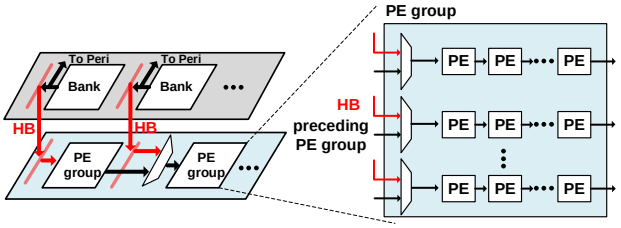
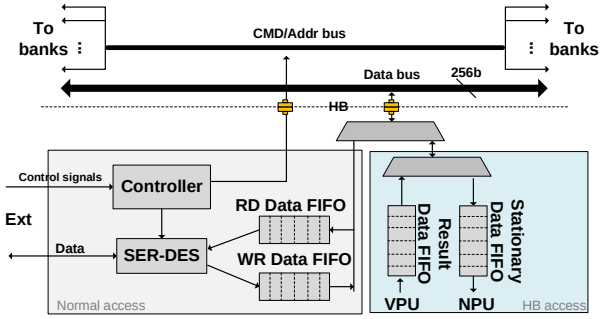
For a fair comparison, we matched the compute-memory ratio of TPUv4i [24] in our design by constructing a single chip consisting of a 2GB DRAM die and a Logic die with a 128×128 systolic array and a Vector Processing Unit (VPU) with 128×8 lanes for BF16.



A. HB-NPU Organization

Fig. 5 shows the overall organization of the proposed HB-NPU architecture, which consists of a DRAM die and a logic die that are connected with HB interconnect. The DRAM bank array and the systolic array are tightly coupled so that a DRAM bank and the corresponding group of Multiply-Accumulate (MAC) processing engines (PEs) are placed at the same coordinate in each die and connected via Local HB I/O vertically. Typically, DRAM peripheral circuits for off-chip interface are located at the center of the DRAM die. Consequently, we also place VPU and peripheral units at the center of the Logic die and connect the logic units with DRAM via Global HB I/O. VPU handles the post-processing of output before writing it back to DRAM via Global HB I/O. The PE array is split into two 128×64 configurations to support the placement.



Memory Organization The DRAM die in HB-NPU consists of 8 channels with 16 banks per channel as shown in Fig. 5. The control signals and data coming into DRAM via Global HB I/O (red line) are broadcast across all banks within the channel but not shared across channels. The column data I/O from each bank is 256-bits that can serve 16 PEs (BF 16) at once. To feed the 128 PEs in a column simultaneously, vertical 8 banks must be always activated. To reduce the bank activation overhead, we align the channels with the PE array column. The DRAM timing constraint, tFAW (Four Activation Window) limits the number of banks *per channel* that can be activated within a specified time window which incurs significant latency overhead.

PE Array Organization As depicted in Fig. 5, following the 8 channels with 16 banks per channel configuration of the DRAM, the PE array in the Logic die is also structured into PE groups with an 8×16 configuration. The left and right sides of the VPU are mirrored, facilitating the connection of Global I/O to the PE interconnection and enabling data transferred into the PE array.

Unlike the DRAM-PIM [11] which can place only 16×1 PEs for each DRAM bank due to the area limitation, HB-NPU places 16×8 PEs as a *PE group* for each DRAM bank counterpart, thereby increasing compute resource significantly. Each DRAM bank supplies input and weight data to the PE group via the Local HB I/O. The final partial sum values are sent to VPU for accumulation and post-processing such as activation functions, normalization, softmax. The completed output data is sent back from VPU to the DRAM die via Global HB I/O and stored in banks.

(a) Local HB connection and datapath of input in a PE group.

(b) Global HB connection of one memory channel. Upper part of dotted line is on DRAM die peripheral and the lower part is on the logic die VPU.

Fig. 6: Datapaths using Dual HB I/O connections.

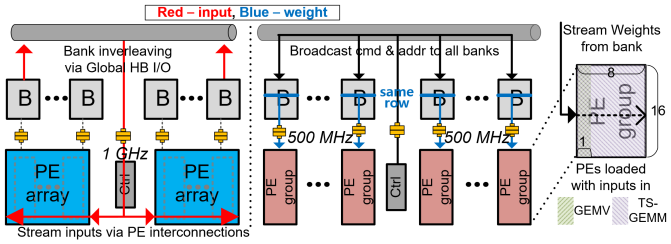


Fig. 7: Reconfigurable dataflow of HB-NPU. We use weight stationary flow with higher frequency for GEMM and input stationary with all-bank activation via Local HB for GEMV/TS-GEMM with lower frequency.

Datapaths using Dual HB I/O Fig. 6 shows the datapaths of Local HB I/O and Global HB I/O. The Local HB I/Os stream data from each DRAM bank to the PE array directly (Fig. 6a). Data coming from the bank either goes to the DRAM peripheral or moves through the Local HB I/O, where the consecutive columns of a bank row are streamed into the PE array sequentially. The first PE columns of each group of PEs can select the input data either from the preceding PE group or upper DRAM bank via the Local HB I/O. Fig. 6b shows the Global I/O datapath of one memory channel. Commands and addresses are sent to the banks by the centralized controller, and data, multiplexed between the external path and the NPU in the logic die, is communicated to the data bus in the DRAM die shared by the banks within each channel. Except for the external I/O interface including controller, Serializer-Deserializer (SER-DES), and data FIFOs, we have two extra FIFOs for result data from VPU and stationary data into NPU. The output data comes out from the systolic array and enters into Result Data FIFO and input data is supplied through the Stationary Data FIFO to load the PE registers. Therefore, we design Dual-IO support with minimal modification of Result Data FIFO and Stationary Data FIFO, exploiting existing DRAM I/Os.

B. Reconfigurable GEMM/GEMV dataflow of HB-NPU

Since each PE group in HB-NPU can receive input either vertically from DRAM or horizontally from the preceding PE group, we can selectively configure the dataflow for GEMM or GEMV kernels based on the given workloads. We adopt the weight-stationary dataflow for GEMM and input-stationary dataflow for GEMV considering the impact of DRAM timing constraints. Weight-stationary dataflow is efficient for GEMM operations since weights have a high chance of reuse. On the other hand, weight-stationary dataflow is inefficient in GEMV case since there is no reuse chance of weights when supplying inputs, necessitating frequent DRAM bank row switching to load the next weight tile. DRAM bank row switching causes substantial energy consumption and significant delay due to timing constraints. Therefore, it is more efficient to preload the input into PE registers and reuse it multiple times by streaming the weight matrix. Consequently, we opt for input-stationary dataflow for GEMV operations in our design.

GEMM Operations For GEMM, as shown in Fig. 7a, weight data is preloaded into PE registers, and input data is streamed into the PEs in a systolic fashion via Global HB I/O at 1 GHz frequency thanks to the bank interleaving technique. As described in Fig. 4b, Global HB I/O can boost memory bandwidth by accessing several banks in an interleaved manner, enabling 1 GHz frequency operation which is 2X higher frequency than the case when Local HB I/O is used.

GEMV Operations For GEMV, conversely, we preload inputs via Global HB I/O. Then, we activate all DRAM banks for memory-intensive weight streaming into PEs via local HB I/O's by broadcasting the command and address to all banks (Fig. 7b). While the operation frequency of PEs is restricted by the DRAM timing constraint by using Local HB I/O, massively parallel weight streaming significantly accelerates GEMV operations compared to conventional NPUs. As described in section III-B, matrix multiplication in LLM does not require a complex memory access pattern. Therefore, we can easily map LLM parameters on DRAM to access the same row of all DRAM banks simultaneously similar to conventional DRAM-PIM architectures. The large PE array in our HB-NPU is divided into 16 PE groups, and in each PE group, only the first PE column is involved in GEMV computation since the streamed weights can be computed by only one input vector.

Tall-and-Skinny GEMM Meanwhile, batch sizes in LLM inference are often limited in multi-batching scenarios due to the pressure on memory capacity by KV cache burden, making inputs become a tall and skinny matrix. On a conventional systolic array (e.g. 128×128), such tall and skinny GEMM (TS-GEMM) workloads lead to reduced PE utilization. The proposed HB-NPU has a unique feature to address both PE utilization and memory bandwidth issues by utilizing input stationary dataflow for TS-GEMM. We run TS-GEMM with high memory bandwidth by streaming weights into the PE groups via Local HB I/Os, while keeping inputs stationary in PE registers. As shown in Fig. 7b (right), larger number of PE columns in each PE group participate in the TS-GEMM computation than the GEMV dataflow in which only the first PE column in each PE group is utilized.

Data Mapping Each input and weight tile is divided into 8 memory channels and distributed to all PE rows via Global HB I/O. Weights are prearranged in DRAM prior to execution. For the activation-activation multiplication in attention layers, we evenly allocate different heads to each PE group, optimizing PE utilization. For arranging input data, since Global HB I/O can access any DRAM banks, VPU can send the completed output data of producer layers to the target

bank locations via Global HB I/O to make them ready for processing of the next consumer layers.

V. Evaluation

A. Methodology

Baselines We assess our architecture against three types of representative LLM accelerators: NPU, DRAM-PIM, and heterogeneous system (NPU+PIM). All baselines and HB-NPU have the same 32GB capacity of DRAM on a board and the boards are interconnected by PCIe 4.0 16x for scaling-out to simulate large-size models. Detailed specifications are provided in Table I.

- **NPU**: NPU baseline features a 4 128×128 systolic array with 8 GB HBM2 and vector processors referring to [24]. We simulated the NPU with ScaleSim cycle-level simulator [26].
- **DRAM-PIM**: DRAM-PIM baseline has a similar configuration to [11], that has 16 processing elements per bank and one global buffer per channel. We built a DRAM-PIM simulator based on the DRAMSim3 simulator [23].
- **Heterogeneous system (NPU+PIM)**: Recently, heterogeneous systems combining NPUs and DRAM-PIMs [17], [18] have been proposed to accelerate both GEMM and GEMV operations in batched LLM decoding. Note that the heterogeneous system has 2x larger DRAM capacity than that of both the baseline and HB-NPU, with a half allocated to NPU and the other half to PIM. We assigned FC layers with GEMM operations to the NPUs and Attention layers with GEMV operations to the PIMs with NPU-PIM pipelining techniques that enhance system utilization.

Cycle-level simulation of HB-NPU We built a cycle-level simulator for HB-NPU based on the DRAMSim3 simulator[1] [23]. We added custom commands for HB-NPU operations and implemented a custom command generator for BLAS functions. We developed a custom Python program to generate a DRAM trace file from model information and memory specifications. Our program allows users to input various LLM workload information (e.g., number of heads, hidden dimensions, etc.), dataflow options, and DRAM specifications (DRAM capacity, device width, etc.). Then the program divides the operand data and allocates them to the physical address of the bank. We also consider chip-to-chip communication overhead for large-scale system. The generated trace file is read into the simulator and our custom command generator then derives DRAM commands from the provided transactions.

LLM Workloads We simulated the OPT model variations [3] across four different parameter sizes for multi-batch inference of LLM. We conducted experiments for batch sizes of 32, 64, and 128 using two token lengths, (1024, 128) and (128, 1024) for input and output tokens. Model parallelism is employed to distribute parameters and KV caches across multiple devices, with a mixture of pipeline parallelism (PP) [27] and tensor parallelism (TP) [28]. While high TP increases communication overhead, high PP divides a batch into several micro-batches, leading to PE under-utilization. Table II shows the LLM configuration with the model parallelism; Tensor parallelism (TP) and Pipeline parallelism (PP) we exploited.

B. Results

Decoding results Fig. 8 shows the simulation results for throughput of baselines and HB-NPU for multi-batch inference cases. While NPU throughput increases as the batch size increases, DRAM-PIM exhibits relatively low throughput because it is optimized to GEMV operations. The heterogeneous system, incorporating both NPU and PIM modules, demonstrates higher performance than NPU-only or DRAM-PIM-only baselines. However, TS-GEMM workloads with low batch sizes cause both NPU and PIM modules to suffer compared to HB-NPU. The HB-NPU, with its support for a reconfigurable systolic array and high bandwidth, demonstrates the highest throughput compared to the baselines. Overall, our HB-NPU shows 3.0x, 4.1x, and 2.0x performance improvement on average over NPU, DRAM-PIM, and the heterogeneous system (DRAM-PIM + NPU), respectively. The higher performance of HB-NPU is particularly noticeable for larger model with lower batch size, which is expected to be a main workload in inference servings due to the increasing demands for larger AI model and longer context [33], [34].

Fig. 9 shows the breakdown of runtime among various inference engines. Fig. 9a represents the case in which computation of attention layer is dominant with long input sequence, while Fig. 9b represents the case when the FC layer is dominant with large model dimension. In Fig. 9a, the NPU is suffering from inefficiency in GEMV computations, because of the large size of KV cache with long input sequence. As batch size increases, both NPU and PIM exhibit significantly larger runtime increases compared to the other two systems, due to their lack of ability to accelerate GEMV or GEMM, respectively. In Fig. 9b, the runtimes for both the NPU and the heterogeneous system (which includes an NPU) decrease as the batch size increases, leading to higher PE utilization. In contrast, DRAM-PIM's computation time for the FC layer increases linearly with batch size, making it significantly slower than the other systems. In both scenarios, HB-NPU exhibits the best performance, effectively computing both FC and attention layers. While heterogeneous system also effectively computes both layers, they feature dedicated processing units for GEMM and GEMV so that the mismatch in the ratio of GEMM

[1]HB-NPU simulator is available at https://github.com/shh8228/HB-NPU-simulator.git

TABLE I: Hardware specification of baselines and HB-NPU.

NPU	Composition	4 128x128 PE arrays, 4 128x8 vector units 144 MB SRAM, 1 GHz
	Memory	2 4H HBM2 of 8 GB (1 GB/slice); off-chip bandwidth of 614 GB/s

(a) Heterogeneous system with doubled DRAM capacity.

(b) Heterogeneous system with the same DRAM capacity as HB-NPU.

Fig. 10: Prefill speedup of HB-NPU compared to heterogeneous system with (a) doubled DRAM capacity and (b) same DRAM capacity as HB-NPU .

to GEMV operations leads to lower PE utilization. In contrast, HB-NPU utilizes reconfigurable processing units, leading to superior performance across various scenarios.

Prefill results Fig. 10a shows the speedup of HB-NPU in prefill, compared to heterogeneous system. HB-NPU shows higher performance than heterogeneous system with 128 input tokens due to the lower operation intensity. With the larger token size 1024, heterogeneous system is slightly faster than HB-NPU because heterogeneous system utilizes larger system resources than HB-NPU. However, considering the difference in the memory capacity and number of PEs, HB-NPU achieves higher efficiency than heterogeneous system.

Implication of DRAM/PE resources in Heterogeneous System In the experimental setting for Fig. 8 and 10a, we assumed that the heterogeneous system has twice larger DRAM size and more PEs than other baselines and our HB-NPU as the heterogeneous system consists of an NPU with dedicated DRAM and a DRAM-PIM similar to [18]. Therefore, for a fair comparison, it is worth comparing HB-NPU with the heterogeneous system that has the same DRAM capacity. Fig. 10b and Fig. 11 show that the performance gap between our HB-NPU and the heterogeneous system increases as the DRAM capacity and the number of PEs in the heterogeneous system are reduced.

C. Area and Energy Analysis

Area overhead of VPU To assess whether the VPU unit can be implemented in the area budget of a conventional DRAM peripheral area [29], we first synthesized the VPU of 128x16 ALUs with

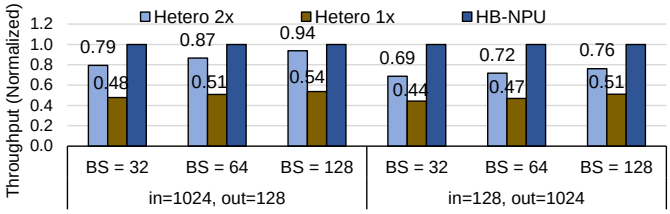

Fig. 11: Throughput comparison of HB-NPU (1024 GB DRAM) with the heterogeneous system with 2048 GB DRAM (Hetero 2x) and 1024 GB DRAM (Hetero 1x) for OPT-66B. Throughput values are normalized to that of HB-NPU.

accumulation buffer following the TPU series setup [30], with a 28nm technology. Then, we scaled the area to 14nm using the equation from [32]. We also included the area of DRAM Physical layer (PHY) based on the HBM3 specification. We observed that the VPU and DRAM PHY consume 83.5% of the target area budget, implying that no extra area is required.

Energy analysis Our HB-NPU consumes much lower energy than other baselines, due to its energy-efficient dataflow using Dual-I/O. HB-NPU consumes lower energy than NPU due to the short HB interconnect. HB-NPU also consumes lower energy than DRAM-PIM thanks to its more energy-efficient GEMM dataflow than that of DRAM-PIM. Overall, simulation results using DRAMsim3 [23] show that HB-NPU consumes about 19x, 9x, 3x lower energy than DRAM-PIM, NPU, and heterogeneous system, respectively, on the OPT-2.7B model.

VI. Conclusion

We introduce HB-NPU, a versatile PNM architecture for LLM inference designed to accelerate both GEMM and GEMV operations leveraging 3D DRAM-to-Logic HB technology. HB-NPU alleviates memory bottlenecks and enhances compute resource density through its centralized controller and dual HB I/O schemes. This reconfigurability for GEMM/GEMV operations is significant, as most existing AI accelerators are optimized for either GEMM or GEMV. Moreover, HB-NPU's support for tall-and-skinny GEMM enables higher performance in LLM inference involving limited batch size. The combination of these features positions HB-NPU as a promising solution for efficient, high-performance LLM inference processing.

***Abstract*—Recent parameter-efficient fine-tuning (PEFT) techniques have enabled large language models (LLMs) to be efficiently fine-tuned for specific tasks, while maintaining model performance with minimal additional trainable parameters. However, existing PEFT techniques continue to face challenges in balancing both accuracy and efficiency, especially when addressing scalability and the demands of lightweight deployment for LLMs. In this paper, we propose an efficient fine-tuning method of LLMs based on dual quantized Tensor-Train adaptation with decoupling magnitude-direction (DuQTTA). The proposed DuQTTA method employs Tensor-Train decomposition and dual-stage quantization to minimize model size and resource consumption. Additionally, it employs an adaptive optimization strategy and a decoupled update mechanism to improve model performance, thereby minimizing suboptimal outcomes and ensuring alignment with the full-parameter fine-tuning goals. Experimental results indicate that the proposed DuQTTA method outperforms existing PEFT methods, achieving up to a 65× compression rate compared to the LLaMA2-7B models, meanwhile delivering improvements of 4.44%, 3.14%, and 0.97% over LoRA on LLaMA2-7B, LLaMA3-8B, and LLaMA2-13B, respectively. The proposed DuQTTA method is effective in compressing LLMs for deployment on resource-constrained edge devices.**

***Index Terms*—LLMs, Tensor-Train, dual quantization, adaptive optimization strategy, magnitude-direction decoupled**

I. Introduction

The leading LLMs today are pre-trained on extensive general-domain datasets, showcasing strong generalization across applications like question-answering, summarization, and translation. However, practitioners often seek to tailor these broad models to specific downstream tasks, particularly smaller, specialized ones. This requires adjusting the pre-trained model's weights to optimize performance on these new tasks. With the rapid expansion in the size of LLMs and their training datasets, full-parameter fine-tuning for downstream adaptation has become computationally prohibitive, as it necessitates extensive weight modifications through costly gradient-based methods.

PEFT methods have been developed for enabling fine-tuning by adjusting only a minimal subset of parameters [1]. One such efficient technique, Low-Rank Adaptation (LoRA) [2], achieves parameter efficiency without altering model architecture. LoRA confines training to added low-rank matrices within the pre-trained weights, significantly reducing the number of trainable parameters and thereby lowering training costs. Tensor decomposition further aids in fine-tuning by reducing the number of parameters required, as seen in LoRETTA [3]. Notably, LoRA's restriction to a low-rank subspace imposes coupling between parameter magnitude and direction changes within this space, limiting independent variation in both dimensions. As observed in [4], LoRA fine-tuning may face suboptimality issues as model width grows, leading them to recommend varied learning rates. Despite these advancements, PEFT methods still struggle to balance accuracy with minimizing trainable parameters.

In this paper, we propose DuQTTA, an ultra-low-parameter and high-precision PEFT method that delivers performance on par with or better than full-parameter fine-tuning while substantially reducing trainable parameters and memory requirements. This approach enhances the efficient deployment of LLMs, especially on edge devices. DuQTTA tackles these challenges by integrating dual quantization (DQ) with Tensor-Train (TT) decomposition, an adaptive optimization strategy (AOS), and a decoupled update mechanism. The main contributions of DuQTTA are as follows:

- We propose dual quantization and TT decomposition within DuQTTA to achieve a substantial reduction in trainable parameters. By first applying TT decomposition, we reparameterize model weights into TT cores. This is followed by dual quantization process: the TT cores undergoes initial quantization, and then a second quantization is applied to the reconstructed tensor. This approach significantly lowers resource cost with minimal accuracy loss.
- We propose AOS that addresses potential suboptimal fine-tuning in large-width conditions by dynamically adjusting learning rates after tensor core reconstruction. By tuning the learning rates across different components, this strategy effectively resolves performance bottlenecks associated with large-scale parameter spaces, boosting fine-tuning efficiency and model performance.
- We propose a magnitude-direction decoupled update mechanism that decomposes pre-trained weights into two components—magnitude and direction—to facilitate fine-tuning. By leveraging TT for directional updates, our approach significantly reduces the number of trainable parameters while enabling more precise updates. This refined parameter adjustment enhances the adaptability and effectiveness of the model across a wide range of downstream tasks.

II. Related Work

A. Parameter-Efficient Fine-Tuning

PEFT reduces the fine-tuning costs of LLMs by training a relatively small subset of parameters to adapt to downstream tasks. Existing PEFT methods can be categorized into adapter-based methods, prompt-based methods, and LoRA and its

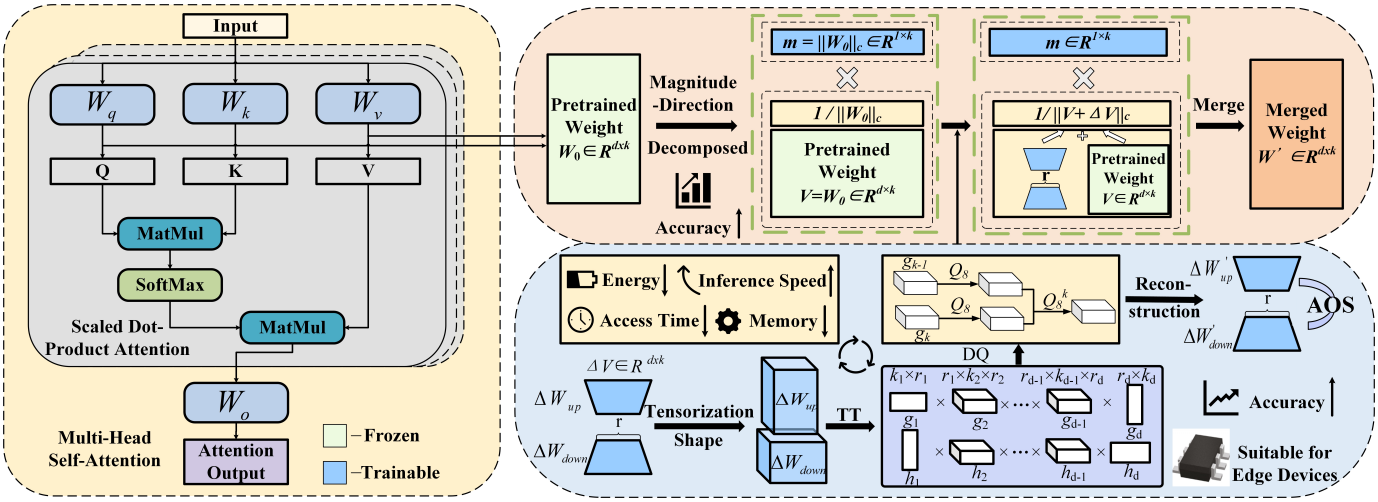

Fig. 1. The overall architecture of the prposed DuQTTA with decoupling magnitude-direction for efficient fine-tuning of LLMs.

variants. The first category, known as adapter-based methods, involves introducing additional trainable modules into the original frozen backbone, as seen in works [5–7]. Houlsby et al. [1] proposed adding linear modules sequentially to existing layers, while He et al. [5] suggested integrating these modules in parallel with the original layers to enhance performance. The second category, prompt-based methods, focuses on introducing trainable tokens into the input or hidden layers of the base model and fine-tuning these vectors, significantly reducing the number of trainable parameters, though sometimes at the cost of accuracy, as shown in [8–10]. However, both types may lead to inference latency compared to the original model, and this issue becomes more pronounced as model size increases.

B. LoRA and Its Variants

During fine-tuning, LoRA introduces low-rank matrices as side branches to approximate weight updates in the original pre-trained weights [2]. This approach avoids additional inference latency while allowing the low-rank matrices for downstream tasks to be seamlessly merged with the pre-trained weights before inference. For instance, Dettmers et al. [11] introduced QLoRA, a quantized version of LoRA, which further reduces computational costs by quantizing pre-trained weights down to as few as 4 bits. Additionally, Yang et al. [3] incorporates Tensor-Train decomposition during fine-tuning, significantly reducing the number of trainable parameters by decomposing the two update matrices of LoRA. Meanwhile, Hayou et al. [4] addresses the suboptimal updates in LoRA under large-width conditions, proposing different learning rates for the two update matrices to improve fine-tuning performance. To further refine the training of quantized LoRA, Li et al. [12] introduced a new method called LoftQ, which enables better initialization for quantized training. Meanwhile, other recent works have focused on reducing the number of parameters in LoRA through various approaches, such as using different ranks for update matrices across layers [13, 14], applying fixed low-rank projections [15], and parameterizing low-rank matrices with a random basis [16].

III. METHODOLOGY

A. Overall Architecture of the Proposed DuQTTA

We propose an advanced architecture named DuQTTA, which achieves high precision while maintaining low resource consumption. Fig. 1 illustrates its optimization process. First, DuQTTA utilizes a magnitude-direction decoupled update mechanism that separates the pre-trained weights obtained from the Q and V components within the attention mechanism of LLMs into distinct magnitude and direction components. The direction component is then decomposed using TT decomposition, significantly reducing the number of trainable parameters. Second, DQ is applied to the TT cores. Each TT core is first quantized to 8-bit precision, followed by an 8-bit quantization of the reconstructed tensor. This approach further reduces memory consumption and power consumption while accelerating inference, making it more suitable for deployment on edge devices. Finally, the architecture incorporates AOS to update the reconstructed matrices, further improving accuracy.

B. Tensorized TT Layer and Tensor Reparameterization

In this section, we present an approximate representation of the linear layers in LLMs that require fine-tuning, achieved by reducing the number of trainable parameters using the TT format [17]. Prior to applying the TT decomposition, the original weight matrix W is reshaped into a d-dimensional tensor $\mathcal{W} \in \mathbb{R}^{l_1 \times \cdots \times l_d}$, where entries are indexed by d indices $p_1, p_2, \ldots, p_k, \ldots, p_d$. Each p_k is within $[1, l_k]$ for $k = 1, 2, \ldots, d$. The high-order tensor $\mathcal{W} \in \mathbb{R}^{l_1 \times \cdots \times l_d}$ can then be decomposed and represented by using a chain of d TT cores $\mathcal{G}_1, \ldots, \mathcal{G}_k, \ldots, \mathcal{G}_d$ [18], where each core $\mathcal{G}^{(k)} \in \mathbb{R}^{r_{k-1} \times l_k \times r_k}$ for $k \in [1, d]$. Each element in W can be derived from these TT cores, given by

$$\mathcal{W}_{p_1, p_2, \ldots, p_d} = \prod_{k=1}^{d} \mathcal{G}_{p_k}^{(k)}, \tag{1}$$

where $\mathcal{G}_{p_k}^{(k)} = \mathcal{G}^{(k)}(:, p_k, :)$ is the p_k-th lateral slice of the k-th TT core $\mathcal{G}^{(k)}$. $r \in \{r_0, r_1, \ldots, r_d\}$, called the TT rank with $r_0 = r_d = 1$, directly affects the compression rate of the TT decomposition. During fine-tuning, only these TT cores are stored, significantly reducing the memory footprint compared to the full weight matrix. It should be noted that the TT decomposition reduces the number of parameters from the original $M \times N$ to $\sum_{k=1}^{d} r_{k-1} \times l_k \times r_k$.

To fully exploit the intrinsic low-rank structure of the weight matrix, we extend the reparameterization of the update matrices by incorporating tensor factorization on top of the

standard LoRA framework. Specifically, the update process can be written as follows:

$$y = W_0 x + \Delta W x = W_0 x + BAx, \tag{2}$$

where x and y represent the input and output vectors, respectively. $W_0 \in \mathbb{R}^{h\times l}$ denotes the pretrained weight matrix, while $B \in \mathbb{R}^{h\times r}$ and $A \in \mathbb{R}^{r\times l}$ are the low-rank matrices that constitute the update matrix ΔW. Here, $r \ll \min\{h, l\}$ is the LoRA rank.

In the proposed DuQTTA method, we reshape the two update matrices ΔW_{up} and ΔW_{down} into tensors of shapes $l_1 \times \cdots \times l_d$ and $j_1 \times \cdots \times j_d$, respectively. Both ΔW_{up} and ΔW_{down} are then decomposed into TT cores. The process of applying a tensorized update in the fully connected layer, which performs a linear transformation on the input x, can be given by

$$\begin{aligned} y &= W_0 x + \text{TT}(\Delta W_{\text{up}}) \cdot \text{TT}(\Delta W_{\text{down}}) x \\ &= W_0 x + \prod_{k=1}^{d} \mathcal{G}_{p_k}^{(k)} \prod_{k=1}^{d} \mathcal{Q}_{p_k}^{(k)} x, \end{aligned} \tag{3}$$

where W_0 represents the pretrained weights, and ΔW_{up} and ΔW_{down} are represented as TT layers. The TT layers consist of TT cores $\mathcal{G}_{p_1}^{(1)}, \ldots, \mathcal{G}_{p_k}^{(k)} \ldots, \mathcal{G}_{p_d}^{(d)}$ and $\mathcal{Q}_{p_1}^{(1)}, \ldots, \mathcal{Q}_{p_k}^{(k)}, \ldots, \mathcal{Q}_{p_d}^{(d)}$.

As a result, the computational complexity can be reduced from $O(n^d)$ to $O(dnr^2)$. Since the TT-ranks are much smaller than n and d, TT decomposition significantly reduces the number of trainable parameters and saves memory usage.

C. Dual Quantization

The core idea is to apply dual quantization to the entire feedforward channel of the linear layers that require fine-tuning during the training process, with emphasis on the fact that weight quantization is integrated into training itself, rather than applied post-training. Before presenting the weight quantization process, we first explain Quant$(\cdot)$, the most commonly used quantization function in the DuQTTA framework. Quant$(\cdot)$ approximates a continuous value x to its nearest discrete counterpart, given by

$$\text{Quant}(x, \text{bits}) = \frac{\text{round}(x \cdot 2^{\text{bits}-1})}{2^{\text{bits}-1}}, \tag{4}$$

where round$(\cdot)$ is the function that rounds the value to the closest integer, and "bits" represents the target bit-width of x. The quantization of weights follows the same procedure throughout backpropagation. For clarity, we employ the same straight-through estimator (STE) approach during backpropagation, as used in most quantization studies [19–21].

For the weights of the linear layers that require fine-tuning, we convert their parameters from FP values to low-bit integers to reduce memory usage and computational cost, given by

$$\text{Quant}\mathcal{K}(x, \text{bits}) = \text{clip}\big(\text{Quant}(x, \text{bits}), -1 + \Delta,\ 1 - \Delta\big), \tag{5}$$

where $\Delta = 1/(2^{\text{bits}-1})$ represents the smallest interval between weight values, and clip$(\cdot)$ projects the data values onto a specified minimum and maximum range. The dual quantization strategy plays a pivotal role and is implemented in two stages, as illustrated in Fig. 2. In the first stage, the TT cores $\mathcal{G}_{p_1}^{(1)}, \ldots, \mathcal{G}_{p_k}^{(k)} \ldots, \mathcal{G}_{p_d}^{(d)}$, obtained through TT decomposition, are quantized based on their weights. This step converts floating-point numbers into low-bit-width integers (typically 8-bit), significantly reducing the memory usage and computational complexity, making it well-suited for resource-constrained hardware deployments. During the inference process, the quantized TT cores are first reconstructed into full linear layers represented in floating-point values. Since the reconstructed tensors are reverted to floating-point representations, a second stage of quantization is applied to compress these reconstructed linear layers back into low-bit-width representations. This additional quantization stage further enhances computational efficiency during inference. The process of dual quantization can be expressed as follows:

$$\begin{aligned} \mathcal{G}_{p_k}^{(k,q)} &= \text{Quant}(\mathcal{G}_{p_k}^{(k)}, 8), \quad k \in \{1, \ldots, d\}, \\ \mathcal{T}_1^q &= \text{Quant}\mathcal{K}(\mathcal{G}_{p_1}^{(1,q)} \times \mathcal{G}_{p_2}^{(2,q)}, 8), \\ \mathcal{T}_i^q &= \text{Quant}\mathcal{K}(\mathcal{T}_{i-1}^q \times \mathcal{G}_{p_{i+1}}^{(i+1,q)}, 8), \quad i \in \{2, \ldots, d-1\}, \end{aligned} \tag{6}$$

where Quant$(\cdot)$ represents the first stage of quantization, applied to the TT cores $\mathcal{G}_{p_k}^{(k,q)}$. Quant$\mathcal{K}(\cdot)$ represents the second stage of quantization, which is applied to the reconstructed TT cores, resulting in $\mathcal{T}_k^q$.

Dual quantization achieves both low memory usage and superior computational efficiency. The first stage focuses on compressing model storage, while the second stage further reduces the computational overhead associated with floating-point operations during inference. This combined dual quantization approach not only allows the model to maintain high accuracy while significantly lowering memory requirements but also greatly enhances inference speed. This dual quantization design, when combined with the TT decomposition approach, creates a fine-tuning strategy highly suitable for devices with limited memory or computational resources, positioning it as an important solution for efficient fine-tuning of LLMs.

D. Adaptive Optimization Strategy

As previously mentioned, we apply TT decomposition to reparameterize the update matrices of linear layers during fine-tuning, while employing dual quantization to further reduce memory usage and computational complexity. However, during forward propagation, the decomposed TT cores are gradually recombined through tensor products, ultimately reconstructing a matrix with the same shape as the original. Under conditions of large matrix width, using a uniform learning rate for these reconstructed matrices can result in suboptimal fine-tuning performance, limiting the model's ability to effectively capture and learn critical features. After TT decomposition, the original weight is represented as two key matrices, which are obtained by the sequential multiplication of multiple TT cores during forward propagation. Due to the differences in the dimensionality and function of these matrices in feature learning, AOS should be employed, rather than applying a uniform learning rate, with adjustments based on the network width n. The first matrix, $\Delta W'_{\text{up}} \in R^{n\times r}$, projects low-dimensional features into a higher-dimensional space. The second matrix, $\Delta W'_{\text{down}} \in R^{r\times n}$, remaps these features back to a lower-dimensional space. To ensure their contributions to the loss function are comparable, we enforce $\eta_{\Delta W'_{\text{up}}} \left\| \frac{\partial \mathcal{L}}{\partial \Delta W'_{\text{up}}} \right\|_1 \approx \eta_{\Delta W'_{\text{down}}} \left\| \frac{\partial \mathcal{L}}{\partial \Delta W'_{\text{down}}} \right\|_1$, where $\eta_{\Delta W'_{\text{up}}}$ and $\eta_{\Delta W'_{\text{down}}}$ are the learning rates for $\Delta W'_{\text{up}}$ and $\Delta W'_{\text{down}}$, respectively, and $\|\cdot\|_1$ denotes the L1 norm, defined as the sum of the absolute values of all components. Assuming the model output is given by $Y = X\Delta W'_{\text{up}}\Delta W'_{\text{down}}$, the gradients of the loss function with respect to $\Delta W'_{\text{up}}$ and $\Delta W'_{\text{down}}$ are given by

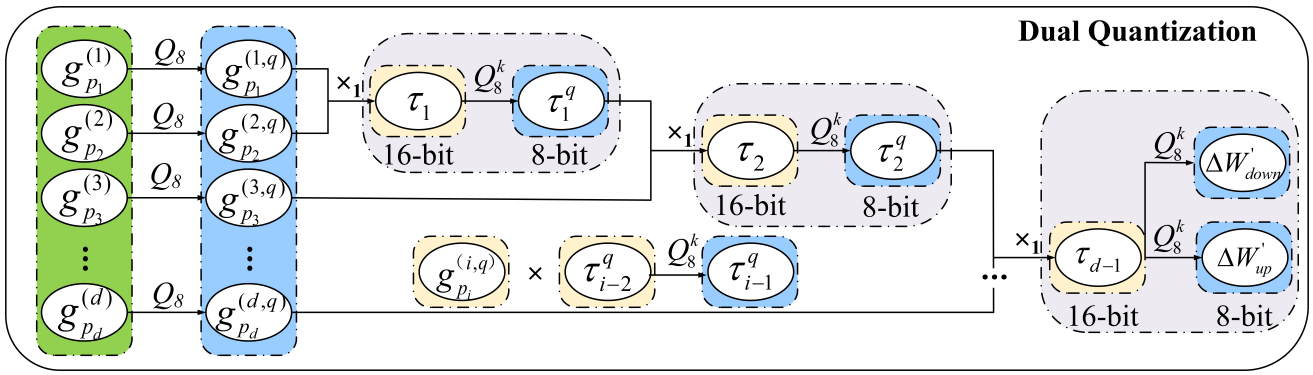

Fig. 2. The update process of TT decomposition based fine-tuning with dual quantization.

$$\begin{aligned}\frac{\partial L}{\partial \Delta W'_{\text{up}}} &= X^{\mathrm{T}}\frac{\partial L}{\partial Y}(\Delta W'_{\text{down}})^{\mathrm{T}},\\ \frac{\partial \mathcal{L}}{\partial \Delta W'_{\text{down}}} &= (\Delta W'_{\text{up}})^{\mathrm{T}}X^{\mathrm{T}}\frac{\partial L}{\partial Y},\end{aligned} \tag{7}$$

where L denotes the loss function, while $\Delta W'_{\text{up}}$ and $\Delta W'_{\text{down}}$ represent the two key matrices obtained after tensor reconstruction. The variable $X \in \mathbb{R}^{b\times n}$ denotes the input feature matrix, and $Y \in \mathbb{R}^{b\times n}$ represents the output feature matrix, with $\frac{\partial L}{\partial Y}$ indicating the gradient of the loss function with respect to the model output. To maintain numerical stability during forward propagation, the initial values of $\Delta W'_{\text{up}}$ and $\Delta W'_{\text{down}}$ are typically initialized based on their standard deviations, set as $\sqrt{\frac{1}{r}}$ and $\sqrt{\frac{1}{n}}$, respectively. This results in the relationship $\eta_{\Delta W'_{\text{up}}} \times \sqrt{\frac{1}{r}} \approx \eta_{\Delta W'_{\text{down}}} \times \sqrt{\frac{1}{n}}$.

From the preceding analysis, we deduce $\frac{\eta_{\Delta W'_{\text{down}}}}{\eta_{\Delta W'_{\text{up}}}} \approx O(\sqrt{n})$ when $r = O(1)$. Therefore, optimal performance can be achieved by setting the learning rate ratio between $\Delta W'_{\text{up}}$ and $\Delta W'_{\text{down}}$ to a fixed constant λ, with $\lambda = O(\sqrt{n})$ and significantly greater than 1. The optimal value of λ depends on the type of LLMs and the specific task at hand. The updates for the reconstructed tensors in AOS are given by

$$\begin{aligned}\Delta W'_{\text{down}} &\leftarrow \Delta W'_{\text{down}} - \eta \times G_{\Delta W'_{\text{down}}},\\ \Delta W'_{\text{up}} &\leftarrow \Delta W'_{\text{up}} - \lambda\eta \times G_{\Delta W'_{\text{up}}},\end{aligned} \tag{8}$$

where η denotes the learning rate, $G_{\Delta W'_{\text{down}}}$ and $G_{\Delta W'_{\text{up}}}$ represent the gradients. We have implemented AOS to ensure that the update pace of the two matrices aligns with their respective dimensional characteristics, as illustrated in Fig. 3. This approach significantly enhances LLMs fine-tuning performance while maintaining training stability and rapid convergence.

E. Magnitude-Direction Decoupled Update Mechanism

Due to the limitations of the fine-tuning approach mentioned above, both the tensor decomposition and reconstruction processes restrict parameter updates to a low-rank subspace. This constraint causes the changes in magnitude and direction to be highly coupled within this subspace, limiting their degrees of freedom. As a result, they tend to update proportionally, making it challenging to adjust direction changes with large or small magnitudes independently. In contrast, full-parameter fine-tuning allows for flexible and independent adjustment of both direction and magnitude. To align with the learning dynamics of full-parameter fine-tuning, we propose the magnitude-direction decoupled update mechanism. This mechanism decomposes the weight matrix W into a magnitude component and a direction component, where the magnitude component m is treated as a trainable parameter, while the direction component V remains fixed, allowing independent optimization of each component, given by

$$W = \text{broadcast}(m) \odot \frac{V}{\|V\|_c}, \tag{9}$$

where $W \in \mathbb{R}^{d\times k}$ is the weight matrix, $m \in \mathbb{R}^{1\times k}$ represents the magnitude component, and $V \in \mathbb{R}^{d\times k}$ denotes the direction component. The notation $\|\cdot\|_c$ indicates the column-wise norm of the matrix, applied to each column vector individually. Here, m is a row vector, and through *broadcasting*, each element m_j of m is applied to the corresponding column $V_{:,j}$ of V, where $j \in \{1, 2, \ldots, k\}$. In this column-wise scaling process, the direction of each column vector $V_{:,j}$ remains unchanged, while its magnitude is controlled by the corresponding element m_j in m. Specifically, *broadcast*(m) means that the vector m is broadcasted to match the shape of the matrix V, and $\odot$ denotes the element-wise multiplication, indicating that each element of m interacts with the corresponding element of V.

Specifically, the magnitude component is initialized by using the norm of the pre-trained weights, while the direction component is refined through TT decomposition, with the fine-tuning update process described as follows:

$$\begin{aligned}W' &= \text{broadcast}(m) \odot \frac{V + \Delta V}{\|V + \Delta V\|_c},\\ &= \text{broadcast}(m) \odot \frac{W_0 + \Delta W'_{\text{up}}\Delta W'_{\text{down}}}{\|W_0 + \Delta W'_{\text{up}}\Delta W'_{\text{down}}\|_c},\end{aligned} \tag{10}$$

where W' represents the updated weights after decoupling via the magnitude-direction components. Given that the direction component accounts for a substantial portion of the model's parameters, the use of TT decomposition significantly enhances computational efficiency.

IV. EXPERIMENTAL RESULTS

We conduct a comprehensive evaluation of the proposed DuQTTA method across various sizes of LLMs on downstream tasks. For LLaMA2-7B and LLaMA3-8B, we select seven datasets CB, BoolQ, WSC, COPA, ReCoRD, SQuAD, and DROP for assessing the performance of DuQTTA in three dimensions: (a) classification ability, (b) reasoning ability, and (c) generation ability. In addition, several PEFT methods are

also evaluated for comparison. Due to limited computational resources, we only report experimental results for LLaMA2-13B on inference tasks and generation tasks. The results indicate that the proposed DuQTTA outperforms existing PEFT methods, such as LoRA, Adapters, and Prefix Tuning, using fewer trainable parameters while achieving results comparable to full parameter fine-tuning. Further experiments confirm that DuQTTA reduces memory usage and power consumption while accelerating inference. We also perform ablation studies on tensor rank to identify optimal rank settings. The batch size ranges from 1 to 2, the learning rate from 5e-5 to 2e-4, and the number of epochs from 1 to 3, respectively. All experiments are conducted using the AdamW optimizer [22] on NVIDIA A100-80GB GPUs, with hyperparameters varying across tasks and models.

A. *Low-Rank Analysis of LLMs*

Inspired by the Layer Selective Rank Reduction (LASER) approach [24], our work explores the intrinsic low-rank nature of LLMs. LASER demonstrated that applying Singular Value Decomposition (SVD) to selected layer weight matrices reduces over-parameterization, while maintaining or even improving the accuracy, thereby supporting the hypothesis of inherent low-rank structures within LLMs. However, LASER's focus on decomposing and approximating individual weight matrices fails to fully capture the potential tensor structures embedded within these matrices. This limitation suggests that LASER may not be optimally leveraging the inherent low-rank characteristics of the model architecture. To address this, our study explores the application of layer-wise TT decomposition. Our objective is to demonstrate that TT decomposition can more comprehensively exploit the intrinsic low-rank characteristics of the model, potentially leading to more efficient compression and improved performance. Fig. 4 presents a comparison between TT and SVD methods applied to MLP layers (gate_proj, up_proj, and down_proj) of the LLaMA2-7B model for FEVER and TruthfulQA tasks. The original MLP layers contain **202,375,168** parameters. SVD reduces this to 37,112,980, while TT decomposition further reduces it to a remarkable **223-fold** reduction with only **906,240** parameters. For the FEVER dataset, where the original model achieves an accuracy of 59.13%, TT decomposition applied to **50%** of the layers not only significantly reduces parameter count but also improves the accuracy. Similarly, for the TruthfulQA dataset, **44%** of the layers exhibit enhanced accuracy following TT decomposition, despite the substantial parameter reduction.

These experimental results indicate that LLMs are over-parameterized with inherent low-rank structures. Selectively applying SVD or TT decomposition reduces parameter count while enhancing model performance, with TT decomposition proving especially effective. Even with a **223-fold** parameter reduction, TT decomposition maintains accuracy comparable to the original model, striking an optimal balance between compression and performance. This makes TT decomposition particularly promising for compressing LLMs for deployment on resource-constrained edge devices, where efficient model performance is crucial.

B. *Comparisons with State-of-the-Art Methods*

Compared to other widely used PEFT methods, the proposed DuQTTA demonstrates superior performance. As shown in Table I, LoRETTArep achieves significant parameter reduction but exhibits lower accuracy. To evaluate the individual contributions of each strategy within DuQTTA, we conduct ablation experiments. The ablation results for the LLaMA2-7B model, as presented in the last three rows of the table, highlight the impact of AOS, DQ, and the magnitude-direction decoupled update mechanism applied to tensorized linear layers. It can be seen from Table I that AOS improves the average performance across seven public tasks by **2.99%** while maintaining a trainable parameter count that is only **one-eighth** of LoRA's. DQ significantly reduces memory usage and computational complexity, with only a minimal decrease in accuracy. Additionally, by using the magnitude-direction decoupled update mechanism, which allows for the

TABLE I
PERFORMANCE COMPARISON OF DIFFERENT FINE-TUNING METHODS ON LLAMA2-7B AND LLAMA3-8B MODELS ACROSS VARIOUS BENCHMARKS.

Model	Method	Params	Classification			Multiple Choice		Generation		Avg
			CB	BoolQ	WSC	COPA	ReCoRD	SQuAD	DROP	
LLaMA2-7B	FT	6738.42M	66.07	84.6	63.46	86	81.1	90.71	51.38	74.76
	Adapter [7]	50.33M	66.07	71.8	62.50	84	78.8	88.45	49.14	71.54
	LoRA [2]	4.19M	67.86	84.8	62.50	81	79.4	90.56	45.96	73.15
	Prefix [23]	1.31M	51.78	78.6	61.53	83	81.0	90.56	45.95	70.35
	LoRETTArep [3]	0.51M	55.35	78.1	57.61	86	80.3	88.47	42.71	69.79

	LoRETTArep [3]	0.50M	73.21	83.0	66.35	90	**83.4**	91.08	66.92	79.14
	DuQTTA	0.67M	**96.43**	**89.1**	**69.23**	**93**	82.9	**93.51**	**70.58**	**84.96**

independent optimization of magnitude and direction components, DuQTTA can align with the learning dynamics of full-parameter fine-tuning, thereby achieving a **4.44%** increase in average accuracy compared to LoRA, with only a 0.26M increase in trainable parameters. Under comparable parameter conditions, DuQTTA also delivers a **9.47%** accuracy improvement over LoRETTArep, while achieving up to a **65**× compression rate compared to other PEFT methods.

DuQTTA continues to demonstrate superior performance in downstream tasks for LLaMA3-8B model. As shown in Table I, with a comparable number of parameters, DuQTTA significantly outperforms LoRETTArep by **7.35%**. Moreover, while DuQTTA uses only **one-fifth** of the trainable parameters of LoRA, it achieves a **3.14%** improvement in average accuracy across the seven tasks.

TABLE II
COMPARISONS OF FINE-TUNING METHODS ON LLAMA2-13B

Method	Params	COPA	ReCoRD	SQuAD	DROP	Avg
LoRA [2]	6.55M	90	83.4	92.7	59.1	81.3
LoRETTArep [3]	0.77M	86	84.4	90.9	53.2	78.6
DuQTTA	1.11M	**90**	**84.7**	**93.0**	**60.7**	**82.1**

Due to limited computational resources, we only report the results for inference and generation tasks using the LLaMA2-13B model. As shown in Table II, DuQTTA significantly outperforms LoRETTArep by 4.43% in accuracy, with a comparable number of parameters. Additionally, while DuQTTA uses only one-sixth of the parameters compared to LoRA, it achieves a 0.97% improvement in accuracy for average performance across both inference and generation tasks.

C. Ablation Study

Effectiveness of Dual Quantization. We conduct ablation studies on the SQuAD, ReCoRD, and BoolQ datasets using the LLaMA2-7B model to verify the effectiveness of DQ. As shown in Table I, the proposed DQ only has 0.28% accuracy drop. However, as illustrated in Fig. 5, this approach provides substantial benefits under identical hyperparameter settings, and it reduces memory usage by 0.93GB, 1.24GB, and **3.43GB** for SQuAD, ReCoRD, and BoolQ, respectively. Additionally, GPU access time is reduced by **5.27%**, 4.47%, and 4.33%, while power consumption decreases by 23.72W, 37.98W, and **30.27W**. Notably, inference speed improves by 5.03×, **8.08**×, and 7.94×. These experimental results demonstrate that, despite a slight accuracy loss, DQ offers significant improvements in GPU memory usage, GPU access time, power consumption, and inference speed. These advantages are particularly notable in resource-constrained edge devices, making DQ a suitable choice for meeting the lightweight requirements of edge computing.

TABLE III
PERFORMANCE ON BOOLQ WITH DIFFERENT RANKS FOR LLAMA2-7B.

Model & Method	Rank	Param	BoolQ
LLaMA2-7B (TT&AOS&DQ)	4	0.33M	83.6
LLaMA2-7B (TT&AOS&DQ)	8	0.52M	**87.1**
LLaMA2-7B (TT&AOS&DQ)	16	1.22M	86.2

Analysis about the Tensor-Train Rank. In this study, the impact of different tensor ranks on model performance is investigated. To isolate the effect of tensor rank, LLaMA2-7B is used as the baseline model and evaluated on the BoolQ dataset, with AOS applied on top of DQ and TT. Tensor ranks of 4, 8, and 16 are tested in separate experiments, making tensor rank the only differentiating factor. As shown in Table III, setting the tensor rank to 8 yields a significant performance improvement compared to a rank of 4, with only a slight increase in trainable parameters. Compared to a tensor rank of 16, a rank of 8 strikes a balance, offering superior performance with fewer trainable parameters. Therefore, a tensor rank of 8 emerges as the most effective choice in our experiments.

V. CONCLUSION

In this work, we propose a lightweight and efficient fine-tuning method named DuQTTA for LLMs. This method employs dual quantization and TT decomposition to effectively reduce memory usage and power consumption, while also accelerating inference with minimal accuracy loss. To address the suboptimal performance of LLMs under large-width conditions, we propose an adaptive optimization strategy that dynamically adjusts the learning rates of the reconstructed tensor. Additionally, we employ a magnitude-direction decoupled update mechanism that separates the update process of TT cores into magnitude and direction components, aligning with the learning dynamics of full-parameter fine-tuning. This further improves the adaptability and effectiveness of the model across various downstream tasks. For LLMs such as LLaMA2-7B, LLaMA3-8B, and LLaMA2-13B, the proposed DuQTTA method demonstrates superior performance over existing PEFT methods, with accuracy improvements of 4.44%, 3.14%, and 0.97% over LoRA, respectively. Furthermore, DuQTTA achieves up to a 65× compression rate compared to LLaMA2-7B, drastically reducing trainable parameters and resource consumption during fine-tuning, while still matching or surpassing the accuracy of full parameter fine-tuning. These advantages make DuQTTA particularly well-suited for efficient implementation on resource-constrained edge devices.

***Abstract*—In electronic design automation, logic optimization operators play a crucial role in minimizing the gate count of logic circuits. However, their computation demands are high. Operators such as refactor conventionally form iterative cuts for each node, striving for a more compact representation - a task which often fails 98% on average. Prior research has sought to mitigate computational cost through parallelization. In contrast, our approach leverages a classifier to prune unsuccessful cuts preemptively, thus eliminating unnecessary resynthesis operations. Experiments on the refactor operator using the EPFL benchmark suite and 10 large industrial designs demonstrate that this technique can speedup logic optimization by $3.9\times$ on average compared with the state-of-the-art ABC implementation.**

***Index Terms*—AND-Invert Graph, Logic Synthesis, Logic Refactoring, Pruning, Machine Learning**

I. Introduction

In logic synthesis, Boolean resynthesis is a technology-independent process that optimizes a logic network to reduce its nodes and levels [1]–[7]. It analyzes the Boolean expressions and iteratively applies local transformations (e.g., operators) to the logic gates and their interconnections. By leveraging these transformations, Boolean resynthesis optimizes digital circuits for lower power consumption, delay, and area. While Boolean resynthesis operators are essential for circuit optimization, they must be used with caution due to their computational expenses.

Since most resynthesis operators are heuristic and suboptimal, iterative runs are necessary to identify further potential improvements in the logic circuit [1]. However, each successive iteration yields diminishing returns in terms of area improvement, while increasing the computational cost of logic synthesis. Moreover, the demand for a shorter turn-around time keeps increasing in the fast-paced electronics industry. By reducing the runtime of key optimization operators, designers can efficiently explore a wider range of design options, leading to better design solutions. Such an improvement of synthesis operators is design-agnostic, benefiting the synthesis process of almost all digital designs.

In recent years, machine learning (ML) has been increasingly leveraged to enhance logic synthesis. Neto et al. [8] employ ML to reinvigorate logic optimization algorithms and explore more advanced designs. Other recent research works utilize ML techniques for sequence tuning to improve the PPA [9]–[13]. However, none of the ML-driven solutions improve the efficiency of the operators, which are the runtime bottleneck for realistic industrial designs with millions of nodes. For example, executing the refactor operator on a synthetic circuit with 23 million nodes in the EPFL benchmark suite [14] can take up to 1.5 hours. Despite some recent efforts in GPU acceleration [15], [16], there might be scenarios with hardware constraints that do not support such parallelism. Also, such GPU parallelism is potentially compatible with other improvements in operators. To the best of our knowledge, no prior work has addressed the redundancy in refactor or proposed a method to prune the unnecessary iterations. In this work, we propose ELF, a novel and general method, which prunes the redundancy in logic optimization operators and significantly accelerates the refactor operator. Our contributions are summarized as follows:

- We present the redundancy problem in logic refactoring, and we provide a detailed examination of redundancy in both academic and industrial designs, which, on average, exhibit a failure to improve a node's cut by 98%.
- Then, we propose an efficient and accurate model to detect redundant operations during the refactoring process. Our model achieves an average accuracy of 87% and recall of 93% on academic circuits, and an average accuracy of 85% and recall of 95% on industrial designs.
- Finally, we propose ELF, an efficient logic refactor [2] operator by integrating the redundancy detection model in the synthesis process. Compared with the state-of-the-art original ABC [17] implementation, our method achieves an average speedup of $5.29\times$ with a minimal design quality loss of less than 0.27% on academic designs. Similarly, on industrial designs, our method achieves a speedup of $2.80\times$ with a negligible design quality loss of less than 0.08%.

The remainder of this paper is structured as follows. Background and related work are reviewed in Section II. Section III provides an in-depth discussion of our proposed technique. Experimental results are presented in Section IV, followed by concluding remarks and future directions in Section V.

II. Background & Related Work

A Boolean network is a directed acyclic graph (DAG) that maps an n-dimensional Boolean vector to an m-dimensional one, such that $\{0,1\}^n \rightarrow \{0,1\}^m$. The input and output vectors are known as primary inputs (PIs) and primary outputs (POs). And-Inverter Graphs (AIGs), containing only two-input AND gates and inverters, are commonly used to represent Boolean networks due to their simplicity and scalability [18].

Logic synthesis transformations can be classified into two categories: local operators, which are fast but achieve limited optimization, and global operators, which are slower but capable of more significant PPA improvements. Local operators only consider a node or small cut, resulting in a runtime linear to the cut size. In contrast, global resynthesis operators consider the entire graph when identifying optimization opportunities. Although global operators can substantially improve PPA, their prohibitive runtime makes them impractical for large industrial circuits.

We focus on the refactor operator, as its an essential component in industrial optimization flows and there has been little effort in literature to improve. While, refactor provides a lower area reduction relative to other operators, its usage is critical since its transformations unlock further optimizations in the AIG [2]. Nevertheless, its

*Corresponding author: Lei Chen (*lc.leichen@huawei.com*)

running time is significant. For example, in a popular logic synthesis flow such as Resyn2, the refactor step typically accounts for $20-40\%$ of the total execution time, despite being invoked only twice, whereas the balance and rewrite steps are invoked three and four times, respectively. Amaru et al. proposed a Boolean filtering for these operators to reduce the number of gates process without affecting the quality of result (QoR) [19]. However in their results they do not report the runtime for the operators, so we cannot evaluate the effectiveness of the method.

1) **Refactor** [2] iterates over all the nodes and forms a large cut for each one of them. Each cut is transformed into an SOP and factored into a more compact form, while maintaining the function of the root node. If there are more removed nodes than nodes added, the new resynthesized subgraph gets committed. As refactor has seen minimal follow-on work since its proposal, research opportunities likely remain.
2) **Rewrite** [1] greedily iterates over all nodes, forming all 4-input cuts. It substitutes each cut with a precomputed minimal subgraph selected from 222 NPN classes. The subgraph with the maximum non-negative gain, i.e. removed nodes minus added nodes, is committed. Recent extensions consider 5-input subgraphs [20], apply rewrite in a sliding window [7], and improvements in the efficiency by utilizing an engineered dynamic-scoring function [21].
3) **Resubstitution** [2] attempts to express the function of a node with other nodes present in the network called divisors. A transformation is accepted if the new implementation is better than the current node implementation using the immediate fanins. Resubstitution can be generalized to k-resubstitution. Let k be the exact number of nodes added and l the nodes within the MFFC of the node. If k-resubstitution is possible and $l > k$, the change is committed as the total number of nodes in the graph decreased. Since the graph is an AIG in our setting, the newly added nodes are two-input AND gates with potential inverters in the inputs or outputs.

III. Methodology

Section III-A presents a general perspective on logic optimization operators and in more detail the refactor operator, motivating the need for our pruned approach, ELF. Section III-B delves into the technical details of the proposed pruning method, ELF, as well as optimizations to enhance performance. Finally, Section III-C enumerates the features uses for the classifier along with their rationale.

A. Logic Optimization Operators & Motivation

There is a range of logic optimization operators such as rewrite, refactor, and resubstitution which differ in their local transformations but, their algorithmic frameworks share key similarities. Each operator iterates through nodes in the same sequence, applying a distinct function to each node. Algorithm 1 illustrates the general pipeline of logic optimization.

In Algorithm 1, the Boolean_Optimization function resynthesizes the cut with fewer nodes, but commits the change only if the gain, defined as removed nodes minus added nodes, is positive. After cut optimization, functionality must be preserved by adding the necessary nodes. However, in most iterations, the cut fails resynthesis, wasting computation time. Specifically in refactor on the arithmetic circuits in EPFL arithmetic benchmark, at most 7.34% of cuts are refactored. Similar trends hold for other operators, which can be even more time-intensive. Therefore, we propose ELF, an efficient learned classifier that given structural cut information, predicts whether a cut can get refactored. A key component behind ELF are the hand-crafted lightweight features that capture salient structural information to create compact cut representations.

Algorithm 1 General form of Logic Optimization

```
for each node in AIG do
    Apply Boolean_Optimization(node, AIG)
    Gain = nodes removed − nodes added
    if Gain > 0 then
        Commit change in AIG
```

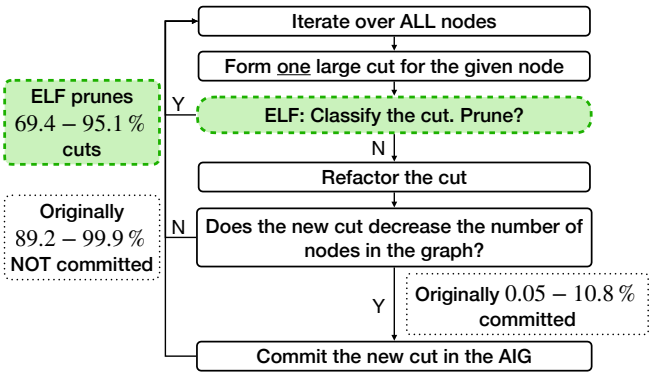

Fig. 1. Flow of ELF and the original refactor demonstrating the redundancy.

B. ELF: Pruning Cuts

As shown in the Algorithm 1, refactor iterates over all nodes in the And-Inverter Graph (AIG), forms a cut for each node and resynthesizes it. However, approximately $89.2-99.9\%$ of the formed cuts may fail to get optimized, wasting computational effort. We address this by classifying each node's benefit from resynthesis prior to function application. Specifically, we predict whether a given node is unlikely to be optimized, pruning it from the search space before proceeding. Only beneficial nodes undergo attempted resynthesis. Figure 1 demonstrates the flow of the original ABC implementation of refactor with its shortcomings and the green cells highlight how ELF changes the flow and prevents unnecessary computation. ELF can be very effective as it can omit to refactor $69.4-95.1\%$ of the nodes.

At the core of our method, ELF, is an efficient and compact classifier. While refactor is time-consuming on large industrial circuits, it operates efficiently on a per-cut basis. This characteristic necessitates rapid inference to effectively reduce overall execution time. The stringent time constraints inherently disqualify most advanced model architectures, such as graph neural networks, for this application. To illustrate, the inference time per cut using a small Graph Convolutional Network (GCN) is approximately 30 times that of resynthesizing the cut itself.

After extensive experimentation with various model architectures, including XGBoost trees and diverse ensemble models, we found that a feedforward neural network offers the optimal balance between execution speed and generalization to unseen circuits, while maintaining high recall and accuracy. The computational complexity of a single layer in a feedforward neural network is $\Theta(m*h+k*h)$, where m represents the number of inputs, k the number of outputs and h the number of hidden units.

Achieving high recall is crucial for our classifier, as our goal is to reduce runtime without compromising area optimization. Recall

Algorithm 2 ELF: Efficient Logic Refactoring

```
Collect features for each node's cut
Classify each node
for each node in AIG do
    if the node is classified to fail then
        Continue
    Refactor(node, AIG)
    Gain = nodes removed − nodes added
    if Gain > 0 then
        Commit change in AIG
```

quantifies the percentage of nodes correctly classified as 1. A recall of 100% ensures no degradation in the quality of logic optimization. This emphasis on recall aligns with our objective of enhancing computational efficiency while preserving the effectiveness of the refactor operator in logic synthesis workflows. Equally crucial is high accuracy, which directly correlates with runtime reduction. As we accurately prune more nodes, we expect a proportional decrease in runtime. The synergy between high recall and accuracy thus forms the cornerstone of our approach, enabling efficient circuit optimization without sacrificing quality.

To further decrease the inference time we use some engineering tricks such as kernel fusion and graph compilation for the model. Additionally, before node iteration, we batch all the cut data into one tensor so that we can maximize vectorization and minimize the process of packing/unpacking the data into tensors. Therefore, the complexity of classifying N nodes with a model that has complexity $\Theta(M)$ is $\Theta(NM)$. Despite concerns about diminished accuracy, experiments validate the viability of the batch classification approach. An intuitive explanation for this phenomenon is that the cuts at the start, are more likely to have available optimizations, which might be lost while refactoring the AIG. Although, we might unnecessarily resynthesize cuts that no longer can be optimized, this will only impose a degradation in the runtime, but not the area. The detailed implementation of ELF is outlined in Algorithm 2.

As seen in Algorithm 1 the logic optimization methods share an overall similar structure. Thus, it is possible to extend ELF to work for other operators other than refactor. The ultimate goal would be to have a unified logic optimization operator where the classifier conducts multiclass prediction to select the Boolean resynthesis function for each node, including skipping non-beneficial nodes. Thus, streamlining the entire process of logic synthesis.

C. Feature Selection

The features must add minimal runtime overhead while encapsulating salient information about the number of nodes to be removed and the logic sharing. Logic sharing refers to nodes that connect to nodes outside the cut. Meaning that their deletion is non-trivial as they affect the functionality of other parts of the circuit. A straightforward approach to represent the cut is to use the cut's root truth table. Although the truth table captures the functionality of the cut, it fails to encapsulate logic sharing. Additionally, large truth tables scale exponentially with the number of leaves, potentially incurring substantial computational costs. Logic optimization operators resynthesize first the cut as an isolated graph then, consider the impact of reinserting the optimized cut. If the nodes that need to be added to maintain the logic sharing exceed the number of nodes removed, the cut does not get committed. Thus, structural cut information can potentially capture both node deletion opportunities and logic sharing information.

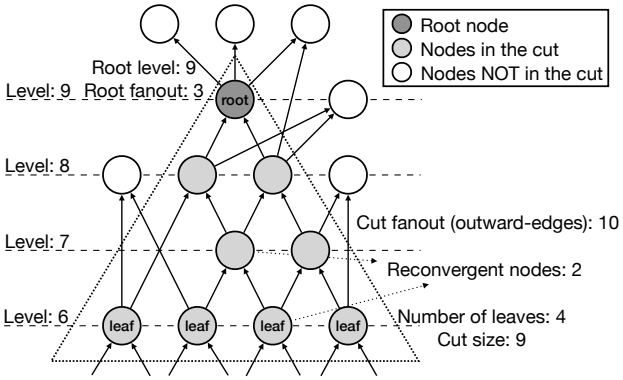

Fig. 2. Example of the features used to represent a cut in an AIG

We represent cuts by 6-dimensional feature vectors, comprising: *root fanout*, *root level*, *total cut fanout*, *cut size*, *number of reconvergent nodes*, and *number of leaf nodes*. Figure 2, contains an example of a cut with its features. In refactor, given a node it forms a reconvergence driven cut, where the given node is the cut's root node. The *root level* refers to the level of the given node within the AIG. The fanout refers to the outward going edges of a node. So, in Figure 2 the cut's *root level* is 9 and has 3 outgoing edges meaning the *root fanout* is 3. The triangle in the figure represents the cut and *cut size* refers to the number of nodes within it, which is 9 in this case. Similarly to the *root fanout*, the *total cut fanout* refers to the cut's total number of outgoing edges, which is 10. For a node to be a leaf there must be at least one path from a primary input (PI) that goes through the leaf and reaches the root of the cut without going through any other leaf. In Fig. 2, there are 4 *leaf nodes*. Finally, if there are two paths starting from a node v_s and ending to the node v_e they are denoted as reconvergent paths and v_s is a reconvergent node. Note that we only count the nodes that are part of reconvergent paths locally within the cut, for simplicity. In Fig. 2 there are only 2 locally *reconvergent nodes* marked with the arrows.

The rationale behind features related to the fanout are that they capture logic sharing as they indicate that they connect with nodes outside the cut. The bigger the fanout, the harder it is to replace the nodes within the cut. The *cut size* indicates the number of nodes to potentially prune, but its role can be to regularize other features. For example, the neural network might learn to divide *total cut fanout* by the *cut size*. The leaves cannot be simplified so a higher *number of leaves* might be less likely to be successfully optimized. The *root's level* implies the importance of a node. The higher level of a node, the more important it might be. Finally, in Theorem 1 in a recent paper by Riener et al. [7], they proved that if a certain type of optimization exists, then reconvergent nodes should exist. Thus, we include the number of *reconvergent nodes* as a feature.

These lightweight features are ideal for our problem as they are cheap to compute. We achieve efficient collection by accumulating the features during cut construction. Our flexible approach can run on CPUs or parallelized to run on GPUs.

IV. Experimental Results

In section IV-A, we introduce the implementation details and information about the datasets. Section IV-B compares the efficiency and effectiveness of the ELF over the baseline method, the original state-of-the-art refactor implementation of ABC, followed by Section IV-C, which presents the experiments on the classifier's quality metrics. Finally, Section IV-D contains explainability experiments

along with an analysis of the features used and their impact on the model's output.

A. Experimental Settings

We evaluate on the EPFL arithmetic benchmarks [14] and industrial designs. While the results are consistent for all the circuits, we show the results for the 6 largest EPFL circuits, and train the model on all the AIGs in the suite except the one we test on. Similarly for the industrial circuits, we train on all the other designs except the one we test on for 10 designs and report the average results. Note, we keep the two datasets separate for reproducibility. Table I and Table II contains statistics for the AIGs in the EPFL benchmarks and industrial designs, on which we report detailed results. The *Refactored* column the percentage represents the ratio of nodes that get resynthesized. It is evident that the datasets are highly imbalanced, since percentage of nodes that do get refactored are mostly around 1%. Although these circuits vary in size, demonstrating the scalability of our method, they are smaller than real industrial circuits, which often contain tens of millions of nodes and exhibit similar trends. Only three AIGs contain a relatively higher number of nodes that can get refactored, *sqrt* in the EPFL benchmarks and two industrial designs *design* 5 and 10, which contain 7.34%, 10.8%, and 4.53% nodes that can be resynthesized, respectively. This imbalance makes the learning significantly more difficult. Additionally, our classifier needs to be recall driven. Meaning that we do not want to misclassify cuts, since it will impact the quality of the operator. High accuracy is relatively easy to achieve, in the current setting, simply by classifying every cut as a 0. The difficulty in our task is to find a good balance between recall and accuracy. Thus, minimizing running time, with minimal impact on the number of AND gates.

To show that the models can generalize to unseen data, we train the classifier to all the arithmetic datasets other than the one we are testing on. Similarly for the industrial design circuits, none of the circuits that get tested are part of training. Additionally, each dataset is standardized individually with mean variance normalization. This way we can make the model infer to sizes that it might have not seen so far. The features we use to train the classifier with, can be calculated with simple accumulators while forming the cut with almost no additional runtime cost. This is necessary as refactor is already an efficient algorithm, leaving little running time available for inference. The features we use are *root fanout*, *root level*, *cut total fanout*, *cut size*, *number of reconvergent nodes*, and *number of leaf nodes*.

The experiments were run on an Intel(R) Xeon(R) Platinum 8180M CPU @ 2.50GHz with 1 thread and 1TB of RAM. The models were trained using pytorch and the model was run directly in C++ within ABC [17] and executed with the ONNX Runtime framework. To efficiently standardize and execute the model we merged a Mean Variance Normalization node directly with the model and run all the cut data into one batch. While ML libraries are quite optimized, they have quite a bit of overhead when it comes to wrapping and unwrapping the data into tensors. Taking advantage of vectorization and limiting the overhead of the tensor objects, inference is very fast.

The model has 4 fully-connected layers with shape $6 \rightarrow 12 \rightarrow 12 \rightarrow 6 \rightarrow 1$ and a total of 325 parameters. Although more sophisticated architectures could potentially achieve better results, they are often prohibited by the tight time-budget. For instance, convolutional layers could be employed to enable the model to learn feature extraction autonomously, but this would require a GPU to fully leverage their capabilities. We initialize the parameters of each layer with Xavier initialization and the biases set to 0. For training we used a batch size of 64, 30 epochs up with early stopping and patience of 10 epochs. The optimizer was Adam with learning rate of 0.1 and a learning rate scheduler of cosine annealing with warm restarts. While we tried a range of losses such as focal loss, class balanced loss and class balanced focal loss, binary cross entropy worked the best. Additionally, to augment the data, we used MixUp [22] to improve generalization and overall model metrics. We tested more data augmentation techniques such as Synthetic Minority Over-sampling Technique [23] and One Sided Selection [24], but a weighted random sampler proved better. Furthermore, we tested dropout layers to potentially improve generalization, but it proved ineffective.

B. Comparison with Baseline

To demonstrate the effectiveness of ELF we compare it against the original implementation of refactor within ABC [17]. Additionally, we call the *rf -l* version of the operator. The quality metrics we report include the number of AND gates, levels, and their relative differences, the runtimes and the speedup of the proposed method. Let the relative difference be δ for a metric m_{ELF} for the proposed method, ELF, and m_{ABC} for the original implementation of refactor in ABC. Then, we measure the differences as $\delta = \frac{m_{\text{ELF}} - m_{\text{ABC}}}{m_{\text{ABC}}} \times 100\%$. From an industrial perspective, the area degradation should not exceed 0.5%, while achieving a $1.25\times$ speedup.

Table III presents the results of applying the original implementation of refactor operator within ABC vs this work, ELF, on the arithmetic circuits in the EPFL benchmark. The experiments show a significant runtime speedup varying from $2.50\times$ up to $7.69\times$. Simultaneously, there is minimal increase in the area. In the worst case, the number of nodes can increase by 0.27% for *div*, while the area difference is 0% for other circuits. The level is the same among all circuits. While, the runtime of the refactor operator is generally small for the circuits in the EPFL benchmark, industrial designs might contain several million nodes making the original implementation expensive i.e. several hours. We later present experiments on large synthetic AIGs.

The significant runtime speedup enables us to apply ELF twice without exceeding the execution of the original implementation of refactor in ABC. Thus, Table IV contains the results of chaining

ELF twice against the baseline. In the worst case, ELF maintained a $1.34\times$ speedup in runtime, but it failed to improve the quality further. Overall, a subsequent application of the proposed method can improve the results except in two circuits, log2 and sqrt. It is important to note that three of the circuits, multiplier, sqrt, and square, do not have any potential improvements in general when applying the original refactor operator twice. In contrast, for *div* and *hyp* by applying ELF twice we can still have a significant speedup in the running time and reduce the area of the AIG. Note that, these two graphs are the two largest arithmetic circuits in the EPFL benchmark.

Table V shows that ELF is equally effective in 10 industrial designs. These circuits are larger than the ones within the EPFL benchmark and vary from 77k-629k nodes. The trend from the results on the circuits in the EPFL benchmark continues to industrial design that are larger. The runtime speedup varies from $2.01\times$ to $4.29\times$, while the added number of nodes is minuscule. In the worst case the number of nodes increased by 0.08%, but was also as low as 0%. No information about these 10 circuits was part of the training data, which demonstrates that the classifier succeeded in generalizing. Thus, demonstrating the effectiveness of ELF and potential applicability to industrial solutions.

Finally, Table VI presents the condensed results of applying the original implementation of refactor operator within ABC vs this work, ELF, on synthetic circuits in the EPFL benchmark. Originally, the runtime of refactor can be longer than 1 hour for circuits such as the one with 23 million nodes, but ELF can theoretically speedup the operator by $2.90\times$ on average with little impact on the And nodes difference. To effectively observe these speedups in practice for large circuits, it is necessary to invest engineering efforts into improving the implementation of reinserting the refactored cut back into the AIG.

C. Model Quality Experiments

To effectively prune cuts our classifier needs to be recall-driven first and also achieve a high enough accuracy. Recall and accuracy are calculated as

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}, \quad \text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FP} + \text{FN} + \text{TN}}.$$

Recall directly affects the area, as it measures the proportion of nodes that were correctly classified as 1. Instead, accuracy is related to the overall runtime. The more accurate the model the more nodes the algorithm can skip. Thus, reducing the running time.

Table VII contains the model quality metrics of ELF on the arithmetic circuits in the EPFL benchmark. The classifier achieves a high recall and accuracy, while it was never trained on the test circuit

at all. Recall is consistently above 93% and up to 100% for some circuits, but it is only 76% for *div*. Finally, accuracy is overall high, varying from 77% up to 96%, even though the recall is also high. Therefore, this justifies the runtime reduction, while maintaining a low impact on the area, varying from 0% to +0.27%.

TABLE VII
MODEL QUALITY METRICS OF ELF ON THE ARITHMETIC CIRCUITS IN THE EPFL BENCHMARK.

Design	Recall	Accuracy	TP	TN	FP	FN
div	76 %	84 %	217	48045	8905	68
hyp	100 %	77 %	1992	162061	50282	0

sqrt	97 %	92 %	1745	20951	1860	61
square	94 %	84 %	167	15422	2885	10

Table VIII contains quality metrics of the ELF classifier. The results are consistent with the ones on the arithmetic circuits. Recall is high varying from 81% to 100% and so is accuracy 81 − 93%. We used the same classifier to test the quality on over 170 industrial designs. Recall is on average 91.8% and accuracy 81.0%.

TABLE VIII

D. Features Study

t-SNE plots [25] are a widely used technique for visualizing high-dimensional data in a two-dimensional space. Figure 3 presents such a visualization of our feature space, where orange points represent instances that underwent refactoring, and blue points indicate those that did not. The plot reveals the presence of distinct clusters, albeit dispersed across the space. This cluster distribution can be attributed to three key factors: the highly imbalanced nature of our dataset, the relatively low dimensionality of our feature space, and the discrete characteristics of our features. Despite these challenges, the discernible separation between clusters suggests that effective classification is feasible.

Figure 4 illustrates the SHAP [26] (SHapley Additive exPlanations) values for each feature in our model. SHAP values quantify the contribution of each input feature to the model's prediction, indicating both the magnitude and direction of influence. Positive SHAP values push the prediction towards 1 (indicating likely refactoring), while negative values push towards 0 (suggesting no refactoring). While SHAP values may not fully capture complex feature interactions, they provide valuable insights. For instance, the plot reveals that a low number of reconvergent nodes decreases the likelihood of refactoring, which aligns with the intuition that reconvergent nodes present optimization opportunities. Conversely, cuts with a high number of leaves, high root node level, or large cut size are less likely to be refactored. These features, while potentially not individually

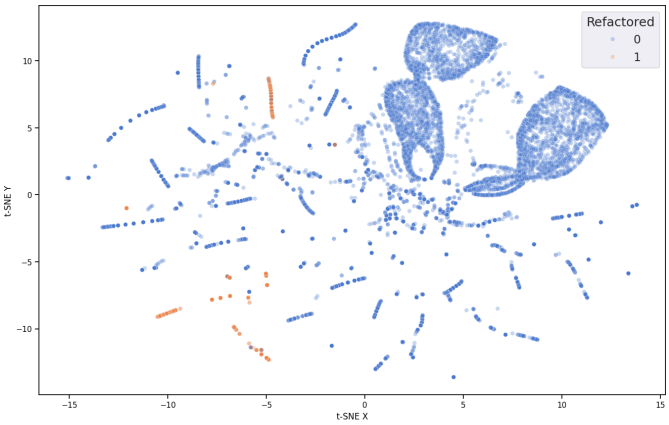

Fig. 3. t-SNE visualization of the feature space

explanatory, can collectively convey important information about the cut. For example, a high leaf count in a moderately sized cut might indicate lower node redundancy, as leaf nodes are irreplaceable. The cut fanout shows ambiguous SHAP values, but the difference between the cut's fanout and the root's fanout represents the number of nodes without external edges, which are crucial for maintaining AIG functionality and thus cannot be replaced.

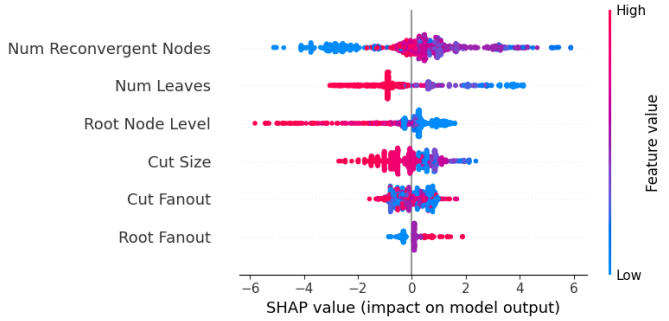

Fig. 4. SHAP (SHapley Additive exPlanations) values for each feature in the model

V. CONCLUSION

In summary we propose ELF a pruning strategy for the refactor operator that can speedup resynthesis by 3.9× on average with a minimal effect on the area. To achieve this we trained a compact model to classify, if the cuts will get successfully refactored. The features used to train the classifier are lightweight and ideal for time sensitive ML applications. An extensive experimental analysis on the EPFL benchmark suite and industrial circuits demonstrates the effectiveness in reducing the running time of the refactor operator. Given the similar structure of other logic synthesis operators such as rewrite and resubstituion, ELF can be adjusted to prune the unnecessary computation of those functions. A further extension of this work is to propose a unified logic optimization operation. Instead of having a sequence of operators, the classifier can choose the function to apply directly to the node or skip it. Such an operator could potentially significantly reduce the running time, achieve better PPA and eliminate the need to perform sequence tuning.

***Abstract*—The Controller Area Network (CAN) bus is a cornerstone of modern vehicles, orchestrating functions from engine control to auxiliary systems. However, its lack of inherent security measures makes it vulnerable to cyberattacks. Accurately mapping CAN signals with car-control actions is critical for detecting security breaches, as it allows pinpointing potential vulnerabilities exploited to compromise vehicular functions. Despite this, existing CAN reverse engineering methods struggle to achieve bit-level resolution due to the huge search space of unique IDs and payload combinations. To address this challenge, we propose a systematic framework for reverse engineering CAN bus messages, achieving precise mapping of control bits in CAN frames to car-control actions. The framework was validated on Tesla Model 3, Leapmotor C10 and C11, demonstrating its versatility across different vehicle platforms. In particular, it successfully identified 43 car-control actions on the Tesla Model 3, showcasing its extensive coverage. Furthermore, its low resource consumption enables seamless integration into compact platforms like the Raspberry Pi, supporting practical deployment in real-world automotive systems.**

Keywords—CAN Bus Reverse Engineering, Signal Boundary Identification, Fuzz Testing

I. INTRODUCTION

The Controller Area Network (CAN) bus is a cornerstone of modern vehicle communication, orchestrating functions from critical engine control to auxiliary systems like lighting and climate management. Its standardized design ensures reliability and efficiency, but also introduces a significant vulnerability: the lack of inherent security measures. As vehicles increasingly rely on software-driven control and connectivity features, this vulnerability leaves them exposed to a variety of cyber threats. Attackers could exploit CAN's openness to inject malicious messages, potentially compromising vehicle safety and user privacy.

Each automotive manufacturer (OEM) uses proprietary DBC files to define the meaning of CAN signals, obscuring the internal logic of its systems and masking unique security flaws. This fragmentation not only complicates cross-manufacturer diagnostics but also hinders the identification and mitigation of potential vulnerabilities. Reverse engineering of CAN bus messages is essential for overcoming these obstacles. By decoding the proprietary definitions in DBC files, reverse engineering enables a detailed interpretation of CAN signals, uncovering hidden security flaws and supporting the development of effective cybersecurity measures.

However, achieving fine-grained decoding of CAN signals faces significant challenges. As illustrated in Figure 1, data frames are continuously transmitted on the CAN bus, each containing an ID field and a payload field. The ID field determines the frame's priority, while the 64-bit payload field indicates the specific information carried by the frame. Within the payload, manufacturers predefine various fields to represent different command content or status information, as seen in the example fields in the figure. Given that a typical vehicle has hundreds of unique IDs and each payload can have up to 2^{64} possible combinations, the search space for identifying precise control bits of car-control actions is huge. This huge search space creates a major barrier to mapping individual bits to specific car-control actions, which is crucial for identifying potential vulnerabilities.

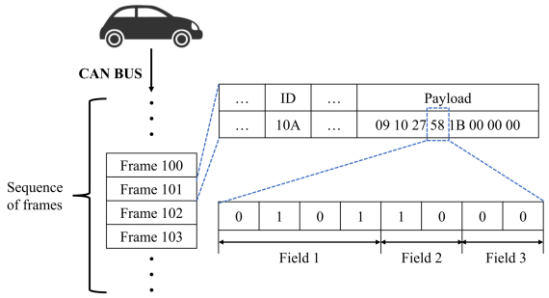

Fig. 1. CAN Bus Data Frame Layout and Search Space Complexity

Although there were many CAN bus signal reverse engineering methods proposed, they cannot address this huge search space problem in CAN signal reverse engineering. Signal boundary identification methods [7–12] delineate broader data field boundaries within CAN messages but do not establish relationships to specific car-control actions or achieve bit-level resolution. Machine learning approaches [13], [17], while helpful in identifying CAN message IDs related to actions, stop at the ID level and lack the capability to decode payload details. OBD-II protocol-based methods [14–16] rely on diagnostic data, which restricts their ability to handle non-diagnostic signals. Together, these limitations underscore the need for a high resolution (bit level) interpretation of the CAN bus, which is vital to pinpoint the car-control actions.

To address these limitations, we present a comprehensive solution designed to efficiently decode CAN signals with high coverage and precision. Our systematic framework for reverse engineering CAN bus messages effectively manages the challenge of huge search spaces while achieving bit-level resolution. By analyzing signal boundaries across different vehicle states, such as stationary or during specific car-control actions (e.g., activating windshield wipers), the framework filters out irrelevant IDs. Targeted fuzz testing further explores payload variations to trigger car-control actions, refining the resolution to the frame level. Finally, control bit analysis isolates the exact bits responsible for specific actions, completing the mapping with bit-level resolution. This streamlined, step-by-step approach not only overcomes technical obstacles but also ensures lightweight and adaptable deployment on compact platforms like the Raspberry Pi. Validated across multiple vehicle models, it proves highly

practical and robust, making it a strong candidate for real-world CAN signal reverse engineering tasks.

The contributions of this paper are threefold:

- We introduce a systematic framework combining state-based signal boundary identification, targeted fuzz testing, and control bit analysis. This approach effectively narrows down the search space for relevant CAN signals, achieving precise bit-level resolution in mapping control bits to car-control actions. This not only overcomes the inherent complexity of CAN signal reverse engineering but also significantly improves accuracy compared to existing methods.
- The proposed framework is highly efficient, with low CPU and memory requirements, enabling seamless integration into compact devices like Raspberry Pi systems. We prototyped a wireless automatic reverse engineering tool (using Raspberry Pi). This design supports on-site and portable automotive testing.
- Our method has been validated on three distinct vehicle models, including Tesla Model 3 and Leapmotor C10/C11. It successfully identified 43 car-control actions in a single model Tesla Model 3, achieving extensive coverage with high adaptability. These findings highlight the framework's practicality and versatility across diverse automotive platforms.

II. Related Work

A. Signal Boundary Identification

Signal boundary identification methods [7–12] focus on delineating data field boundaries within CAN messages but vary in their resolution and scope. The READ framework [7] introduced the first automated approach using bit-flip rate analysis, establishing the foundation for subsequent advancements. Building on READ, LibreCAN [8] optimized boundary identification and linked car-control actions with CAN IDs, though it did not achieve bit-level resolution. Choi et al. [9] further refined boundary accuracy with statistical analysis of bit-flip time series but lacked action-specific mapping. Later methods, such as CA-CRE [10] and ACRE [11], employed classification and heuristics to improve format identification but remained limited in granularity. Karamolegkos et al. [12] extended this line of research to protocol-level reverse engineering but similarly fell short of identifying precise control bits.

B. Machine Learning-Based Approaches

Machine learning approaches assist in identifying CAN message IDs related to car-control actions but generally stop at the ID level, lacking the capability to decode payload details. Buscemi et al. [16] applied pattern recognition to identify ID-action relationships but do not decode payload bits. Young et al. [17] used unsupervised learning to classify CAN message IDs, improving functional ID recognition but without detailed payload analysis.

C. OBD-II Diagnostic Protocol-Based Methods

The OBD-II diagnostic protocol, widely used for vehicle diagnostics, provides access to real-time data from the electronic control unit (ECU). In OBD-II-based reverse engineering, Kang et al. [13] introduced an automated tool that correlates OBD-II responses with CAN traffic to identify basic control signals. Building on this, Blaauwendraad and Kieberl [14] applied statistical correlation methods to improve the accuracy of matching OBD-II data to CAN signals across different vehicles. Song and Kim [15] advanced this approach by mapping specific signal boundaries within CAN data to car-control actions, offering a more detailed view of CAN signal content. However, all these methods are fundamentally constrained by the OBD-II protocol's request-response structure, which limits reverse engineering to predefined Parameter Identifiers (PIDs). Since the ECU only responds to specific, and manufacturer-defined PIDs, the scope of reverse-engineered information is restricted to the data fields allowed by these definitions, excluding many non-diagnostic control signals crucial for comprehensive CAN analysis.

III. The Proposed Reverse Engineering Method

A. Overview

The proposed method uses both state-based signal boundary identification and targeted fuzz testing, systematically narrowing down the search space to locate control bits for specific car-control actions. The workflow begins with collecting CAN messages under stationary and operational states, where the stationary state provides baseline data and the operational state captures vehicle control actions such as door unlocking and window adjustments, as shown in Figure 2. After grouping messages by CAN ID, payload fields are extracted and organized into a matrix for further analysis (in section III. *B*).

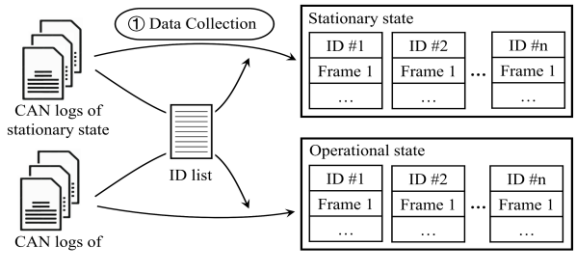

Fig. 2. State-Based CAN Message Collection and Preprocessing Workflow

Signal boundaries are identified using bit-flipping rate (BFR) analysis, which classifies fields into constant, counter, random, and co-flipping types (in section III. *C*). As illustrated in Figure 3, this classification highlights key areas for subsequent exploration and provides a foundation for related-ID locating. By comparing signal classifications across states, the related-ID locating step identifies IDs exhibiting state-dependent changes, capturing IDs most likely to be relevant for car-control actions (in section III.*C*.2).

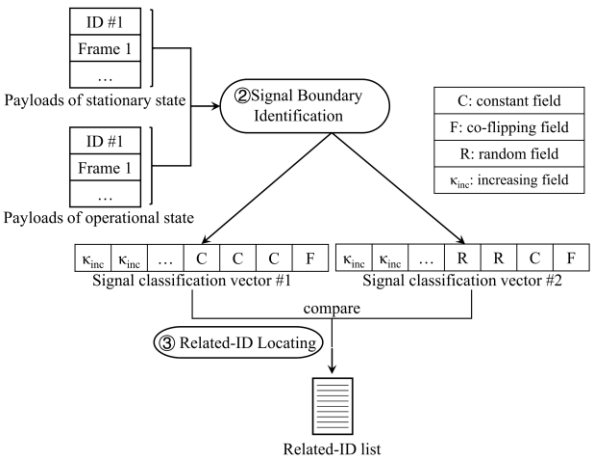

Fig. 3. Signal Boundary Identification and Related-ID Locating Workflow

Fuzzed data is then generated and injected into the CAN bus to provoke specific function controls or abnormal responses (in section III.*D*). Binary search techniques isolate the responsible frames and bits, enabling both validation and discovery of car-control actions, as shown in Figure 4. Finally, control bit analysis, comprising commonality analysis and selective bit testing, confirms the role of each individual bits in initiating specific actions (in section III.*E*). This approach achieves bit-level resolution, offering a significant advancement in reverse engineering techniques.

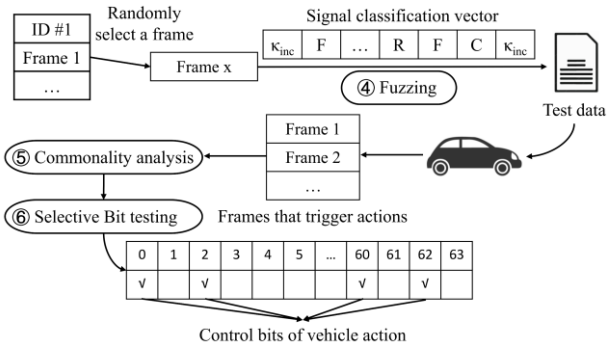

Fig. 4. Fuzz Testing and Control Bit Analysis Workflow

The notations used in this paper are listed in Table I.

TABLE I. NOTATIONS USED IN THIS PAPER

Notations	*Description*
$\boldsymbol{M_s}$	CAN data messages collected in the stationary state
$\boldsymbol{M_o}$	CAN data messages collected in the operational state
Ω_{op}	Set of specific car-control actions in the operational state, such as unlocking, wiper control
$\boldsymbol{P_{d,s/o}}$	A bit matrix representing the payloads of CAN ID d under stationary state (s) or operational state (o). $\boldsymbol{P_{d,s/o}}[i]$ is the i-th column of bits within $\boldsymbol{P_{d,s/o}}$ and $\boldsymbol{P_{d,s/o}}[i][j]$ is the i-th bit of the j-th frame within $\boldsymbol{P_{d,s/o}}$
$\boldsymbol{bfr_{d,s/o}}$	A bit-flipping rate vector for $\boldsymbol{P_{d,s/o}}$ and $\boldsymbol{bfr_{d,s/o}}[i]$ is the bit flipping rate for $\boldsymbol{P_{d,s/o}}[i]$ (The i-th column of bits within $\boldsymbol{P_{d,s/o}}$)
$\boldsymbol{\tau_{d,s/o}}$	A signal classification vector that maps each bit index i in the payload $\boldsymbol{P_{d,s/o}}$ to its types: constant (C), incrementing counter (κ_{inc}), decrementing counter (κ_{dec}), co-flipping (F_k), or random (R). The i-th element $\boldsymbol{\tau_{d,s/o}}[i]$ is the classification of the i-th bit in $\boldsymbol{P_{d,s/o}}$
$\Sigma_{related}$	Set of IDs with signal boundaries that differ between states, possibly associated with specific car-control actions
$\boldsymbol{P_{d,fuzzed}}$	A bit matrix of fuzzed payloads for CAN ID d generated through a mutation-based fuzzer. Each row $\boldsymbol{P_{d,fuzzed}}[i]$ represents a fuzzed payload as a 64-bit vector.
$\boldsymbol{M_{d,fuzzed}}$	Complete fuzzed data messages for CAN ID d, ready for injection
ω_i	A specific car-control action
Ω_{tr}	Set of all ω_i observed during the injection process
Φ_{d,ω_i}	Set of payload vectors for CAN ID d that independently trigger car-control action ω_i
$\boldsymbol{\chi_{d,\omega_i}}$	A marked vector produced by commonality analysis on Φ_{d,ω_i}.
$\boldsymbol{\bar{\chi}^{(i)}_{d,\omega i}}$	A test vector derived from $\boldsymbol{\chi_{d,\omega_i}}$ by flipping the i-th bit, while fixing all x-marked positions to 0. Used in selective bit testing.
$\boldsymbol{\mathcal{C}_{d,\omega_i}}$	Set of control bits for ω_i , representing the indices of bits in the payload of CAN ID d frames that directly control ω_i . This set is determined through selective bit testing.

B. Data Collection and Preprocessing

To gather the necessary data for reverse engineering, CAN messages are collected in two distinct states: a stationary state, denoted as $\boldsymbol{M_s}$, with no active car-control actions, and an operational state, denoted as $\boldsymbol{M_o}$, with car-control actions which is denoted as Ω_{op}, e.g., unlocking the car, controlling the windows, or activating the windshield wipers.

During the preprocessing phase, the collected CAN messages are grouped by CAN ID. For each CAN ID n, the payload, denoted as $\boldsymbol{P_{n,s}}$ or $\boldsymbol{P_{n,o}}$, is extracted under stationary or operational state, respectively. $\boldsymbol{P_{n,s/o}}$ is a bit matrix, where each row represents the 64-bit payload of a single frame, and each column corresponds to a specific bit position. The matrix has N rows, where N represents the number of frames with ID n in $\boldsymbol{M_{s/o}}$ ($\boldsymbol{M_s}$ or $\boldsymbol{M_o}$). In $\boldsymbol{P_{n,s/o}}$, the bit index i starts from 0 on the leftmost column, corresponding to the most significant bit (MSB), and increases to 63 on the rightmost column, corresponding to the least significant bit (LSB).

C. Bit-Flipping Analysis Model

This step leverages the bit-flipping rate (BFR) to classify and differentiate signal fields within CAN messages. For each ID n and its payload $\boldsymbol{P_{n,s/o}}$, the bit-flipping rate for $\boldsymbol{P_{n,s/o}}[i]$ (the i-th column of bits within $\boldsymbol{P_{n,s/o}}$) is denoted as $\boldsymbol{bfr_{n,s/o}}[i]$, representing the percentage of times bit i changes (flips) between consecutive data frames within $\boldsymbol{P_{d,s/o}}$. It is calculated as follows:

$$\boldsymbol{bfr_{n,s/o}}[i] = \frac{1}{N-1}\sum_{j=1}^{N-1} \mathbb{I}\left(\boldsymbol{P_{n,s/o}}[i][j] \neq \boldsymbol{P_{n,s/o}}[i][j+1]\right) \quad (1)$$

where:

- $\boldsymbol{N}$ is the total number of frames with ID n in $\boldsymbol{M_{s/o}}$,
- $\boldsymbol{P_{n,s/o}}[i][j]$ is the value of the i-th bit in the payload of the j-th frame for CAN ID n under stationary or operational states,
- $\mathbb{I}(\cdot)$ is an indicator function that equals 1 if the argument is true (indicating a flip between consecutive frames) and 0 otherwise.

The bit-flipping rate vector $\boldsymbol{bfr_{n,s/o}}$ summarizes the flipping probabilities for all bit indices within $\boldsymbol{P_{n,s/o}}$. A $\boldsymbol{bfr_{n,s/o}}[i]$ of 0% means the bits never changes within $\boldsymbol{P_{d,s/o}}[i]$, while 100% means the bit flips between every pair of consecutive frames. This bit-flipping rate is essential for identifying signal boundaries and categorizing fields based on their roles in car-control actions.

1) Signal Boundary Identification: To systematically classify and represent the fields within $\boldsymbol{P_{d,s/o}}$, a Signal Classification Vector $\boldsymbol{\tau_{d,s/o}}$ is defined, where each element $\boldsymbol{\tau_{d,s/o}}[i]$ represents the field type of the i-th bit in $\boldsymbol{P_{d,s/o}}$, categorized into the following types:

- C: Constant fields – Bits that remain unchanged across all frames.
- κ_{inc} and κ_{dec}: Incrementing and decrementing counter fields – Bits that exhibit structured sequential behavior.

- F_i: Co-flipping fields – Bits that flip simultaneously with other bits.
- R: Randomly changing fields – Bits that do not fit any other classification.

The classification of each bit is based on its behavior across frames in $\boldsymbol{P}_{d,s/o}$ determined by the following rules:

a) Constant Fields (C): If all bits in $\boldsymbol{P}_{d,s/o}[i]$ are identical, the i-th bit is classified as a constant bit, i.e. $\boldsymbol{\tau}_{d,s/o}[i]=C$.

b) Counter Fields (κ_{inc} and κ_{dec}): Consecutive bits $\boldsymbol{P}_{d,s/o}[i{\sim}j]$ form a counter field if they satisfy the following:

- The bit-flipping rate $\boldsymbol{bfr}_{n,s/o}[i]$ of each higher-order bit k ($i \le k < j$) is approximately half that of its adjacent lower-order bit k+1.
- During a higher-order bit flip: For incrementing counters (κ_{inc}): The lower-order bit flips from 1 to 0, indicating a carry. For decrementing counters (κ_{dec}): The lower-order bit flips from 0 to 1, indicating a borrow.

If these conditions hold, all bits in the range $[i, j]$ are classified as counter bits:

$$\boldsymbol{\tau}_{d,s/o}[k] = \kappa_{\text{inc}} \text{ or } \kappa_{\text{dec}}, \qquad \forall k \in [i,j] \tag{2}$$

c) Co-flipping Fields (F_i): Bits in $\boldsymbol{P}_{d,s/o}[i]$, $\boldsymbol{P}_{d,s/o}[j]$ and others form a co-flipping group if they:

- Have identical bit-flipping rates.
- Flip simultaneously across all frames in $\boldsymbol{P}_{d,s/o}$.

Each group is assigned an identifier F_i, where i is the lowest index within the group:

$$\boldsymbol{\tau}_{d,s/o}[k] = F_i, \qquad \forall k \in \{i, j, \dots\} \tag{3}$$

d) Randomly Changing Fields (R): Bits that do not fit any of the above categories are classified as randomly changing:

$$\boldsymbol{\tau}_{d,s/o}[i] = R \tag{4}$$

The following pseudocode summarizes the classification process:

Algorithm 1 Pseudo-Code of the Classification Step

```
For each bit position i in range(0, 63):
  If bfr_{d,s/o}[i] = 0:
    τ_{d,s/o}[i] ← C
  Else if bfr_{n,s/o}[i] ≈ 2 ×bfr_{n,s/o}[i+1] :
    If CheckIncrementingCounter(P_{d,s/o}, i):
      τ_{d,s/o}[i] ← κ_inc
    Else if CheckDecrementingCounter(P_{d,s/o}, i):
      τ_{d,s/o}[i] ← κ_dec
  Else if CoFlippingDetected(P_{d,s/o}, i):
    τ_{d,s/o}[i] ← F_k
  Else:
    τ_{d,s/o}[i] ← R
Return τ_{d,s/o}
```

For example, the classification result for CAN ID 273 in the stationary state ($\boldsymbol{\tau}_{273,s}$) is: $\boldsymbol{\tau}_{273,s}$ = [C, C, κ_{inc}, κ_{inc}, κ_{inc} , R, R, …]. This illustrates how each bit in $\boldsymbol{P}_{273,s}$ is assigned a type based on its observed behavior across frames.

2) Related-ID Locating: The signal classification vectors $\boldsymbol{\tau}_{d,s}$ and $\boldsymbol{\tau}_{d,o}$, representing the signal classifications for CAN ID d in stationary and operational states, are compared to determine whether d belongs to the related-ID set $\Sigma_{related}$. If there is any bit index i such that $\boldsymbol{\tau}_{d,s}[i] \neq \boldsymbol{\tau}_{d,o}[i]$, the ID is classified as related and included in $\Sigma_{related}$; otherwise, it is considered unrelated.

Figure 5 illustrates this process using $\boldsymbol{\tau}_{2C2,\,s}$ and $\boldsymbol{\tau}_{2C2,\,o}$ as an example. The vectors show differences in certain bit classifications, such as a transition from C to R, therefore $2C2 \in \Sigma_{related}$. In contrast, for $\boldsymbol{\tau}_{273,\,s}$ and $\boldsymbol{\tau}_{273,\,o}$, no differences are observed, so $273 \notin \Sigma_{related}$.

This direct comparison approach ensures that $\Sigma_{related}$ is constructed efficiently, capturing IDs most likely to be relevant for car-control actions.

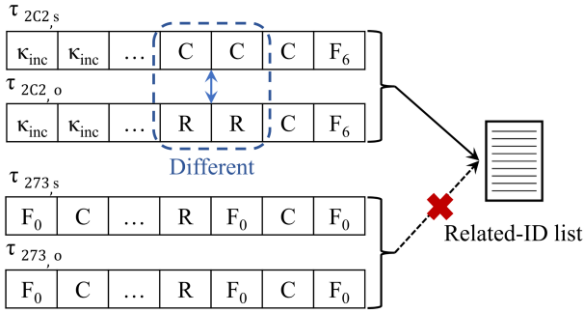

Fig. 5. Examples of Determining Related and Unrelated IDs Using Signal Classification Vectors

D. Fuzzed Data Generation and Injection

For each CAN ID d, fuzzed data generation begins by selecting an initial data frame from $\boldsymbol{P}_{d,o}$, representing the payloads collected in the operational state. This initial frame become the first row of the fuzzed data matrix, denoted as $\boldsymbol{P}_{d,fuzzed}[0]$. Each subsequent row $\boldsymbol{P}_{d,fuzzed}[n]$ ($n \ge 1$) is derived iteratively from the previous row $\boldsymbol{P}_{d,fuzzed}[n\text{-}1]$ by applying mutation rules based on $\boldsymbol{\tau}_{d,o}$.

Given the previous generated frame $\boldsymbol{P}_{d,fuzzed}[n\text{-}1]$, for each frame $\boldsymbol{P}_{d,fuzzed}[n]$, which represents the new frame to be generated based on the previously generated frame $\boldsymbol{P}_{d,fuzzed}[n\text{-}1]$, each bit i is mutated as follows:

If $\boldsymbol{\tau}_{d,o}[i] = C$, the i-th bit remains constant:

$$\boldsymbol{P}_{d,fuzzed}[n][i] = \boldsymbol{P}_{d,fuzzed}[n-1][i]. \tag{5}$$

If $\boldsymbol{\tau}_{d,o}[i] = R$, the i-th bit flips independently with a probability equal to $\boldsymbol{bfr}_{d,o}[i]$:

$$\boldsymbol{P}_{d,fuzzed}[n][i] = \begin{cases} 1 - \boldsymbol{P}_{d,fuzzed}[n-1][i], & \text{with probability } \boldsymbol{bfr}_{d,o}[i], \\ \boldsymbol{P}_{d,fuzzed}[n-1][i], & \text{otherwise.} \end{cases} \tag{6}$$

If $\boldsymbol{\tau}_{d,o}[i] = F_k$, all bits in the group F_k flip together, with a probability determined by $\boldsymbol{bfr}_{d,o}[k]$,consistent across the group:

$$\boldsymbol{P}_{d,fuzzed}[n][i] = \begin{cases} 1 - \boldsymbol{P}_{d,fuzzed}[n-1][i], & \text{if group flip occurs,} \\ \boldsymbol{P}_{d,fuzzed}[n-1][i], & \text{otherwise.} \end{cases} \tag{7}$$

If $\forall k \in [i, j]$, $\boldsymbol{\tau}_{d,o}[k] = \kappa_{inc}$ or κ_{dec}, the bits spanning $i \sim j$ are mutated according to the following rules. For the least significant bit ($k = j$), the flipping probability is determined by its bit-flipping rate $\boldsymbol{bfr}_{d,o}[j]$:

$$\boldsymbol{P}_{d,fuzzed}[n][j] = \begin{cases} 1 - \boldsymbol{P}_{d,fuzzed}[n-1][j], & \text{with probability } \boldsymbol{bfr}_{d,o}[j], \\ \boldsymbol{P}_{d,fuzzed}[n-1][j], & \text{otherwise.} \end{cases} \tag{8}$$

For higher-order bits ($i \le k \le j$), flipping is determined by whether a carry (for incrementing counters) or a borrow (for decrementing counters) propagates from lower-order bits:

$$\boldsymbol{P}_{d,fuzzed}[n][k] = \begin{cases} 1 - \boldsymbol{P}_{d,fuzzed}[n-1][k], & \text{if carry/borrow affects bit } k, \\ \boldsymbol{P}_{d,fuzzed}[n-1][k], & \text{otherwise.} \end{cases} \quad (9)$$

Using these mutation rules, the fuzzed data matrix $\boldsymbol{P}_{d,fuzzed}$ systematically explores variations in payloads for CAN ID *d*. After constructing $\boldsymbol{P}_{d,fuzzed}$, the payloads are combined with frame headers and footers to create the complete fuzzed dataset $\boldsymbol{M}_{d,\,fuzzed}$, which is injected into the vehicle's CAN bus.

If any $\boldsymbol{M}_{d,\,fuzzed}$ triggers a specific car-control action ω_i, binary search is performed to isolate the exact frames responsible. The payloads of these frames are recorded as $\Phi_{d,\omega i}$, an unordered set of payload vectors $\boldsymbol{P}$, an unordered set of payload vectors for CAN ID *d* that independently trigger ω_i.

The set of all triggered responses ω_i is denoted as Ω_{tr}, a set encompassing all car-control actions observed during the injection process.

E. Control Bit Analysis

This step identifies the exact bits in the payload that are responsible for triggering a specific car-control action ω_i. The analysis has two key steps: (1) commonality analysis, which isolates potentially relevant bits, and (2) selective bit testing, which refines these relevant bits to identify the exact control bits. Together, these steps form a precise methodology for identifying and verifying control bits for ω_i.

In the commonality analysis, $\Phi_{d,\omega i}$ is analyzed. Here, each vector $\boldsymbol{P}$ in $\Phi_{d,\omega i}$ represents the payload of a single CAN frame that triggered ω_i. The analysis produces a marked vector $\boldsymbol{\chi}_{d,\omega i}$, which captures the consistent and variable bit positions across all payloads $\boldsymbol{P}$. Each bit in $\boldsymbol{\chi}_{d,\omega i}$ is defined as:

$$\boldsymbol{\chi}_{d,\omega_i}[i] = \begin{cases} 1, & if\ \boldsymbol{P}[i] = 1,\ \forall \boldsymbol{P} \in \Phi_{d,\omega_i} \\ 0, & if\ \boldsymbol{P}[i] = 0,\ \forall \boldsymbol{P} \in \Phi_{d,\omega_i} \\ x, & if \oplus_{\boldsymbol{P} \in \Phi_{d,\omega_i}} \boldsymbol{P}[i] = 1. \end{cases} \quad (10)$$

Here, *x* indicates that the *i*-th bit varies across payloads, suggesting it is unrelated to ω_i. The marked vector $\boldsymbol{\chi}_{d,\omega i}$ eliminates irrelevant bits (*x*) and retains only those (0s and 1s) potentially related to ω_i.

In the selective bit testing, the marked vector $\boldsymbol{\chi}_{d,\omega i}$ is systematically tested to determine which bits directly influence ω_i. For each bit *i* marked 1or 0 in $\boldsymbol{\chi}_{d,\omega i}$, a test vector $\bar{\boldsymbol{\chi}}^{(i)}_{d,\omega i}$ is generated by flipping the *i*-th bit in $\boldsymbol{\chi}_{d,\omega i}$, while all *x* positions are set to 0. In total, *n* test vectors $\bar{\boldsymbol{\chi}}^{(i)}_{d,\omega i}$ are produced, where *n* is the number of 1s or 0s in $\boldsymbol{\chi}_{d,\omega i}$. Each test vector $\bar{\boldsymbol{\chi}}^{(i)}_{d,\omega i}$ is injected as a CAN frame, and its effect is observed. If the injection of $\bar{\boldsymbol{\chi}}^{(i)}_{d,\omega i}$ fails to trigger ω_i, the *i*-th bit is identified as a control bit. This implies that flipping this bit disrupts ω_i.

The final control bit set $C_{d,\omega i}$, storing the indices of all identified control bits, is defined as:

$$\mathcal{C}_{d,\omega_i} = \left\{ i \middle|\, \bar{\boldsymbol{\chi}}^{(i)}_{d,\omega i}\ fails\ to\ trigger\ \omega_i \right\} \quad (11)$$

Through these steps, the control bit analysis provides precise identification of the control bits for ω_i, enabling bit-level resolution reverse engineering of car-control actions.

IV. Performance Evaluation

In this section, we evaluate the performance of our CAN bus reverse engineering method. Our experiments were conducted on the Tesla Model 3 (2023) and the Leapmotor C11 and C10 (2024).

A. Experimental Setup

As described in section III. *B*, the data collection phase involves capturing CAN bus data ($\boldsymbol{M}_{s/o}$) in two distinct states: a stationary state and an operational state. During the operational state, a series of car-control actions (Ω_{op}, defined in section III. *B*) were manually triggered. These car-control actions are the actions that we aim to reverse engineer and they form the foundation for subsequent analysis.

In our experiment on Tesla Model 3, Ω_{op} included the following car-control actions, as shown in Table II:

TABLE II. Car-control Actions Triggered Manually (Ω_{op}) during Data Collection Phase

Window Up	Trunk Open	High Beam
Window Down	Trunk Close	Horn Activation
Multi-Level Wiper Control	Rearview Mirror Fold	Rearview Mirror Angle Adjustment
Left-turn Signal	Front Trunk Open	Door Lock
Right-turn Signal	Front Trunk Close	Door Unlock

B. Experimental Results

Through our methodology, we successfully obtained the control bits of a series of car-control actions, collectively defined as Ω_{tr}. The contents of Ω_{tr} are summarized in Table III. In our experiments, Ω_{op} consists of 8 manually triggered car-control actions, while Ω_{tr} includes a total of 43 actions, including both the predefined actions and additional function controls or abnormal responses discovered during the analysis.

TABLE III. Car-control Actions that Can Be Interpreted

Vehicle Function Controls	Abnormal Responses
Window Up/ Down	Window Sensors Deception
Front/Back Trunk Open/ Close	Front Seat Sensors Deception
Keyless Driving	Display Reboot
Turn Signals	Headlight Flicker
Multi-Level Wiper Control	Battery Warning Light
Long/ Short Horn Activation	Air Conditioning Shutdown
Silent Mode for Media	Climate Control Malfunction
Glove Box Open/ Close	Internal Circulation Off
High/ Low Beam	Defrost Function Error
Window Gap Open/ Close	Light Sensors Deception
Door Lock/ Unlock	Volume Display Flickering
Brake Light	Start Status Detection
Double-flash	Screen Display Error
Volume Control	A Tiny Slit of Window Landed
	Air Conditioning Airflow Malfunction

As described in section III.*B*, the data collection phase involves capturing CAN bus data ($\boldsymbol{M}_{s/o}$) in two distinct states: a stationary state and an operational state. During the operational state, a series of car-control actions (Ω_{op}, defined in section III.*B*) were manually triggered. These car-control actions are the actions that we aim to reverse engineer and they form the foundation for subsequent analysis.

The experimental results reveal several key insights:

1) Coverage: As shown in Table II and Table III, all 15 actions in Ω_{op} are fully contained within Ω_{tr}, confirming 100% coverage of the predefined car-control actions. This

demonstrates the effectiveness of our methodology in identifying control bits for these targeted actions.

2) Additional Car-control Actions: Beyond the 15 predefined actions, Ω_{tr} includes an additional 14 function controls and abnormal responses, bringing the total number of car-control actions to 43. These unexpected entries arise from the fuzzed data generation process, which efficiently produces plausible yet novel data frames beyond the original dataset. Such frames may activate related but untested actions or trigger conflicts within the ECU, resulting in abnormal responses. These anomalies are particularly significant as they reflect vulnerabilities in the ECU's processing logic, including insufficient error handling or flawed prioritization mechanisms.

C. Comparison with Existing Methods

To establish the efficiency and effectiveness of our method, we compared it against several existing approaches as shown in Table IV below.

TABLE IV. COMPARISON WITH EXISTING METHODS

Existing work	Experimental vehicles	Functions Controls	Abnormal Responses	Resolution
Fowler et al. [19]	1	×	×	Moderate (frame-level)
Zhang et al.[20]	1	×	×	Not mentioned
Jia et al. [21]	1	LED indicating car lock	√	Moderate (frame-level)
Fowler et al.[22]	×	Unlock the car door	√	High (bit-level)
Zixiang Bi et al. [23]	1	×	×	Low(ID-level)
Zixiang Bi et al. [24]	1	20 functions including lighting, wipers, etc.	×	High (bit-level)
Our work	3	43 actions and some high-risk actions involved (shown in Table III)	√	High (bit-level)

From Table IV, we can draw the following conclusions regarding our method's performance compared to others:

1) Car-control Actions Identification: Our method successfully reverse-engineered 43 car-control actions, achieving bit-level resolution for all identified actions. In contrast, most previous works, such as Fowler et al. [19, 22] and Jia et al. [21], primarily focused on frame-level or ID-level analysis, limiting their ability to identify precise control bits. Even Bi et al. [24], which achieved bit-level resolution, covered fewer actions than our method.

2) Unexpected Responses: Our approach extends beyond predefined car-control actions by efficiently uncovering additional related function controls and abnormal responses through fuzzed data generation. Previous works, such as Zhang et al. [20] and Bi et al. [24], did not explore unexpected responses, limiting their ability to detect unexpected ECU behaviors or potential conflicts.

3) Applicability Across Vehicles: Our method was validated on three real vehicle models, including the Tesla Model 3 and Leapmotor C11/C10, showcasing its robustness and generalizability. While some previous works, such as Fowler et al. [22] and Zhang et al. [20], were limited to a single vehicle, our broader applicability demonstrates its potential for diverse automotive platforms.

These results highlight the strengths of our methodology in achieving higher resolution and more extensive coverage, compared to existing approaches.

D. Overhead of Our Approach

The overhead of our approach includes a total time of 2 minutes for data collection, 30 seconds for data preprocessing, 3 seconds for bit-flipping analysis, 15 seconds for fuzzed data generation, and 20 minutes for control bit analysis (manual effort involved).

Resource utilization remains low, with an average CPU usage of 6% and memory consumption of approximately 73 MB, demonstrating the efficiency of the method on standard hardware.

E. Wireless Automatic Reverse Engineering Tool Development

We developed an automatic reverse engineering tool based on a Raspberry Pi 4b, equipped with a 2-CH CAN FD HAT for CAN communication. This tool is capable of receiving commands wirelessly from a laptop, reverse engineering, and performing car-control actions remotely via the CAN bus shown in Figure 6.

Fig. 6. The Wireless Automatic Reverse Engineering Tool Connected to Tesla Model 3in

The compact design and wireless capability make this tool portable and suitable for on-site experiments, enabling efficient execution of reverse-engineering tasks.

V. CONCLUSION

This paper presents a systematic framework for reverse engineering CAN bus messages, achieving bit-level resolution. The proposed method has been validated across multiple vehicle models, including the Tesla Model 3 and Leapmotor C10 and C11, demonstrating versatility across different vehicle platforms. On a single vehicle Tesla, it successfully identified 43 car-control actions, showcasing its extensive coverage of car-control actions. Furthermore, the method's low resource consumption allows seamless integration into compact platforms like the Raspberry Pi, facilitating practical deployment in real-world automotive systems. It establishes a practical and systematic method for precise bit-level identification.

***Abstract*—Adjoint sensitivity analysis is an exceptionally efficient method for computing the gradient of an objective function with respect to given parameters, playing a crucial role in modern circuit design and verification. According to the principles of the adjoint method, it is necessary to store all essential system state information, such as state vectors and Jacobian matrices, at each time step during the forward integration process in order to construct the adjoint equations during the backward integration. Therefore, the memory overhead of the adjoint method is proportional to the system size and the number of time steps, resulting in prohibitive memory costs for solving large-scale dynamic systems.**

In this paper, we propose a novel, memory-efficient adjoint sensitivity analysis method that significantly reduces the memory overhead of storing system state information by employing error-bounded lossy compression techniques. Our compression algorithm effectively utilizes the spatiotemporal characteristics of data in circuit simulations and incorporates stringent error control mechanisms. This approach achieves a two-order-of-magnitude reduction in memory overhead during simulation while ensuring that the accuracy of the adjoint solution remains unaffected.

***Index Terms*—Lossy compression, Circuit simulation, Adjoint sensitivity analysis**

I. Introduction

Sensitivity analysis involves calculating the gradient of the objective function with respect to given parameters, serving as a powerful tool for evaluating how perturbations in system parameters impact system outputs. This method provides significant guidance in modern integrated circuit (IC) design and verification, making it widely applied in areas such as performance modeling [1], circuit optimization [2, 3], and yield estimation [4]. Sensitivity analysis encompasses two methods: the direct method and the adjoint method. The direct method is not suitable for dynamic systems with a large number of parameters [5], hence the adjoint method has become the standard in modern simulations.

A major drawback of the adjoint method is its high memory overhead [6]. During the forward solution process, it is necessary to store critical historical information at each time step, such as the state vectors, to construct differential equations during the adjoint process [7]. In large-scale simulations, this approach incurs substantial spatial and temporal costs. An alternative strategy involves storing additional state variables, such as the Jacobian matrix at each time step, to avoid recomputation during the reverse process and thereby reduce computational time. However, this approach further exacerbates the issue of memory overhead [8]. It is worth noting that during the simulation, Jacobian matrices can share indices [9], meaning that the primary memory overhead in adjoint sensitivity analysis stems from storing large-scale floating-point data.

One potential approach to reducing memory overhead during simulation is data compression. However, the mantissa of floating-point numbers often exhibits significant randomness, which limits the compression ratio achievable with traditional lossless compression algorithms [10], rendering them insufficient for the demands of large-scale simulations. Fortunately, advanced error-bounded lossy compression algorithms offer a promising solution to this challenge.

Error-bounded lossy compression, a current research hotspot in the field of high-performance computing (HPC), can significantly reduce data size while ensuring accuracy. It is widely regarded as the best solution for addressing the challenges posed by large-scale scientific data [11]. However, in circuit simulations, the complexity of circuit spatial topologies and the diversity of device parameters result in data exhibiting significant spikiness in the spatial dimension. Most existing compression algorithms heavily rely on data smoothness [12, 13], making them ineffective for handling circuit simulation data.

To address the low compression ratio of existing algorithms on circuit simulation data, we propose a novel error-bounded compression algorithm that efficiently compresses vector and matrix data in circuit simulations while ensuring high precision. This algorithm leverages the unique characteristics of circuit-related vectors and matrices to effectively smooth simulation data. It then applies a hybrid predictor based on the properties of data regions to decorrelate the data. Finally, a rigorous data quantization mechanism and an efficient encoding scheme are used to significantly reduce the size of simulation data while preserving simulation accuracy.

To the best of our knowledge, this is the first error-bounded compression algorithm capable of efficiently compressing both matrices and vectors in circuit simulations. Experiments demonstrate that the proposed compression algorithm can reduce simulation memory overhead by two orders of magnitude.

II. Background

A. Adjoint Sensitivity Analysis

In circuit design, sensitivity analysis is essential for evaluating the effects of parameter variations on performance. For sensitivity analysis, the circuit we are interested in can be represented by a set of differential algebraic equations (DAE) [14]:

$$\boldsymbol{g}(\boldsymbol{x}, t, \boldsymbol{p}) = \frac{d}{dt}\boldsymbol{q}(\boldsymbol{x}, \boldsymbol{p}) + \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{p}) + \boldsymbol{b}(t, \boldsymbol{p}) = \boldsymbol{0} \quad (1)$$

where $\boldsymbol{x} \in \mathbb{R}^D$ is the state vector, t is time, $\boldsymbol{p} \in \mathbb{R}^M$ is the parameter vector with respect to which we require sensitivities, $\boldsymbol{q} \in \mathbb{R}^D$ and $\boldsymbol{f} \in \mathbb{R}^D$ represent the dynamic and static elements, respectively, $\boldsymbol{b} \in \mathbb{R}^D$ is the input. To obtain adjoint sensitivity, we take derivative of formula (1) with respect to p:

$$\frac{dO}{dp} = \sum_{i=0}^{n}\sum_{k=i}^{n}(\frac{\mathrm{d}\boldsymbol{O}}{\mathrm{d}\boldsymbol{x}})_k(\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{x}})_k^{-1}\left(\prod_{j=k-1}^{i}(\frac{1}{h_t}\frac{\partial \boldsymbol{q}}{\partial \boldsymbol{x}})_j(\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{x}})_j^{-1}\right)(\frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{p}})_i \quad (2)$$

This process is akin to the reverse of transient analysis, with the storage and reuse of matrices and vectors from the forward process significantly speeding up sensitivity analysis [15]. However, the requirement to preserve these matrices and vectors for numerical integration in the reverse process incurs substantial memory overhead. Thus, while sensitivity analysis is invaluable for design optimization, it also imposes significant computational resource demands.

B. Floating-Point Number

The IEEE 754 standard [16] defines floating-point (FP) data to be in 32-bit single-precision and 64-bit double-precision format. The single-precision includes one bit for the positive or negative sign, 8 bits for the exponent, and 23 bits for the mantissa. The double-precision format includes one sign bit, 11 exponent bits, and 52 mantissa bits, as demonstrated in Figure 1. The actual value of a floating-point data is represented as:

$$x = (-1)^{\text{sign}} \times 2^{(\text{exponent-bias})} \times 1.\text{mantissa}$$

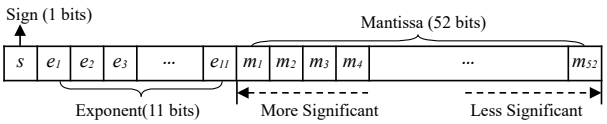

Fig. 1: IEEE 754 64-bit double-precision FP format.

C. Lossy Compression for Floating-Point Data

Error-bounded lossy compressors may have distinct designs and implementations. All existing error-bounded lossy compressors can be categorized into two groups: data-prediction based and domain-transform based.

Data-prediction-based compression model tries to predict each data point as accurately as possible based on its neighborhood in spatial or temporal dimension and then shrinks the data size by some coding algorithm, such as SZ [17] and FPZIP [18].

Domain-transform-based compression model needs to transform the original data to another non-orthogonal coefficient domain for decorrelation and then shrink the data size by applying some optimized coding algorithms such as embedded coding, e.g., ZFP [19].

However, all existing error-bounded lossy compressors are mainly designed to reduce storage overhead rather than memory overhead, considering error propagation. Only a few works [20–22] have utilized lossy techniques for memory compression, but these have not been optimized for the specific requirements of compression quality in circuit simulations.

III. Motivation

A. Lossy Compression Brings Higher Compression Ratio

Traditional lossless compression algorithms are less effective for domain-specific data due to low compression ratios. In contrast, lossy compression algorithms can achieve higher compression by allowing controlled information loss. As shown in Table I, lossy methods offer compression ratios 1 to 2 orders of magnitude higher than lossless ones [23]. However, some lossy algorithms, such as ZFP and FPZIP, do not adapt well to circuit simulation data, resulting in relatively low compression ratios.

TABLE I: Compression ratio comparison.

Dataset	Lossless Compression			Lossy Compression under 1×10^{-2} Relative Error			
	GZIP	ZSTD	BZIP2	ZFP [19]	FPZIP [18]	SZ1.4 [17]	SZ2.1 [17]
add20(vec)	5.23	6.03	4.33	8.52	189.8	1824.81	1783.85
add20(mat)	2.52	9.74	7.19	14.6	52.51	509.418	214.24
mem_plus(vec)	2.57	2.08	3.45	7.34	67.27	1933.368	1515.33

B. Existing Lossy Compression Algorithms Introduce Significant Errors in Simulation

Circuit simulation, particularly during transient analysis, requires high precision. While lossy compression algorithms like SZ improve compression ratios (see Table I), they introduce significant errors that accumulate over time, compromising simulation accuracy, as shown in Figure 2. ZFP controls errors better, but its compression ratio remains low. Moreover, the varying error levels across different lossy compression methods underscore the challenge of maintaining data integrity. Therefore, there is an urgent need to develop lossy compression algorithms that reduce data size while preserving the precision necessary for reliable simulations.

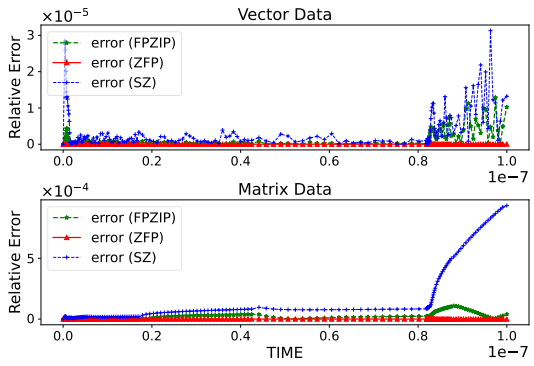

Fig. 2: The simulation error introduced by the compression algorithm under a relative error bound of 1×10^{-8}.

C. Existing Compressors Fail to Work Effectively on Circuit Simulation Data

As shown in Figure 3, the matrices and vectors generated by circuit simulation at each time step are spiky data with very low spatial autocorrelation. Existing compressors mostly rely on the smoothness of the data, so their performance will be greatly reduced on circuit simulation datasets. For example, ZFP, its domain transformation will lose effectiveness on simulation data, thus leading to low compression ratio. Due to the typically short time steps in numerical integration, data at adjacent time points exhibit strong correlations in the time dimension. This naturally suggests storing historical vectors or matrices as reference vectors or matrices to reduce data redundancy through prediction. However, this approach incurs significant memory overhead and struggles to handle dependencies in the data prediction process for lossy compression. Therefore, enhancing the smoothness of data in the spatial dimension is essential for simulation data compression.

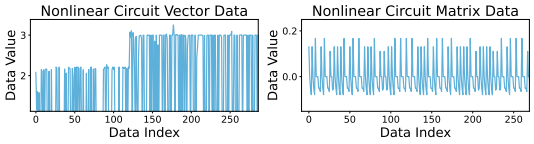

Fig. 3: The vector and matrix data of circuits exhibit pronounced spikiness.

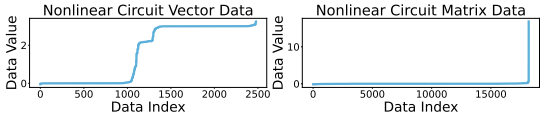

Fig. 4: After applying the reference sorting smoothing technique, the data exhibits strong autocorrelation.

IV. Error-Bounded Lossy Compression for Simulation

The proposed error-bounded compression algorithm efficiently compresses vectors and matrices during simulation with minimal overhead while ensuring precise floating-point error control. It effectively resolves the memory overhead challenges of traditional adjoint methods. As shown in Figure 5, the workflow consists of three main steps: (1) efficiently smooth the simulation data using **reference sorting**; (2) apply **RLE-FP** or **polynomial interpolation** predictors to decorrelate data based on regional characteristics; and (3) **quantize floating-point data** within a user specified error bound and encode it, achieving a significant data reduction.

A. Data Smoothing via Reference Sorting

Smoothing spiky data is essential for simulation data compression. Traditional smoothing techniques, such as wavelet transforms, are unsuitable due to their high time complexity [24]. To address this, we propose reference sorting, an efficient smoothing technique tailored for circuit simulation data. It consists of three main steps: (1) sort the floating-point queue in an ascending order at the initial time step, record the sorting indices, and use this sorting as a reference; (2) reorder the data in subsequent time steps based on the reference sorting; and (3) for longer integration processes, set validity check points to reinsert invalid data points into the sorted queue and update the reference sorting.

This approach is based on three key observations: (1) In circuits, nodes with large admittance (or small impedance) connections typically have identical or similar potentials [25]. Sorting the state vector groups these corresponding floating-point values together. This property is strongly linked to the circuit topology and device parameters, ensuring the reference sorting remains highly effective. (2) For matrices, elements with similar parameters contribute stamping values that are also similar [9], and sorting naturally clusters these corresponding floating-point values. (3) In time series data, values at adjacent time points are often similar or identical [26], leading to overall similarity in sorting across time steps.

Figure 4 illustrates the vector and matrix data of the nonlinear circuit at the 200th time step after applying the proposed smoothing technique. It can be observed that the data exhibits strong autocorrelation, which is highly advantageous for compression algorithms. The time overhead of reference sorting primarily arises from the sorting operation at the initial time step and the subsequent correction of a small number of out-of-order data points. The space overhead stems from storing the integer indices of a single time step, which is highly compressible and can be further reduced using integer compression algorithms. These time and space overheads are negligible compared to the original simulation costs.

B. Decorrelation by Hybrid Predictors

After data smoothing, we apply a hybrid predictor to decorrelate the data, significantly reducing its size. We observe that the smoothed data contains both numerically large steady regions and regions with small rapid numerical growth. To fully exploit the characteristics of these regional data patterns, we organize the entire dataset into different regions (or blocks) and apply distinct compression prediction techniques based on the data properties within each region.

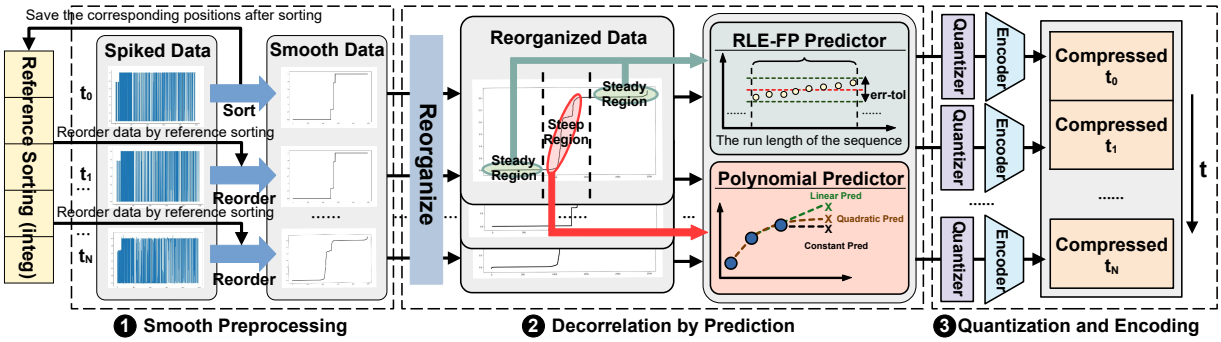

Fig. 5: The overall framework for error-bounded lossy compression of simulation data.

As shown in Figure 6, in the steady region, we introduce the RLE-FP technique for efficient decorrelation of the data. In the regions with rapid numerical growth, termed steep regions, we employ a prediction technique based on polynomial interpolation. This approach takes advantage of the varying data characteristics across different regions, optimizing the compression process.

We organize the sorted dataset into N regions. If the value at the right end of a region satisfies (3), we classify it as a steady region; otherwise, it is considered a steep region.

$$V_{right} < n\frac{V_{max} - V_{min}}{N} + V_{min} \tag{3}$$

In the text, V_{max} and V_{min} represent the maximum and minimum values in the dataset, respectively. n and N represent the total number of regions and the current region number from left to right, respectively. V_{left} represents the value at the leftmost end of the current region.

1) RLE-FP: The main idea of "RLE-FP" is to record consecutive values within the same error range in a floating-point sequence in order to achieve sequence compression.

Specifically, starting from the first floating-point number V_l at the left end of the steady region, we scan the floating-point sequence to identify the smallest $\hat{V}_m$ that satisfies $\hat{V}_m - V_l < e$ (where e is the user-specified error bound) and record this value as the center of the interval. From $\hat{V}_m$, we continue scanning to find the largest V_r such that $V_r - \hat{V}_m < e$, marking the right boundary of the interval. In other words, all floating-point numbers within this interval lie within a range centered at $\hat{V}_m$ with a radius of e. The process stops when a value outside the error range is encountered, and the length of the interval and $\hat{V}_m$ is recorded.

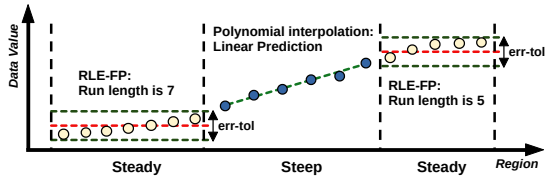

Fig. 6: Hybrid Predictors: RLE-FP for steady region and polynomial interpolation for steep region.

2) Polynomial Interpolation Prediction: The polynomial interpolation predictor is a predictor based on polynomial functions, which predicts future values by fitting historical data points. The current predicted value can be determined by the predicted values of the past n data points:

$$\hat{V}_n = \sum_{i=1}^{n} \alpha_{n-i} \hat{V}_{n-i} \tag{4}$$

To solve for the coefficient α, we substitute the historical predicted values into equation (4), yielding:

$$\hat{V}_n = \sum_{i=1}^{n} (-1)^{i+1} \binom{n}{i} \hat{V}_{n-i} \tag{5}$$

From equation (5), we can obtain the predicted value for each point, thereby achieving decorrelation in the steep regions. It is worth noting that using a polynomial interpolation predictor of order zero to two already provides sufficiently accurate predictions.

C. Error-Controlled Quantization and Data Encoding

A quantizer is responsible for quantizing the error between predicted values and true values, as well as handling unpredictable values. It significantly reduces the entropy of the original data while respecting the user-specified error boundaries.

We provide both absolute error bounds (denoted as ϵ) and relative error bounds (denoted as δ). To ensure simulation accuracy, both of these error bounds must be satisfied simultaneously. Therefore, there is a requirement between the true value V and the predicted value $\hat{V}$ (which is also the decompressed value):

$$\left|V - \hat{V}\right| \leq \epsilon \quad and \quad \frac{\left|V - \hat{V}\right|}{|V|} \leq \delta \tag{6}$$

So the final error bound e specified by the user is:

$$e = min(\epsilon, \delta|V|) \tag{7}$$

Clearly, when $|V| < \frac{\epsilon}{\delta}$, we focus solely on relative error; in contrast, we pay more attention to absolute error.

The quantizer calculates the error between the predicted value and the true value. If the result falls within the error bound e, the quantizer represents the true value with the predicted value. Otherwise, we refer to this true value as unpredictable.

For unpredictable values, we perform an XOR operation with their neighboring unpredictable values, use 2 bits to record the number of leading zero bytes in the residual, and finally truncate the insignificant bit planes based on the user-specified error bounds.

By analyzing the binary representation of floating-point numbers, it can be concluded that to satisfy absolute error bounds, the minimum number of mantissa bits required is:

$$R_{abs} = \begin{cases} 0, & p(V) - p(\epsilon) < 0 \\ 52, & p(V) - p(\epsilon) > 52 \\ p(V) - p(\epsilon), & otherwise \end{cases} \tag{8}$$

Algorithm 1: Compressing Simulation Data at t_n.

Input: Floating-point array of a matrix or vector $\{V_1, V_2, \ldots, V_M\}$ at t_n, user-specified error bound e
Output: compressed data stream in form of bytes

if $t_n = start_time$ **then**
  Sort the floating-point array.
  Save the sorting indices as reference sorting.
else
  if $t_n = checking_time$ **then**
    Check and maintain the validity of the reference sorting.
  end if
  Reorder the floating-point array by shared sorting.
end if
Organize data based on the regional characteristics of the sorted dataset.
for $(V_i,\ i = 1, 2 \cdots M)$ **do**
  if V_i is in a steady region. **then**
    if V_i is within the tolerance range. **then**
      $++run_length$
    else
      Save run_length and predicted value.
    end if
  else if V_i is in a steep region. **then**
    Determine the predicted value $\hat{V}_i$ using a polynomial predictor.
    Predict V_i using the $\hat{V}_i$.
  end if
  Quantize the unpredictable value and save the residual.
end for

Here, p represents the exponent of the floating-point number, and 52 denotes the number of mantissa bits for double-precision floating-points (23 for single-precision). To meet the absolute error bounds, larger floating-points require retaining more mantissa bits. Therefore, in implementations, the largest value within the range is used instead of V to determine the number of mantissa bits to retain. This approach not only improves precision but also ensures uniformity in the retained mantissa bits for all floating-points within the range.

To satisfy the relative error, the number of retained mantissa bits R_{rel} must satisfy $2^{R_{rel}} \leq \delta$. Therefore, we can derive:

$$R_{rel} = -p(\delta) \tag{9}$$

By calculating the significant bits to retain for floating-points using the above method and truncating the less important bit planes, we achieve quantization of unpredictable floating-points.

After quantization, we encode the indices generated during the compression process. Smaller integers can be represented with fewer bits, so we store only the differences between consecutive indices along with the first value. This reduces the magnitude of the integers, which are then encoded using variable-length encoding to significantly reduce the size of the indices. Finally, an advanced lossless compressor, ZSTD [27], is used for further compression of the data.

V. Integrating Compression in Sensitivity Simulation

As shown in Figure 7, we integrate the proposed error-bounded lossy compression algorithm into the simulation process, effectively reducing memory usage during both forward and backward propagation. In transient analysis, after successfully solving each time step, we store all the necessary state variables (e.g., state vectors and Jacobian matrices), denoted as D, and compress them to reduce storage. Subsequently, during the adjoint process, these variables are decompressed at the necessary moments to reconstruct the differential equations.

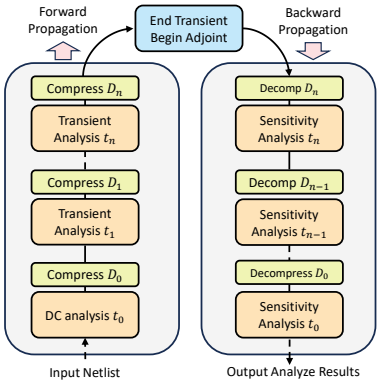

Fig. 7: Proposed memory-efficient simulation.

VI. Experimental Evaluation

TABLE II: Dataset information.

Dataset	Circuit Type	#CirElem	Dimension Size	Data Size

nonlinear circuits. As shown in Table II, the first column represents the name of the circuit and whether it is vector data or matrix data, the second column is the type of the circuit, the third column indicates the number of elements in the circuit, and the fourth and fifth columns respectively represent the dimensions and size of the data.

Baselines. We compare the proposed algorithm with the state-of-the-art lossless compressor ZSTD [27], the lossless compression algorithm MASC [8] specifically designed for matrices, and two cutting-edge lossy compressors, ZFP [19] and SZ [17]. All algorithms use the latest versions.

Configuration. In scientific computing, the absolute and relative error bounds for lossy compression are typically set to 10^{-5} and 10^{-3} [21], respectively, providing sufficient accuracy while significantly reducing simulation memory overhead. We adopt this configuration for our experiment as well.

B. Compression Performance

As shown in Table III, we compare the proposed error-bounded lossy compression algorithm with the aforementioned compression methods. In terms of compression ratio, our algorithm achieves average ratios of 23.70× and 39.07× higher than the state-of-the-art lossless compression methods ZSTD and MASC, respectively. This result highlights the superior capability of lossy compression in handling floating-point data. When compared to advanced lossy compression methods such as ZFP and SZ, the proposed algorithm achieves compression ratios of 36.24× and 2.44× higher, respectively. Thus, the simulation memory overhead can be reduced by two orders of magnitude.This improvement can be attributed to the algorithm's effective exploitation of the characteristics of circuit simulation data. By leveraging efficient smoothing techniques and predictive modeling, the algorithm effectively eliminates data redundancy in vectors and matrices. In terms of compression and decompression time, the time consumed by the five compression algorithms for both compression and decompression is negligible compared to the overall time cost of the sensitivity simulation itself.

C. Error Impact Evaluation

As shown in Figure 8, we integrate the proposed error-bounded lossy compression algorithm into the adjoint sensitivity simulation to analyze the impact of floating-point errors introduced by lossy compression on the accuracy of sensitivity simulation results. The absolute error bound is set to 10^{-5}, and the relative error bound to 10^{-3}. Using the compression algorithm, we reduce the memory overhead caused by storing vectors and matrices during the simulation process. It can be observed that the sensitivity analysis results at each time point remained within the predefined error bounds after integrating the lossy compression. This is attributed to the proposed algorithm's strict quantization of errors introduced during the compression process. Therefore, the proposed error-bounded lossy compression significantly reduces memory overhead while effectively preserving simulation accuracy.

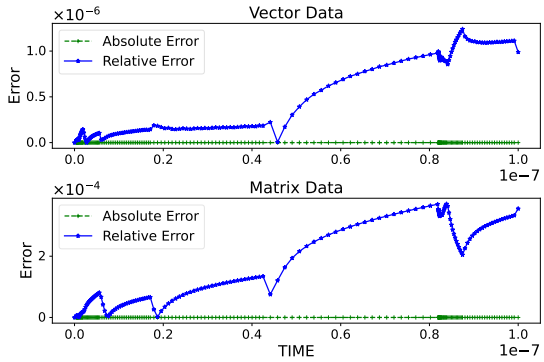

Fig. 8: Error comparison by integrating lossy compression algorithm into transient adjoint sensitive analysis with add20.

VII. Conclusion

This work introduces the first error-bounded lossy compression algorithm capable of efficiently compressing both vector and matrix data in circuit simulations. This approach significantly reduces memory overhead in adjoint sensitivity simulations. Based on the characteristics of data in circuit simulations, we propose an effective smoothing method tailored for simulation data. Subsequently, we design different data prediction algorithms for regions with distinct properties. Finally, through rigorous error quantization and efficient data encoding, the proposed approach significantly reduces the data size while preserving accuracy.

***Abstract*—Time-Sensitive Networking (TSN) provides bounded latency and low jitter for cyber-physical systems, such as industrial control. As a key component of TSN, the Time-Aware Shaper (TAS) applies gate control rules to control the transmission time of frames in critical flows. TAS stores the gate control rules for each frame in the gate control table. However, in typical industrial setups, the memory usage of the table could reach over tens of megabits and even exceed the total memory capacity of TSN switches.**

To address this issue, we propose a memory-efficient TAS design named METAS. It transitions from a per-frame to a *per-flow* approach. METAS stores one *persistent rule* for a flow and dynamically generates a *temporary rule* for a frame only when the frame arrives. We prototyped METAS on an FPGA, and experimental results show that METAS reduces memory usage from 14.34 Mbits to 288 Kbits when supporting 1,024 flows, using just 1.56% of the FPGA's logic resources while maintaining microsecond-level latency and nanosecond-level jitter for critical flows.

***Index Terms*—Time-Sensitive Networking, Time-Aware Shaper, Gate Control List, memory-efficiency, Push-In First-Out**

I. Introduction

Time-Sensitive Networking (TSN) is an emerging real-time Ethernet technology that guarantees bounded latency and minimal jitter for critical network flows [1]. This capability is particularly important in industrial internet of things and cyber-physical systems such as industrial automation [2], [3], automotive [4]–[7], and aerospace [8], [9], making TSN a promising solution in these fields [10], [11].

Time-Aware Shaper (TAS) is a key shaping mechanism in TSN designed to ensure bounded latency and minimal jitter for critical flows [12]. TAS stores a *gate control table*, with each row storing a *gate control rule*. These rules determine when gates should open or close, thus controlling the transmission time of each frame of critical flows [1]. Through the gate control table, TAS effectively shapes critical flows with precise timing control.

A gate control table stores gate control rules for a single *hyperperiod* instead of the system's entire lifetime. The hyperperiod in TSN describes the periodicity of all critical flows [13], and is defined as the least common multiple of the periods of all critical flows. By cyclically executing the gate control table over this hyperperiod, TAS can effectively control the transmission time of each frame throughout the system's lifetime.

A key issue with TAS is the high memory consumption of the gate control table. Each critical frame requires two gate control rules (one for open and another for close) in the table. Consequently, the per-frame approach results in the number of gate control rules in the table growing linearly with the number of critical frames within the hyperperiod. As *the number of frames within a hyperperiod can be substantial*, the gate control table results in significant memory consumption. In a typical industrial application [14], [15] involving the shaping of 400 flows comprising 72,040 frames, our evaluation on a FPGA shows that the gate control table requires 19.83 Mbits of static random-access memory (SRAM). This exceeds the FPGA's available SRAM capacity of 15.6 Mbits.

The substantial memory demand poses a significant challenge for deploying TSN, particularly given the limited on-chip memory available in TSN switch implementations. The gate control table is typically stored in on-chip memory to ensure rapid access and low latency [16]. However, on-chip memory resources in modern hardware platforms, such as FPGAs and ASICs, are constrained by considerations of area, cost, and power consumption [17], [18]. Consequently, the high memory usage of gate control tables can interfere with other critical switch functions, such as forwarding tables and packet buffering [19]. It may even exceed the available memory capacity of TSN switches.

To address the memory issue, we propose a memory-efficient TAS design called METAS. It transitions from a per-frame shaping approach to a per-flow shaping approach. Specifically, METAS introduces two types of rules: persistent rules for each flow and temporary rules for each frame. Only persistent rules are stored in the gate control table. Temporary rules are temporarily stored for frames that are currently within the switch because a temporary rule is dynamically generated from the persistent rule when a frame arrives and is released when the frame is transmitted. Since the number of frames buffered simultaneously in a switch is typically small (often fewer than a dozen) [16], [20]–[22], the memory consumption for temporary rules is minimal. This design trades off a small increase in logic resources required to compute temporary rules for significant memory savings in storing persistent rules.

We implemented the METAS prototype and integrated it into an open-source TSN switch [23] on the Xilinx Kintex-7 FPGA. Results show that METAS reduces the memory consumption of the gate control table from 14.34 Mbits to 288 Kbits when supporting 1,024 flows (51,968 frames) in a typical industrial application [14], [15], with only a 1.26% increase in logic resource usage relative to the total logic resources on the FPGA. When METAS is deployed to shape critical flows in a real TSN system, the latency of critical flows meets microsecond-level requirements, with jitter in the hundreds of nanoseconds, demonstrating that METAS ensures their real-time performance.

The main contributions of this paper are as follows:

- We propose a memory-efficient TAS design that significantly reduces the memory consumption of the gate control table.

[1] In this paper, a flow is defined as a sequence of Ethernet frames that share specific field values.

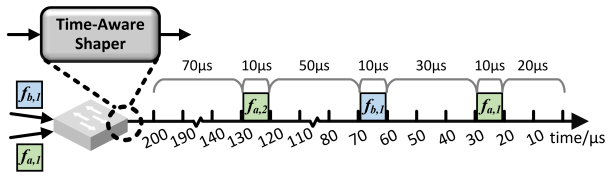

Fig. 1: TAS precisely controls the transmission time of each frame at the output port of a TSN switch.

- METAS shifts from a per-frame shaping approach to a per-flow shaping approach to achieve memory efficiency.
- We verified the significant reduction in memory usage achieved by METAS in a typical industrial TSN application while ensuring that the end-to-end latency and jitter requirements of the critical flows are still met.

II. Background and Motivation

This section introduces the TAS and its gate control table, followed by a simple example to illustrate the motivation of our work.

A. Time-Aware Shaper and Gate Control Table

Time-Aware Shaper (TAS), introduced by the IEEE TSN standard [12], is designed to shape critical flows, which are safety- and time-critical flows with strict periodicity, requiring bounded latency and ultra-low jitter. TSN also supports non-critical flows with relaxed constraints, but this work focuses exclusively on critical flows.

TAS controls the transmission time of each frame in critical flows at the output port of a TSN switch, as shown in Fig. 1. These times are pre-determined by a traffic [2] planning algorithm and expressed as *gate control rules*. The rules are written and statically stored in the TAS *gate control table* (Fig. 2). This configuration is completed prior to runtime (i.e., before any flows are transmitted).

During network runtime, the *gates* execute gate control rules stored in the gate control table to shape traffic, as shown in Fig. 2. Frames arriving at the TAS are dispatched to first-in first-out queues based on a pre-configured mapping. The gates after the queues execute the control rules, each consisting of two fields: an `interval` and the `states` of each gate. A gate transitions to the state (open or closed) specified by the `states` and remains in that state for the duration defined by the `interval`. When a gate is open, frames in the corresponding queue are transmitted. Gates execute the gate control rules cyclically, starting from the first rule, proceeding sequentially to the last, and then looping back to the first. This cyclic execution allows TAS to achieve precise control of frames' transmission times over the entire lifetime of the network.

The total duration covered by the gate control table is referred to as the hyperperiod. The hyperperiod, which models the cyclic transmission behavior of critical flows, is defined as the least common multiple (LCM) of all flow periods [13]. In Fig. 2, flows f_a and f_b have periods of 100 µs and 200 µs, respectively. Consequently, the hyperperiod is 200 µs, and the total duration of the gate control table (i.e., the sum of all `interval`) is also 200 µs.

B. Observations on TAS

Regarding the TAS defined in the TSN standard [12] (referred to as naive TAS in this paper), we make two observations:

First, each frame occupies two gate control rules: one to open the gate and another to close it. For example, in Fig. 2, the transmission of frame $f_{a,1}$ corresponds to the second and third rules, where the second rule opens gate2 for 10 µs and the third rule closes it. Similarly, frame $f_{b,1}$ corresponds to the fourth and fifth rules, and frame $f_{a,2}$ corresponds to the sixth and seventh rules.

Second, flows with shorter periods occupy more gate control rules within a hyperperiod due to having multiple frames. For instance, in Fig. 2, within the 200 µs hyperperiod, flow f_a (with a 100 µs period) has two frames, occupying four gate control rules in total.

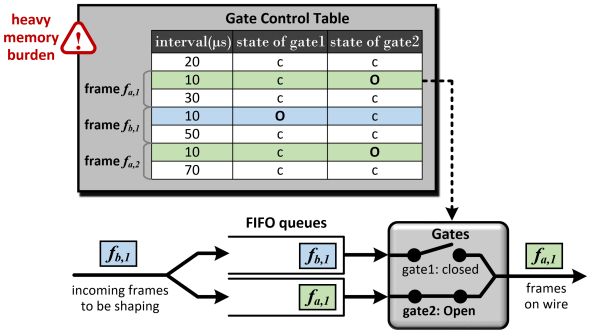

Fig. 2: Gate control table and gates in TAS. The gates executes gate control rules in the gate control table.

C. Memory Burden of Gate Control Table

The TAS described in Fig. 2 leads to a significant memory overhead in the gate control table. The primary reason for this heavy memory demand is that each frame requires two gate control rules, and the number of frames within a hyperperiod can reach a considerable amount. For example, consider a scenario with two flows: flow f_a and flow f_b. If their periods are 10 ms and 100 ms, respectively, the hyperperiod is 100 ms. During this hyperperiod, flow f_a has 10 frames, resulting in 20 gate control rules. However, if the period of flow f_a is 0.1 ms, it has 1000 frames within the hyperperiod, leading to 2000 gate control rules.

The large number of frames within the hyperperiod results in significant memory consumption for the gate control table. To assess this, we synthesized the gate control table on a Xilinx Kintex-7 FPGA. Our evaluation shows that, in a typical industrial application [14], [15] supporting 400 flows and a total of 72,040 frames, the gate control table requires 19.83 Mbits of memory. This memory demand exceeds the FPGA's maximum available memory capacity of 15.6 Mbits. Furthermore, in 62.94% of flow configurations within the industrial application, the memory usage of the gate control table surpasses the FPGA's memory capacity (§VI-B).

This heavy memory usage poses a significant challenge for deploying TSN due to the limited on-chip memory available in TSN switch implementations. Gate control tables are typically implemented using on-chip SRAM to ensure real-time performance. However, SRAM on-chip is severely constrained in hardware platforms such as FPGAs and ASICs due to cost, area, and power limitations [17], [18]. The excessive memory usage not only limits the resources available for critical functions such as forwarding tables and packet buffering [19], but also potentially exceeds the memory capacity of TSN switches. This makes memory consumption a critical bottleneck in TAS design.

III. Key Idea

We observe that the transmission times of a critical flow exhibit periodicity. Specifically, frames within the same flow are transmitted at consistent intervals. Such periodic behavior is frequently observed in the transmission schedule computed by many traffic planning algorithms [21], [24]–[26]. This periodicity serves as the foundation for our subsequent design.

[2]Traffic refers to the set of all critical flows.

Leveraging this periodicity, METAS shifts from a per-frame shaping approach to a per-flow shaping approach. The per-flow approach introduces two types of rules: persistent rules and temporary rules.

- A *persistent* rule records the period and transmission time of the *previous* frame for a flow, which are then used to compute the transmission time of the next frame upon arrival.
- A *temporary* rule records the transmission time of a frame that is currently within the switch. The temporary rule uses the transmission time to guide the gate on when to open or close.

METAS stores N persistent rules in the gate control table using SRAM, where N represents the number of flows. A temporary rule is dynamically generated from the persistent rule. It is created only when a frame arrives at the switch and is released once the frame is transmitted. Thus, a temporary rule only needs to be temporarily stored in the register while the corresponding frame is buffered in the switch. Since the number of frames buffered in the switch at any given time is typically small (usually fewer than a dozen) [16], [20]–[22], the temporary rules consume minimal register resources, which constitute only a small fraction of the total register resources on the hardware platform (§VI-A).

METAS significantly reduces the SRAM usage of the gate control table, with a slight increase in logic resources for dynamically computing temporary rules and a minimal amount of register resources for storing these temporary rules. Overall, METAS achieves a substantial decrease in total memory usage.

IV. Design

Following the key idea discussed in §III, METAS has two main focuses. The first is organizing the persistent rules to ensure efficient storage and fast access. The second addresses the temporary rules, detailing how to compute, manage, and execute them. The architecture of METAS, as illustrated in Fig. 3, consists of four components:

- *Gate Control Table with Persistent Rules*: Stores N persistent rules, one for each of the N flows. Each rule contains the flow's period and the transmission time of its *previous* frame.
- *Temporary Rule Generator*: For each arriving frame, it computes a temporary rule by calculating its transmission time. The transmission time is determined based on the flow's period and the transmission time of the previous frame.
- *Push-In First-Out Queue (PIFO)*: Temporarily stores and manages temporary rules. As a hardware priority queue, PIFO allows elements to be inserted at any position and permits output from the head [27]. In METAS, temporary rules are stored in the PIFO and sorted by transmission time, with the earliest placed at the head.
- *PIFO-based Gate*: Executes temporary rules by comparing the current time with the transmission time of the temporary rule at the PIFO head. When they match, the gate opens to transmit the corresponding frame.

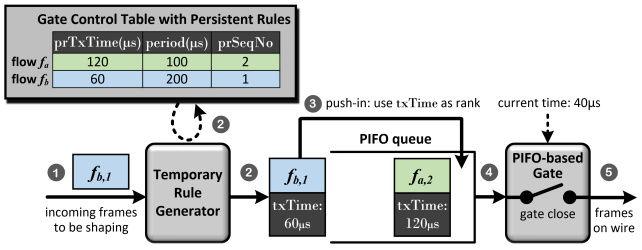

Fig. 3: Architecture of METAS.

A. Gate Control Table with Persistent Rules

The Gate Control Table with Persistent Rules stores N persistent rules, one for each critical flow, indexed by the unique flow identity. Fetching a rule based on the flow identity from the table has $\mathcal{O}(1)$ time complexity.

Each persistent rule contains three fields: `prTxTime`, which stores the transmission time of the previous frame of the flow; `period`, which represents the period of the flow; and `prSeqNo` records the sequence number of the previous frame to handle the rare occurrence of frame losses. The `prTxTime` and `prSeqNo` are updated by the Temporary Rule Generator upon the arrival of a new frame in the flow.

The table is configured before the switch begins operation. To initialize the table, a virtual "0-th" frame is created for each flow. This virtual frame records the transmission time of the frame preceding the first actual frame. Its transmission time is set to the first frame's transmission time minus the flow's period.

B. Temporary Rule Generator

The Temporary Rule Generator (referred to as Generator for simplicity) computes temporary rules for arriving frames. A temporary rule records the transmission time of a frame.

The Generator performs three actions for each frame. First, it calculates the transmission time `txTime` based on the persistent rule in the gate control table. After the transmission time is calculated, it is updated into the `prTxTime` field of the persistent rule. The sequence number of the current frame `seqNo` is also updated to the `prSeqNo` fields in the table. Finally, the frame, along with the temporary rule, is enqueued into the PIFO for shaping.

The transmission time calculation includes two scenarios: without frame loss (the typical case) and with frame loss (a rare edge case [14], [15], [28]).

Transmission Time Calculation Without Frame Loss. In the vast majority of cases without frame loss, the transmission time for each frame is calculated as:

$$f_{i,j}.\texttt{txTime} = (f_i.\texttt{prTxTime} + f_i.\texttt{period}) \bmod HP \quad (1)$$

This formula leverages the periodic nature of frame transmissions. By adding the flow's period to the `prTxTime` of the previous frame, the transmission time for the current frame $f_{i,j}$ is derived. The modulo operation with the hyperperiod (HP) ensures that the transmission time is represented as an offset within HP. Using offsets instead of absolute time aligns with TSN standards [29] and simplifies the representation and comparison of time values [21].

Transmission Time Calculation With Frame Loss. Although TSN employs robust reliability mechanisms, frame loss may still occur under rare conditions [28]. In such cases, the transmission time calculation must account for the lost frames.

We use the sequence number to detect frame loss. Each critical frame is assigned a sequence number [28], which increases sequentially within a flow. Frame loss is detected by comparing the sequence number of the newly arriving frame with the expected value, which is the previous frame's sequence number `prSeqNo` incremented by one. A mismatch indicates frame loss.

When frame loss occurs, the transmission time `txTime` is recalculated as follows:

$$f_{i,j}.\texttt{txTime} = (f_i.\texttt{prTxTime} + x \cdot f_i.\texttt{period}) \bmod HP \quad (2)$$

Here, x represents the number of skipped transmission cycles, which is the difference between the sequence number of the arriving frame and the sequence number of the previous frame.

Latency Analysis. The additional computation for transmission time introduced by the Generator may slightly increase the processing latency of each frame within the switch. In TSN, the upper bound of frame processing time in a switch can be considered during offline planning and is typically much smaller than the frame's sending interval. By appropriately adjusting this upper bound through offline planning, we can ensure that the increased processing time does not lead to performance degradation in terms of end-to-end latency or jitter [24]. In §VI-C, we evaluate the end-to-end latency and jitter in a real TSN system, showing that METAS effectively shapes traffic without compromising real-time performance.

C. PIFO for TAS

The PIFO queue temporarily stores and manages temporary rules, sorting them by transmission time with the earliest at the head. PIFO sorts incoming frames in just two clock cycles [27], outperforming traditional methods such as min-heap and binary comparator tree. This efficiency makes PIFO an optimal choice for TAS design.

Length of PIFO. In TSN, queues for critical flows are typically shallow because the number of frames buffered in a switch at any given time is small, often fewer than a dozen [16], [20]–[22]. Our design uses a PIFO queue depth of 10, which is sufficient to handle critical flows efficiently without over-provisioning.

PIFO uses flip-flops (the basic storage units of registers) to maintain the ordered list of temporary rules [27]. Under our queue length, experimental results show that the flip-flop consumption does not exceed 0.19% of the available resources on the FPGA (§VI-A). Therefore, the resource consumption for storing temporary rules is minimal.

Sorting of PIFO. The PIFO in our design follows the "earliest transmission time first" principle to sort temporary rules and their frames. However, since `txTime` values are represented as relative offsets within the hyperperiod rather than absolute times, directly ordering rules by `txTime` alone can lead to incorrect scheduling in certain cases.

For example, assume the current time is 15. A frame $f_{a,i}$ arrives with a `txTime` of 0, indicating it should be transmitted in the *next* hyperperiod. Meanwhile, a frame $f_{b,j}$ already in the queue has a `txTime` of 30. If we strictly order by `txTime`, $f_{a,i}$ would incorrectly be placed ahead of $f_{b,j}$, even though $f_{a,i}$ belongs to the next hyperperiod. This results in an invalid transmission order.

To address this, we adjust the `txTime` of temporary rules. If a rule's `txTime` is less than the current time, we add a hyperperiod HP to it, placing the rule in the next hyperperiod. This adjusted `txTime` is used only for sorting and is not updated in the persistent rule. When a new hyperperiod starts (i.e., when the current time resets to 0), the temporary rules in the queue are updated: if the `txTime` of a temporary rule exceeds a hyperperiod HP, we subtract HP from it. Since the PIFO queue is short, the cost of this update is negligible.

D. PIFO-based Gate

The PIFO-based Gate executes temporary rules and functions as follows.

If the PIFO queue is non-empty and the transmission time of the head rule matches the current time, the gate opens, allowing the critical frame to be transmitted immediately. Once the transmission is complete, the gate closes. In all other cases, the gate remains closed. This occurs when the PIFO queue is non-empty but the head rule's transmission time has not yet arrived, i.e., the current time is earlier than the transmission time, or when the PIFO queue is empty.

This simple mechanism ensures that frames are scheduled strictly according to their transmission times.

Interaction with Other Shaping or Scheduling Mechanisms. The PIFO-based Gate operates independently of other scheduling algorithms in TSN, such as credit-based shaping or strict-priority scheduling [29]. These algorithms, which manage non-critical traffic, are active only during idle slots, when the PIFO-based Gate is not scheduling critical flows. As a result, there is no interference between the PIFO-based Gate and other mechanisms.

E. Memory Usage Analysis

METAS stores persistent rules in the gate control table. The memory usage of the table is given by:

$$\mathbb{M}(\text{METAS}) = (w_{\texttt{prTxTime}} + w_{\texttt{period}} + w_{\texttt{prSeqNo}}) \times N \tag{3}$$

where $w_{\texttt{prTxTime}}$, $w_{\texttt{period}}$, and $w_{\texttt{prSeqNo}}$ are the widths of the respective fields in a persistent rule, and N is the total number of critical flows, which also represents the depth of the gate control table in METAS. According to the equation above, the space complexity of the gate control table in METAS is $\mathcal{O}(N)$.

For comparison, the memory usage of the naive TAS is as follows:

$$\mathbb{M}(\text{naiveTAS}) = (w_{\texttt{interval}} + w_{\texttt{states}}) \times D(\text{naiveTAS}) \tag{4}$$

where $w_{\texttt{interval}}$ and $w_{\texttt{states}}$ are the widths of the interval and gates states fields in each gate control rule of the naive TAS. The total number of gate control rules $D(\text{naiveTAS})$ is given by:

$$D(\text{naiveTAS}) = 2 \times \sum_{i=1}^{N} \frac{\text{LCM}(P_1, P_2, \ldots, P_N)}{P_i} + 1 \tag{5}$$

Here, P_i is the period of flow f_i, and the sum represents the total number of frames within a hyperperiod, where the hyperperiod is the least common multiple (LCM) of the periods $P_1, P_2, \ldots, P_N$. Thus, the space complexity of naive TAS is $\mathcal{O}(M \cdot N)$, where M is the average number of frames for flows within a hyperperiod.

METAS reduces the space complexity from $\mathcal{O}(M \cdot N)$ to $\mathcal{O}(N)$, making it a memory-efficient solution.

F. Limitation

Scalability of PIFO. Scalability concerns can arise with PIFO queues due to their resource consumption. Prior studies have shown that when the queue length reaches 1,024, PIFO implementations consume significant logic and register resources [27], [30]. However, since the PIFO queue in our design is shallow, scalability limitations are effectively mitigated, ensuring resource-efficient implementation.

Requirements for Planning Algorithms. Our approach leverages the periodicity of frame transmission times, which imposes a requirement on offline traffic planning algorithms: the transmission times of frames belonging to the same flow traversing the same link must exhibit periodicity. Fortunately, this condition holds for the majority of existing algorithms [24]–[26]. For algorithms that do not inherently meet this requirement, adapting them to METAS is straightforward, as simply adding a periodicity constraint is sufficient.

V. Implementation

We prototyped METAS on a Xilinx Kintex-7 FPGA, and integrated it into OpenTSN [23], an open-source TSN switch.

The gate control table is implemented using dual-port RAM. The fields `prTxTime`, `period`, and `prSeqNo` have widths of 20 bits, 20 bits, and 16 bits, respectively. The values of `prTxTime` and `period` are in multiples of 1 microsecond, as the minimum

planning granularity is typically 1 microsecond on 1 Gbps network links [24]. Thus, the 20-bit width for these fields is sufficient to represent durations up to one second, which is adequate for most TSN applications [14], [31]. The 16-bit width of `prSeqNo` corresponds to the frame sequence number used in the switch integrated with our prototype. The gate control table has a depth of 1024 entries, allowing the prototype to support up to 1024 critical flows.

PIFO is implemented using the classic parallel comparator-and-shift architecture [27], [32], supporting one push and one pop operation per cycle. To improve efficiency, two PIFO queues are used: one for temporary rules and one for frame metadata. This separation reduces the bit width of data that needs to be compared, as rules are sorted based on their transmission time. The depth of both queues is set to 10, which is typical for TSN designs [16], [20]–[22]. The rule queue has a width of 20 bits, matching the size of `prTxTime`, while the metadata queue has a width of 70 bits. The 70-bit frame metadata represents the frame itself, as the OpenTSN switch processes metadata instead of full frames throughout the entire pipeline to enhance efficiency.

The generator is implemented using two parallel circuits to compute `TxTime` for both frame loss and no frame loss scenarios, ensuring minimal processing time. In the case of frame loss, we use a straightforward iteration approach: repeatedly adding `period` to `txTime` to account for the lost frames, avoiding the use of multiplier digital signal processors. Since frame loss is rare and the number of consecutive frames lost typically only ranges from 3 to 4 [14], [15] due to the reliability mechanisms of TSN [28], the iteration count remains minimal. The modulus operation in Equation (1) is implemented using a comparator and subtractor. Since the value to be modded can exceed at most one hyperperiod, we simply subtract one hyperperiod to obtain the correct result, avoiding the need for more complex components.

VI. Evaluation

This section details the FPGA resource usage of the METAS prototype, evaluates memory savings in industrial settings, and evaluates its real-time performance in a TSN system.

A. Prototype

The METAS prototype was implemented on a Xilinx Kintex-7 FPGA [33], which provides 203,800 lookup tables (LUTs), 407,600 flip-flops (FFs), 15.6 Mbps of block random-access memory (BRAMs) and four 1 Gbps Ethernet interfaces. Each of the four Ethernet ports on the FPGA requires TAS deployment. Therefore, we evaluated the total resource consumption of the prototypes deployed in all four ports. For comparison, a naive TAS was also implemented as a baseline.

METAS supports 1,024 flows with arbitrary periods. To describe the capability of the naive TAS, we consider two flow periods commonly found in industrial applications: 100 µs and 20 ms [14], [15]. Based on these flow periods, the naive TAS can support 1,024 flows, but only if no more than 25% have a 100 µs period (equivalent to no more than 51,968 frames).

Table I summarizes the resource usage of the METAS and naive TAS prototypes, including BRAMs, FFs, and LUTs. These resources represent the consumption of SRAM, register and logic on the FPGA, respectively. The table also lists the utilization of these resources as a percentage of the FPGA's total capacity.

The BRAM consumption of the gate control table in METAS is only 288 Kbits. In contrast, the naive TAS nearly exhausts all available memory resources on the FPGA, consuming 14.34 Mbits, which accounts for 91.69% of the total memory capacity. METAS uses more FFs than the naive TAS, as the PIFO queue relies on FFs to maintain a sorted list [30]. However, FF usage increases by only 0.11% of the total available FFs on the FPGA. Similarly, LUT usage increases by 1. 26% due to dynamic computation and management of temporary rules in METAS. These results demonstrate that METAS achieves a highly efficient trade-off between SRAM savings and increased logic and register utilization.

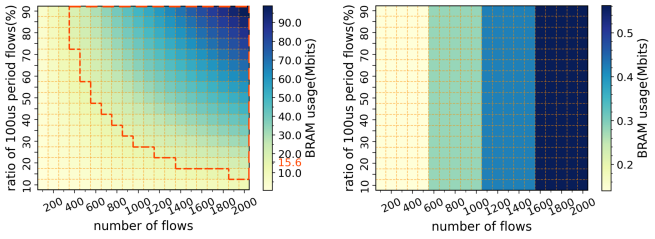

TABLE I: Footprint of naive TAS and METAS on a Xilinx Kintex-7 FPGA

Metric	BRAM	FF	LUT
Naive TAS	14.34 Mbits (91.69%)	313 (0.08%)	607 (0.30%)
METAS	288 Kbits (1.80%)	770 (0.19%)	3179 (1.56%)

B. Memory Usage

This section presents the synthesis results on the selected FPGA, focusing on the memory consumption of the gate control table in METAS and the naive TAS. These results were obtained in different flow setups. For flow setups, we selected typical traffic characteristics from an industrial application [14], [15], considering various combinations of flow periods and flow counts, which result in different numbers of frames within the hyperperiod. Specifically, we chose two representative periods: 100 µs and 20 ms, with flow counts ranging from 100 to 2,000 in increments of 100. The proportion of flows with a 100 µs period was progressively increased from 10% to 90%.

The results, shown in Fig.4a and Fig.4b, illustrate the memory resource usage across different flow counts and period ratios. The reported memory consumption is the total resource usage of METAS or naive TAS across all four Ethernet ports on the FPGA. Each Ethernet port deploys a separate instance of the METAS or naive TAS prototype, so the values in the figures represent the sum across all four ports. And the widths of the gate control tables in METAS and naive TAS are consistent with the descriptions in §V.

(a) naive TAS (b) METAS

Fig. 4: Memory usage comparison of naive TAS and METAS for different flow configurations

The memory usage of METAS consistently remained below 576 Kbits across all setups, whereas the memory consumption of naive TAS reached up to 99 Mbits. In approximately 62.94% of the setups, naive TAS exceeded the available BRAM capacity of the selected FPGA, which is 15.6 Mbits. The setups where the memory usage of naive TAS exceeds the available memory capacity are highlighted in Fig. 4a. A red dotted line marks the area in the upper right corner. The BRAM usage in this area was estimated using the fixed primitives algorithm, the same BRAM concatenation method. These results highlight the high memory efficiency of METAS.

As the proportion of 100 µs period flows increases from 20% to 80%, the memory usage of METAS remains constant, while naive

TAS's memory usage grows significantly (Fig. 5). This difference arises because METAS's resource consumption depends only on the total number of flows, whereas naive TAS's consumption scales with the number of frames within the hyperperiod. As the proportion of 100 µs period flows increases, the number of frames within the hyperperiod rises, leading to higher memory usage for naive TAS. This highlights a key distinction: METAS employs a per-flow approach, while naive TAS uses a per-frame approach.

Another notable observation is the "layered" pattern in METAS's memory usage. For example, the BRAM usage is consistently 144 Kbits for 100, 200, 300, ..., 500 flows, and 288 Kbits for 600, 700, ..., 1000 flows. This pattern results from BRAM concatenation in FPGA, where larger memory is created by combining basic BRAMs of fixed size. As a result, the synthesized memory usage exceeds the theoretical requirement, as shown in Fig. 6.

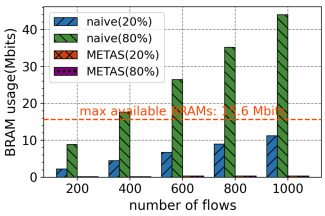

Fig. 5: BRAM usage of naive TAS and METAS under varying flow parameters

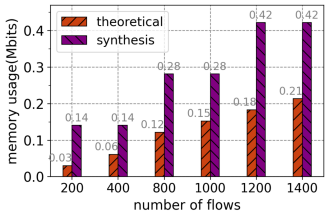

Fig. 6: Theoretical memory usage and synthesized memory usage on FPGA

C. Real-Time Performance

To evaluate the impact of METAS on real-time performance, we conducted tests in a real network built with OpenTSN switches, with METAS integrated into each switch. The network topology, shown in Fig. 7, is a dumbbell shape, consisting of four endpoints and two switches. The network contains 10 critical flows, five of which have a period of 100 µs and the remaining five have a period of 20 ms. The end-to-end latency requirements for each flow are 100 µs and 200 µs, respectively, with a jitter requirement of less than 1 µs. Additionally, each endpoint generates a background flow at line rate to serve as interference. The paths for these flows are randomly assigned. Each frame is 64 bytes in size, and the link rate is set to 1 Gbps. The precision of time synchronization is 48 nanoseconds.

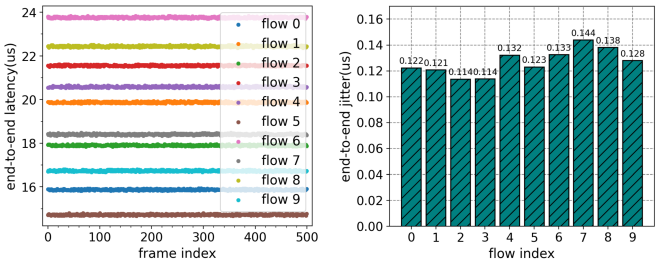

Fig. 7: Diagram and real system of dumbbell topology

We collected end-to-end latency data for 500 frames per flow, as shown in Fig. 8a. The results show that all ten flows meet their end-to-end latency requirements, all within the microsecond range. The jitter is minimal, as illustrated in Fig. 8b. For all ten flows, the jitter is approximately 120-140 nanoseconds, satisfying the stringent jitter requirements of the most demanding applications [34]. These results demonstrate that METAS improves memory efficiency without compromising the system's real-time performance.

VII. Related Work

Optimization for Gate Control Table in TSN. Current TSN research has primarily focused on generating gate control rules for TAS, i.e., traffic planning algorithms [21], [24]–[26], [35], with limited research addressing the memory usage of these gate control

(a) End-to-end latency (b) End-to-end jitter

Fig. 8: End-to-end latency and jitter of flows in the real system

rules. The work in [36] proposes an algorithm that reduces the number of gate control rules by merging multiple frames into a single rule, namely, transmitting them consecutively (back-to-back). While this approach reduces the rules, it has two key drawbacks: it doesn't address the underlying memory challenges in TAS, and it introduces jitter, as the order of the merged frames is non-deterministic [25]. Another work, [37], optimizes policing rules for critical flows in TSN. These rules are used to determine whether a frame arrives within the expected time window. They also face memory challenges due to a similar underlying cause as TAS. Although this design also uses a per-flow approach similar to METAS, it is limited by the number of flows with distinct periods. For example, it can support 1,024 flows with 8 distinct periods, but cannot support 9 flows with 9 periods. The same limitation is observed in a commercial TSN switch [38], one of the few for which TAS design details are publicly available.

Priority Queue. The METAS uses the priority queue, PIFO, to achieve fast sorting. PIFO provides a queue abstraction that allows elements to be inserted at any position based on their priority, while dequeuing elements from the head of the queue [27]. The time complexity for PIFO's enqueue and dequeue operations is $\mathcal{O}(1)$, requiring just one clock cycle to perform two push operations and one pop operation. However, its scalability is limited, particularly when the queue depth exceeds 1,024 [30]. To address this limitation, subsequent works such as AIFO [39], SP-PIFO [40] and BMW-Tree [41] have focused on improving PIFO's scalability. Push-In Extract-Out queue [30] and P-Heap [42] are priority queues that allow sorting of elements based on multiple priority levels. However, since METAS only requires sorting based on the transmission time of data frames, PIFO is sufficient for our purposes. In addition to PIFO, other data structures like min-heaps and binary comparator tree can also be used to implement priority queues. However, these structures have higher time complexity for dequeue operations, $\mathcal{O}(logn)$, where n is the queue length, making them less efficient than PIFO for fast shaping.

VIII. Conclusion

TAS in TSN controls the output timing of frames in critical flows by executing the gate control rules stored in the gate control table, ensuring bounded latency and low jitter. However, the traditional per-frame approach of TAS leads to considerable memory consumption in the gate control table, which can surpass the total memory capacity of TSN switches. Our proposed solution, METAS, achieves a memory-efficient TAS design by adopting a per-flow approach instead of the per-frame approach. METAS stores only one persistent rule for each flow in the gate control table and dynamically generates the corresponding temporary rules upon the arrival of each frame. With this design, METAS significantly reduces the memory usage of TAS at the cost of a slight increase in logic resources, while maintaining microsecond-level latency and nanosecond-level jitter.

3D-SubG: A 3D Stacked Hybrid Processing Near/In-Memory Accelerator for Subgraph GNNs

***Abstract*—Subgraph Graph Neural Networks (GNNs) are emerging as a promising approach to enhance GNN expressiveness, but their more complex graph structures with numerous independent and irregular subgraphs pose significant hardware deployment challenges. In this work, we propose 3D-SubG, a 3D stacked hybrid processing-near/in-memory accelerator for subgraph GNNs. With hybrid bonding packaging technology, a logic die is 3D stacked with a DRAM die for highly parallel memory accesses. The logic die employs digital SRAM-based processing-in-memory (PIM) macros to boost computation density and minimize data transfer. We further propose a bit-level non-zero gathering method to exploit graph sparsity for PIM, a workload-balanced mapping strategy for subgraph allocation onto different logic-to-DRAM blocks, and a distributed global pooling approach to reduce inter-block data movements. Experimental results show that 3D-SubG achieves average improvements of 146.11× in performance, 934.18× in area efficiency, and 1171.80× in energy efficiency compared to RTX 3090Ti.**

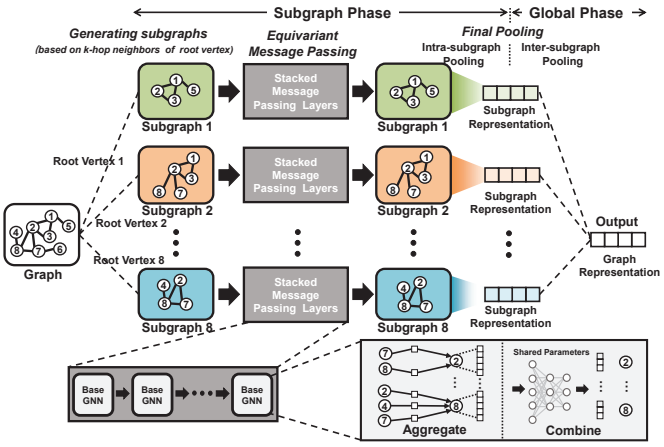

Fig. 1. An illustration of general subgraph GNN architecture.

I. Introduction

Graph Neural Networks (GNNs) have exhibited exceptional capabilities in handling graph-structured data across diverse domains, including graph mining [1], [2], recommendation systems [3], biology [4], chemistry [5], and so on. However, there is a growing consensus that traditional GNNs suffer from limited expressive power [6]–[9], constrained by the first-order Weisfeiler-Leman (1-WL) test [10], which is a common measure of GNN expressiveness. Studies indicate that GNNs equivalent to the 1-WL test fall short in capturing essential structural concepts, like motif counting (e.g., cycles, triangles) [9], [11], [12], which are proven to be pivotal in fields such as bioinformatics and chemoinformatics [13].

Recently, subgraph GNNs [9], [14]–[17], as illustrated in Fig. 1, are emerging to surpass the expressive power of traditional GNNs, approaching the level of 3-WL [9], [14], [18]. A general subgraph GNN operates in two phases: the subgraph phase, which confines computations to individual subgraphs, and the global phase, which processes all subgraphs. By decomposing a graph into multiple subgraphs processed by independent base GNNs, subgraph GNNs boost expressive power. However, they demand significantly higher hardware complexity due to the need to process numerous subgraphs with vertices often vastly exceeding the original graphs by orders of magnitude, as shown in Table II. It is worth noting that the same vertices shared among different subgraphs cannot reuse vertex feature vectors, because after message passing, the feature values of the same vertex differ across subgraphs.

Subgraph GNNs pose greater challenges for hardware deployment. Both CPUs and GPUs are inadequate for efficiently deploying GNN models [19]–[21], let alone the more complex subgraph GNNs. Existing GNN accelerators [19]–[22] are optimized for conventional GNNs. However, subgraph GNNs involve numerous independent subgraph operations performed by stacked base GNNs, requiring not only high computing power and memory bandwidth but also the ability to handle subgraph-level parallelism with irregular data accesses. The conventional GNN accelerators, optimized for single-graph processing, struggle with the parallel processing of subgraphs and the accompanying challenges, such as load balancing and massive uneven data movements.

To facilitate the efficient deployment of subgraph GNNs, we propose 3D-SubG, an accelerator that integrates 3D processing-near-memory (PNM) architecture with digital processing-in-memory (PIM) macros. The PNM architecture [23], [24] based on 3D hybrid bonding packaging technology achieves a tight coupling between DRAM and logic dies through numerous metal pillars. It boasts dense I/Os with a density about 110,000/mm² by around 3μm pitch [23], ensuring exceptionally high bandwidth communication be-

tween the two dies. By deploying subgraph GNNs using the 3D PNM architecture, 3D-SubG not only benefits from extremely high off-chip bandwidth but also leverages the parallel processing capabilities of multiple distributed logic-to-DRAM (L2D) blocks. Each logic block can independently interact with its corresponding DRAM block to fully exploit the inherent parallelism of subgraphs. Furthermore, we employ PIM macros [25], [26] on the logic die to execute matrix multiplications (MMs) during the combination stage of base GNNs, enhancing the computation density and minimizing weight (W) movements. In addition, the aggregation in base GNNs, formulated as a substantial MM between an ultra-sparse adjacency matrix A and a comparatively sparse feature matrix X, is remarkably irregular and sparse. This makes it more suited for SIMD-based engines, which are designed to flexibly handle such aggregation stage and other vector operations. The contributions are summarized as follows:

- Through comprehensive analysis and profiling, we propose 3D-SubG, a 3D stacked hybrid processing near/in-memory accelerator tailored for subgraph GNNs.
- PIM macros with fixed and regular computation pattern can hardly exploit sparsity in base GNNs. Thus, we employ a Digital PIM (DPIM) macro featuring flexible dataflow and propose bit-level non-zero gathering technique to further leverage data sparsity.
- To efficiently manage the varied workloads of subgraphs, we propose a greedy-based subgraph mapping algorithm, which mitigates workload imbalances among L2D blocks during the subgraph phase.
- The final global pooling step involves aggregating information across all subgraphs, which can lead to extensive inter-block data movement. We introduce a distributed pooling approach, which reduces the substantial inter-block data transfers and alleviates inter-block load imbalance.
- We have implemented 3D-SubG using 22nm technology. In comparison to RTX 3090Ti GPU, 3D-SubG demonstrates an average performace improvement of 146.11×, an area efficiency improvement of 934.18×, and an energy efficiency improvement of 1171.80×.

II. Basis of Subgraph GNNs

Fig. 1 illustrates the execution process of Subgraph Graph Neural Network (Subgraph GNN) models. After extracting the subgraphs from the initial graph based on the k-hop neighbors of the root vertices, the subgraph GNNs operate two phases: subgraph phase and global phase.

Subgraph phase comprises equivariant message-passing and intra-subgraph pooling. Stacked equivariant message-passing layers consist of base GNNs for subgraphs, which serve as the primary components in subgraph GNNs. The t-th iteration of the base GNN process within the k-hop subgraph G_v^k of vertex v can be expressed as follows:

$$h_v^t = \sigma^{(t)}\left(h_v^{(t-1)}, \sum_{w \in \mathcal{N}^1_{G_v^k}(v)} h_w^{(t-1)}\right) \tag{1}$$

TABLE I
NOTATIONS OF SUBGRAPH GNNS

Notation	Meaning	Notation	Meaning
$\mathbf{G}$	graph $\mathbf{G} = (\mathcal{V}, \mathcal{E})$	$\mathcal{V}$	vertices of $\mathbf{G}$
$N_G^k(v)$	k-hop neighbors of v in G	v	vertex of $\mathbf{G}$
G_v^k	k-hop subgraph of v	$\mathcal{E}$	edges of $\mathbf{G}$
h_v	feature of vertex v	$h_{\mathbf{G}}$	representation of $\mathbf{G}$

TABLE II
DATA VOLUME OF ORIGINAL GRAPHS AND SUBGRAPHS.

Dataset	Num. Graphs	Sum Vertices	Num. Subgraphs	Sum Vertices (Subgraph)			
				1-hop	2-hop	3-hop	4-hop
MUTAG	188	3371	3371	10813	21669	33181	43385
BZR	405	14479	14479	45549	97819	164545	234879
ENZYMES	600	19578	19578	94144	193130	289884	375652
PROTEINS	1113	43471	43471	205559	435963	701931	979121

where $\sigma^{(t)}$ is an arbitrary continuous function, h_v^t is the feature of vertex v at t-th iteration and $\mathcal{N}^1_{G_v^k}(v)$ denotes the 1-hop neighbors of v in its k-hop subgraph. Intra-subgraph pooling involves pooling the vertex features within each subgraph to derive the corresponding subgraph representation.

Global phase generates the final graph representation through inter-subgraph pooling. Specifically, the pooling is executed across all subgraphs to combine their representations into the final graph representation. This process can be expressed as:

$$h_{\mathbf{G}} = P^G\left(\left\{h_{G_v^k} \mid v \in \mathbf{G}\right\}\right) \tag{2}$$

Here, P^G represents the graph pooling, $h_{G_v^k}$ is the subgraph representation and $h_{\mathbf{G}}$ is the final graph representation.

III. Architecture and Mapping of 3D-SubG

A. Overview of 3D-SubG Hardware Architecture

The overall architecture of 3D-SubG is depicted in Fig. 2. It consists of a DRAM die featuring a 6 × 6 block configuration, with a logic die densely integrated beneath it using uniformly distributed copper metal pads at the bond interface. Similarly, the logic die is segmented into 6 × 6 blocks, constrained by packaging technology. Each logic block is required to be vertically aligned with its respective DRAM block, enabling direct high-bandwidth data exchanges within this logic-to-DRAM (L2D) block. Additionally, the logic blocks are interconnected through an on-chip 2D mesh network, facilitating efficient data communication among all L2D blocks.

A DPIM-based GNN engine is implemented on the logic die within a L2D block to deliver efficient parallel computing capabilities. Each GNN engine is equipped with eight DPIM macros, segmented into four combination lanes for MM operations required in GNN combination calculations. The combination calculations are characterized by their regular and static memory access patterns suitable for DPIM macros. The engine also includes SIMD cores for handling irregular and dynamic memory accesses in aggregation tasks and other vector computations, such as pooling. To harness the inherent

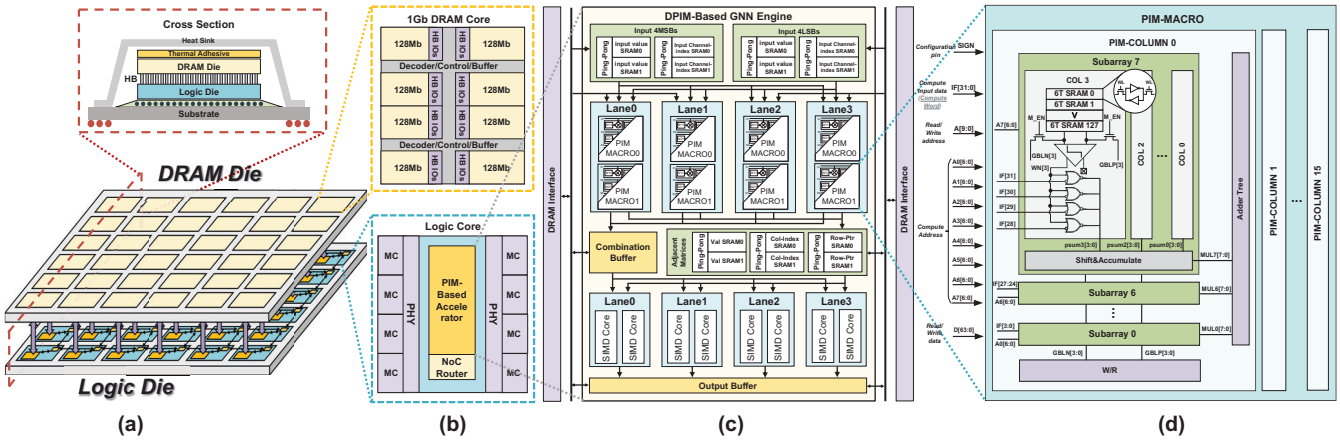

Fig. 2. An overview of the proposed 3D-SubG architecture: (a) the hybrid bonding PNM architecture, (b) a logic-to-DRAM block with a DRAM block and a logic block, (c) micro-architecture of DPIM-based GNN engine inside a logic block, and (d) the micro-architecture of DPIM.

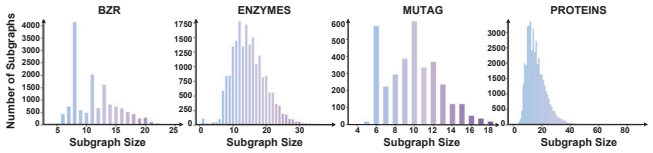

Fig. 3. The count of subgraphs (hop=3) of specific sizes across four datasets reveals an uneven distribution of subgraph sizes.

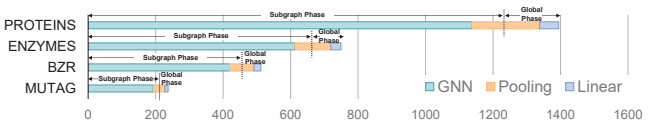

Fig. 4. Runtime breakdown of a subgraph GNN (NGNN) on four different datasets with over 95% attributed to base GNN and pooling.

sparsity of GNNs, a specialized channel-independent DPIM is used in conjunction with our bit-level non-zero (NZ) value gathering method depicted in Fig. 5. For aggregation, the Compressed Sparse Row (CSR) format is used for the adjacency matrix A with 4 flexible SIMD lanes performing sparse matrix multiplication to enhance efficiency in sparse data processing.

During the subgraph processing phase of subgraph GNN, workloads are distributed to L2D blocks at the granularity of subgraphs. This mapping strategy maximizes the parallel execution of subgraphs by leveraging the spatially distributed nature of L2D blocks. Specifically, the 6 × 6 array of L2D blocks enables concurrent processing of up to 36 subgraphs. Once the subgraph phase is completed, the central block collects the computational results from its neighboring blocks and proceeds to execute the final global pooling phase.

B. Sparse-Aware DPIM with Bit-Level Non-Zero Gathering

The primary operator of subgraph GNN is the base GNN, as depicted in Fig. 4. The input matrix X exhibits high sparsity, as evidenced in Table III. Traditional PIM macros, constrained by their rigid dataflow, often find it challenging to effectively

TABLE III
SPARSITY STATISTICS OF THE GNN PART IN NGNN [14]

manage sparse data. As illustrated in Table III, among the two matrices involved in the combination stage, weight matrix W has very low sparsity and can be treated as dense, whereas input X displays significantly higher sparsity. Therefore, a weight-stationary DPIM can directly utilize W without additional optimization. The primary focus of optimization efforts should be on how to efficiently exploit the sparsity of X.

This work introduces a channel-independent digital PIM (DPIM) macro for sparse combination computations. Conven-

tional DPIMs are constrained by their reliance on a single subarray address signal, limiting them to selecting weights only from the same position within each subarray. Our DPIM macro, however, allows each input channel to have its unique subarray address signal. This enables concurrent feeding of data from multiple input channels into the DPIM macro for multiplication with different weights stored at various addresses within the subarrays. This design provides an opportunity to leverage sparsity by exchanging input data within the same input channel across different compute words. Different input channels can independently select weights from distinct subarray addresses, ensuring computational accuracy after data exchange. For clarity, we use the term "compute word" to describe the input data that a DPIM macro can process within one clock cycle, analogous to the "word" in SRAM, which denotes the data that can be written or read in a single clock cycle. Furthermore, our DPIM macro employs a 4-bit serial computing approach instead of the conventional 1-bit serial computing, significantly boosting its computing capability.

The bit-level non-zero (NZ) gathering method we propose is illustrated in Fig. 5. The principle of this method involves exchanging data among different compute words within the same input channel. This process gathers non-zero values into specific compute words, thereby increasing the number of all-zero compute words that can be bypassed during computation. It is important to note that compute words composed of different bits from the same data cannot be exchanged, as this would disrupt the proper functioning of the accumulator. Fig. 5 illustrates this method using a DPIM macro with a 4×4 compute word as an example. Before optimization, all four compute words need to be computed. However, after applying NZ gathering, only two compute words remain for processing. While element-level NZ gathering is effective, Table III demonstrates that higher bit-level sparsity makes bit-level NZ gathering even more advantageous, as will be further evidenced in the evaluation results.

C. Load-Balanced Mapping of Subgraphs onto L2D Blocks

In the subgraph phase, the workload is allocated to the L2D blocks at the subgraph granularity. The significant size differences among subgraphs, as presented in Fig. 3, can lead to an imbalanced workload across blocks during parallel computation. To address this issue, we introduce a balanced mapping strategy, as shown in Algorithm 1. It is based on the assumption that the workload of a subgraph generally correlates positively with its vertex count, although the irregular sparsity of the subgraph also plays a role. To estimate the workload of a subgraph, we consider its vertex count and employ a greedy algorithm for subgraph assignment. Initially, we sort the subgraphs in descending order based on their vertex counts. Subsequently, we sequentially assign each subgraph to a target L2D block. The target block is determined based on the number of tasks already assigned to each block. The block with the fewest tasks is the target block. After each subgraph assignment, the record of the block with the fewest tasks is updated, ensuring next subgraph to be assigned in a load-balanced manner.

Algorithm 1: Load-Balanced Mapping of Subgraphs

Input: Subgraph Array $SubG_{array}$, Adjacency matrices array A_{array}, L2D Block Array $Block_{array}$, Gragh Array G_{array}
Output: Block Workload Array BW_{array}

for *each graph* $g \in G_{array}$ **do**
  Update $SubG_{array}$, A_{array}
  for *each subgraph* $subg \in SubG_{array}$ **do**
    $Size[subg] = Number\ of\ rows\ in\ A_{array}[subg]$
  end
  Sort $SubG_{array}$ by $Size$ in descending order
  $Minblock$: the block with the fewest allocated workloads
  for *each subgraph* $subg \in SubG_{array}$ **do**
    for *each block* $b \in Block_{array}$ **do**
      if $BW_{array}[b] < BW_{array}[Minblock]$ **then**
        $Minblock = b$
      else
        Continue
      end
    end
    $BW_{array}[Minblock] = BW_{array}[Minblock] + Size[subg]$
  end
end

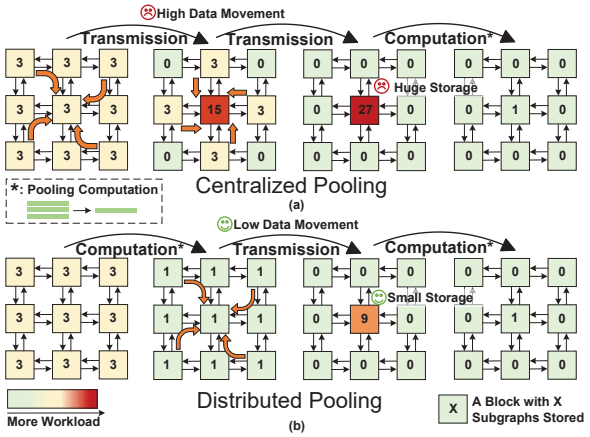

Fig. 6. (a) Centralized global pooling lead to massive data tranfer and imbalanced computation. (b) The proposed distributed pooling method reduces the inter-block data transfer and alleviates workload imbalance.

D. Distributed Global Pooling Approach

Although pooling is often overlooked, global pooling in subgraph GNNs involves significant inter-block data movement, making its optimization crucial. During the subgraph phase, subgraphs are distributed to different L2D blocks. Global pooling requires aggregating computational data from all subgraphs. The most straightforward approach is to use NoC to transmit all subgraph data to a central block, which then performs the final pooling. However, this approach incurs an $O(n)$ data transmission cost through the NoC, where n is the number of subgraphs. The Table II demonstrates that the

number of subgraphs is exceptionally large and continues to increase with the addition of hops. Furthermore, as illustrated in the Fig. 6(a), this method concentrates all computational loads on the central block, resulting in a highly unbalanced load distribution.

Considering the characteristics of pooling, local pooling can be performed within a block first, followed by global pooling. After local pooling, the data volume of each block is reduced to that of a single subgraph. Consequently, the total amount of data that needs to be transferred shifts from being proportional to number of subgraphs to being proportional to number of blocks, thereby significantly mitigating load imbalance and reducing data movement overhead, as shown in Fig. 6(b).

IV. Evaluation

A. Experimental Setup

Architecture Configuration. The specification of 3D-SubG is shown in Table IV, which features a configuration of 6×6 L2D blocks. Every logic block is equipped with eight PIM macros, each comprising a 1024×64-bit SRAM cell array. These SRAM cells are organized into an 8×16 subarray structure, capable of processing 8×16 INT8-by-INT4 operations every two clock cycles. Additionally, each logic block incorporates a total of 276 kB ping-pong SRAM buffers. The NoC on logic die employs a mesh topology with a 64-bit flit width. The DRAM specifications are based on previous research [24] and appropriately scaled to align with this work. The DRAM blocks are arranged in a 6×6 configuration, mirroring the layout of logic blocks. Each DRAM block has a capacity of 16 MB and provides a die-to-die bandwidth of 4.8 GB/s.

Hardware Implementation. The DPIM macro on logic die is evaluated using Cadence Virtuoso for area and power consumption. The on-chip SRAM is generated with ARM Artisan SRAM Compiler, which also supplies data on area and power. The remaining digital components are synthesized using Cadence Genus. The logic die is synthesized using commercial 22nm process, operating at clock frequency of 200 MHz and voltage of 0.8V. The energy cost of DRAM access is estimated as 0.88 pJ/bit [25]. The energy cost of NoC is estimated as 1.1 pJ/bit/hop [27]. Moreover, a C++ simulator is developed to assess the performance, data transfer rates, and utilization of the overall 3D-SubG system.

Benchmarks and Datasets. To comprehensively evaluate 3D-SubG, we deployed and evaluated the Nested GNN (NGNN) [14] on four widely-used datasets in the subgraph GNN domain: BZR [28], MUTAG [29], ENZYMES [30], and PROTEINS [31], all of which belong to TU datasets [32]. NGNN adheres to the general subgraph GNN structure. No specific optimizations were implemented, thereby enabling an unbiased evaluation of 3D-SubG's compatibility with the general subgraph GNN framework. For the model configuration, we adopted the setup outlined in [14], utilizing NGNN with GCN as the base GNN, a hop value of 3, and a hidden dimension of 32. We trained the floating-point model and then quantized it, where the adjacency matrix A and weights W were quantized to INT4, while the graph representation matrix X and model outputs were quantized to INT8. We demonstrated that this quantization scheme has a negligible impact on model accuracy across all four datasets examined, as shown in Table V.

TABLE IV
Specifications of Logic Die and DRAM Die

Logic Die	Specification
Area	98.22 mm^2
Technology	22nm
Block	6×6 blocks
DPIM	12.8GOPS/macro (int8 mul int4)

[1] The training process employed the 10-fold cross-validation method.

Baselines. To the best of our knowledge, 3D-SubG is the pioneering accelerator tailored for subgraph GNNs. For fairness, we refrain from comparing it with conventional GNN accelerators, whose target task is traditional GNNs. To validate the efficacy of the proposed techniques, we utilize an unoptimized variant of 3D-SubG as the benchmark for comparison. Lastly, we also conducted a comparative analysis of latency, power consumption, and area efficiency with an NVIDIA RTX 3090Ti utilizing PyTorch Geometric.

B. Evaluation Results

Efficiency Evaluation for Bit-Level Non-Zero Gathering. As in Fig. 7, bit-level NZ gathering achieves an average reduction of 2.5×, 1.5×, 1.53×, and 1.93× compute words on BZR, MUTAG, ENZYMES, and PROTEINS, respectively, with the reduction directly proportional to DPIM's computation time. Additionally, we compared bit-level versus element-level NZ gathering, observing reductions of 1.38×, 1.08×, 1.13×, and 1.12× across the datasets. The technique's effectiveness depends on data sparsity and distribution, with BZR showing the greatest improvement due to its highest sparsity as in Tabel III.

Efficiency Evaluation for Load-Balanced Subgraph Mapping. The benefits of load-balanced subgraph mapping are shown in Fig. 8. On the BZR, MUTAG, ENZYMES, and

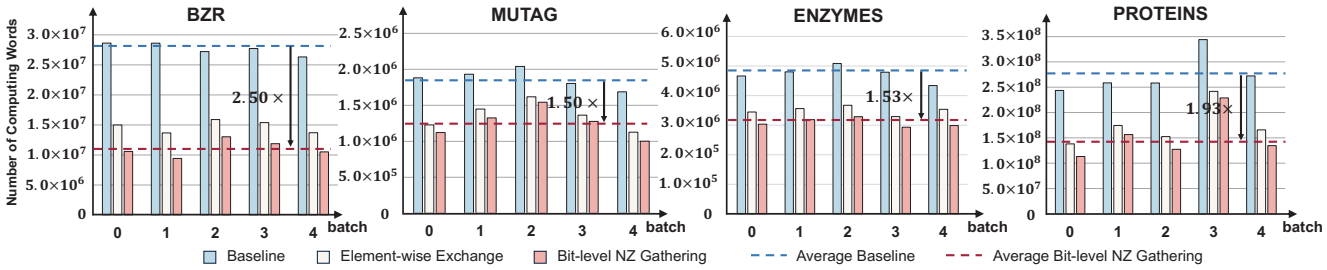

Fig. 7. Number of compute words for DPIM on four datasets.

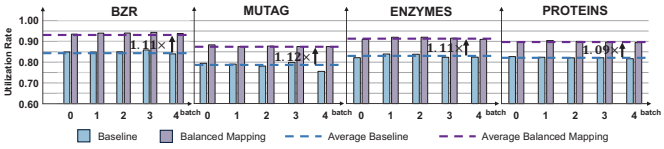

Fig. 8. Average utilization rate of L2D blocks in the subgraph phase.

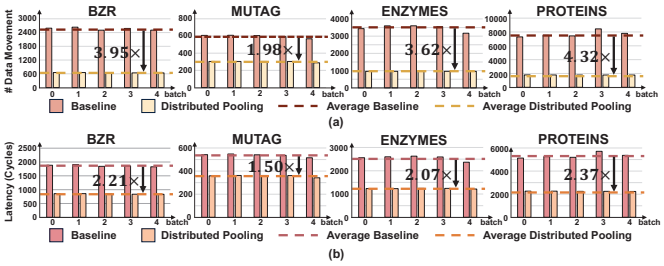

Fig. 9. (a) Amount of data transferred on NoC during the global phase; (b) The latency of global pooling.

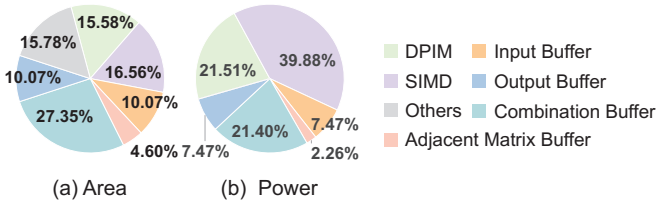

Fig. 10. Area and power breakdown of logic die.

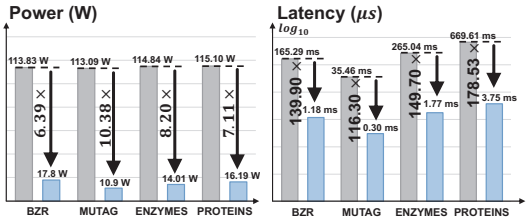

Fig. 11. Comparison results of 3D-SubG with RTX 3090Ti GPU.

PROTEINS datasets, this technique improved the L2D block utilization by 1.11×, 1.12×, 1.11×, and 1.09×, respectively, increasing the overall utilization from around 80% to approximately 90%.

Efficiency Evaluation for Distributed Global Pooling. Distributed global pooling theoretically diminishes the data transfer required for global pooling from $O(n)$ to $O(m)$, where n and m denote the number of subgraphs and L2D blocks, respectively. Experiments confirm this, indicating that on the BZR, MUTAG, ENZYMES, and PROTEINS datasets, distributed pooling attains reductions in inter-block data movement by 3.95×, 1.98×, 3.62×, and 4.32×, respectively, as shown in Fig. 9. By distributing the computational load across all blocks and markedly decreasing data transfer, the total latency of global pooling is also decreased, achieving reductions of 2.21×, 1.50×, 2.07×, and 2.37× on four datasets.

Area and Power Overhead. The implementation results show that the total area of the logic die is 98.22mm^2, with a total power consumption of 4.17W. The area and power breakdowns are shown in Fig. 10.

Overall Performance. We compare 3D-SubG with RTX 3090Ti GPU using PyTorch Geometric, with results presented in Fig. 11. This comparison includes power consumption related to die-to-die and NoC data transmission, as well as DRAM static power consumption. Across four datasets, 3D-SubG outperforms GPU in latency performance by 139.90×, 116.30×, 149.70×, and 178.53×, respectively. Simultaneously, it achieved significant reductions in power consumption by 6.39×, 10.38×, 8.20×, and 7.11×. On average, 3D-SubG exhibited 146.11× improvement in performance, 1171.80× increase in energy efficiency, and 934.18× enhancement in area efficiency compared to RTX 3090Ti GPU.

V. Conclusion

We develop a 3D stacked accelerator, named 3D-SubG, tailored for subgraph GNNs. 3D-SubG is built upon a processing-near-DRAM architecture enabled by hybrid bonding packaging to achieve parallel memory accesses, where the DRAM die is 3D stacked with logic die equipped with PIM macros. For the subgraph phase and global phase in subgraph GNNs, we have proposed load-balanced subgraph mapping and distributed global pooling strategies, respectively. To efficiently manage sparse computations to benefit PIM, we introduced a bit-level non-zero gathering method. On average, 3D-SubG outperforms RTX 3090Ti GPU by 146.11× in performance, 934.18× in area efficiency, and 1171.80× in energy efficiency.

***Abstract*—In recent years, AI-assisted IC design methods have demonstrated great potential, but the availability of circuit design data is extremely limited, especially in the public domain. The lack of circuit data has become the primary bottleneck in developing AI-assisted IC design methods. In this work, we make the first attempt, SynCircuit, to generate new synthetic circuits with valid functionalities in the HDL format.**

SynCircuit automatically generates synthetic data using a framework with three innovative steps: 1) We propose a customized diffusion-based generative model to resolve the Directed Cyclic Graph (DCG) generation task, which has not been well explored in the AI community. 2) To ensure our circuit is valid, we enforce the circuit constraints by refining the initial graph generation outputs. 3) The Monte Carlo tree search (MCTS) method further optimizes the logic redundancy in the generated graph. Experimental results demonstrate that our proposed SynCircuit can generate more realistic synthetic circuits and enhance ML model performance in downstream circuit design tasks.

I. Introduction

The ever-increasing demands for chip performance have caused escalating integrated circuit (IC) complexity, challenging traditional Electronic Design Automation (EDA) methodologies. In recent years, AI-assisted IC design techniques have demonstrated remarkable potential in accelerating the chip design process. Notable AI for EDA applications include automated chip design generation [1], [2], [3], fast chip quality prediction [4], [5], [6], [7], [8], [9], [10], and automated chip design planning [11].

SynCircuit: Pathway to Big Data in Circuits. Compared with generating datasets with limited circuits in the public domain, we believe the automated generation of a large number of *synthetic* circuits is the most promising way to *completely solve* the circuit data availability problem in the foreseeable future. In this work, we demonstrate the feasibility of this promising direction with a novel synthetic circuit generation framework named SynCircuit.

To the best of our knowledge, SynCircuit proposed in this work is the first technique to automatically generate brand-new synthetic circuits with valid functionalities. Specifically, we achieve this with novel customized graph learning algorithms and follow-up refinement techniques. The synthetic circuits are in the RTL stage and support hardware description language (HDL) code format. They can be automatically synthesized into regular netlists and turned to layouts with commercial tools. These synthetic designs can not only enhance the training and robustness of AI models by providing diverse and extensive datasets but also may serve as benchmarks for assessing the performance of existing design algorithms [12], [9], [13]. In addition, our proposed directed graph generation framework potentially applies to other tasks, such as neural architecture search (NAS) and Bayesian optimization [14], [15], [16].

SynCircuit generates synthetic circuits with 3 phases:

Phase 1. Generation of Large Directed Cyclic Graph (DCG). Circuit design code (i.e., HDL code) can be equivalently represented as directed cyclic graphs (DCG), allowing the utilization of graph generation algorithms to create synthetic circuit designs. However, most machine learning (ML) research on graph generation has focused on undirected graphs [17], [14], [18], [19], [20], leaving unsolved challenges on generating *directed graphs*. For instance, edge predictions in these prior works are determined by applying a *symmetric operator* to the pairwise node embeddings. Also, spectrum-based generation techniques like Spectre [21] and DiGress [22] rely on properties specific to undirected graphs, such as *symmetric Laplacian matrices*. Some works generate directed graphs in an autoregressive manner following the topological order [15], [23]. However, they do not apply to directed *cyclic* graphs, where a topological sort does not exist. In summary, the generation of DCG is not a well-solved problem, not only for synthetic circuit data generation in EDA applications, but also in the general AI community.

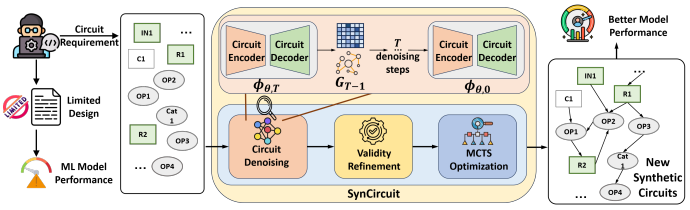

Fig. 1: The overview of SynCircuit. It addresses the serious design scarcity issue by generating new synthetic circuits. Through a three-stage process consisting of denoising, validity refinement, and optimization, SynCircuit can generate an unlimited number of synthetic circuits suitable for downstream ML tasks.

In response to the challenges posed by large directed cyclic graphs in circuit designs, we propose a graph generation algorithm for digital circuits. We employed a diffusion generation framework for graph generation and designed an efficient and low-cost denoising network that includes an encoder and a decoder. For the graph encoder, a directed messaging-passing neural network is utilized to better capture the local features of graphs while only requiring a relatively low memory consumption. For the decoder, we model the directed edge relation based on learnable translated embeddings.

Phase 2 & 3. Refinement of Synthetic Circuits. Additionally, how to ensure the graph validness, i.e., satisfying the circuit constraints, is not also fully explored in graph generation, especially in a one-shot manner. Given the fanin constraints and combinational loop prevention requirements, we propose a probability-guided graph post-processing strategy to further refine the invalid synthetic graph obtained from the denoising process. This technique sequentially processes the fan-in edges of each node, which not only ensures that the resulting circuit satisfies the constraints but also preserves the generative information of the diffusion model as much as possible.

We also point out the logic redundancy problem in the synthetic circuits. To further alleviate the redundancy of the generated designs and improve their utility as data augmentation in downstream tasks, we also employ Monte Carlo Tree Search (MCTS) to further fine-tune the generated graphs. This approach allows us to obtain higher-quality graphs that are better suited for real applications.

We summarize our contributions as follows:

- To the best of our knowledge, we are the first to propose a framework for generating digital circuits at the RTL level from a graph generation perspective. This framework comprises three components in the generation phase: directed cyclic graph generation, probability-guided postprocessing, and MCTS-based optimization.
- We propose a graph generative model solution targeting the challenging directed cyclic graph generation task. We utilize the diffusion framework and reconstruct the edge direction information through an asymmetric edge decoder.

- To further alleviate the redundancy of the generated designs and improve their utility as data augmentation in downstream tasks, we employ MCTS to further fine-tune the generated graphs. This approach obtains higher-quality graphs with optimized logic redundancy which are better suited for real applications.
- We conducted experiments on graph structural property similarity evaluation and demonstrated that SynCircuit generates more realistic graphs. Experiments on early RTL-stage PPA prediction show that SynCircuit can help alleviate the data availability problem in AI-based solutions for EDA tasks.

II. Problem Formulation

DCG representation of HDL code. Given a circuit design HDL code D, it can be mapped to a circuit graph representation G through a bijection function $f : D \leftrightarrow G$ using our developed parser. Here, G is a directed cyclic graph represented as (V, E, X), where V denotes the set of nodes, E represents the set of edges with $e_{i,j} \in E$ indicating a directed edge from v_i to v_j, and X represents the attributes of the nodes. The node attributes include node *type* and *width*. The node types are primarily categorized into IO port, arithmetic operator, register (reg), bit selection, and concatenate operator. The width attribute reflects the output signal width of the corresponding node.

Circuit constraints $\mathcal{C}$. To ensure that the graph can be parsed back into HDL code, valid G must satisfy two types of constraints:

- The node type uniquely determines the number of parent nodes. For example, a node of the type "mux" requires three parent nodes, while the type "add" requires two.
- The graph must not contain any combinational loops. The combinational loop is defined as a cycle that does not include any registers, which would cause timing violations.

Generate new large circuits. In order to provide generation flexibility, we will use the generative model to produce edges E conditioned on the specified node number V and attributes X by users. Our objective is to learn the probability distribution $P(G \mid V, X)$ from a set of real circuit HDL codes through their graph representations $\{G_i\}$. This will enable the generation of a series of new synthetic circuit graphs $\{G_i^{syn}\}$. We aim for these synthetic circuit design graphs to closely resemble real designs in terms of topological structure and satisfy all the circuit constraints $\mathcal{C}$. Moreover, considering most registers in real designs will not be removed in the synthesis stage, we require the generated circuits to have as low logic redundancy as possible.

III. Overview of SynCircuit

Initially, the realistic designs are converted into directed cyclic graph representation. We subsequently trained a diffusion model $P(G \mid V, X)$ on these designs. In the generation stage, as Figure 2 shows, our proposed circuit generation process consists of three phases: initial graph generation, validness post-process, and optimization refinement.

$$P(G) \xrightarrow{\textcircled{1}} G^{ini} \xrightarrow{\textcircled{2}} G^{val} \xrightarrow{\textcircled{3}} G^{opt}$$

In the generation phase of ❶, we adopt the trained diffusion model and apply the denoising process to obtain an initial synthetic graph G^{ini} with a corresponding edge probability matrix $P_E^{(t=0)}$. The value of (i, j) in P_E represents the directed edge $e_{i,j}$ existence probability. In phase ❷, we propose an autoregressive method to determine the edges based on the G^{ini} to ensure that the refined graph G^{val} satisfies all the circuit constraints $\mathcal{C}$. In the final phase ❸, we address the issue of significant logical redundancy in the generated circuits. G^{val} is fine-tuned by the MCTS-based method, reducing logic redundancy and thereby enhancing the performance of downstream tasks. In the following subsections, we will explain each stage in detail.

IV. Phase 1. DCG Generation Technique

Limitation of prior works on DCG generation. Many prior graph generation works utilize a symmetric operator or semi-positive-definite Laplacian matrix to assign edges. This symmetric assumption does not support the asymmetric edge in the directed cyclic graph. For directed acyclic graphs (DAGs), previous work [23], [15] addresses DAG generation by sorting node order based on the topological structure and then generating nodes in a layerwise manner. Topological sorting ensures that a node's parent nodes always precede it in the order. Consequently, the edge direction is automatically determined. However, there is no topological node ordering in the DCG graph since the nodes in a loop share the same topological level.

The proposed DCG generation technique overview. To the best of our knowledge, we are the first to address the task of generating directed cyclic graphs using a diffusion model framework. The method involves a forward diffusion process and a reverse denoising process. In the **forward process**, we gradually corrupt the adjacency matrix A by adding noise, transforming it from the original data distribution into a noisy distribution. The goal of the reverse process is to reconstruct the original adjacency matrix from the noisy version by reversing this corruption. During the **reverse denoising process**, a denoising neural network ϕ_θ with an *encoder* and a *decoder* is trained with real circuits. The *encoder* processes the node attributes and the noisy adjacency matrix to generate node representations that consist of rich graph structural information at each denoising step. The *decoder* utilizes these node representations to effectively reconstruct the ground truth edge connections. By training ϕ_θ in the reverse process, the model learns to progressively denoise the graph structure, ultimately generating synthetic circuits similar to realistic ones.

A. Forward Process

In the forward diffusion process, we progressively corrupt the adjacency matrix A by applying a series of predefined transition matrices, introducing noise at each time step t. Specifically, starting from the initial graph $G^{(0)} = (X, A^{(0)})$, the corrupted adjacency matrix $A^{(t)}$ at time t is obtained via a Markov process:

$$A^{(t)} = A^{(t-1)}\tilde{Q}_A^{(t)}$$

where $\tilde{Q}_A^{(t)}$ is the noise transition matrix at time t. By iteratively applying these transitions, we gradually transform $A^{(0)}$ into a noisy distribution. To control the degree of corruption, we employ a scheduling strategy (e.g., cosine schedule [24]) to adjust the noise level over time. The scheduling ensures that the corrupted adjacency matrices $A^{(t)}$ smoothly transit from the original data distribution to a predetermined noise distribution.

B. Denoising Process

In the denoising diffusion process, our goal is to recover the original adjacency matrix $A^{(0)}$ from the noisy matrix[1] $A^{(T)}$. Based on the node attributes[2] X, we model the conditional probability $p_\theta(G^{(t-1)}) = p_\theta(A^{(t-1)}|A^{(t)}, X, t)$, parameterized by a denoising network $\phi_{\theta,t}$. In the generation stage, the $\phi_{\theta,t}$ will reconstruct a probability matrix P_E^{t-1} given $G^{(t)}$. The new graph G^{t-1} will be updated by sampling the edge existence probability matrix P_E^{t-1}.

C. Encoder Design for Large Graphs

In the denoising network architecture $\phi_{\theta,t}$, the encoder is to capture the structural information of the input noisy graph $G^{(t)}$. Handling large-scale graphs with more than 10K nodes poses computational challenges. To address this, we design an efficient encoder based on Message Passing Neural Networks (MPNNs), which have a computational complexity linear to the number of edges $|E|$.

The encoder generates the representation for each node. When initializing the node embeddings, we use an MLP to obtain a time embedding for the current step t and combine it with the node attributes. By introducing the time step information t which conditions the encoder at different noise levels, we can improve the denoising

[1] In training, the $A^{(T)}$ is obtained from the forward process. In inference, we randomly sample a completely noisy adjacency matrix

[2] In training, the X is obtained directly from the real circuits. In inference, we can either use the $P(X)$ distribution from the real design or set it according to the user's specifications.

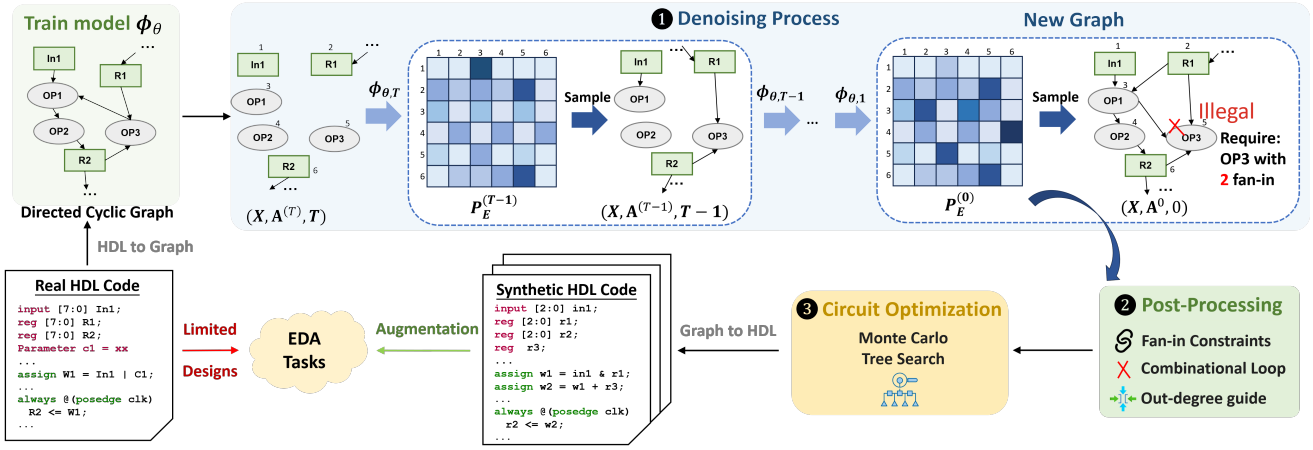

Fig. 2: Overview of SynCircuit framework. The circuit generation process starts with the specified node number V and attributes X. In **Phase 1**, the model performs a reverse diffusion process, where it predicts the probability of an edge existing between any pair (i, j) to obtain $P_E^{(t)}$. Then we sample from $P_E^{(t)}$ to update a graph $G^{(t)}$ as a new time state. After T denoising steps, the $G^{ini} = G^{(0)}$ is obtained. However, the generated graph may not necessarily be valid. In **Phase 2**, during post-processing, we sequentially assign parents to each node based on $P_E^{(t=0)}$, ensuring at each step that the circuit satisfies the constraints. In **Phase 3**, considering that some synthetic circuits exhibit significant logic redundancy, we employ an MCTS-based optimization technique, thereby reducing the generated design redundancy and better serving the downstream tasks.

performance at different diffusion steps. The node representation of each node j is updated through several layers of message passing:

$$H_j^{l+1} = \sigma\left(W_h^l H_j^l + \sum_{i \in \mathcal{P}_j} \frac{1}{|\mathcal{P}(j)|} W_m^l H_i^l\right)$$

where H_j^l is the representation of node j at encoder layer l, $\mathcal{P}(j)$ denotes the parents of node j, W_h^l and W_m^l are learnable weight matrices of the MPNN-based encoder, and σ is Relu function.

D. Decoder Design

In the denoising model $\phi_{\theta,t}$, the decoder will decide the existence of directed edges between pairs of nodes based on their encoded representations H_i from the encoder. In the context of directed graphs, conventional symmetric operations are insufficient to distinguish the directionality of edges. For example, the dot product [25] or Euclidean distance [15] of node embeddings H_i, H_j are commutative (i.e., $H_i^\top H_j = H_j^\top H_i$ and $\|H_i - H_j\|_2 = \|H_j - H_i\|_2$), failing to differentiate an directed edge from node i to j or from node j to i.

To address this limitation, we model the directed edge $e_{i,j}$ by associating H_i and H_j with a learnable relation embedding $r(t)$ [26], capturing the inherent directionality of the edge. In an asymmetric relation, the fundamental idea is that the embedding of the source node H_i, when translated by the relation embedding $r(t)$, is supposed to be close to the embedding of the target node H_j. We define the decoder's prediction for the existence probability of $e_{i,j}$ at time step t as follows:

$$\begin{aligned} P_E^{(t-1)}(i,j) = \hat{p}_{ij}^{(t-1)} &= p_\theta\left(A_{ij}^{(t-1)} = 1 \mid H_i^{(t)}, H_j^{(t)}, t\right) \\ &= \mathrm{MLP}\left(\left\{\left(H_i^{(t)} + r(t)\right) \odot H_j^{(t)}\right\} \oplus d(t)\right) \end{aligned}$$

where $H_i^{(t)}$ and $H_j^{(t)}$ are the representations of nodes i and j at time step t from the encoder, $r(t)$ is the learnable relation embedding obtained by $r(t) = MLP_r(t)$, $\odot$ denotes element-wise multiplication, $\oplus$ denotes vector concatenation, $d(t)$ is the learnable embedding of the time step t obtained by $d(t) = MLP_d(t)$.

V. Phase 2. Probability-Guided Graph Post-Processing

In phase 1, we obtain the G^{ini} and the edge existence probability $P_E^{(t=0)}$. But the G^{ini} will mostly likely violate circuit constraints $\mathcal{C}$. Therefore, we need to utilize the edge existence probability $P_E^{(t=0)}$ to refine G^{ini} and produce designs G^{val} that meet all predefined circuit constraints. We propose a probability-guided sequential post-processing approach to leverage the $P_E^{(t=0)}$ for parent node selection while ensuring both fanin limitations and combinational loop prevention which are required by constraints $\mathcal{C}$.

The post-processing algorithm iteratively processes each node in the circuit graph. For each node i, if its parent edges in G^{ini} are valid, then we will skip this node. If this node violates $\mathcal{C}$, we leverage the predicted edge probabilities from the previous diffusion model, sorting potential parent nodes by their connection probabilities in descending order. Before adding an edge from a candidate parent j, we need to check if the combinational loops would be created by this new edge. It can be achieved by checking if there exists a path from i to j in the subgraph that excludes register-type nodes. This sequential processing continues until the required number of valid parents is found.

VI. Phase 3. Refinement on Circuit Redundancy

Logic redundancy problem. Another important yet rarely studied challenge is logic redundancy. In real circuits, human designers will not likely introduce too much redundant logic into the circuit, which can be reflected by the sequential cell count in the optimized netlist. We define a metric, sequential cell preservation ratio (SCPR) which is calculated by dividing the number of sequential cells in the synthesized netlist by the total number of bits in sequential signals in the pre-synthesis HDL design. Our experiments show that the SCPR is usually between 70% to 100% in real designs. But some synthetic designs G^{val} can not even reach a 10% SCPR, which shows a serious logic redundancy problem.

Our objective in ❸. To better align the generated circuits with real ones not only in the topological aspects but also in the redundancy perspective, we aim to refine G^{val} and obtain G^{opt}, thus reducing the ratio of removed registers by the synthesis tool.

A. Challenges and optimization overview.

To optimize synthesized circuit designs, we face the challenges of an immense exploration space. To tackle this issue, we optimize the driving cone for the target register[3] one by one. In the cone optimization procedure, we introduce an MCTS-based effective strategy for navigating the large design space and finding circuits with better logic preservation quality.

[3]The term "driving cone for a register" refers to the set of nodes obtained by performing a reverse breadth-first search starting from a register node. This search traces back through the parent nodes until nodes of type "const", "in", or other "reg" nodes are encountered. The nodes traversed during this process collectively constitute the driving cone for our target particular register.

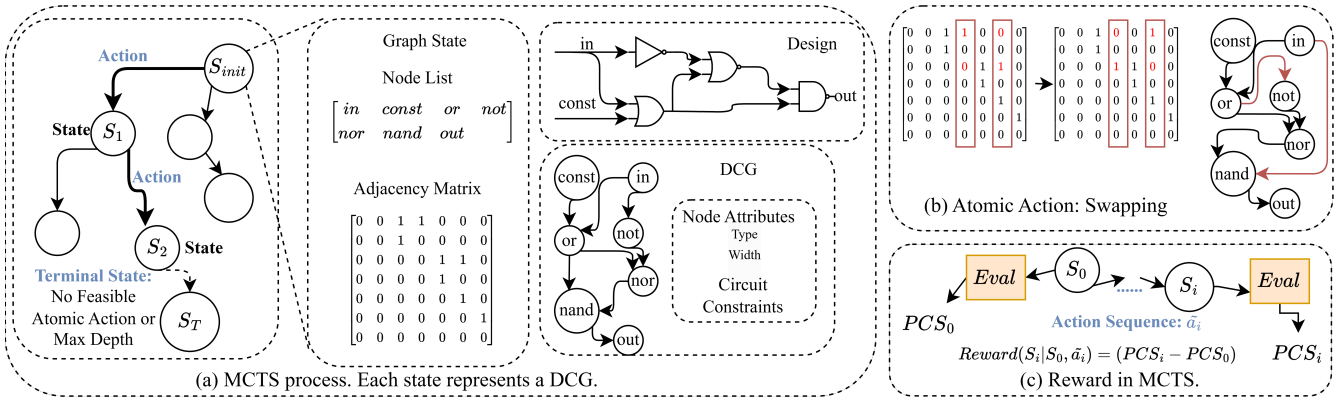

Fig. 3: MCTS-based circuit optimization flow overview. (a) The search tree is on the left and each state node represents an adjacency matrix. (b) A swapping atomic operation on the adjacency matrix facilitates state transformations during the search. (c) We propose a new metric, post-synthesis size (PCS) as the reward model to guide the search process.

B. Monte Carlo tree search-based exploration.

We detail the MCTS process in Figure 3. It guides the exploration and optimization of the design space, driving the search toward solutions with reduced hardware redundancy. Within this framework, each state node represents an adjacency matrix. We define a swapping atomic operation on the adjacency matrix, facilitating state transformations during the search.

Hardware redundancy metric as MCTS reward. To reflect the cone redundancy, we defined the post-synthesis circuit size (PCS). It is calculated by dividing the post-synthesis area by the number of nodes before synthesis. The rationale is that a larger PCS indicates fewer components have been optimized out, implying less redundancy in the synthetic circuit design. The overarching goal of the MCTS is to maximize the PCS while preserving the validity of the circuit.

Action space. The action space for transforming the circuit design during the MCTS process is defined by our proposed atomic swapping operation. For State S_i with $A(i,j) = 1$ and $A(p,q) = 1$, the new state S_{i+1} can be obtained by simply swapping the parents of node j and q, i.e., S_{i+1} with $A(p,j) = 1$ and $A(i,q) = 1$. Each atomic action should be checked if it violates $\mathcal{C}$. The advantage of this atomic operation lies in its ability to ensure that the number of edges in the graph remains unchanged, while also maintaining the out-degree and in-degree of each node in G^{val}.

Selection and expansion. In the selection phase, the MCTS algorithm traverses down the tree, selecting the most promising state which also meets circuit constraints $\mathcal{C}$ to expand based on the UCB1 criterion [27]:

$$a = \arg\max_{a} \left[Q(S,a) + \sqrt{2} \cdot \sqrt{\frac{\ln N(S)}{N(S,a)}} \right]$$

where $Q(S,a)$ is the empirical mean reward of action a in state S, $N(S)$ is the total number of visits to state S, $N(S,a)$ is the number of times action a has been chosen in state S. This formula balances the exploitation of known high-search reward actions with the exploration of less-tried actions. During the expansion step, the MCTS algorithm generates new child nodes by applying the atomic operation to the current node.

Simulation and backpropagation. Due to our objective of identifying the optimal state encountered during the search trajectory rather than optimizing for terminal states, we modify the traditional MCTS simulation and backpropagation mechanisms. In our approach, the reward for each simulation is defined as the maximum state reward $Reward_{max}$ encountered during that search path, rather than the terminal state value. During backpropagation, we update $Q(S,a)$ [27] using the $Reward_{max}$.

VII. Experimental Results

Application of SynCircuit in our experiments. The register-transfer level (RTL) stage offers maximum optimization flexibility in VLSI flow. Recently, machine learning-based RTL-level Power, Performance, and Area (PPA) prediction methods have been proposed, which can directly predict the performance of designs without requiring logic synthesis [6] [5] [28], thereby significantly accelerating the design iteration process. However, the application of these methods is limited by the insufficient availability of open-source RTL code.

Experiments objectives. In this experiment, our primary objective is to explore the effectiveness of new synthetic circuits for PPA modeling at the RTL level. Additionally, we are also interested in investigating the differences between synthetic circuits and real designs from not only the graph structure but also the logic redundancy perspectives. The comprehensive evaluation for SynCircuit may help us gain more insights into the digital circuit generative model.

A. Experimental Setup

Circuit design preparation. Firstly, we developed a dataset comprising 22 designs based on open-source RTL. The detailed dataset information is provided in Table I. It encompasses a diverse range of digital circuit modules, representing some of the high quality designs available within the open-source community.

Source Benchmark	#. of Designs	Original HDL Type	Design Scale (#K Gates) {Min, Median, Max}
ITC'99[29]	6	VHDL	{9, 19, 45}
OpenCores[30]	8	Verilog	{2, 6, 35}
Chipyard[31]	8	Chisel	{12, 19, 52}

TABLE I: Dataset composition and design size information.

Design label preparation. To obtain netlist labels including design area, register slack (SL), worst negative slack (WNS), and total negative slack (TNS), we employed Synopsys Design Compiler® 2021 with the NanGate 45nm technology library. To align with real-world scenarios, multiple parameters within the Design Compiler were adjusted, and a set of the PPA values along the Pareto frontier were utilized as ground truth labels.

Training-testing data splitting. We randomly selected 7 designs from the dataset as the test set, while the remaining 15 designs were used as the training set in the downstream PPA prediction task. To prevent data leakage, all the graph generative models mentioned in this paper were only trained on these 15 training designs.

Graph generative model baselines. We selected several representative and most closely related baselines, including GraphRNN [17], DVAE [15], SparseDigress [32] and GraphMaker [25]. These 4 baselines all need to be adapted to the circuit generation task. GraphRNN [17] and DVAE [15] are node ordering-based autoregressive

TABLE II: Evaluation for structural properties similarity with original realistic circuits, best results are in **bold**. Lower W_1 and $\left|\mathbb{E}_{\hat{G}\sim p_\theta}\left[M(\hat{G})/M(G)\right]-1\right|$ reflect a better graph similarity with the realistic ones. All 4 baselines were adapted to generate directed circuit graphs without violating the constraints.

generative approaches. These methods cannot be directly applied to generate directed cyclic graphs. We have to break the cycles in the training circuits and use the topological order of nodes as the sequence for the model training and inference. During generation, edge directions are automatically determined by the topological order. In the sequential generation process, we introduced a validity checker for circuits to ensure that the resulting digital design is valid. **But since these two models can only be applied on DAGs, the generated graph contains no cycles which is very different from the real designs.**

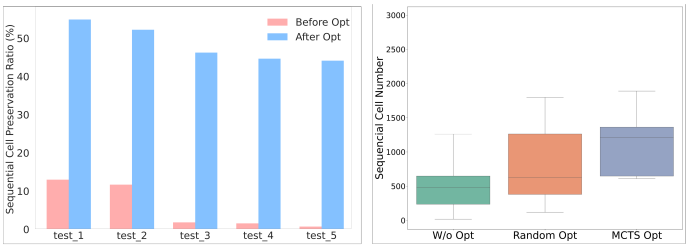
For GraphMaker [25] and SparseDigress [32], these are one-shot approaches that ignore edge direction information, generating only undirected graphs. We applied the Gravity-Inspired Graph Autoencoders [33] method to process the generated undirected graph by assigning the direction for each edge. To ensure the validity of the generated graphs by GraphMaker [25] and SparseDigress [32], we must refine the parent edges in a specific node order. The synthesis tool removed most part of the generated circuits, so these two baseline models can only be used for comparing graph characteristics and cannot support valid designs for downstream tasks.

SynCircuit setup. For our proposed graph generative model, we set the diffusion steps to 9 and utilized a 5-layer MPNN. Both the node attribute embeddings and hidden embeddings were set to 256. In the circuit optimization phase, to accelerate the evaluation process, we replaced the slow synthesis tool with a trained discriminator to approximate the PCS. In the MCTS process, we set the number of simulations to 500 and the maximum exploration depth to 10 for each register cone. All these experiments were conducted on a platform with an Intel(R) Xeon(R) Gold 6438Y+ processor and 8*4090 GPUs.

B. Experimental Results

1) Graph structural properties evaluation: To evaluate the similarity of the generated graph structures with realistic ones, we follow GraphRNN [17] and GraphMaker [25] and report distance metrics for node out degree, clustering coefficient, and four-node orbit count distributions. We use the 1-Wasserstein distance to model statistic distributions from the original and generated graphs, respectively. A lower W_1 value indicates better similarity.

Beyond distribution distance metrics, we also directly compare several scalar-valued statistics [25], [34]. Let $M(G)$ be a non-negative statistic; we report $\mathbb{E}_{\hat{G}\sim p_\theta}\left[M(\hat{G})/M(G)\right]$, where $\hat{G}$ is a generated graph. A value closer to 1 indicates better performance. For the M statistics, we choose triangle count, $\hat{h}(A,X)$ [25], [34] and two-hop correlations $\hat{h}(A^2,X)$. $\hat{h}(A,X)$ reflects the correlation between graph structure and node types.



The results are shown in Table II. We can see that our SynCircuit has the best performance among 5 out of the 6 metrics. Benefiting from the diffusion model and the out-degree guidance in the postprocessing phase, the degree distribution of our synthetic circuits is more similar to the real designs. This feature is important because the digital circuits are indeed scale-free networks[4] [35].

[4]A Scale-Free Network is a type of network characterized by a degree distribution that follows a power law. This means that in such networks, the probability $P(k)$ that a node has k connections (or degree k) decreases polynomially as k increases

SynCircuit w/o diff is an ablation study where we remove the diffusion model and randomly construct edges when generating G^{ini} and $P_E^{(0)}$, but applying post-processing to ensure certain predefined constraints. We observe that its performance is greatly inferior to the complete SynCircuit, demonstrating the effectiveness of our designed generative diffusion model.

2) Logic redundancy and timing evaluation: We employ Monte Carlo Tree Search (MCTS) to optimize the register cones within G^{val}. For comparison, we implement an ablation study of randomly altering edge connections on G^{val} while still ensuring every step is valid. We utilize the same number of simulations as MCTS and adopt the optimal solution identified throughout the process as the results. The SCPR enhancement is illustrated in Figure 4(a), demonstrating that MCTS can significantly reduce logic redundancy.

Figure 4(b) displays the number of sequential cells saved during the logic synthesis using different optimization techniques. We can see that by introducing our MCTS-based refinement, the registers saved in the netlist have been greatly improved over no optimization and the optimization performance is also better than that using a random optimization method.

(a) SCPR before and after MCTS-based optimization

(b) No. of Sequential Cell Saved in the Netlist Stage

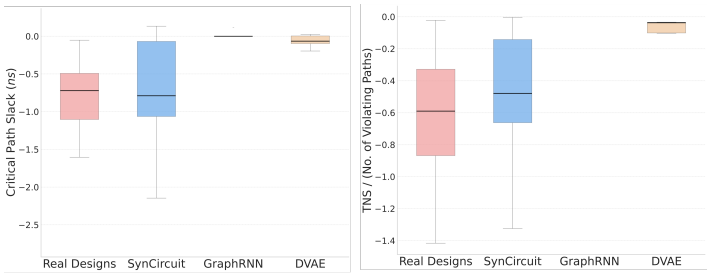
Fig. 4: (a) Logic redundancy metric SCPR is calculated by dividing the number of sequential cells in the synthesized netlist by the total number of bits in sequential signals in the pre-synthesis HDL design. Here we select the five G^{val} examples with the most significant logic redundancy. The register ratio (SCPR) cannot even reach 20% if we do not optimize G^{val}. After the MCTS optimization, the SCPR is greatly improved and exceeds 50% in some synthetic circuits. (b) The number distribution of registers preserved after logic synthesis. The logic redundancy is greatly reduced by our proposed MCTS optimization method.

Netlist timing statistics comparison We use two metrics to evaluate the design's timing characteristics: Worst Negative Slack (WNS) and Total Negative Slack divided by the number of violated paths (TNS/NVP).

- WNS represents the most severe timing violation in the design, indicating the largest negative slack among all timing paths, which points to the longest delay and the most critical bottleneck in signal propagation.

Model	Register Slack			WNS			TNS			Area		
	R → 1	MAPE ↓	RRSE ↓	R → 1	MAPE ↓	RRSE ↓	R → 1	MAPE ↓	RRSE ↓	R → 1	MAPE ↓	RRSE ↓
Basic training data (No-pseudo circuits)	0.70	27%	0.83	0.86	20%	0.83	0.81	50%	0.97	0.89	30%	0.62
GraphRNN [17]	0.70	27%	0.83	0.88	21%	0.83	0.80	54%	0.97	0.84	44%	0.75
DVAE [15]	0.69	29%	0.94	0.88	24%	0.86	0.78	50%	0.97	0.84	61%	0.86
SynCircuit w/o opt	0.72	24%	0.79	**0.90**	23%	0.85	0.80	48%	0.86	0.86	39%	0.72
SynCircuit w/ opt	**0.77**	**16%**	**0.70**	0.89	**20%**	**0.80**	**0.97**	**45%**	**0.64**	**0.95**	**25%**	**0.34**

(a) Basic training dataset contains 15 real designs. Lower $|R-1|$, MAPE and RRSE reflect better model prediction performance.



Model	Register Slack			WNS			TNS			Area		
	R → 1	MAPE ↓	RRSE ↓	R → 1	MAPE ↓	RRSE ↓	R → 1	MAPE ↓	RRSE ↓	R → 1	MAPE ↓	RRSE ↓
Basic training data (No-pseudo circuits)	0.52	34%	1.1	NA	52%	2.1	NA	67%	1.1	0.65	66%	1.3
GraphRNN[17]	0.52	34%	1.1	0.71	42%	1.7	-0.30	74%	1.1	0.51	77%	1.6
DVAE[15]	0.49	36%	1.3	0.75	77%	2.6	0.76	93%	1.1	0.70	86%	2.4
SynCircuit w/o opt	0.56	35%	1.2	0.65	47%	1.9	0.72	70%	0.85	0.63	62%	1.1
SynCircuit w/ opt	**0.67**	**25%**	**0.76**	**0.87**	**34%**	**1.2**	**0.98**	**61%**	**0.63**	**0.95**	**36%**	**0.61**

(b) Basic training dataset contains 5 real designs. Lower $|R-1|$, MAPE and RRSE reflect better model prediction performance.

TABLE III: Model Performance on the Register Slack, WNS, TNS, and area prediction. The basic training dataset in (a) and (b) contains 15 and 5 real designs respectively. In (a) and (b), the augmentation datasets are added to the basic training set, each always with 25 pseudo-circuits, generated from SynCircuit, GraphRNN [17], and DVAE [15]. R with NA means that the model prediction is the same for all testing designs

- The metric TNS/NVP provides the average negative slack per violated path, reflecting the overall severity of timing violations and offering insights into the distribution of delays.

From Figure 5, We observe that the graphs generated by GraphRNN [17] and DVAE [15] exhibit very small WNS (critical path slack) and TNS/NVP values, failing to capture the inherent delay characteristics of circuits. In contrast, our SynCircuit demonstrates a more similar distribution of the two metrics to real designs. This suggests that SynCircuit is more effective in modeling the diverse timing behaviors present in real circuits.

(a) Critical Path Slack (ns) (b) TNS / No. of Violating Paths (ns)

Fig. 5: Netlist statistics for the three synthetic datasets and real benchmarks. The distributions of two statistic metrics: Critical Path Slack (WNS) and the ratio of Total Negative Slack to the Violating Path Numberare shown in (a) and (b), respectively. The dataset generated by SynCircuit exhibits *more similar statistics distributions* to those of the real designs compared to GraphRNN [17] and DVAE[15].

3) SynCircuit application in RTL tasks: In this part, we explore the application of synthetic circuit generation for ML-based RTL-level PPA prediction model, primarily referencing the overall design evaluation methods (i.e., area, WNS, and TNS) proposed by MasterRTL [5] and the fine-grained timing slack evaluation by RTL-Timer [28]. We employ three metrics to assess model performance: correlation coefficient (R), Mean Absolute Percentage Error (MAPE), and Root Relative Squared Error (RRSE). Lower MAPE and RRSE values indicate better model performance.

We randomly selected 5 and the full 15 training real designs to create two basic training datasets. For each basic training dataset, we augmented it with different synthetic datasets (three sets of 25 designs each), generated respectively by SynCircuit, GraphRNN [17], and DVAE [15], to study how these synthetic designs affect model performance.

The results are shown in Table III. We can see that in both training settings, models trained on datasets augmented with Synthetic-generated data consistently outperformed those trained solely on real designs, achieving the best results across all metrics. And we have more model performance gain when the basic training dataset contains 5 designs. The Register Slack MAPE is reduced by 10% in both basic training settings. And we have a 30% area MAPE reduction in the 5 basic training dataset settings.

Notably, models augmented with DVAE [15]-generated and GraphRNN [17]-generated data performed worse, regardless of the training dataset size. This may indicate a significant gap between the data generated by these baselines and the real designs due to logic redundancy. As observed in Figure 5, the synthetic data generated from GraphRNN [17] and DVAE [15] contain very few paths with large delays. This discrepancy may have caused the model's learning to deviate from the normal timing features for Register Slack, WNS, and TNS tasks.

We also included non-optimized circuits SynCircuit w/o opt (G^{val}) as part of an ablation study. It can be observed that the excessive design logic redundancy introduced may have adversely affected the model's predictive performance, rendering it inferior to scenarios involving only real training circuits. This observation indirectly demonstrates the importance of optimizing logic redundancy in generating synthetic circuits that more closely resemble real-world designs.

VIII. Conclusion And Future Work

Data-driven automation techniques have become increasingly prevalent in digital circuit design in recent years. Nevertheless, the availability of open-source circuits is often limited. To address this issue, we propose the SynCircuit, an automatic digital circuits generation framework. It consists of three stages: directed cyclic graph generation, probability-guided postprocessing, and MCTS-based optimization. Our experiments demonstrate that the designs generated by SynCircuit not only exhibit structural properties that closely resemble those of real designs, but also enhance model performance in ML-based power, performance, and area (PPA) prediction tasks at the RTL early stage.

***Abstract*—The automatic generation of RTL code (e.g., Verilog) through natural language instructions has emerged as a promising direction with the advancement of large language models (LLMs). However, producing RTL code that is both syntactically and functionally correct remains a significant challenge. Existing single-LLM-agent approaches face substantial limitations because they must navigate between various programming languages and handle intricate generation, verification, and modification tasks. To address these challenges, this paper introduces MAGE, the first open-source[1] multi-agent AI system designed for robust and accurate Verilog RTL code generation. We propose a novel high-temperature RTL candidate sampling and debugging system that effectively explores the space of code candidates and significantly improves the quality of the candidates. Furthermore, we design a novel Verilog-state checkpoint checking mechanism that enables early detection of functional errors and delivers precise feedback for targeted fixes, significantly enhancing the functional correctness of the generated RTL code. MAGE achieves a 95.7% rate of syntactic and functional correctness code generation on VerilogEval-Human v2 benchmark, surpassing the state-of-the-art Claude-3.5-sonnet by 23.3%, demonstrating a robust and reliable approach for AI-driven RTL design workflows.**

I. INTRODUCTION

Digital hardware design usually requires engineers to define the architecture and functionality of hardware by writing code in hardware description languages (HDLs), such as Verilog and VHDL. As VLSI designs become more complex, hardware design workflows are increasingly time-consuming and error-prone [1]–[3]. Although electronic design automation (EDA) tools have advanced to support this workflow [4]–[7], the demand for more efficient and automated hardware design solutions remains crucial.

Large Language Models (LLMs) [8], [9] have recently shown promising potential in assisting and improving hardware design [10]–[13]. Recent studies explored leveraging LLMs to improve the correctness of RTL code generation through model fine-tuning [10], [14], [15], training of domain-adaptive models [16], and single-agent methods [13], [17], [18] that augment LLMs by incorporating results and feedback from compilers or simulators to refine the generated code.

However, previous studies using a single LLM or a single agent face substantial limitations. First, these approaches fall short of the context-switch between tasks, programming languages, and knowledge domains. As a result, the quality of RTL design suffers: for instance, a single Claude-3.5-sonnet agent [9] has a functionality pass rate of only 75.0% even for simple design tasks [19]–[21]. Second, HDLs are specifically designed to describe the logic and architecture of digital hardware at a low level, focusing on the flow of data between registers, the timing of operations, and hardware characteristics such as propagation delays and signal dependencies. Directly adopting general-purpose LLM or multi-agent designs will produce low-accuracy RTL code that fails to meet timing constraints, resulting in wrong designs [10], [16], [19], [20].

To address these challenges, we propose **MAGE**, the first open-source **M**ulti-**AG**ent **E**ngine to achieve automatic high-quality RTL code generation. Different from the existing single-agent RTL code generation frameworks [13], [17], [18], MAGE enables specialized agents to handle distinct aspects in the RTL development pipeline. Inspired by real-world RTL design workflows, where specialists focus on distinct stages, our approach, MAGE, employs a specialized multi-agent architecture composed of four types of key agents: the RTL code generation agent, testbench generation agent, judge agent, and debug agent. Each type plays a specific role, working collaboratively within our tailored recursive framework to generate optimized and reliable RTL code.

MAGE consists of three key **design principles**. First, mimicking the iterative nature of human RTL design teams in addressing complex design challenges, we developed a high-efficiency collaboration workflow with a delicate design context communication protocol. Second, we propose a novel high-temperature RTL candidate sampling and debugging system, which leverages both high-temperature sampling and simulation-based scoring to identify promising candidates. Our key insight is that higher temperatures result in more diverse LLM outputs, while also increasing the likelihood of including the highest-quality candidates for optimization in the next stage. Finally, we propose a novel Verilog-state checkpointing and validation scheme, which substantially improves the functional correctness. Unlike conventional methods that provide feedback only on the final output mismatch [13], [17], [18], MAGE validates an RTL design by comparing state values with expected outputs at each clock edge. This enables early detection of functional errors and provides precise feedback

* Equal Contribution

[1]MAGE is open-sourced at https://github.com/stable-lab/MAGE-A-Multi-Agent-Engine-for-Automated-RTL-Code-Generation.

for targeted fixes.

In summary, we make the following contributions:

- We design MAGE, the first open-source LLM-based multi-agent system for robust and accurate Verilog RTL code generation. By decomposing a complex hardware design into manageable sub-tasks, we design LLM agents to handle sub-tasks and design the system to enable effective agent communication and collaboration.
- We propose a novel high-temperature RTL candidate sampling system, notably enhancing generated code quality by exploring the benefits of high-randomness generation.
- We propose a novel Verilog-state checkpoint checking mechanism, which provides precise feedback for targeted fixes, significantly improving the RTL code quality.
- MAGE achieves a **95.7%** rate of syntactic and functional correctness code generation on the VerilogEval- Human v2 benchmark, surpassing all existing methods, representing a critical step toward automating and optimizing hardware design workflows, offering a more robust methodology for AI-driven RTL design.

II. Background and Motivation

A. Characteristics and challenges of LLM-based RTL design

Decomposing Complex Traditional RTL Design. Traditional digital hardware design flows necessitate hardware engineers to iteratively perform: (1) implement Verilog code to specify hardware architectures and behaviors, (2) customize test benches to rigorously verify the correctness of these hardware descriptions (3) iterate between Verilog simulations, signal waveform reasoning, and code refining until all output signals match expected behavior. This iterative loop among design, verification, and refinement makes the RTL design process not only challenging but also highly demanding in terms of both time and expertise. The complexity of traditional Verilog RTL design calls for decomposing the whole process into multiple manageable sub-stages and adopting different specialists (agents) for different sub-stages.

Related Work on LLM-based RTL Design. Recent works [10], [15], [16], [22], [23] train or fine-tune general code generation LLMs by incorporating RTL domain knowledge to enhance the correctness of RTL code generation. Single-agent methods [13], [17], [18] further integrate simulation results and introduce more stages in the code generation process, such as planning, verification, and code refining based on the feedback from simulation. However, this process involves generating both synthesizable and non-synthesizable code for RTL generation and verification, and context switches among different sub-tasks in multiple iterations, necessitating different domain knowledge and problem-solving abilities. Thus, adopting a single agent for all these tasks in the hardware design process leads to sub-optimal results, as they have to process such complex contexts in each interaction and maintain consistency through a long conversation history.

In contrast, multi-agent systems distribute tasks among agents with independent conversation histories, enabling specialized task handling and greater modularity. However, Aivril [24] only implements a basic two-agent division between code generation and review, still requiring a single agent to handle both synthesizable RTL and non-synthesizable verification code, thus failing to address the fundamental context-switching challenges. Verilogcoder [25] further constrains accessibility and system adaptability through its closed-source implementation and reliance on proprietary components (e.g., its Abstract Syntax Tree and Waveform Tracing Tool).

Temperature Sampling for LLM-based RTL Design. Given an input requirement, LLMs rely on a specific decoding strategy to generate the code auto-regressively. Temperature sampling method [26] uses a temperature coefficient T (usually $\in [0, 1]$) to control the sampling randomness. Increasing the temperature avoids overly conservative results and promotes diversity in code generation, thus enhancing the chance of exploring the correct answers. However, this comes at the cost of introducing more noise and errors in the generation results. Recent studies [27], [28] show that high-temperature sampling can improve correctness in software code generation through multiple sampling iterations. However, higher temperatures tend to result in poorer performance for RTL design as explored in recent studies [10], [21]. We found a key reason for this is that single-agent mechanisms restrict the ability to design independent and efficient sampling and feedback, thereby hindering the optimization potential of high-temperature sampling for RTL code.

B. Opportunity on Effective Code Generation

To tackle the aforementioned limitations of both existing single-agent and multi-agent systems for RTL code generation, we identify potential opportunities to develop effective RTL code generation frameworks to improve correctness.

First, to further reduce the mutual influence between non-synthesizable testbenches and synthesizable RTL code generation, as well as to decrease the complexity of tasks assigned to each agent, we recognize the necessity of appropriately distributing tasks among multiple agents and organizing the workflow effectively. Specifically, previous works (e.g., [17], [24]) employed a single agent to generate both non-synthesizable testbenches and synthesizable RTL code simultaneously. However, [29] found that generating testbenches and code together within the same conversation may lead to a corresponding decrease in effectiveness. Moreover, test cases generated in this manner can become biased and influenced by the code, resulting in a loss of objectivity and diversity.

Second, based on our analysis in Sec. II-A, we thoroughly reviewed existing multi-agent systems [24], [25], where we found that all of them are closed-source and dependent on third-party proprietary tools that are not LLM-directly-adapted. This inevitably limits system extensibility and transparency. Therefore, we identify the need for an open-sourced multi-agent system.

Finally, to address the limitation of high-temperature sampling for RTL code generation described in Sec. II-A, we summarize the key to efficiently sampling RTL code candidates process to mitigate the impact of randomness while leveraging

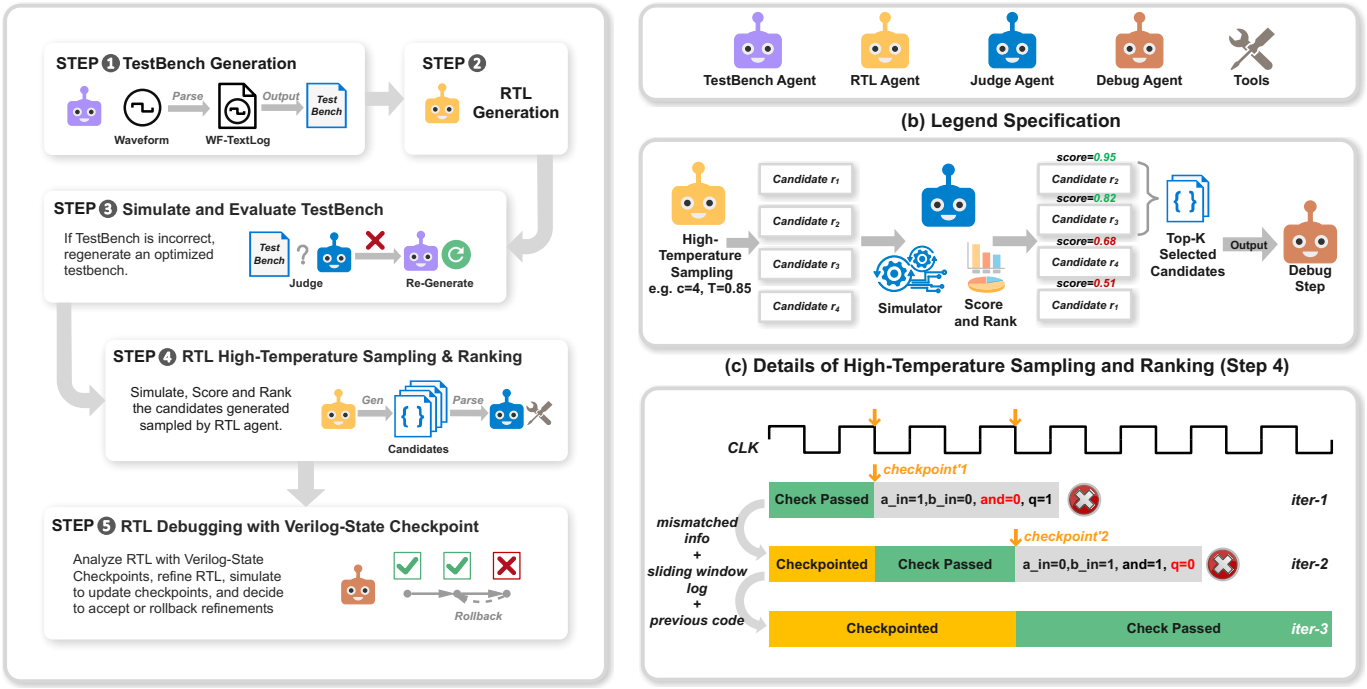

Fig. 1: (a) The overview of MAGE, (b) the roles of four types of agents, (c) state check module, and (d) sampling and debugging module.

the exploration benefits. Given that RTL code is synthesizable and a practical miscount scoring method is applicable, we prioritize candidate selection at an early stage by identifying top-scoring candidates. This approach allows us to reduce the exploration cost by filtering suboptimal results early.

C. Opportunity on Effective Code Debugging

Most existing LLM approaches for RTL code generation [13], [17], [18] rely on the direct application of original golden testbenches, which can only provide pass rates. This provides very limited feedback to LLMs in fine-tuning RTL code as pass rates alone lack detailed insights into crucial aspects such as timing analysis, signal interactions, variable values, and mismatch information, all of which are essential for ensuring high-quality RTL design. VerilogCoder [25] applies closed-source Abstract Syntax Tree (AST) analysis, which significantly restricts flexibility and transparency. Furthermore, the introduction of tools that output in graphical form, which LLM can not directly apply, increases the complexity of tasks for LLMs and reduces their effectiveness. Therefore, we identify the requirement for an optimized testbench, which will output a log resembling a simulated waveform in text form, which can be directly adaptable by LLMs. This shifts the reliance on closed-source tools to a fully open-source LLM-based textual protocol, alongside significant improvements in LLM RTL code debug effectiveness, improving both the extension of the framework and the quality of the analysis.

III. MAGE Design

We present MAGE, a multi-agent engine designed specifically for RTL. This system integrates an RTL-specific context communication protocol with high-efficiency, LLM-adapted tools for fine-tuning RTL, all within a productive process.

A. Multi-Agent System Overview

Figure 1 depicts a comprehensive overview of the workflow implemented in MAGE. Inspired by the collaborative division of work approaches of human RTL design teams, our framework incorporates four types of agents, each playing a specific and concrete role in the automation process. Figure 1 (b) specifically delineates the responsibilities and tasks assigned to each agent, ensuring a clear understanding of the workflow. (1) A Testbench Generation Agent is responsible for creating optimized test benches in a textual-waveform-output format based on the natural language specifications and any available golden test benches. (2) A RTL Generation Agents convert these specifications along with the optimized test bench into Verilog code, incorporating syntax checking to ensure code validity. (3) A Judge Agent then takes over by simulating and evaluating the generated RTL code against the optimized test bench. It scores the RTL code candidates and decides whether any require debugging or if the test bench needs to be regenerated. (4) A Debug Agent performs iterative refinements on any code that fails initial tests, using textual waveform-like simulation outputs as feedback for improvements. Our method mimics the division of labor in human teams and enhances the efficiency and accuracy of automated RTL design. It should be noted that, whether in RTL code generation or debugging, the agent will perform at most $s = 5$ iterations to automatically fix syntax errors.

Based on the distinct and specific roles of multiple agents, we have designed an efficient workflow to ensure that each agent's unique contributions are seamlessly integrated, fa-

cilitating a coherent progression throughout the workflow. Figure 1 (a) demonstrates the entire process is systematically divided into five main steps as depicted as follows:

Step ❶ – Generate initial textual-waveform-output testbenches. To reduce the limitations of pass-rate-output golden testbenches, which is analyzed in Sec. II-C, we directly utilize natural language specifications to generate optimized testbenches that can output State Checkpoints, which will be used in Step ❺ (see Figure 1 (d) and Sec. III-C). Furthermore, since natural language specifications may contain ambiguities, we combine the input with the golden testbench if available.

Step ❷ – Based on the natural language specifications and the optimized testbench, we generate an initiate RTL code.

Step ❸ – If the initial RTL code cannot pass the optimized testbench, the judge agent evaluates the testbench and regenerates it if deemed incorrect.

Step ❹ – If the RTL code is deemed correct, we will employ an **High-Temperature RTL Sampling and Scoring Process** (see Figure 1 (c) and detailed in Sec. III-B) to generate and rank RTL code Candidates.

Step ❺ – If the RTL code candidates still have function errors, we will employ a **RTL Debugging with State Checkpoint Mechanism** (see Figure 1 (d) and Sec. III-C) to make effective debug trials and debug the selected RTL code candidates.

B. High-Temperature RTL Sampling and Scoring

As depicted in Sec. II-B, high-temperature sampling has a better chance of exploring the correct code. However, in prior studies on Temperature Sampling for RTL code generation like [27], [28], it is commonly acknowledged that high-temperature sampling introduces significant randomness, often resulting in reduced correctness. To address this issue, we first explore the potential opportunity of using multiple RTL code generation candidates in high-temperature sampling to reduce simulated mismatch counts in one iteration. Fig. 2 shows the distribution of normalized mismatch counts for the best candidates at two different temperatures. We observe that the best candidate with high temperature has a lower mismatch count for most problems. This suggests that, despite increased randomness, high-temperature sampling yields better performance when the sampling is sufficiently extensive. The improvement in pass rates at each stage, as shown in Fig. 2, indicates the potential benefits of performing an effective sampling policy at high temperatures.

Based on the above observation, we propose a High-Temperature Sampling and Ranking Process as follows:

1. We sample c RTL code candidates for issue i:

$$\mathcal{R}_i = \{r_i^1, r_i^2, \ldots, r_i^c\}, r_i \sim P_T\left(r \mid p_{sys}, SP_i, TB_i\right) \quad (1)$$

Here, T is the temperature, p_{sys} denotes the system prompt of the RTL code generation, SP_i is the natural language specification of the issue i, and TB_i is the corresponding testbench. The term $P_T\left(r \mid p_{sys}, SP_i, TB_i\right)$ represents the probability distribution of the generated RTL code given the temperature, system prompt, specification, and testbench.

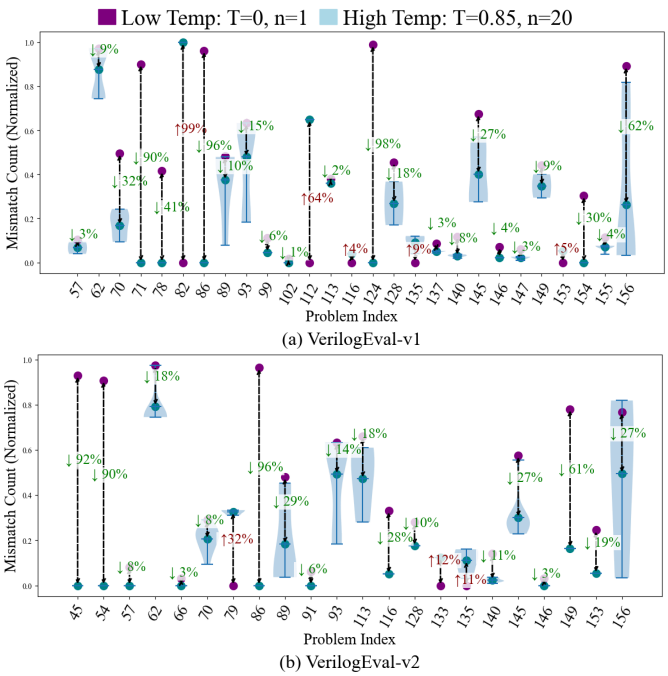

Fig. 2: Normalized mismatch count of generated testbenches at different stages under varying temperature configurations, using the Claude 3.5 Sonnet model (dated 2024-10-22) across two benchmarks: VerilogEval-v1-Human [20] and VerilogEval-v2 [21]. Problems that passed before Step ❹ and those with zero mean mismatches in both configurations are not shown in the figure. The blue violin plot shows that candidates (blue dots) generated with high-temperature sampling typically have lower mean mismatch counts across most problems compared to those generated with low temperatures (purple dots).

2. We select the Top-K candidates from $\mathcal{R}_i$ based on their scores. Specifically, each candidate in $\mathcal{R}_i$ is evaluated to obtain a normalized mismatch-based score as follows:

$$s(r) = 1 - \frac{m(r)}{tc(r)} \quad (2)$$

where $m(r)$ is the mismatch count and $tc(r)$ is the total number of checks of the generated RTL code r. We then select the K candidates with the highest scores, denoted as follows:

$$\mathcal{R}^{\star}_{i,0} = \underset{A \subseteq \mathcal{R}_i, |A|=K}{\arg\max} \sum_{r \in A} s(r) \quad (3)$$

3. We employ a debug agent to perform debugging trials, generating a new candidate $r^{\star}_{trial} = D(r^{\star})$ for each selected candidate $r^{\star}$, where $D(r)$ denotes the debug trial for RTL code r. The selected candidate set at iteration m is then updated as:

$$R^{\star}_{i,m} = \{ \underset{r \in \{D(r^{\star}), r^{\star}\}}{\arg\max} \; s(r) \mid r^{\star} \in \mathcal{R}^{\star}_{i,m-1} \} \quad (4)$$

And this process repeats until $\underset{r \in R^{\star}_{i,m}}{max}\; s(r) = 1$ or the iteration limit is reached.

C. RTL Debugging with State Checkpoint Mechanism

Our objective is to design a mechanism that is entirely LLM-based, independent of third-party closed-source tools,

and effective in improving RTL debugging efficiency. To achieve this, we propose the RTL Debugging with State Checkpoint Mechanism, which follows these steps:
1. Utilizing the optimized testbench generated in Step ❶ and ❷, we extract the input vector **I**, the DUT, and the output **O**, and subsequently identify the earliest mismatch point as:

$$t_m = \min\{t \mid \mathbf{O}_{DUT}(t) \neq \mathbf{O}_{exp}(t), t \geq 0\} \tag{5}$$

where $\mathbf{O}_{\text{DUT}}(t)$ is the output vector from the DUT at time t, and $\mathbf{O}_{\text{exp}}(t)$ is the expected output vector at time t.
2. We generate the State Checkpoint and collect the textual waveform window as:

$$W = \Big\{ \big(\mathbf{I}(t'), \mathbf{O}_{DUT}(t'), \mathbf{O}_{exp}(t')\big) \mid t' \in \big[\max(t_m - L_W, 0), t_m\big] \Big\} \tag{6}$$

where W represents the waveform window, L_W is the window length, and $\mathbf{I}(t')$ is the input vector at clock edge t'.
3. The debugging agent then takes the textual waveform window W and the original testbench as inputs, generates a new trial of debugged RTL code, and performs replacement actions to correct the identified faults in the RTL. The simulation is subsequently rerun to verify if the mismatch is resolved in the updated State Checkpoint.

IV. Experiments

A. Experimental Setup

Benchmarks. Two widely used benchmarking datasets: VerilogEval-v1-Human [20] and VerilogEval-v2 [25]. **Model.** Claude 3.5 Sonnet 2024-10-22 [9]. **Baselines.** i. Vanilla models: Generating RTL code in a single pass using language models, including both general-purpose LLMs (e.g. GPT-4o [30], Claude 3.5 Sonnet [9]) and RTL-specified models (e.g. ITERTL [22], CodeV [23]). ii. LLM Agent systems: Agent-based systems designed to enhance LLM performance for RTL code generation, including open-source solutions (OriGen [13]) and closed-source ones (e.g. VeriAssist [17], AutoVCoder [18], VerilogCoder [25], AIVRIL [24]). **Configurations.** Our implementation of MAGE integrates the open-source Verilog compiler and simulator Icarus Verilog [31] with an LLM-agnostic API interface offered by the open-source framework LlamaIndex [32]. Based on the superior performance [24], [33], [34] of Claude 3.5 Sonnet [9] in multiple coding tasks, we choose to run experiments with that language model. In accordance with the VerilogEval V1 [20] and V2 [21] benchmark, we conducted experiments to measure Pass@1 under 2 settings: *Low Temperature* (T=0, top_p=0.01, n=1) and *High Temperature* (T=0.85, top_p=0.95, n=20). Here, temperature T is described in Sec. II-A. Top_p limits the output pool to a cumulative probability threshold. n represents the number of evaluation runs. **Metrics.** Following prior works [17], [18], [21], the Pass@1 metric is computed as:

$$pass@k = \mathbb{E}_{\text{Problems}}\left[1 - \frac{\binom{n-c_p}{k}}{\binom{n}{k}}\right] \tag{7}$$

where $k = 1$, and c_p is the number of passing runs. This Pass@1 metric, which accounts for multiple runs, reflects the expected percentage of problems that the system solves correctly when executed once for each problem.

TABLE I: Pass rates of different temperature configurations in MAGE.

Config	VerilogEval-Human Pass@1	VerilogEval-V2 Pass@1
High Temp	**94.8**	**95.7**
Low Temp	89.1	93.6

As shown in Table I, the High Temperature setting achieves higher Pass@1, so it is adopted for subsequent experiments.

B. Key Results

Table II shows the comparison of MAGE and baselines. For a fair comparison, we select the highest pass rate among their experiment configuration. MAGE achieves the best performance on both benchmarks, delivering consistent improvements over specialized (e.g., VerilogCoder) and general-purpose systems(e.g., GPT-4, CodeQwen). Specifically, MAGE obtains a Pass@1 score of 94.8% on VerilogEval-Human and 95.7% on VerilogEval-V2, surpassing all baselines. These results underline the effectiveness of MAGE in advancing the capabilities of LLM-driven coding systems.

MAGE not only outperforms closed-source systems but also demonstrates substantial improvement over accessible solutions, including vanilla models and open-source coding systems. For instance, compared to the highest-performing vanilla LLMs (e.g., Claude 3.5 Sonnet), MAGE achieves a relative improvement of +19.8% on VerilogEval-Human and +23.3% on VerilogEval-V2. Similarly, against open-source systems like OriGen (54.4% Pass@1 on VerilogEval-Human), MAGE significantly improves the functional correctness, showcasing its superior performance in scenarios where accessible and reproducible solutions are prioritized.

C. Ablation Study

Multi-Agent System. We conducted an ablation study to assess the effectiveness of task distribution among multiple agents. The study compared three configurations: (a) Vanilla LLM, which involves one-pass RTL code generation using a single LLM; (b) Single-Agent, where different agent roles in the MAGE system were merged into a single agent; and (c) Multi-Agent(). As shown in Table III, the multi-agent configuration achieves the highest pass rate (93.6%), outperforming both the vanilla (72.4%) and single-agent (83.9%) setups. These results indicate that effective task partitioning can significantly enhance the performance of LLM-based systems, particularly for complex tasks like RTL code generation, which require handling both synthesizable RTL code and non-synthesizable testbenches.
RTL Code State Checkpoint Mechanism. We also conducted case studies to evaluate the effectiveness of the proposed RTL Code State Checkpoint mechanism. For example, Fig. 3 illustrates a debugging case study with and without state checkpoints. Without checkpoints, when only the log is provided

TABLE II: Pass rates of recent LLMs and Coding Systems. The highest Pass@1 among different temperature settings is reported.

System	System Type	LLM Model	VerilogEval-Human Pass@1	VerilogEval-V2 Pass@1
Generic LLM	N/A	GPT-4o	51.3	N/A
	N/A	Claude 3.5 Sonnet	60.3	N/A
	N/A	Claude 3.5 Sonnet 2024-10-22	75.0	72.4
RTL-specified LLM	N/A	ITERTL [22]	42.9	N/A
	N/A	CodeV [23]	53.2	N/A

to the LLM Debug Agent, the agent can only approximate the problematic location in the buggy RTL code, making it unlikely to identify and fix the issue. In contrast, with state checkpoints included in the log, the LLM Debug Agent can reason more effectively, pinpointing mismatches in the output and identifying missing logic terms. This leads to a more accurate and efficient bug-fixing process.

Sampling and Debugging Mechanisms. Our experimental data demonstrates the effectiveness of the proposed sampling and debugging mechanisms in enhancing the quality of generated RTL. Fig. 4(a) illustrates that the RTL generated with the sampling strategy consistently outperforms the RTL without sampling across different problems. The score distribution

TABLE III: Multi-Agent task distribution ablation study: Pass Rates with Claude 3.5 Sonnet 2024-10-22, Low-Temperature Setting.

Config	Type	VerilogEval-V2 Pass@1
Vanila LLM	Pass%	72.4
Single-Agent	Pass%	83.9
	Improvement(Δ)	**+11.5**
Multi-Agent	Pass%	93.6
	Improvement(Δ)	**+21.2**

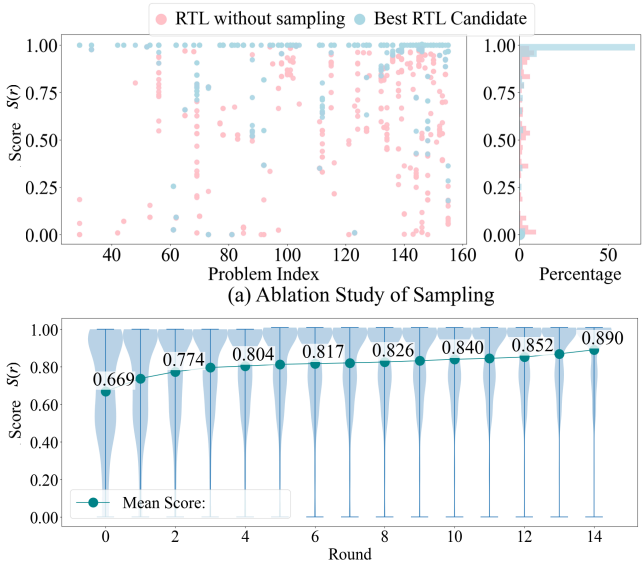

Fig. 4: Score $S(r)$ improvement of RTL by sampling and debugging. (a) Score distribution: generated RTL without sampling versus sampled and selected best RTL candidate; (b) Score distribution and the mean score of generated RTL in each debug round. Data of problems fixed before entering the debug stage are not included.

indicates that, without sampling, the RTL scores are nearly uniformly spread across the range $[0, 1]$. However, after applying the sampling method, the scores are concentrated near 1, reflecting a significant quality improvement. Fig. 4 (b) depicts the improvement in the mean score across multiple rounds of debugging, starting from an initial score of 0.669 and reaching 0.890 after sufficient refinement. This consistent increase in score demonstrates the cumulative benefit of iterative debugging, leading to more optimal RTL solutions.

V. Conclusion

In this paper, we propose MAGE, the first open-source LLM-based multi-agent system designed for automated and accurate Verilog RTL code generation. Integrated with a novel High-Temperature RTL Sampling and Scoring process, MAGE effectively explores more potentially correct candidates, leading to higher pass rates than prior studies. Augmented with RTL Debugging with State Checkpoint Mechanism, MAGE further optimizes the code with more precise feedback. Our system represents a critical step toward automating and optimizing hardware design workflows, offering a more robust methodology for AI-driven RTL design.

***Abstract*—Directed Acyclic Graphs (DAGs) are widely deployed as task models in autonomous systems, including vehicles and drones, to capture functional dependency. DAG scheduling has been extensively investigated by various communities to shorten makespan, under the common assumption that the model itself is given a priori. This work studies a rarely touched problem — construction of DAG models — and considers time-triggered blended task chains predominant in autonomous systems. We report representation semantics and a topology optimization method. Experiments show that the average end-to-end response time reduction is 4.8 times of the conventional Floyd algorithm. Our time complexity is $\mathcal{O}(n^2)$, making it suitable for handling dynamic tasks as well.**

I. Introduction

Autonomous systems are increasingly applied in fields such as vehicles and drones. These systems typically need to perform a series of tasks in real-time to interpret the environment and make behavioral decisions. For instance, autonomous vehicles utilize multiple sensors to collect environmental data, and then process these data through a sequence of tasks such as data preprocessing and data fusion, which enable the identification of pedestrians, obstacles, and road signs in real-time. Beside the timely requirements, autonomous systems are usually resource-constrained. To enhance the system's real-time performance and resource utilization, much research has focused on task scheduling. However, the construction of task models is often overlooked. Most studies assume that task models and their dependencies are predefined, but in reality, the way tasks are modeled directly influences the effectiveness of scheduling. The design of task models, including how tasks and their relationships are abstracted, is crucial to the resulting performance of task execution.

Tasks in autonomous systems can be either time-triggered or event-triggered, but the majority are time-triggered, with each task having its own job release period. For example, in Autonomous Driving Systems (ADS), data sampling tasks are periodically triggered by various sensors, such as LiDAR and cameras [1]. Different tasks may be organized into one or more task chains to accomplish complex system functions [2]. Therefore, task dependencies must be carefully designed to enable their effective collaboration execution. Modeling these tasks as periodic Directed Acyclic Graphs (DAGs) facilitates task scheduling and behavior analysis, especially when tasks are synchronized over time, as DAGs effectively capture execution order and inter-task dependencies [3]. However, constructing a DAG that accurately reflects task dependencies and optimizes system performance presents significant challenges due to the complex data dependencies and varying periods of individual tasks.

We note that several methods have been proposed to address DAG modeling and conversion in autonomous systems. For instance, Verucchi et al. [4] introduced a method for converting a multi-rate DAG task set with time constraints into a single-rate DAG, aiming to optimize schedulability and end-to-end latency. Zhao et al. [3] focused on DAG scheduling and analysis by modeling parallelism and dependencies. Similarly, Sun et al. [5] proposed an integrated framework to analyze the schedulability of individual tasks and the end-to-end delay of task chains in a DAG. While these works consider DAG construction, they do not sufficiently address the execution efficiency of the resulting DAGs. Moreover, they emphasize using scheduling algorithms to enhance system performance.

In fact, purely relying on scheduling algorithms has limited potential to further improve time performance and resource utilization, as many algorithms are already approaching their optimal performance. However, approaching the problem from the perspective of task modeling may offer a new breakthrough. This paper delves into the construction of DAG models that accurately represents all jobs released by each task modules within a hyper-period, along with their dependencies. Our main contributions are as follows:

- A novel DAG construct approach is proposed. The approach first represents the jobs released by each task module on the chain within the hyper-period as vectors, and then apply the Kronecker product to obtain a matrix capturing all jobs and their relationships based on module dependencies, thereby constructing the initial DAG.
- A DAG simplification method, DRM, is reported. DRM can enhance the execution efficiency of the constructed DAG by reducing its redundant edges, leading to high average waiting times for jobs. Compared to the Floyd algorithm, which has a time complexity of $O(n^3)$, DRM

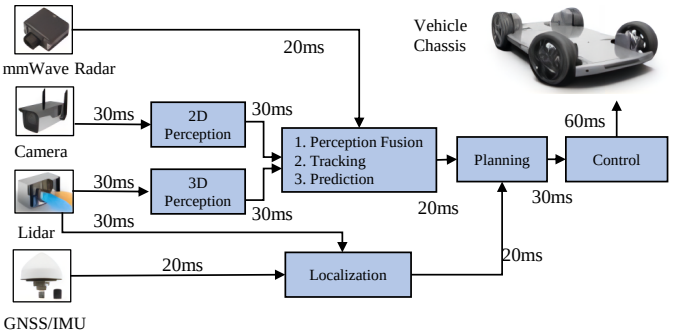

Fig. 1. An example of an ADAS (Advanced Driver Assistance System) in an intelligent vehicle

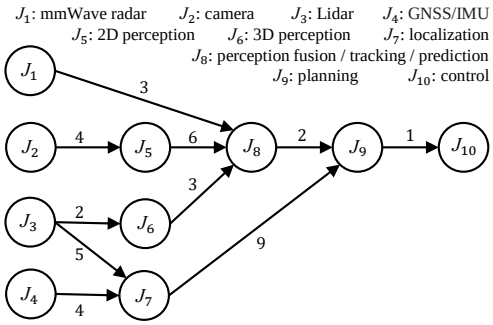

Fig. 2. Modeling the ADAS in Fig. 1, which includes 10 task modules and their dependencies.

achieves a lower time complexity of $O(n^2)$. Furthermore, to demonstrate that our method achieves a shorter average end-to-end response time, we used classic scheduling algorithms like HEFT and PEFT to schedule three types of DAGs: the unoptimized DAG, the DAG optimized by the Floyd algorithm, and our optimized DAG. Experimental results indicate that the Floyd algorithm-optimized DAG reduces the average end-to-end response time by about 2%, while our optimized DAG achieves a reduction of approximately 9.6%.

These contributions address existing limitations by providing a flexible, efficient task management framework that improves real-time responsiveness and resource allocation in autonomous systems, ultimately advancing their operational robustness.

II. Models and Problem Statement

A. Function Model

In autonomous systems, a function is often regarded as a task chain consisting of a series of task modules that periodically release jobs. These task modules can operate either sequentially or in parallel. Fig. 1 illustrates the ADAS (Advanced Driver Assistance System) in an intelligent vehicle, where modules such as Data Acquisition (DA), Data Perception (DP), Data Fusion (DF), Path Planning (PP), and Body Control (BC) form a task chain to collaboratively execute tasks. Each module has its own period; for example, the camera samples frames every 30ms, while the BC operates every 60ms. Clearly, this is an example of a directed acyclic graph of periodic tasks with data dependencies.

A function's major feature is reflected in the task modules it has and the relationships between them. Therefore, we model a function as: $F = \{J_1, J_2, \ldots, J_m, \boldsymbol{R}\}$. Here, $J_1, J_2, \ldots, J_m$ represent the task modules of the function, each defined as a tuple $J_i = (t_i, EC_i)$, where t_i denotes the time interval at which module J_i releases a job, and EC_i represents its execution cost. The term $\boldsymbol{R}$ represents the relationships between the m modules and is given by the following matrix:

$$\boldsymbol{R} = \begin{pmatrix} r_{1,1} & r_{1,2} & \cdots & r_{1,m} \\ r_{2,1} & r_{2,2} & \cdots & r_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ r_{m,1} & r_{m,2} & \cdots & r_{m,m} \end{pmatrix}. \quad (1)$$

- $r_{i,j} = 0$ represents that there is no dependency between modules J_i and J_j. Modules J_i and J_j can be executed in parallel.
- $r_{i,j} = 1$ indicates that module J_i is a direct predecessor of module J_j. In this case, an additional communication cost $C_{i,j}$ is often required to send the processing results of J_i to J_j.

Fig. 2 illustrates an example of a function model with 10 modules abstracted from the ADAS shown in Fig. 1. The related parameters of modules are listed in Table I.

TABLE I
Parameter settings for each module in Fig. 2

Modules	J_1	J_2	J_3	J_4	J_5	J_6	J_7	J_8	J_9	J_{10}
Job period	20	30	30	20	30	30	20	20	30	60
Execution cost	10	9	6	5	8	7	10	6	5	2

B. End-to-End Response Time Model

The jobs activated by module J_i within a hyper-period T can be denoted as the set $\boldsymbol{J}_i = \{J_{i,1}, J_{i,2}, \ldots, J_{i,T/t_i}\}$. Similarly to existing studies, we set $T = lcm(t_1, t_2, \ldots, t_m)$. Correspondingly, the set of all jobs can be expressed as $\boldsymbol{J} = \{\boldsymbol{J}_1 \cup \boldsymbol{J}_2 \cup \cdots \cup \boldsymbol{J}_m\}$. If $r_{i,j} = 1$, indicating that module J_i is the predecessor of J_j, it is essential to ensure that no data is lost during the transmission from the predecessor to the successor within the hyper-period T [6]. To achieve this, every job $J_{j,k'} \in \boldsymbol{J}_j$ must have a corresponding precursor $J_{i,k} \in \boldsymbol{J}_i$, and conversely, each $J_{i,k} \in \boldsymbol{J}_i$ must have a corresponding successor $J_{j,k'} \in \boldsymbol{J}_j$. For convenience, we denote the sets of predecessors and successors of $J_{i,k}$ as $pre(J_{i,k})$ and $suc(J_{i,k})$, respectively. A job with no predecessors is referred to as an entry job J_{entry}. Similarly, a job with no successors is referred to as an exit job J_{exit}. A function can have multiple entry jobs, but it usually produces only one output. Therefore, we assume that the function has a unique exit job J_{exit}, and use $\boldsymbol{J}_{\text{entry}}$ to represent the set all of entry jobs, $\boldsymbol{J}_{\text{entry}} = \{J_{i,k} \mid J_{i,k} \in \boldsymbol{J},\ |pre(J_{i,k})| = 0\}$.

The end-to-end response time refers to the time from the arrival of the entry job released by module J_i to the completion of the unique exit job J_{exit}, and is given by

$$RT(J_{i,k}) = FT(J_{\text{exit}}) - AT(J_{i,k}),\ J_{i,k} \in \boldsymbol{J}_{\text{entry}} \cap \boldsymbol{J}_i. \quad (2)$$

Here, $AT(J_{i,k})$ represents the arrival time of $J_{i,k}$, which can be obtained by adding an offset of $k-1$ periods to $AT(J_{i,1})$.

$$AT(J_{i,k}) = AT(J_{i,1}) + (k-1) \times t_i. \tag{3}$$

$FT(J_{\text{exit}})$ is the finish time of the exit job J_{exit}. Since the focus of this paper is on the construction of the model rather than the scheduling strategy, we directly use classic algorithms, such as HEFT [7] and PEFT [8], to calculate $FT(J_{\text{exit}})$.

Since each task generates a potentially infinite sequence of jobs, a schedulability interval is needed to capture the overall system behavior [6]. For this interval, Goossens et al. [9] proposed a calculation method. Within the hyper-period T, multiple entry jobs can be released. We calculate the average end-to-end response time for all entry jobs in $\boldsymbol{J}_{\text{entry}}$ as follows:

$$ART(\boldsymbol{J}_{\text{entry}}) = \frac{1}{|\boldsymbol{J}_{\text{entry}}|} \times \sum_{J_{\text{entry}} \in \boldsymbol{J}_{\text{entry}}} RT(J_{\text{entry}}). \tag{4}$$

C. Problem Statement

With the above models, our problem can be formulated as follows: Given a function $F = \{J_1, J_2, \ldots, J_m, \boldsymbol{R}\}$, along with the job release period t_i and execution cost EC_i for each task module J_i ($1 \le i \le m$), the goal is to construct a DAG that can capture the dependencies of the jobs $\boldsymbol{J}$ released from the function within a hyper-period $T = lcm(t_1, t_2, \ldots, t_m)$. The resulting DAG should minimize the average end-to-end response time of jobs in the function as much as possible when scheduled by existing algorithms.

III. DAG Construction and Optimization

Directed Acyclic Graph (DAG) modeling not only clearly represents job dependencies but also facilitates parallelism analysis.

A. DAG Construction

Each task module J_i actives a job at intervals t_i time. Within a given time T, the number of jobs activated by module J_i is T/t_i. For the function with m task modules, the number of activated jobs within time T is

$$n = \sum_{i=1}^{m} T/t_i. \tag{5}$$

To represent the relationships among the n jobs, we construct a DAG $\boldsymbol{G}$ and represent it as an adjacency matrix, denoted as:

$$\boldsymbol{G} = \begin{pmatrix} \boldsymbol{G}_{1,1} & \boldsymbol{G}_{1,2} & \ldots & \boldsymbol{G}_{1,m} \\ \boldsymbol{G}_{2,1} & \boldsymbol{G}_{2,2} & \ldots & \boldsymbol{G}_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ \boldsymbol{G}_{m,1} & \boldsymbol{G}_{m,2} & \ldots & \boldsymbol{G}_{m,m} \end{pmatrix}_{n \times n}. \tag{6}$$

Each element $\boldsymbol{G}_{i,j}$ is a sub-matrix of size $T/t_i \times T/t_j$, representing the dependency between the T/t_i jobs of module J_i and the T/t_j jobs of task module J_j.

It is evident that the value of $\boldsymbol{G}_{i,j}$ depends on the relationship between modules J_i and J_j. Generally, jobs within the same module are independent of each other, while the dependency between jobs from different modules is determined by the dependency between those modules. If module J_i is a direct predecessor of module J_j, i.e., $r_{i,j} = 1$, then any job in $\boldsymbol{J}_i$ may be a predecessor of each job in $\boldsymbol{J}_j$. Since the dependencies between modules are defined by the matrix $\boldsymbol{R}$, $\boldsymbol{G}_{i,j}$ can be calculated as follows:

$$\boldsymbol{G}_{i,j} = r_{i,j} \times \left(\mathbf{1}_{T/t_i \times 1} \otimes \mathbf{1}_{1 \times T/t_j}\right). \tag{7}$$

Here, $\mathbf{1}_{T/t_i \times 1}$ is a $T/t_i \times 1$ row vector with all elements equal to "1"; $\mathbf{1}_{1 \times T/t_j}$ is a $1 \times T/t_j$ column vector with all elements equal to "1"; the sign "$\otimes$" stands for the Kronecker product. Note that the sub-matrix $\boldsymbol{G}_{i,j}$ represents a temporarily constructed redundancy dependency between jobs, rather than an inherent characteristic of the jobs.

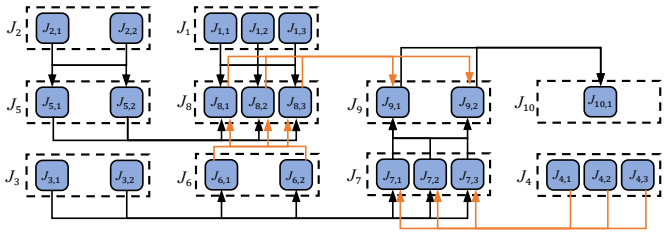

Fig. 3. The detailed structure of the DAG $\boldsymbol{G}$ with 23 jobs and 58 dependencies.

Take the ADAS in Fig. 1 as an example. Given time $T = 60$, we can construct a DAG $\boldsymbol{G}$ with 23 jobs and 58 dependencies, as shown in Fig. 3. To distinguish the different dependencies among jobs, we use different colors to label them in Fig. 3.

B. DAG Structure Optimization

Although we can use Eqs. (6) and (7) to construct a DAG representing the desired function, the resulting DAG is complex due to the intricate interconnections and hierarchical structure, complicating scheduling and parallel processing. Therefore, optimizing the DAG structure is crucial to enhance parallelism and execution efficiency.

1) Lower Bound Analysis of Dependencies: The DAG structure can be simplified by deleting redundant dependencies between jobs. According to ahead definition, the dependencies between jobs $\boldsymbol{J}_i$ and $\boldsymbol{J}_j$ are captured by $\boldsymbol{G}_{i,j}$. For convenience, we represent the element of $\boldsymbol{G}_{i,j}$ as $g_{k,k'}$, $g_{k,k'} \in \{0, 1\}$. In a real function, each task module transmits its processed results to the subsequent modules. To ensure the normal execution of the function, the following conditions for each job $J_{i,k} \in \boldsymbol{J}$ must be satisfied while optimizing the structure of the DAG $\boldsymbol{G}$.

- Satisfy the reachability of each job to the unique exit job;
- If $r_{i,j} = 1$, each job $J_{i,k} \in \boldsymbol{J}_i$ has at least one successor $J_{j,k'}$ released from module J_j, that is,

$$\sum_{k'=1}^{T/t_j} g_{k,k'} \ge 1; \tag{8}$$

- If $r_{i,j} = 1$, each job $J_{j,k'} \in \boldsymbol{J}_j$ has at least one predecessor $J_{i,k}$ released from module J_i, i.e,

$$\sum_{k=1}^{T/t_i} g_{k,k'} \ge 1. \tag{9}$$

Eqs. (8) and (9) ensure that each job can receive data from its predecessors and transmit its output to its successors.

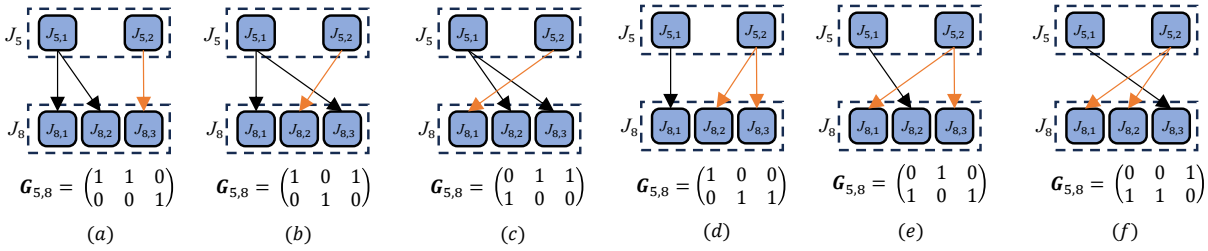

Fig. 4. 6 simple structures for sub-matrix $\boldsymbol{G}_{5,8}$ to improve parallelism and execution efficiency.

Theorem 1. *The minimum number of dependencies of DAG* $\boldsymbol{G}$ *is* $\sum_{i=1}^{m}\sum_{j=1}^{m} r_{i,j} \times max\{T/t_i, T/t_j\}$.

Proof: For each sub-matrix $\boldsymbol{G}_{i,j}$, when $t_i \le t_j$ (or $t_i > t_j$), setting $\sum_{k'=1}^{T/t_j} g_{k,k'} = 1$ (or $\sum_{k=1}^{T/t_i} g_{k,k'} = 1$) for each job $J_{i,k}$ (or $J_{j,k'}$), we can obtain that $\sum_{k=1}^{T/t_i}\sum_{k'=1}^{T/t_j} g_{k,k'} = \max\{T/t_i, T/t_j\}$. This setting ensures that both jobs $J_{i,k}$ and $J_{j,k'}$ satisfy the constraints of Eqs. (8) and (9), respectively. The same goes for other sub-matrices. ∎

Taking $\boldsymbol{G}_{5,8}$ in Eq. (6) as an example, $t_5 = 30$, $t_8 = 20$ and $T = 60$, so the minimum number of dependencies in sub-matrix $\boldsymbol{G}_{5,8}$ is $\max\{60/30, 60/20\} = 3$. Then, the minimum number of dependencies in matrix $\boldsymbol{G}$ in Fig. 3 is 27. Theorem 1 provides the minimum number of dependencies for the DAG, but identifying which redundant dependencies to delete requires further exploration. While there are various ways to remove redundant dependencies, our goal is to enhance the parallelism and execution efficiency of the DAG through their removal.

2) Removal of Dependencies: In DAG task scheduling, parallelism refers to the number of tasks that can be started simultaneously without violating dependencies. Therefore, a DAG with fewer dependencies has a relatively high parallelism. From Eq. (7), it follows that $\boldsymbol{G}_{i,j}$ is a $T/t_i \times T/t_j$ matrix, with all elements equal to "1" when $r_{i,j} = 1$. According to Theorem 1, the number of "1" in $\boldsymbol{G}_{i,j}$ can be reduced to $\max\{T/t_i, T/t_j\}$. In other words, $T/t_i \times T/t_j - \max\{T/t_i, T/t_j\}$ dependencies can be removed from $\boldsymbol{G}_{i,j}$ without compromising the correctness of the DAG.

To determine which dependencies can be removed, we assume the simplified $\boldsymbol{G}'_{i,j}$ as

$$\boldsymbol{G}'_{i,j} = \begin{pmatrix} g_{1,1} & g_{1,2} & \cdots & g_{1,T/t_j} \\ g_{2,1} & g_{2,2} & \cdots & g_{2,T/t_j} \\ \vdots & \vdots & \ddots & \vdots \\ g_{T/t_i,1} & g_{T/t_i,2} & \cdots & g_{T/t_i,T/t_j} \end{pmatrix}. \tag{10}$$

Based on Eq. (10), the problem of removal of dependencies becomes to solve the following equation.

$$\begin{cases} \sum_{k=1}^{T/t_i}\sum_{k'=1}^{T/t_j} g_{k,k'} = \max\left\{\frac{T}{t_i}, \frac{T}{t_j}\right\}, g_{k,k'} \in \{0,1\}; & \text{(I)} \\ g_{k,1} + \cdots + g_{k,\frac{T}{t_j}} \ge 1,\ \forall k, 1 \le k \le \frac{T}{t_i}; & \text{(II)} \\ g_{1,k'} + \cdots + g_{\frac{T}{t_i},k'} \ge 1,\ \forall k', 1 \le k' \le \frac{T}{t_j}. & \text{(III)} \end{cases} \tag{11}$$

It is obvious that Eq. (11) has multiple solutions.

Theorem 2. *The number of solutions that satisfy Eq. (11) is*

$$N = \binom{ab}{c} - a\binom{(a-1)b}{c} - b\binom{a(b-1)}{c} + ab\binom{(a-1)(b-1)}{c}, \tag{12}$$

where $a = T/t_i$, $b = T/t_j$, *and* $c = max\{a, b\}$.

Proof: The total number of choices to place "1" in c positions in the matrix $\boldsymbol{G}'_{i,j}$ is $N_{(\mathrm{I})} = \binom{ab}{c}$, satisfying condition (I) in Eq. (11). Condition (II) indicates that each row at least has one "1", which is similarly to Condition (III) corresponding to each column. The number of options that fail to meet them are $N_{(\mathrm{II})} = a\binom{(a-1)b}{c}$ and $N_{(\mathrm{III})} = c\binom{a(b-1)}{c}$, respectively. The case that both a row and a column have no "1" has $N_{(\mathrm{II})\&(\mathrm{III})} = ab\binom{(a-1)(b-1)}{c}$ options. Therefore, the number of solutions satisfying Eq. (11) is given by $N = N_{(\mathrm{I})} - N_{(\mathrm{II})} - N_{(\mathrm{III})} + N_{(\mathrm{II})\&(\mathrm{III})}$. ∎

Each solution corresponds to a specific structure of the DAG $\boldsymbol{G}$. Although these structures have the same number of dependencies, they may have difference execution efficiency. For sub-matrix $\boldsymbol{G}_{i,j}$, to demonstrate the impact of different structures on execution efficiency, we consider the Average Waiting Time (*AWT*) of jobs $\boldsymbol{J}_j$, which is defined as

$$AWT(\boldsymbol{J}_j) = \frac{1}{|\boldsymbol{J}_j|} \times \sum_{J_{j,k'} \in \boldsymbol{J}_j} WT(J_{j,k'}), \tag{13}$$

where $WT(J_{j,k'})$ represent the waiting time of job $J_{j,k'}$, measured from their release time to their start time, and is defined as

$$WT(J_{j,k'}) = ST(J_{j,k'}) - (k'-1) \times t_j. \tag{14}$$

If $g_{k,k'} = 1$ in $\boldsymbol{G}_{i,j}$, the start time of job $J_{j,k'}$ is given by

$$ST(J_{j,k'}) = ST(J_{i,k}) + EC_i + C_{i,j}. \tag{15}$$

Note that the start time in Eq. (14) does not take the availability of processors into account, as specific scheduling strategies are not employed and processor contention is not considered. Therefore, the start time of job $J_{i,k} \in \boldsymbol{J}_i$ can be considered as its release time, $ST(J_{i,k}) = (k-1) \times t_i$.

Illustration. We use $\boldsymbol{G}_{5,8}$, which illustrates the dependencies between jobs $\boldsymbol{J}_5$ and $\boldsymbol{J}_8$, as an example. According to Theorem 2, the number of all solutions of $\boldsymbol{G}_{5,8}$ that satisfy Eq. (11) is calculated as follows, $N_{\boldsymbol{G}_{5,8}} = \binom{6}{3} - 2\binom{3}{3} - 3\binom{4}{3} + 6\binom{2}{3} = 6$. Fig. 4 shows 6 possible structures ($a \sim f$) for $\boldsymbol{G}_{5,8}$.

Algorithm 1 Dependencies Removal Method (DRM)

Input: $\boldsymbol{G}$, m, T
Output: The simplified DAG $\boldsymbol{G}$

1: **for** i from 1 to m **do**
2: **for** j from 1 to m **do**
3: **if** $T/t_i \geq T/t_j$ **then** $\boldsymbol{G}_{i,j} = \boldsymbol{G}_{i,j}^{\mathrm{T}}$;
4: $N_{\mathrm{r}} = \min\{T/t_i, T/t_j\}$; $N_{\mathrm{c}} = \max\{T/t_i, T/t_j\}$;
5: **if** $N_{\mathrm{r}} > 1$ **then**
6: **for** k from N_{r} to 2 **do**
7: *minWT* = $+\infty$; // The minimal waiting time.
8: **for** k' from N_{c} to 1 **do**
9: $wt = WT(J_{j,k'})$ // using Eq. (14)
10: $minWT = wt < minWT \ ? \ wt : minWT$;
11: **end for**
12: Remove the dependencies from the sub-matrix $\boldsymbol{G}_{i,j}$ with $WT(J_{j,k'}) > minWT$;
13: **end for**
14: **end if**
15: **if** $T/t_i \geq T/t_j$ **then** $\boldsymbol{G}_{i,j} = \boldsymbol{G}_{i,j}^{\mathrm{T}}$;
16: **end for**
17: **end for**

Some parameters are given in the functionality model: $t_5 = 30$, $t_8 = 20$, $ET_8 = 8$, and $C_{5,8} = 6$. For structure *(a)* in Fig. 4,

$$AWT(\boldsymbol{J}_8) = \big((8+6)+(20-20)+(30+8+6-40)\big)/3 = 6.$$

The average waiting times for the other five structures are 12.33, 14.67, 14.0, 16.0, and 22.67, respectively. Obviously, structure *(a)* in Fig. 4 accelerates the start of each job in $\boldsymbol{J}_8$, resulting in higher execution efficiency compared to the others.

Algorithm description. With the execution efficiency in mind, we design the DRM (Dependencies Removal Method) approach as shown in Algorithm 1. The DRM optimizes each sub-matrix $\boldsymbol{G}_{i,j}$, and their operations are concentrated in lines 5-13. Lines 7-12 remove redundant dependencies with large waiting time between jobs $J_{i,k}$ and $\boldsymbol{J}_j$. By calling DRM for each sub-matrix, we obtain the simplified DAG $\boldsymbol{G}$. Fig. 5 shows the simplified structure of the DAG $\boldsymbol{G}$ in Fig. 3, consisting of 23 jobs and 27 dependencies. Compared to the original DAG, 31 dependencies have been removed.

Time complexity analysis. The most computationally intensive operation occurs in Lines 9 and 10, iterating through all elements of the matrix $\boldsymbol{G}$. Lines 9 and 10 require a total execution count given by $N_{et} = \sum_{i=1}^{m}\sum_{k=1}^{T/t_i}\sum_{j=1}^{m}\sum_{k'=1}^{T/t_j} 1$. According to Eq. (5), the number of jobs is $n = \sum_{i=1}^{m} T/t_i$. Obviously, we have $N_{et} = n \times n$. Therefore, the time complexity of the DRM algorithm is equal to $\mathcal{O}(n^2)$. Since DRM only traverses the edges of the DAG, its time complexity is lower compared to other optimization algorithms. The time complexity of the Floyd-Warshall algorithm is $\mathcal{O}(n^3)$, the Dijkstra algorithm (multi-source) is $\mathcal{O}(n^2(\log n + n))$, and the Bellman-Ford algorithm (multi-source) is $\mathcal{O}(n^4)$.

IV. Experimental Results and Discussion

A. Experiment Setup

To validate the effectiveness of our task modeling and optimization approach, we conduct extensive simulation experiments and compare it with *Floyd* [10]. All experiments are simulated using Python on a computer with an 11th Gen Intel(R) Core(TM) i7-11800H CPU at 2.30 GHz and 32.0 GB of RAM.

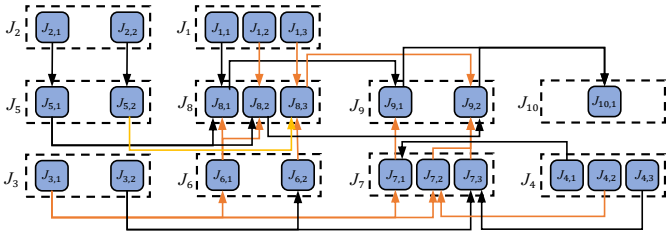

Fig. 5. A simplified structure of the DAG $\boldsymbol{G}$ in Fig. 3 with 23 jobs and 27 dependencies.

*1) **Workload Settings**:* The proposed DMR algorithm constructs the DAG based on the constraints between task modules, job periods, and loads. In our experiments, these parameters for task modeling are set as follows:

- *Number of modules.* $m \in \{10, 15, 20, 25\}$.
- *Module properties.* Each module J_i will active a job with execution cost EC_i at intervals t_i time, where $EC_i \in [1, 10]$ms and $t_i \in \{10, 25, 50\}$ms. The communication cost between modules J_i and J_j is set to $C_{i,j} \in [1, 4]$ms, $1 \leq i, j \leq m$.
- *Dependencies between modules.* We utilize a dependency generation tool sourced from the open-source project in [11] to simulate the relationship matrix $\boldsymbol{R}$ between modules. In this project, it is necessary to specify the number of modules, the in-degree and out-degree for each module (chosen from the set $\{1, 2, 3, 4, 5\}$), and the probability of each dependency being added (chosen from the set $\{0.3, 0.4, 0.5, 0.6\}$).

*2) **Platform Configuration**:* We consider computing platforms containing 8 identical processors.

*3) **Comparison Metrics**:* This section introduces two comparison metrics used in the experiments, as follow:

- *Average Waiting Time* (*AWT*). Refer to Eq. (13).
- *Average end-to-end Response Time* (*ART*). An important indicator of system execution efficiency.

B. Effectiveness of Task Modeling and Optimization

According to our workload settings, we will first construct numerous DAGs. Next, we shall simplify these DAGs using our approach DRM and the Floyd algorithm, respectively. Finally, we schedule both the simplified and unsimplified DAGs using the well-known HEFT and PEFT algorithms and compare their respective results. In our experiments, 1000 DAGs are synthesized with different numbers of modules.

*1) **Experiment 1**:* The results of scheduling using HEFT are shown in Fig. 6. We observe that the unsimplified DAGs have a higher *AWT* compared to the simplified cases using Floyd and DRM. Our proposed DRM achieves the smallest *AWT* compared with the unsimplified and Floyd. The specific *AWT* values for the unsimplified, Floyd, and DRM are 53.43ms, 50.18ms, and 42.52ms, respectively. Compared

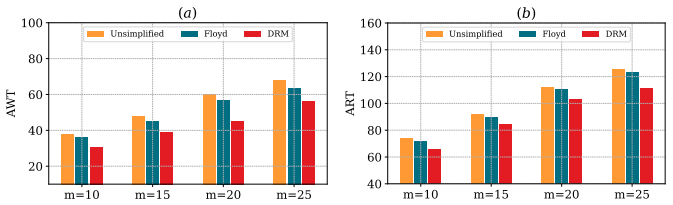

Fig. 6. Results of *AWT* and *ART* for the unsimplified, Floyd, and DRM, obtained by HEFT.

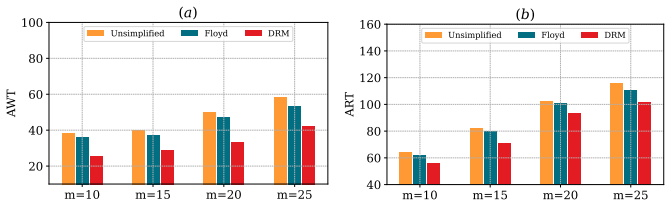

Fig. 7. Results of *AWT* and *ART* for the unsimplified, Floyd, and DRM, obtained by PEFT.

with unsimplified, Floyd and DRM reduce *AWT* by 6.08% and 20.42%, respectively. Clearly, Floyd has a smaller *AWT* compared to the unsimplified case, and our proposed DRM is smaller than Floyd. Through calculation, the *ART* values of the unsimplified, Floyd, and DRM are 101.04ms, 99.05ms, and 91.31ms, respectively. Compared with unsimplified, Floyd and DRM reduce *ART* by 1.97% and 9.63%, respectively. In summary, the relationship between the *AWT* and *ART* values for the unsimplified, Floyd, and DRM methods can be summarized as follows:

$$\begin{cases} AWT_{\text{Unsimplified}} > AWT_{\text{Floyd}} > AWT_{\text{DRM}}, \\ ART_{\text{Unsimplified}} > ART_{\text{Floyd}} > ART_{\text{DRM}}. \end{cases} \tag{16}$$

Therefore, we can be concluded that reducing the *AWT* of jobs can reduce the end-to-end response time to some extent. This also indicates that considering the *AWT* of jobs during the DAG structural optimization process is advisable.

*2) **Experiment 2**:* The results of scheduling using PEFT are shown in Fig. 7. The specific *AWT* values for the unsimplified, Floyd, and DRM are 46.43ms, 43.18ms, and 32.27ms, respectively. Compared with the *AWT* values in ***Experiment 1***, the *AWT* values obtained by PEFT are smaller than those of HEFT, which is attributed to the scheduling advantages of PEFT over HEFT. The *ART* values of the unsimplified, Floyd, and DRM are 90.03ms, 88.30ms, and 80.30ms, respectively. We can conclude that Eq. (16) holds true using PEFT. Compared to the unsimplified , Floyd and DRM reduce the *AWT* (*ART*) by 7.0% (1.92%) and 30.5% (10.81%), respectively.

The above two sets of experiments further validate the importance of optimizing the DAG structure and the rationale for considering the average waiting time of jobs during the structure optimization process.

V. Conclusion

In this paper, we have investigated the critical role of DAG construction in enhancing the real-time performance and resource utilization of autonomous systems, particularly in environments that have required intelligent decision-making across multiple task modules. We have introduced a novel approach to DAG abstraction and simplification that has considered task dependencies within a hyper-period, emphasizing both accurate representation and improved parallelism.

The proposed method has leveraged the Kronecker product to construct an initial DAG and has introduced an innovative edge simplification technique that has reduced average job waiting time while maintaining computational efficiency. Compared to traditional methods such as the Floyd algorithm, our approach has achieved a significant reduction in time complexity from $\mathcal{O}(n^3)$ to $\mathcal{O}(n^2)$ and has delivered superior performance in reducing the average response time of task chains. Experimental results have confirmed that the DAG optimized using our method has reduced the average response time by approximately 9.6%, significantly outperforming the 2% improvement achieved by the Floyd algorithm.

This work has highlighted the importance of DAG construction as a foundational step in performance optimization through scheduling strategy and has laid the groundwork for future research into real-time task management in autonomous systems. Potential future directions include extending the proposed methods to dynamic task environments and exploring integration with adaptive scheduling algorithms for enhanced robustness and scalability.

***Abstract*—Quasi-cyclic moderate density parity-check McEliece (QMM) cryptosystem is designed to mitigate the security threat posed by quantum computers, and is considered to be a promising candidate for post-quantum cryptography (PQC). However, the growing requirement of data encryption pose severe challenges for QMM implementation in terms of latency and hardware overhead. In this work, we firstly propose ACIM-QMM, an analog computing-in-memory (CIM) accelerator design for QMM cryptosystem. The use of analog circuits and CIM enables the design to efficiently generate key and encrypt ciphertext while breaking the performance bottleneck constrained by digital computing paradigm in PQC. In the experiment, ACIM-QMM can work in low relative error, and it can achieve 31.4× ∼ 288.1× speedup compared with SOTA hardware of QMM cryptosystem. Furthermore, the results indicate that ACIM-QMM can achieve a maximum of 3.12× area efficiency and 20.32× energy efficiency compared to other PQC hardware for 256-bit security.**

***Index Terms*—ReRAM, Circuit design, Analog Computing-in-Memory, QC-MDPC McEliece**

I. Introduction

Different from other post-quantum cryptography (PQC), code-based McEliece cryptography has maintained its security to this day [1], [2]. In the fourth round of NIST PQC standardization process, it was selected as a key encapsulation mechanism finalist [4], [6]. However, code-based cryptosystems inherently grapple with the challenge due to the large key sizes, which impose a significant burden on limited hardware resources and make existing implementations of the McEliece cryptosystem inefficient and impractical [1], [3], [5].

To achieve a compact key while maintaining security, numerous alternatives have been proposed to reduce the size of public key [2]. QC-MDPC McEliece (QMM) cryptosystem stands out as a notable implementation, requiring only 1.2 kilobytes for a 128-bit security level (SL) [5]. Security analyses and research have validated its potential, positioning it as a promising variant within McEliece-type cryptosystems [5]. However, despite its compact nature, further efficient and rapid designs are required to meet the urgent demands of massive data encryption in the context of exponential data growth.

Unlike Lattice-base and Hash-based PQC, code-based QMM cryptosystem requires numerous matrices operation [7], [8]. Therefore, it naturally fits with the crossbar-based computing-in-memory (CIM) circuits for matrices operation, which can avoid the bottleneck of data transmission [9]. Within CIM, different from digital CIM (DCIM) , analog CIM (ACIM) circuits can perform matrices operation in one step due to the computation speed of electromagnetic waves [9]. Additionally, ACIM significantly reduces the use of hardware resources by avoiding signal conversion [10]. However, existing implementation of QMM cryptosystem mainly depends on von-Neumann architecture and digital computing paradigm, the use of which have difficulty in satisfying the aforementioned requirement, and there is no ACIM accelerator design for QMM cryptosystem currently.

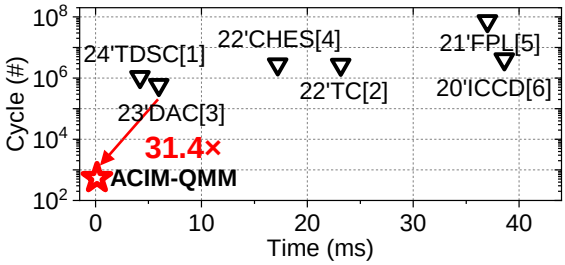

Fig. 1. Comparison with the state-of-the-arts.

Motivated by this, we introduce ACIM-QMM, an analog CIM accelerator leveraging resistive random-access memory (ReRAM) for rapid execution of QMM key generation and encryption. To address the limitation of analog circuits in performing matrix operations in Galois Fields (2) (which is abbreviated as GF (2)), we propose a data-flow deployment and accelerator design. This enables swift GF(2) matrix operations on analog circuits, achieving large-key computations within limited circuits, thereby drastically reducing hardware costs. ACIM-QMM stands out in high-speed, energy-efficient encryption hardware, efficiently tackling any SL task of QMM cryptosystem, outperforming traditional architecture and digital circuits. As illustrated in Fig. 1, ACIM-QMM significantly outpaces other hardware in 128-bit SL evaluations. We believe our design holds great potential for exploring analog circuits to empower PQC. The key contributions of this work are:

- **GF(2) Matrix Deployment:** Our data-flow scheme enables efficient GF(2) matrix operations in analog circuits, handling large-key computations for any SL QMM cryptosystem within limited resources.
- **ACIM-QMM Accelerator:** As the first ReRAM-based ACIM accelerator for QMM cryptosystem, ACIM-QMM significantly accelerates key generation and encryption while lowering hardware costs.
- **Performance Evaluations:** Comprehensive experiments showcase ACIM-QMM's superiority over other hardware, as illustrated in Fig. 1 and Section 4, with the proposed

strategies to mitigate non-ideal analog circuit factors, ensuring robust performance.

II. Background and Related Work

A. Key generation and encryption of QMM cryptosystem

According to the specification of QMM cryptosystem, its procedure of key generation and encryption is shown in Algorithm 1. Notably, the traditional approach to implementing QMM cryptosystems involves crafting gate arrays and digital circuits tailored for each operation. However, as encryption demands grow due to big data, digital circuits and gate arrays face increasing latency and hardware costs. While analog circuits excel in mitigating these issues and executing tasks swiftly and efficiently, they struggle with GF(2) matrix operations. Analog circuits are adept at handling continuous variable problems and can perform matrix calculations in one-step by constructing and mapping mathematical structures. However, unlike digital computing's sequential logical operations, analog circuits cannot establish the necessary mathematical framework for GF(2) matrices, which prevents them from directly executing modulo-2 operations and completing key generation and encryption in QMM cryptosystem within a single matrix operation step. Aiming at the above problem,

Algorithm 1 Key generation and Encryption algorithm in QMM cryptosystem

Require: n,t,r,w,n_0: Parameters; m: Message; e: Error vector; (n= $n_0 \times r$)

Ensure: H:Private Key; G: Public Key; x: Cipher Text.

1: Generate a (n, r, w)-QC-MDPC code $h \in F_2^n$ of weight $w = \sum_{i=0}^{1} w_i$ at random.
2: $r-1$ quasi-cyclic shifting h and obtaining parity-check matrix H, where $H = [H_0|H_1|...|H_{n_0-1}]$.
3: Generate public key $G = [H_{n_0-1}^{-1}H_0|...|H_{n_0-1}^{-1}H_{n_0-2}|I_{n\times n}]$ and $G \in F_2^{(n-r)\times n}$.
4: Generate $e \in F_2$ of $wt(e) \leq t$ at random.
5: Calculate Cipher text $x = mG^T + e$.

we propose a data-flow deployment for GF(2) matrices operation in analog circuits, and ACIM circuits design which can efficiently generate key and ciphertext.

B. Related work

McEliece-type cryptosystems hardware: Current implementations of McEliece cryptography focus on general computing platforms (CPUs, GPUs) and FPGAs, including both classic and QC-MDPC versions. Some relative researches have aimed to reduce ciphertext length for faster encryption [7], [11] and optimize memory usage for better performance [13]. However, the used von-Neumann architecture poses a challenge, limiting the achievement of highly efficient encryption, especially for the requirement of high security levels and large data processing. FPGA implementations have improved speed and power consumption [1], [3], [4], but still face difficulties in maintaining low latency and minimal hardware overhead with increasing data sizes due to the limitations of digital circuits.

CIM architecture for PQC: CIM architecture facilitates in-situ computing within the storage unit, significantly reducing data transmission and hardware overhead, making it ideal for high-speed, efficient hardware-based PQC solutions. Ding et al. proposed an MRAM-based CIM accelerator for LPN-based PQC protocols, achieving speeds 216.8 times faster than CPU and FPGA [14]. Li et al. introduced a CIM-based crossbar design that significantly accelerates polynomial multipliers using the Number Theoretic Transform [15]. These works clearly demonstrate substantial acceleration for PQC. However, they primarily concentrate on digital computing and overlook the benefits of non-volatile devices in analog computing [9]. As computing dimensions and SL escalate, these designs may encounter challenges due to frequent signal conversions and excessive peripheral circuit redundancy.

In summary, the rapid growth of data necessitates a novel hardware design for PQC that can fulfill the increased SL and dimensional data encryption demands.

III. ACIM-QMM Design

In this section, we propose a data-flow deployment and ACIM circuits, which address two issues: (1) enabling analog circuits to directly perform GF(2) matrix operations, including key generation and encryption for QMM cryptosystem; (2) improving efficiency of circuits in latency and performance.

A. GF(2) Matrix Deployment Scheme

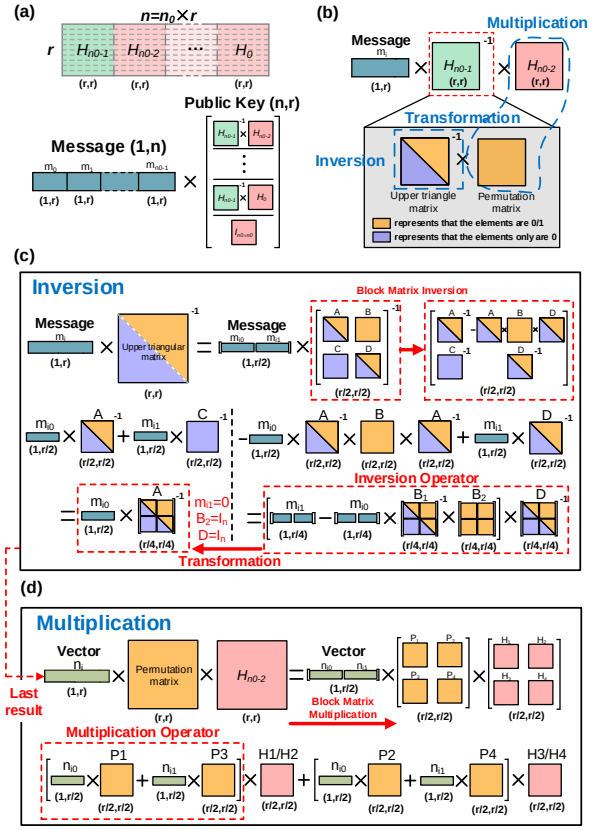

Fig. 2. (a) Parity-check matrix and transformation for H_{n_0-1}; Example of the matrices inversion (b) and multiplication (c) in key generation adopting the proposed scheme; (d) Procedure of cipher-text encryption.

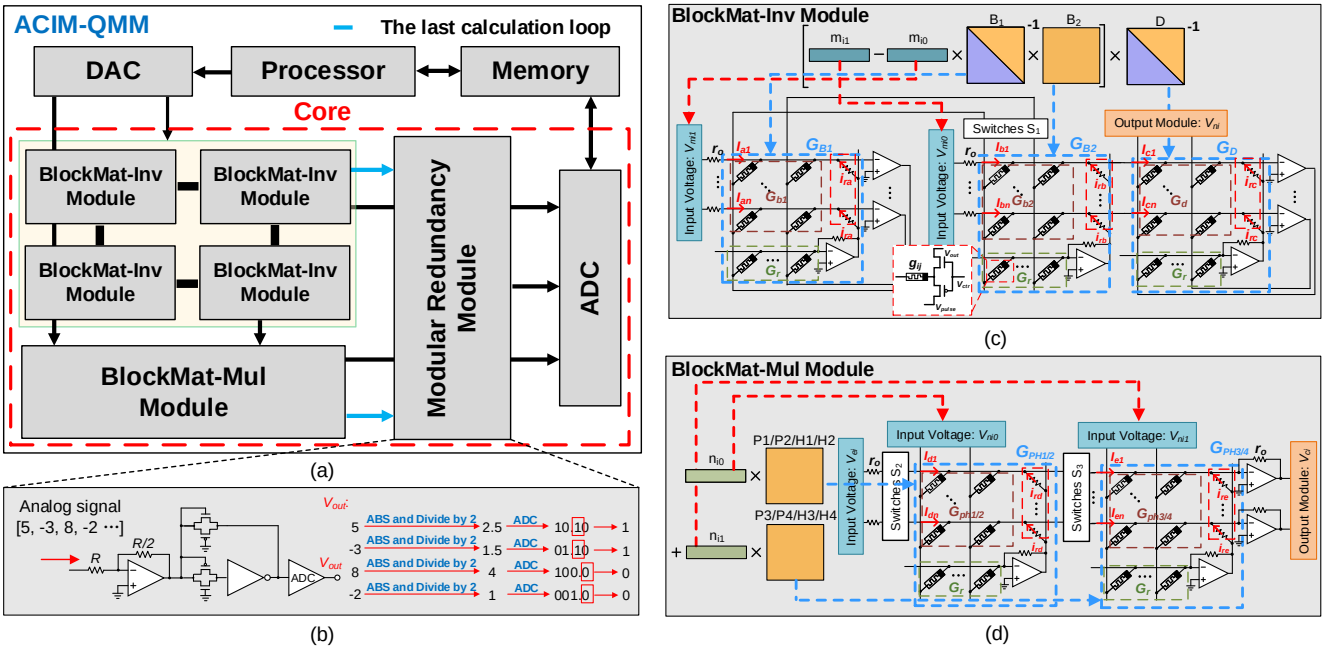

Fig. 3. (a) Overview of ACIM-QMM architecture; (b) Module for modular redundancy operation; (c) BlockMat-Inv circuit for IO in key generation; (d) BlockMat-Mul circuit for MO in key generation and ciphertext encryption.

The generated parity-check matrix H is divided into blocks, with H_{n_0-1} inverted as shown in Fig. 2(a). Algorithm 1 involves multiplying the message m by the public key matrix G built from H. In the process, m can be divided into n_0-1 vector m_i (where $i \in \{0, ..., n_0 - 1\}$), corresponding to the rows of the block matrices in G. Consequently, multiplying m by G can be broken down into a series of operations: multiplying n_0-2 vectors m_i by matrix $inv\,(H_{n_0-1})$ and H_i, and directly multiplying m_r by the identity matrix I_{n_0}, as shown in Fig. 2(a).

Given the inherent challenges of matrix inversion in analog circuits over GF(2), we propose a novel approach in the Fig. 2(b). We decompose H_{n_0-1} into an upper triangular matrix and a corresponding permutation matrix, both defined over GF(2). By inverting the upper triangular matrix and then multiplying it by the permutation matrix, we derive the inverse matrix modulo 2. By multiplying each message vector m_i with this inverse matrix and H_i, adding a randomly generated error e, and subsequently combining multiple block matrices, we can efficiently complete the entire key generation and encryption process.

For 80-bit to 256-bit SL encryption tasks, the dimension of H_{n_0-1} ranges from 3079 to 32771. However, limited ReRAM-based crossbars cannot directly handle such large matrix operations. Matrix multiplication can reduce complexity by segmenting matrices into blocks and sequentially performing block matrix multiplication and addition, allowing efficient execution on limited crossbars. However, matrix inversion does not lend itself to straightforward decomposition. To overcome this, we decompose the inversion matrix of the aforementioned upper triangular matrix and its corresponding permutation matrix. The inversion of the upper triangular matrix can be achieved by following these rules:

$$\begin{bmatrix} A & B \\ 0 & D \end{bmatrix}^{-1} = \begin{bmatrix} A^{-1} & -A^{-1}BD^{-1} \\ 0 & D^{-1} \end{bmatrix} \tag{1}$$

where block matrices A and B are the upper triangle matrices. Based on the rule, we can multiply the message vector m_i multiply with the inversion of upper triangular matrix, which is as demonstrated in Fig. 2(c) and has the following form:

$$m \begin{bmatrix} A & B \\ 0 & D \end{bmatrix}^{-1} = \begin{bmatrix} m_{i0}A^{-1} & (m_{i1} - m_{i0}A^{-1}B)D^{-1} \end{bmatrix} \tag{2}$$

where m_{i0} and m_{i1} are the sub-vector from vector m_i and the dimension relation is shown in Fig. 2(c). In the process of multiplying the inverse matrix of H_{n_0-1} with the message vector m_i the main operation involves $m_{i1} - m_{i0}A^{-1}BD^{-1}$, referred to as the Inversion Operator (IO) in this manuscript. By setting m_{i1} to 0 and matrices B and D to identity matrices, $m_{i0}A^{-1}$ can be calculated using this operator. According to block matrix rules, we can further decompose the operator and continuously reduce the scale of the upper triangular matrix to be compatible with limited-scale crossbars.

The above results following need to multiply permutation matrix P and matrix H_i. This process is illustrated in Fig. 2(c) and it follows:

$$\begin{aligned} nP &= \begin{bmatrix} n_0 & n_1 \end{bmatrix} \begin{bmatrix} P_1 & P_2 \\ P_3 & P_4 \end{bmatrix} \\ &= \begin{bmatrix} n_0P_1 + n_1P_3 & n_0P_2 + n_1P_4 \end{bmatrix} \end{aligned} \tag{3}$$

Through analysis, it is evident that there is a basic operator: $n_0P_1 + n_1P_3$, which can be adapted by replacing the permutation matrix P with matrix H_i to perform operations with H_i, and it is called as Multiplication Operator (MO) in this manuscript. Similarly, the block matrices used can be further decomposed to perform vector-matrices multiplication within them. Consequently, we can implement matrix inversion op-

erations in GF(2) on analog circuits. Based on the proposed operators, we can design domain-specific analog circuits that pave the way for executing key generation and encryption tasks of any SL QMM with limited hardware resources.

B. ACIM-QMM Circuits and Architecture

Using the aforementioned GF(2) matrix deployment scheme, we design analog circuits based on the operator and accelerator architecture shown in Fig. 3. The crossbar employed in our design adopts a 2T1R structure, and the programming method is based on the model described in [10].

The BlockMat-Inv circuit is proposed for mapping with IO, which is primarily composed of three 256×256 crossbar. Specifically, the messages m_{i1} and m_{i0} in IO are mapped to the input voltage source within the module, while the computed matrices B_1, B_2 and D are mapped to the crossbars, which is illustrated in Fig. 3(c). Since ReRAM cannot directly represent 0/1 elements in GF(2), we propose an equivalent matrix expression circuit comprising sub-crossbars and a common ReRAM row. For instance, $G_{B1}$is composed of a sub-crossbar G_{b1} and common ReRAM row G_r. Under the same voltage V, the following relation holds:

$$I = VG_{b1} - VG_r vec(1)^T \tag{4}$$

where I represents the current obtained by applying voltage V into the sub-crossbar G_{b1} in conjunction with the common ReRAM row G_r; $vec(1)$ denotes a vector of all ones. Utilizing operational amplifiers (OAs), the current resulting from voltage V applied to G_r can be redirected to flow back into the sub-crossbar G_{b1}. Consequently, we can derive the equivalent matrix $G_{B1} = G_{b1} - G_r vec(1)^T$. This equivalent matrix G transforms the high and low states of ReRAM into a 0/1 expression. Initially, when voltage V_{mi1} is applied into crossbar G_{B1}, the following principle applies:

$$\begin{cases} V_o = -\left(V_{mi1}/r_o\right) \cdot \left(G_{b1} - G_r\right)^{-1} \\ V_{mi1}/r_o = I_a + i_{ra} \\ I_a = V_o/G_{b1}, i_{ra} = -V_o/G_r \end{cases} \tag{5}$$

where G_{B1} is the equivalent matrix of the city constructed by G_r and G_{b1}. In there, the use of OAs and negative-feedback principle, the circuit converts the current into the voltage, and it is formally equivalent to taking the reciprocal of conductance G according to the principle of trans-impedance amplifiers (TIA). Based on the equivalent matrix, the sub-circuit achieve matrix inversion of upper triangle matrix B_1. After obtaining results V_o, under the control of switches, the remainder sub-circuits have the following principles:

$$\begin{cases} V_{ni} = \left[V_{mi1}/r_o + V_o\left(G_{b2} - G_r\right)\right] \cdot \left(G_d - G_r\right)^{-1} \\ V_{mi1}/r_o = I_b + i_{rb} + I_c + i_{rc} \\ I_b = V_o/G_{b2}, I_c = V_{ni}/G_d, i_{rb} = -V_o/G_r, i_{rc} = -V_{ni}/G_r \end{cases} \tag{6}$$

where $G_{b2} - G_r = G_{B2}$ and $G_d - G_r = G_{D2}$. The current flowing into matrix inversion circuit is obtained from voltage V_{mi0}, V_o and crossbar G_{B2}, and then the right sub-circuit converts the input current into voltage. Based on the above all analysis, the BlockMat-Inv circuit has the following relation:

$$V_{ni} = -\left[V_{mi1}/r_o - S \cdot \left[V_{mi0}/r_o \cdot G_{B1}^{-1}\right] \cdot G_{B2}\right] \cdot G_D^{-1} \tag{7}$$

where V_{ni} is the output, r_o is the resistor which can convert voltage into current, S is the control signal from Switches. The BlockMat-Inv circuit perform the IO operation when $S = 0$, otherwise it can map with the term $m_{i0}A^{-1}$.

The BlockMat-Mul circuit of Fig. 3(d) can achieve the MO operator, and the BlockMat-Mul circuit is composed of 512×512 ReRAM-based crossbar. The aforementioned result voltage V_{ni} is transferred to this circuit, it also divided into two vector n_{i0} and n_{i1}, which are respectively mapped with input voltage source. The block matrices of P and H in Fig. 2 can respectively map with the crossbar $G_{PH1/2}$ and $G_{PH3/4}$. Therefore, the principle is as follow:

$$V_{ci} = -r_o \cdot \left[S_2 \cdot \left(V_{ei}/r_o\right) + I_{ni}\right] \tag{8}$$

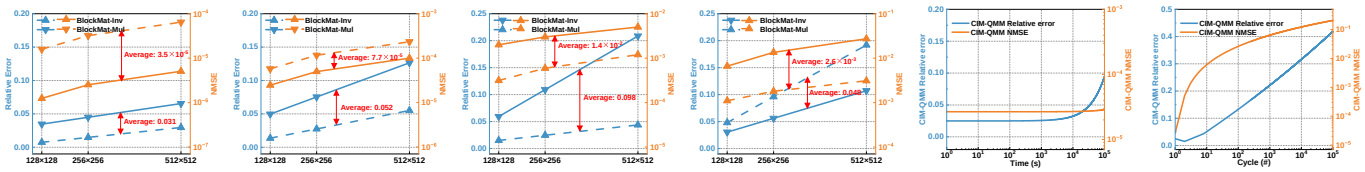
$$\begin{aligned} I_{ni} &= S_3 \cdot \left(V_{ni0}G_{PH1/2}\right) + V_{ni1}G_{PH3/4} \\ &= S_3 \cdot \left(I_d + i_{rd}\right) + I_e + i_{re} \end{aligned} \tag{9}$$

where S_2 and S_3 respectively represent the Switches. To be specific the above principle , it has the following form:

$$I_{ni} = S_3 \cdot \left(V_{ni0}G_{ph1/2} - V_{ni0}G_r\right) + V_{ni1}G_{ph3/4} - V_{ni1}G_r \tag{10}$$

The BlockMat-Mul circuit identically adopts equivalent matrices, it's kernel is to perform MVM operation. It will perform the operation that the multiplication of calculating results and permutation matrix P/block matrix H_i when $S_3 = 1$, the error vector also will be added if $S_2 = 1$ (which achieve map with the Process 9 of Algorithm 1), otherwise it will only perform multiplication of single block matrix.

The modular reduction operation can be the final step after completing all matrix operations, as noted in [16]. Moreover, we also propose a circuit design to perform modular reduction aiming at analog circuits, as shown in Fig. 3(b), which should be used after the other operation. The design consists of switches, OAs, inverters and analog to digital converter (ADC). The module has the following discipline:



$$C\left(x, y\right) = \begin{cases} 1, x > y \\ 0, x \leqslant y \end{cases} \tag{11}$$

$$f\left(i\right) = C\left(\left|\frac{V_c}{2}\right|, \frac{V_r}{2^n}\left(2^{i+1} - 2\right)\right) + C\left(\left|\frac{V_c}{2}\right|, \frac{V_r}{2^n}\left(2^{i+1} - 1\right)\right) \tag{12}$$

$$V_{final} = \operatorname{sgn}\left(\sum_{i=1}^{n} f\left(i\right)\right) \tag{13}$$

where sgn represents sign function, V_r is the reference voltage of ADC, n is the bits number of ADC. When signal input, it becomes absolute value and divides into 2 by using switches and inverter. After 4-bit ADC conversion, the analog signal converts as digital signal. If 1 exists on the decimal place of the the modular reminder, the result should be 1, otherwise 0.

The above circuits together form the ACIM-QMM architecture, which is shown in Fig. 3(a). In this architecture, we use four BlockMat-Inv Modules for performing IO operation

(a) (b) (c) (d) (e) (f)

Fig. 4. Relative error and NMSE in the BlockMat-Inv and BlockMat-Mul circuits (a), under wire resistance impact (b), under device deviation impact (c), under noise impact (d), under device retention impact (e) and under device endurance impact (f).

and one BlockMat-Mul Module for performing MO operation. For any SL key generation and encryption task, we can continuously decompose the matrix until it fits the circuit scale of ACIM-QMM based on the above data-flow deployment method, and programming the decomposed block matrices into the crossbar sequentially. The results calculated by the modules of Fig. 3(c) and Fig. 3(d) are transferred into the Modular Redundancy Module, which performs the modulo-2 operation. The obtained results are the generated ciphertext.

IV. Results and Analysis

ACIM-QMM architecture is simulated for its performance in this section. The circuits are designed and tested in TSMC 180nm and 65nm CMOS library in the Cadence tool. All parameters of the ReRAM cells are set to the values in [17].

A. Evaluation for Calculation

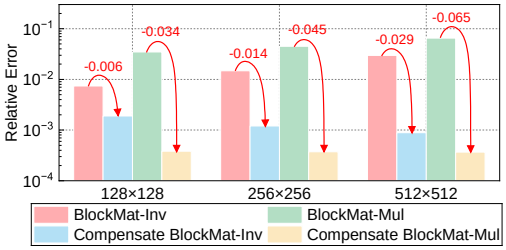
Since ReRAM is easy to be influenced by some non-ideal factors, we test the proposed circuits under various non-ideal factors, as shown in Fig. 4. Fig. 4(a) shows the relative error and normalized mean square root (NMSE) of it, which do not consider non-ideal factor impact, Fig. 4 respectively considers 2.5Ω wire resistance, 2% device deviation and 5% signal noise interference. The above data demonstrates it has good accuracy and minor difference comparing with ideal results.

However, it's worth noting that the relative error from analog circuits may adversely affect ACIM-QMM's performance in key generation and encryption. Accumulated errors can lead to incorrect modular operation results. While small errors in QMM cryptosystem can be tolerated and corrected by the decoding algorithm using the parity-check matrix, excessive errors can severely compromise ciphertext generation. In evaluation, the small NMSE indicates minimal deviation from ideal results. To mitigate error impact, we propose a compensation scheme tailored for QMM cryptosystem. This scheme consists of two parts: adjusting the resistor R in the negative terminal of the OA in Fig. 3(b), and adding a compensating voltage in the Modular Redundancy module. Using Fig. 4(a) as an example, we set R as following:

$$R_{comp} = \frac{R}{1 - RE} \tag{14}$$

where RE is the average value of BlockMat-Inv module's and BlockMat-Mul module's the relative error. Moreover, it can be performed that add complementary voltage in the BlockMat-Mul module, the complementary voltage set as follow:

$$V_{comp} = \frac{\lfloor \lfloor n/\omega \rfloor / r \rfloor}{a} \tag{15}$$



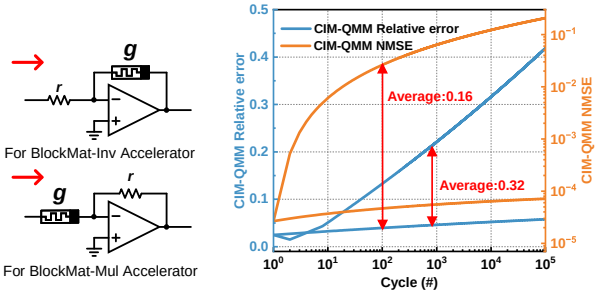


Fig. 5. Compensated accuracy for the proposed modules

where a is the seting parameter; n, r and w are the same as Algorithm 1. Therefore, as shown in Fig.5, the relative error has been reduced to below 10^{-3} and do not impact the results.

In the evaluation of endurance and retention, it can be found that the accelerator under retention has less impact in Fig. 4(e) and it does not influence the final results, but the accelerator under endurance can not be utilized due to large relative error and NMSE in Fig. 4(f). Aiming at the problem, we propose a circuit-level scheme to alleviate the impact, the compensating circuits of Fig. 6(a) is used in the input ports, it can make the input voltage having the same change relation with the conductance of ReRAM under different cycles. Therefore, the input voltage and conductance of ReRAM all obey the identical attenuation curve, which can minimise the relative error and NMSE, as shown in Fig. 6(b).

(a) (b)

Fig. 6. (a) Compensating circuits for ACIM-QMM; (b) Results.

B. Evaluation for Performance

In this section, we evaluate ACIM-QMM in the area and power consumption, and compare it with other PQC accelerator. Firstly, the area and power consumption are evaluated in Fig. 7, it shows that OAs has the most occupation in power, and DAC and OAs need more area overhead in the design.

Moreover, we compare the performance of ACIM-QMM, CPU and GPU platforms over the standard QMM cryptosystem. The CPU experiments were carried out on an Intel

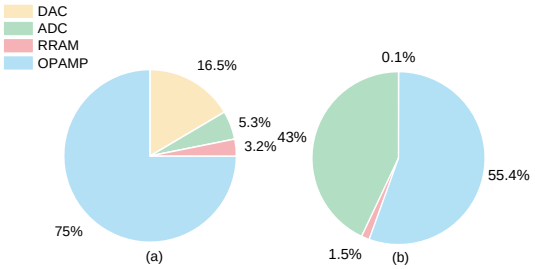

Fig. 7. (a) Power consumption and (b) area consumption of the ACIM-QMM.

TABLE I
PERFORMANCE COMPARISON OF ACIM-QMM WITH OTHER PQC HARDWARE.

Scheme	SL[bit]	Time(ms)		Area (mm^2)	Energy (μJ)
		Gen	Enc./Sig.		
ACIM-QMM	80	0.036		0.42	18.4
	128	0.134			68.6
	256	1.290			660.5
Kyber [18]	128	3.32	4.27	0.67	140.9
	256	7.73	8.96		307.7
Frodo-KEM [19]	128	159	161	0.28	2177.6
	256	994	99		13425.3
Dilithium [20]	128	3.84		1.31	26.6
	256	10.2			82.5

Xeon(R) Platinum 8352V processor. The GPU evaluation is based on the NVIDIA A800-80GB and V100-32GB. All parameters of the tasks are instantiated referencing [7]. Fig. 8 shows that it has great improvement in speed, especially it can achieve maximum 3E6× improvement in 256-bit SL comparing with GPU A800.

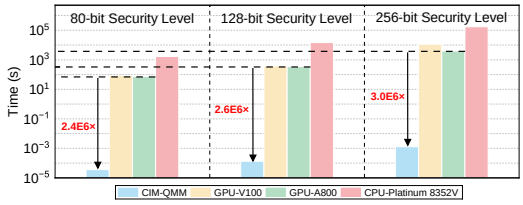

Fig. 8. Comparison with GPU and CPU in executing time.

Table I compares ACIM-QMM with other PQC cryptography hardware, including Kyber, Frodo-KEM, and Dilithium, which offer encryption and signature capabilities. Under a 256-bit SL evaluation, ACIM-QMM achieves a minimum of 7.9× and a maximum of 847.3× improvement in key generation and encryption/signature time. In terms of energy, it offers up to 31.7× and 20.3× improvement for 128-bit and 256-bit SLs, respectively. This significant improvement is attributed to ACIM-QMM's use of ACIM, which performs matrix operations in one-step, drastically lowering power and area overhead. Therefore, we believe that ACIM-QMM can offer a solution for advancing PQC hardware design.

V. CONCLUSION

In summary, we propose an efficient and robust ReRAM-based CIM circuit design for accelerating the QMM cryptosystem, which can rapidly perform key generation and encryption. To address the challenge of analog circuits' inability to perform GF(2) matrix operations, we propose a dataflow deployment method. This method not only resolves the aforementioned issues, but also enables the efficient execution of key generation and encryption for any SL on analog circuits with limited scale. Our experimental results demonstrate that the innovative design can achieve maximum 288.1× speedup compared to SOTA, and maximum 31.7× energy improvement compared to other PQC hardware in 128-bit of security.

***Abstract*—We introduce the ReMaP framework, which generates expert-quality macro placements through recursively prototyping and periphery-guided relocating. A key innovation is ABPlace, an angle-based analytical method that arranges macros along an ellipse to facilitate a rough distribution near the periphery, while optimizing dataflow, minimizing overlap, and ensuring convergence. Based on the results of ABPlace, an efficient heuristic is proposed to position macros along the chip's periphery, mirroring practices often employed by experts. Our framework outperforms three leading macro placers in both WNS and TNS across eight test cases, achieving improvements up to 34.15% in WNS and 65.39% in TNS, as tested on the popular OpenROAD-flow-scripts infrastructure. Additionally, our parameter auto-tuning method further improves timing by 8.75%.**

I. Introduction

The macro placement problem has been a significant focus in both academia and industry for decades. Ineffective macro placement can obstruct essential core areas of a chip, leading to overcrowded and elongated paths that delay timing and complicate the positioning of standard cells. This issue has become increasingly important as chips grow in size and complexity, requiring the integration of more macros, which makes achieving efficient placement more challenging.

Due to its critical role, macro placement has traditionally required experts who use specialized knowledge for each specific case. This includes optimizing dataflow to enhance timing, placing macros along chip periphery to reduce routing congestion, tiling macros to improve power management, and positioning macros away from pin areas to facilitate pin access [9], [10]. Experts also use feedback from back-end evaluations and front-end engineers to refine the results iteratively, which can take weeks or months to complete [19].

To achieve expert-quality placement results and reduce turn-around time (TAT), automated placement algorithms emulate expert behaviors and incorporate heuristics into their optimization processes. Our work focuses on positioning macros along the chip periphery, and incorporating specific strategies to enhance placement regularity. It's important to distinguish between periphery placement and regularity, as they serve different purposes. Some approaches address them separately [9], [14], while others do not [22], [26]. Periphery placement helps preserve central regions for standard cell placement, reducing routing congestion and detours, which enhances overall timing performance. Improving regularity involves tiling macros of the same size and minimizing notch and dead areas [9], [14], which not only benefits power planning but also helps placement and routing for large-scale, high-utilization cases.

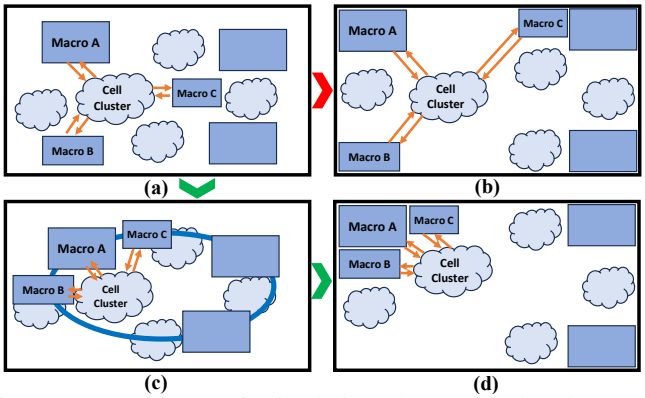

Fig. 1: (a) Prototype of mixed-size placement. (b) Placement result following the direct application of the periphery-pushing heuristic. (c) Optimization of macros on an ellipse, called ABPlace. (d) Periphery-guided relocating of macros based on their placement along the ellipse.

The general motivation and strategy of our flow is shown in Fig. 1. We begin with a mixed-size prototyping as shown in Fig. 1(a). An intuitive yet less effective method, shown in Fig. 1(b), involves moving each macro towards the nearest corner or periphery of the chip layout. No matter where we place the cell cluster, the total communication cost remains high due to the considerable distances between macros A, B, and C. Alternatively, to relocate macros to the periphery, we fix all cell clusters and optimize macro positions along an ellipse, considering dataflow cost and macro overlap, as shown in Fig. 1(c). The macros are then strategically moved to optimal locations considering dataflow and periphery cost, as illustrated in Fig. 1(d). This sequence of steps (a), (c), and (d) is repeated recursively. The number of macros placed at each iteration is tuned to balance efficiency and accuracy.

Our contributions are summarized as follows:

- We develop a macro placement framework, **ReMaP**, that delivers expert-quality results through a recursive process of prototyping and periphery-guided relocating. Our algorithm naturally handles pre-placed macro scenarios by iteratively placing and fixing macros in stages. We have open-sourced the code at https://github.com/lamda-bbo/DAC25-ReMaP and provided detailed evaluation scripts and metadata to facilitate replication.
- We introduce ABPlace, an innovative angle-based ana-

* Equal contribution.

lytical method that arranges and optimizes macros along an ellipse. This approach considers the dataflow strength between macros and macro-cell clusters, and helps distribute macros uniformly near the chip periphery. With a single angle variable to optimize for each macro, ABPlace achieves easy convergence across all test cases.
- We design an efficient heuristic to relocate macros to the chip periphery, guided by the results from ABPlace. We propose two criteria to determine the placement order: one emphasizes dataflow, while the other enhances layout regularity. By dividing the feasible placement region into grids, we then optimize dataflow through greedy selection.
- Our extensive comparisons with three leading macro placement tools—RTL-MP [9], Hier-RTLMP [10], and DREAMPlace 4.1.0 with macro placement enhancements [2], [18]—demonstrate that the proposed ReMaP achieves superior post-route WNS and TNS across all eight chip cases from the OpenROAD-flow-scripts [1]. We also involve Bayesian optimization for parameter autotuning and performance improvement.

II. Related Works

Generally, macro placement techniques can be classified into three categories: zeroth-order methods, analytical methods, and learning-based methods.

Zeroth-order methods are extensively utilized in the field of design automation, as most of the power, performance and area (PPA) metrics are black-box and non-differentiable. There are two fundamental components for a zeroth-order method for macro placement: solution representation and evaluation. Initial research efforts mainly focus on proposing effective data structures to represent a placement solution, including corner block list [7], sequence pair [20], B*-tree [25], slicing tree [27], and so on. The evaluation criteria mainly include wirelength and total area. Then zeroth-order optimization algorithms like simulated annealing or evolutionary algorithms are applied to optimize the solution. Recently, dataflow has emerged as a prominent optimization target [24], offering insights into RTL-level information. It aims to reveal the underlying connection relationships between macros [28]. Specifically, RTL-MP [9] and Hier-RTLMP [10] incorporate multilevel clustering through dataflow extraction to enhance placement regularity and performance. These methods employ a weighted sum of seven distinct targets as the optimization objective, effectively integrating engineering know-how. Another representative work by Lin et al. [15] uses corner stitching [21] to represent the solution, effectively addressing the challenges associated with pre-placed blocks and enhancing overall efficiency.

Analytical methods [2], [3], [17], [18] try to distribute macros and cells simultaneously by optimizing the wirelength and placement density. Post-processing steps such as macro adjustment or legalization are then applied to further enhance the placement. These methods have the merit of efficiency and the global view of wirelength. Recently, DG-RePlAce [11] and DAPA [16] try to involve dataflow as a constraint into the global placement, trying to capture the critical datapaths and optimize them accordingly. Another recent work IncreMacro [22] identifies macros placed away from the periphery and incorporates smoothed cost as a nonlinear optimization metric.

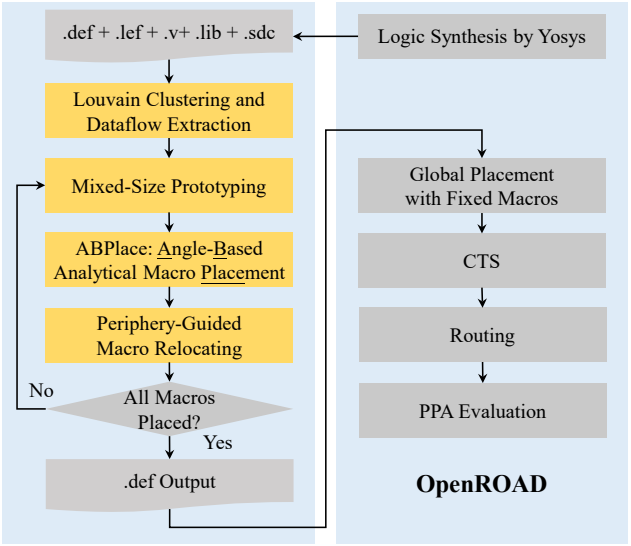

Fig. 2: Overflow of our proposed ReMaP method. Components in yellow are key steps of ReMaP.

Learning-based methods have recently gained attention, starting with Google's Graph Placement [19]. These methods employ reinforcement learning for macro placement, yet face challenges with reward shaping. Providing rewards only after all macros are placed [4], [19] leads to sparse feedback, while using incremental wirelength as a dense reward [6], [12], [13], [23] often misaligns with PPA metrics.

Despite advancements, the macro placement challenge remains largely unresolved. Traditional zeroth-order methods may fail to capture the locations of standard cells after global placement. Recent approaches like RTL-MP [9] and Hier-RTLMP [10] attempt to address this by involving dataflow and using a sequence pair to simultaneously represent macros and cell clusters. However, the positions of cell clusters determined by simulated annealing may not align with those from an actual global placement. Analytical methods are also widely adopted, but they face convergence issues for mixed-size designs. Moreover, further refining and legalizing macros typically involve heuristics [2], [22], which can lead to inevitable performance degradation when all standard cells are treated as fixed [22].

III. Proposed ReMap Framework

In this section, we introduce ReMaP, a novel macro placement framework that generates expert-quality macro placement layouts. As shown in Fig. 2, our process begins with a synthesized netlist, from which we perform clustering and extract dataflow connections among macros and cell clusters. We employ DREAMPlace 4.1.0 [2], [18] to establish a mixed-size placement prototype, setting initial positions for each macro and cell cluster. It is followed by ABPlace, an angle-based analytical method that optimizes macro positions on a predefined ellipse (or a circle for square chip canvas). We then relocate macros to optimize the dataflow and periphery cost on a discretized canvas. In each iteration, we process a subset

of macros, fix their positions, and cycle the remaining macros back into the loop for next iteration. The final PPA evaluation is performed using the full OpenROAD-flow-scripts [1].

A. Clustering and Dataflow Extraction

To reduce complexity and uncover connections among macros and cells, we begin our placement process with clustering. We use star decomposition to break down nets into individual edges, forming an undirected graph. The modularity-based Louvain algorithm [5] then identifies communities within this graph, while also considering pre-placed I/O pins. For precise macro placement, each macro is extracted and treated as its own cluster. After forming all clusters, we traverse the initial graph to calculate the **direct** dataflow strength between each cluster pair, acquiring the dataflow matrix A. The process above is only performed once during the entire placement process.

Although several hierarchical clustering and dataflow extraction methods have been proposed [8]–[10], we opt for the straightforward Louvain algorithm and focus on direct connections for dataflow analysis, which have already yielded superior results. Our ReMaP framework can be integrated with any advanced clustering method for enhanced performance.

B. Mixed-Size Prototyping

Incorporating cell locations into macro placement is crucial, as these combinational components occupy significant space and connect macros. Traditional macro placers often model cell clusters as soft blocks and optimize them alongside macros. However, determining the area and shape of these clusters is challenging, and the final cell positions may differ after analytical placement. Direct mixed-size global placement can also face divergence issues, leading to suboptimal results.

To accurately estimate cell cluster positions and avoid divergence, we adopt a self-adaptive analytical mixed-size placement approach. Initially, a high target density facilitates convergence when many macros are movable. As more macros become fixed, the target density decreases to align with the low-density design's final cell placement[1]. Using this mixed-size prototype, we can determine the locations of macros and cell clusters by averaging the positions of all cells within each cluster.

C. ABPlace: Angle-Based Analytical Macro Placement

After acquiring the positions of macros and cell clusters, we fix the cell clusters and map each macro to the boundary of an ellipse. Let the width and height of the chip core be W and H. The center of the ellipse aligns with the chip's center, both at the origin. The ellipse's semi-major a and semi-minor b axes are scaled by β and shrink with each iteration by γ. Thus, the ellipse's equation at the k-th iteration is:

$$\begin{cases} a = \beta\gamma^k W/2,\ b = \beta\gamma^k H/2 \\ x^2/a^2 + y^2/b^2 = 1 \end{cases}$$

where x and y describe the coordinates of points on the ellipse. When $W = H$, the ellipse becomes a circle. To map macros onto the ellipse, we draw a ray from the ellipse center to the macro center. The intersection point with the ellipse is the macro's new position. Given the original coordinates (x_i^0, y_i^0) of macro i, the mapped position (x_i, y_i) is calculated by:

$$\theta_i = \arctan\frac{y_i^0}{x_i^0},\ x_i = a\cos\theta_i,\ y_i = b\sin\theta_i,$$

where $\theta_i \in [0, 2\pi)$ represents the angle of macro i.

After mapping, we fix cell clusters and optimize macro positions using angle-based analytical optimization. With macros restricted to the ellipse, we only optimize the angle vector $\boldsymbol{\theta}$:

$$\min_{\boldsymbol{\theta}} \left(\sum_{i\in M}\sum_{j\in N} \text{dist}(i,j)A_{i,j} + \lambda \sum_{i,j\in M, i\neq j} \text{overlap}(i,j) \right), \tag{1}$$

where A is the dataflow matrix indicating connection strength, M is the set of all unplaced macros, and N includes all macros and cell clusters. We use Euclidean distance for dist function. The overlap penalty between macros i and j is defined as:

$$\begin{aligned} \text{overlap}(i,j) = &\max\{(w_i + w_j)/2 - |x_i - x_j|, 0\} \\ &* \max\{(h_i + h_j)/2 - |y_i - y_j|, 0\}, \end{aligned}$$

where w_i and h_i are the width and height of macro i, respectively. The $\max$ function has discontinuities at zero, which can complicate gradient calculations. We use `torch.clamp` to handle the boundary conditions. Additionally, we approximate the absolute value using a smoothing function $\sqrt{x^2 + \epsilon^2} - \epsilon$ to maintain differentiability throughout the optimization process.

Considering our ultimate goal of placing macros regularly along the chip's periphery while minimizing data flow loss, ABPlace offers two key advantages by incorporating an ellipse: it positions macros close to their final periphery locations in a uniform manner while considering dataflow cost, and it allows for easy convergence without extensive parameter tuning.

D. Periphery-Guided Macro Relocating

After optimizing macro positions on the ellipse, we relocate certain macros to the chip's periphery, aiming to minimize dataflow loss. The problem is formulated as follows: given a chip layout with several placed macros, we relocate a set of macros previously positioned on the ellipse boundary, one by one. At each placement step, we solve two key problems: selecting which macro to place and determining its location.

We propose two criteria for selecting macros to place:

- **Descending order of macro's overlapping area**: Larger macros in crowded regions on the ellipse are prioritized for placement. This approach enhances regularity in two ways. First, placing larger macros near the periphery and smaller ones towards the core improves the utilization of outer space. Second, macros with similar shapes and sizes tend to be sorted and placed together.
- **Ascending order of dataflow strength**: Macros with weaker dataflow connections are placed first, allowing macros with stronger connections to be positioned closer to the core. This strategy reduces the negative impact on overall dataflow from periphery placement. Additionally,

[1]This dynamic approach is designed for OpenROAD-flow-scripts benchmarks [1] with low utilization and target density, as shown in Table I. We will extend ReMaP to larger, high-density designs in the future.

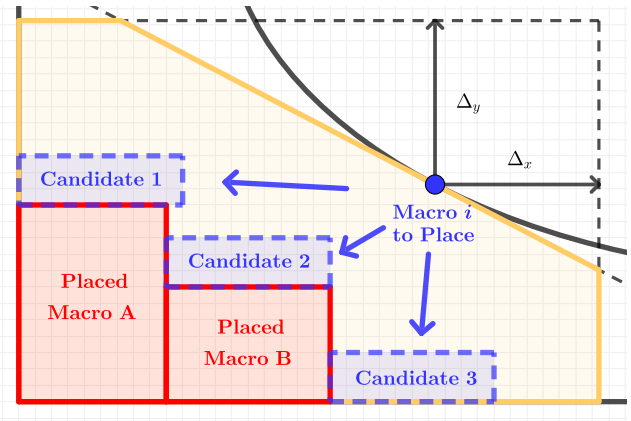

Fig. 3: Illustration of periphery-guided macro relocating: With macros A and B already placed in previous iterations, macro i is optimized on the ellipse by ABPlace in the current iteration. It will be placed in one of three candidate positions.

macros of the same size and group often share similar connection strengths, so they tend to be placed together, further enhancing placement regularity.

We choose the second criterion as our default setting for potentially better timing performance. The first criterion is also tested in ablation studies IV-B, producing layouts with higher regularity and occasionally better timing in specific cases. Overall, the second criterion generally performs better.

Next, we determine macro positions along the chip periphery inside a discretized feasible region. As illustrated in Fig. 3, we draw a tangent to the ellipse at macro i. Then we draw lines parallel to the x and y axes at distances Δ_x and Δ_y from the macro center. This forms a pentagon, shaded in yellow in Fig. 3, representing the placable region for macro i. We discretize this region into grids, and traverse feasible grids (x, y) that avoid overlaps, minimizing two cost functions c_{peri} and c_{df}:

$$c_{\text{peri}} = \min\{W - x, x\} + \min\{H - y, y\},$$
$$c_{\text{df}} = \sum\nolimits_{j \in P} \text{dist}(i, j) A_{i,j},$$

where c_{peri} and c_{df} represent the periphery cost and dataflow cost, respectively, and P includes placed macros and all cell clusters. We first consider c_{peri} using a Pareto dominance approach. Grid (x, y) dominates (x', y') if and only if:

$$\begin{cases} \min\{W - x, x\} \leq \min\{W - x', x'\} \\ \min\{H - y, y\} \leq \min\{H - y', y'\} \end{cases}$$

We select grids that are not dominated by others as candidates. Such selection prefers locations that are close to the chip corner. As shown in Fig. 3, only three candidate positions remain. We then compute c_{df} for each candidate grid, and choose the grid with the optimal (minimal) c_{df} value.

E. Summary and Implementation Details

The proposed ReMaP is presented in Algorithm 1. Lines 1–3 prepare the initial data for placement optimization. We extract only direct connections as the dataflow matrix, as discussed in Sec. III-A. While we attempted to incorporate indirect connections, like one-hop and two-hop links [10], [28], the improvement was negligible and it required further parameter tuning for these weaker connections. With accurate standard cell positions integrated into our optimization, direct connections suffice in our practice.

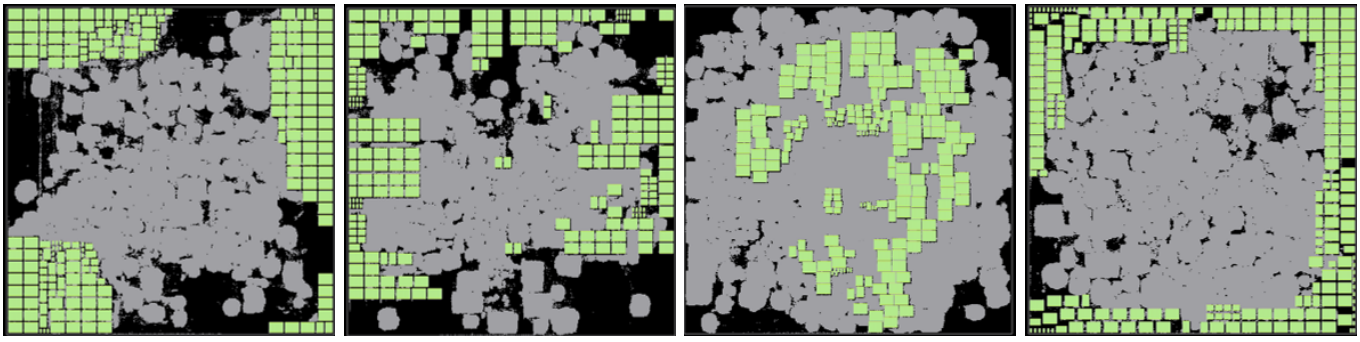
Algorithm 1 ReMaP Framework

Input: .def, .lef, .v, .lib, .sdc, decay factor γ, scale factor β, number k of macros to place per iteration, number n of macros.
Output: .def with all macros placed.
Process:

1: Cluster all macros and cells using the Louvain algorithm.
2: Extract dataflow matrix A.
3: Separate macros from clusters, treating each as an individual cluster.
4: $iter \leftarrow 0$
5: **while** there remain unplaced macros **do**
6: Perform a preliminary mixed-size placement and compute the centroid of each cell cluster.
7: $a \leftarrow \beta\gamma^{iter}W/2$, $b \leftarrow \beta\gamma^{iter}H/2$
8: Map each unplaced macro onto the ellipse defined by a and b.
9: Execute ABPlace for angle-based analytical placement.
10: Rank macros by specified criteria and select the top k.
11: **for** each macro in the top k **do**
12: Select the optimal grid considering dataflow and periphery cost.
13: Place and fix the macro.
14: **end for**
15: $iter \leftarrow iter + 1$
16: **end while**

Lines 5–16 iteratively optimize macro placement. In each iteration, k macros are placed and fixed. The parameter k balances efficiency and accuracy; setting k to 1 maximizes accuracy but increases runtime, especially for circuit with numerous macros. We typically set k to $\lceil n/10 \rceil$ to ensure that the algorithm completes within 10 iterations. The ellipse size is updated in each iteration. Initially, it is large to reach the periphery of the layout. As more macros are placed, the ellipse size reduces to fit the available space. We set the scale factor β to 0.9 and keep it fixed. The decay factor γ, however, is adjusted based on specific cases. During ABPlace in line 9, the Lagrange multiplier λ in Eq. (1) is crucial; high values ensure uniform distribution, while low values emphasize dataflow. We manually choose and fix λ throughout placement.

Our algorithm primarily requires tuning γ and λ. Our main results in Table I are slightly tuned manually. We further employ Bayesian optimization for automatic tuning and promote the performance, as detailed in Sec. IV-D.



IV. Experimental Results

We implement ReMaP in Python and evaluate it on a Linux server with a 52-core Intel Xeon CPU (2.60 GHz), an NVIDIA RTX 2080S GPU, and 128GB RAM. We use eight RTL designs from the OpenROAD-flow-scripts[2] (ORFS) repository, synthesized with the Nangate45 library. For timing

analysis, we increase the frequency of cases without violated timing paths. Then we place macros using different placers, followed by global placement, clock tree synthesis, and routing using OpenROAD [1]. The released version[3] of DREAMPlace 4.1.0 [2] is used as our mixed-size placer for prototyping.

A. Main Results

Table I compares post-route PPA metrics of three baselines and our ReMaP method. We use RTL-MP [9] and Hier-RTLMP [10] with default settings from ORFS, and DREAMPlace 4.1.0 with macro placement enhancements [2]. ReMaP achieves the best WNS and TNS in all eight cases, with average improvements of 8.39% and 16.57%, and maximum improvements of 34.15% and 65.39% for WNS and TNS compared to the strongest baseline on each case. ReMaP also performs above average in routing wirelength, power, and routing overflow, excelling in overflow due to the regularly placed macros.

Fig. 4 visualizes the placement results. RTL-MP shows regular placement but poor timing, while Hier-RTLMP improves timing but lacks regularity with large notch regions.

DREAMPlace struggles with timing and core congestion. Our ReMaP achieves both superior timing and regularity.

B. Ablation Study

Section III-B discusses our choice of dynamic target density for mixed-size prototyping, which decreases from 0.91 to 0.5 across all eight cases. We also explore fixed densities of 0.5 and 0.91. Additionally, we propose two criteria for macro relocating order in Section III-D. By default, we prioritize weaker dataflow strength for better timing performance, but we also evaluate an overlap criterion for more regular placements. As shown in Table II, while the ablation methods occasionally excel, the default settings generally perform best. Given the variability in macro placement challenges, it's clear that no single fixed setting can address every scenario effectively.

C. Runtime Analysis

In Table I, we compare the runtime of our ReMaP method with baselines. For smaller cases, as shown in Fig. 5(a), a significant portion of our runtime is due to gradient calculations during prototyping. This is an inherent limitation of our approach owing to recursive prototyping. However, for larger cases like bp_quad, as shown in Fig. 5(b), our method's runtime does not escalate steeply, thanks to DREAMPlace's efficient gradient propagation. Despite the case scale increasing by over ten times, the absolute time spent on gradients only increases by about 12.5%. The majority of the runtime, however, is consumed by benchmark I/O, primarily due to DREAMPlace's inefficiency with recursive calls. We are working on improving the I/O efficiency of our framework, and these engineering challenges will be addressed soon. Our method shows potential for greater efficiency in modern, large-scale designs.

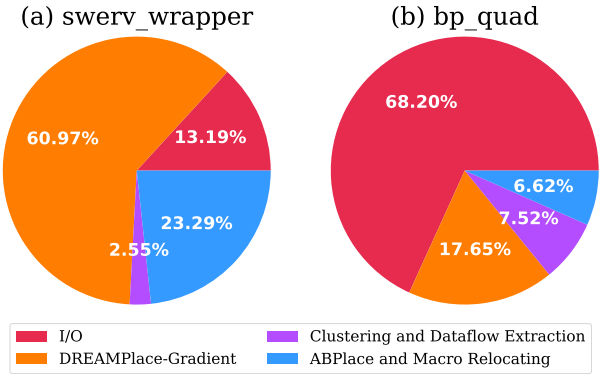

Fig. 5: Runtime breakdown of ReMaP on two representative designs swerv_wrapper and bp_quad.

TABLE III: Results of automatic parameter tuning.

Benchmark	Methods	Params		Metrics	
		γ	λ	WNS	TNS
ariane133	*hand-crafted*	0.943	0.006	-1.07	-2615.74
	50-round BO	0.956	0.001	**-1.02**	**-2484.17**
bp_be	*hand-crafted*	0.943	0.006	-0.90	-98.00
	50-round BO	0.990	0.440	**-0.78**	**-76.26**

D. Parameter Auto-tuning

As highlighted in Sec. III-E, our ReMaP method requires tuning of only two parameters: the decay factor γ and the Lagrange multiplier λ. While we manually adjust these parameters for our main results, we also explore their full potential using Bayesian optimization (BO) for automatic tuning. Table III shows that after 50 rounds of BO, there is an average improvement of 8.75% on WNS and TNS metrics in the ariane133 and bp_be cases compared to our manually tuned parameters.

V. Conclusion

In this work, we introduce and open-source the ReMaP framework, which optimizes macro placement through recursively prototyping and relocating. Our ABPlace method uses angle-based distribution to place macros on an ellipse, followed by periphery-guided relocating, yielding regular layouts with superior timing performance, as confirmed by extensive experiments. While recursive prototyping may reduce efficiency in smaller cases, ReMaP shows promise for scaling to larger cases after addressing engineering challenges.

***Abstract*—To meet the computational requirements of modern workloads under tight energy constraints, general-purpose accelerator architectures have to integrate an ever-increasing number of extremely area- and energy-efficient processing elements (PEs). In this context, single-issue in-order cores are commonplace, but lean dual-issue cores could boost PE IPC, especially for the common case of mixed integer and floating-point workloads. We develop the COPIFT methodology and RISC-V ISA extensions to enable low-cost and flexible dual-issue execution of mixed integer and floating-point instruction sequences. On such kernels, our methodology achieves speedups of 1.47x, reaching a peak 1.75 instructions per cycle, and 1.37x energy improvements on average, over optimized RV32G baselines.**

***Index Terms*—RISC-V, dual-issue, energy efficiency, general purpose**

I. Introduction

With the end of Dennard scaling, energy-efficiency has become a primary constraint in the design of high-performance computer architectures [1]. Simultaneously, the rapid growth of Machine Learning (ML) models, requiring immense computational resources for training and inference, are dramatically escalating the demand for high-performance computing power [2].

To meet this challenge, modern high-performance architectures integrate an ever-increasing number of cores, designed to meet extreme area- and energy-efficiency targets to enable large-scale replication [3]. In-order single-issue cores with shallow pipelines are favoured over power- and resource-hungry deeply-pipelined out-of-order processors.

Within the context of massively-parallel general-purpose accelerators, few architectures propose cores with limited multiple-issue capabilities. Nvidia's Turing architecture, for instance, implements concurrent execution of FP32 and INT32 operations [4], allowing the Floating-Point (FP) math datapath to remain active during the execution of non-FP-math instructions. According to the authors, this results in a 36% average increase in throughput across several gaming workloads. Unfortunately, due to the proprietary nature of the architecture, implementation details and their area and power impact remain undisclosed.

A similar form of dual-issue execution was implemented in the Snitch processor [5], coupling a tiny streamlined single-issue in-order RV32I control core and a 64-bit SIMD-capable Floating Point Unit (FPU). Instructions are fetched and issued by the control core, and offloaded to the FPU as required. To support dual-issue execution, the Floating Point Subsystem (FPSS) integrates a small instruction buffer to cache small FP loop bodies, the Floating Point Repetition (FREP) buffer. FP instructions are first issued by the integer core, and cached in the FREP buffer. In the remaining loop iterations, the FREP sequencer can independently issue instructions, while the integer core is free to fetch, and potentially execute, successive instructions. Its authors refer to this scheme as *pseudo dual-issue execution*.

This approach implies the following constraints:

- the FP loop body must be small enough to fit entirely in the FREP buffer;
- the programmer or compiler need to explicitly mark the FP loop for FREP execution in software;
- there can be no dependencies between the FP and integer threads.

The latter constraint follows from the asynchronous execution of the two threads, between which no ordering guarantees are enforced. While this enables Snitch's dual-issue capabilities at a very low power and area cost, it limits flexibility. In particular, it hinders the execution of computations featuring a mix of interdependent integer and FP instructions. We refer to these as mixed integer and FP instruction sequences.

In this paper, we present *COPIFT*, a generic method to develop **C**o-**O**perative **P**arallel **I**nteger and **F**loating-point **T**hreads in Snitch, overcoming the limitation imposed by pseudo dual-issue, and enabling low-cost dual-issue execution of mixed integer and FP instruction sequences.

To summarize our contributions, we:

- Present COPIFT, a generic methodology to enable sustained dual-issue execution of mixed integer and

FP instruction sequences in Snitch, a state-of-the-art open-source RISC-V processor.
- Develop a set of Instruction Set Architecture (ISA) extensions to broaden the range of applications suited for pseudo dual-issue execution, in conjunction with the COPIFT method.
- Implement COPIFT-accelerated codes for selected mixed integer and FP instruction sequences, achieving average speedups of 1.47× over optimized RV32G baselines, and a peak IPC of 1.75.
- Present a first account of the energy-efficiency of pseudo multiple-issue execution schemes, demonstrating average energy reductions of 1.37× with COPIFT, over optimized RV32G baselines.

Our implementation is fully open source and performance experiments are reproducible using free software. [1]

II. Implementation

A. COPIFT Methodology

Akin to other ISAs, RISC-V defines distinct Register Files (RFs) for the RV32I base integer ISA and the "D" standard extension [6]. As a result, integer and FP instructions operate mostly on independent sets of registers. This fundamental characteristic allows us to define two threads with independent state, comprising respectively the integer RF and RV32I instructions and the FP RF and "D" extension instructions. Several notable FP instructions, however, also require access to the integer RF, consuming operands from integer source registers (FP load, store, conversion and move instructions) or producing results into integer destination registers (FP comparisons). Such instructions conflict with the independent thread abstraction, precluding pseudo-dual issue execution.

Partly relaxing this constraint, Snitch implements Stream Semantic Registers (SSRs) [7], a custom ISA extension to stream data from memory directly into the RF, eliminating explicit load and store instructions. SSRs support any *affine stream* or memory access pattern which can be described as an affine function of the induction variables of a four-dimensional loop nest. Extending the SSR mechanism, Indirection Stream Semantic Registers (ISSRs) [8], further provide support for *indirect streams* or arbitrary memory access patterns, provided a list of relative addresses encoding the pattern. SSRs enable memory accesses without introducing dependencies on the integer RF, solving only a particular instance of the problem. Conversely, our methodology tackles any form of interdependency between integer and FP threads.

Consider the code in Figure 1a, computing the exponential of an array of single-precision FP numbers. Compiling this code for the RV32G architecture results in the mix of integer and FP instructions shown in Figure 1b. Dependencies between these instructions are marked with red and blue boxes in the consuming and producing instructions, respectively. These can be classified into:

Type 1 Dynamic memory dependencies, from FP load-stores with dynamically-computed addresses.

Type 2 Static memory dependencies, from FP load-stores with statically-determined addresses.

In the most general case, a third type may be present:

Type 3 Register dependencies, from FP conversion, move and comparison instructions.

Due to these dependencies, we cannot trivially partition integer and FP instructions for pseudo dual-issue execution. The COPIFT method addresses the problem by eliminating or increasing the distance between dependent instructions. It involves the following steps:

Step 1 Construct a Data Flow Graph (DFG) from the RISC-V assembly and identify all dependencies between integer and FP instructions.

Step 2 Partition the DFG on the identified edges, such that there exists an acyclic precedence-relation among the subgraphs, and the number of edges between them is minimized.

Step 3 Reorder the instructions according to the subgraph ordering established in Step 2.

Step 4 Apply loop tiling to block the data, and loop fission to reschedule the subgraph computations on each block.

Step 5 Apply software pipelining and multiple buffering to overlap subgraph computations.

Step 6 Map all FP load-store instructions to SSRs.

Step 7 Map all FP loops to FREP loops, and reorder them to preceed the integer loop.

To clarify each step, we walk through how to apply COPIFT to the exponential kernel in Figure 1a.

Figure 1c shows the DFG of the basic block in Figure 1b. For brevity, we omitted instructions 24 and 25 and associated dependencies, as we will see that these can be simplified in Step 6. Following Step 2, we cut edges $4 \rightarrow 5$, $12 \rightarrow 18$ and $14 \rightarrow 18$. This alone results in two subgraphs for which a precedence-relation cannot be established. We therefore further partition the graph, cutting edge $21 \rightarrow 22$. We obtain three subgraphs, each defining a phase of the computation with clear ordering requirements w.r.t. the others: FP Phase 0 must precede integer Phase 1, which in turn must precede FP Phase 2. This allows us to reorder the instructions in consecutive groups of integer-only or FP-only instructions, while respecting the dependencies within each loop iteration (Step 3). The resulting code would resemble Figure 1d, where each function would be replaced by the respective inline assembly code.

In Step 4, we then apply loop tiling [9] to obtain the code in Figure 1e. Each phase is now applied to an entire block of inputs, before passing on a block of intermediate results to the next phase. Implicitly, this step requires allocating block-sized buffers for each variable associated to an edge between subgraphs. Additionally,

[1] https://github.com/colluca/snitch_cluster/tree/copift

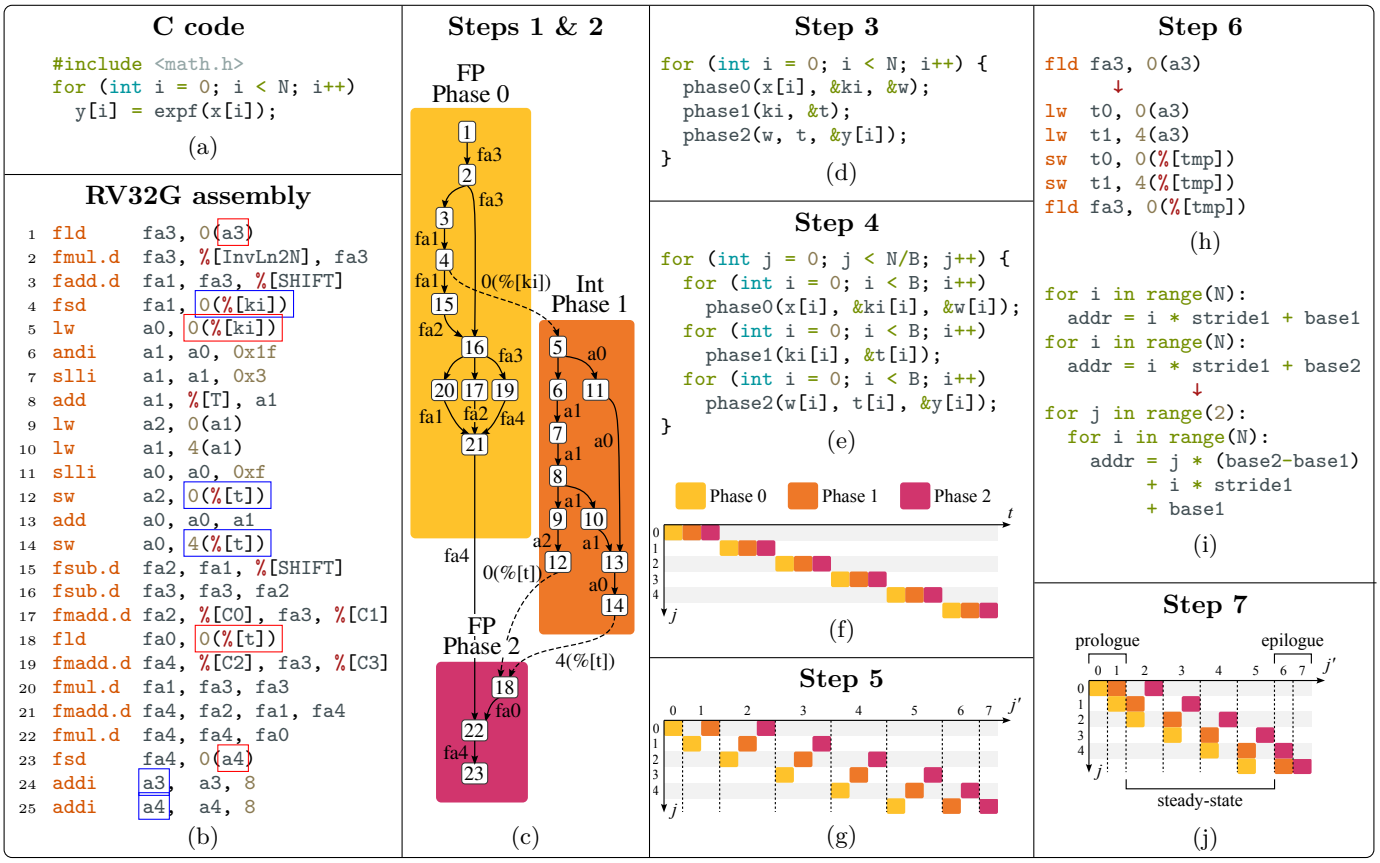

Fig. 1: Illustration of the COPIFT methodology applied to a kernel calculating the exponential of a vector.

all inter-phase communication originally through the RF, must be preventively spilled to memory. To reduce spill communication overheads and memory requirements, it is important to minimize the number of edges between subgraphs in Step 2.

Step 5 prepares for the parallel execution of the FP and integer phases, by applying software pipelining [10] to increase the distance between dependent phases. Figures 1f and 1g illustrate the original and modified block schedules, respectively. Within each j' iteration in the new schedule, every phase operates on different blocks of data j, allowing them to be parallelized in Step 7. Implicitly, this requires replicating the buffers, as e.g. Phase 0 produces different blocks of w before the first is consumed by Phase 2. The exact number of replicas for each buffer equals the distance between the subgraphs connected by the respective edge in the total ordering established in Step 2, plus one. In our example, the w buffer, associated to the edge between Phase 0 and 2, must be replicated three times.

Steps 6 to 7 enable the integer and FP phases within each block iteration to be executed in parallel. In Step 4, we spilled all inter-phase communication through the RFs to memory, introducing additional load-store instructions. In Step 6, we eliminate all FP load-stores by mapping the respective memory accesses to SSRs. The accesses performed by the two FP phases in our example can be described as a combination of 6 one-dimensional streams: reads from blocks of x, w and t, and writes to blocks of w, ki and y. All streams originate from tiling in Step 4, and can thus be naturally represented as regular accesses into contiguous arrays. Special treatment is required to convert streams of addresses originating from Type 1 dependencies, into regular streams of data for the FP thread. This can be done in software by converting Type 1 to Type 2 dependencies as shown in Figure 1h. This involves prefetching the data in the integer thread and storing it in a regular layout for the SSRs. Alternatively, Type 1 dependencies can be directly mapped to ISSRs, performing the indirection on the regular stream of addresses in hardware. Finally, we note that in cases where the Type 1 address stream can be statically generated by an affine function of up to four variables, the entire address calculation can be eliminated and performed by an SSR, which is the case for the x and y streams in our example. The associated dependency and all artifacts produced by our methodology can be optimized away, which allowed us to ignore instructions 24 and 25 from the start.

To map the 6 streams to the 3 SSRs available in every Snitch core, we apply a *stream fusion* technique, which involves mapping multiple lower-dimensional affine streams

Kernel	Baseline			Step 4		Steps 5 to 6		Max Block	COPIFT		I'	S''	▼S'

TABLE I: Characteristics of the evaluated kernels, ordered by expected speedup S'.

to a single higher-dimensional affine stream. Figure 1i illustrates the process of merging two one-dimensional affine streams. Using this technique, we merge the x and t read streams and the w, ki and y write streams.

Finally, FP block computations are mapped to FREP loops (Step 7). Since instructions for the first iteration of an FREP loop are issued by the integer core, the FREP loops must preceed the integer loop in program order, such that remaining iterations overlap with the integer thread. Similarly, for the integer thread to overlap with both FP Phase 0 and 2, these should be fused to a single FREP loop in block iterations where both phases are performed. The resulting schedule is shown in Figure 1j.

The steps in this methodology can be followed by developers to obtain an optimized mixed C and assembly representation.

B. COPIFT ISA Extensions

FP conversion and comparison instructions are critical for mixed integer and FP workloads. To support these, we can alter their semantics under FREP operation, to operate entirely on the FP RF. Communication between the integer and FP RFs is spilled to memory, through the use of additional load-store instructions, decoupling it from the computation, so the target instructions can find all operands directly in the FP RF. This technique can be combined with SSRs, to implicitly encode the FP load-store operations.

Albeit not strictly necessary, we chose to develop custom instructions to carry the altered semantics, for each of the relevant "D" extension instructions, i.e. `fcvt.w[u].d`, `fcvt.d.w[u]`, `feq.d`, `flt.d`, `fle.d` and `fclass.d`. We copy the original encodings, allocating the new instructions in the `custom-1` opcode space [6].

III. Results

We implement a Snitch cluster hosting one compute core in GlobalFoundries' 12LP+ FinFET technology using Fusion Compiler, with a target clock frequency of 1 GHz. Our extensions introduce negligible area and timing overheads, within the margin of synthesis process variability.

All experiments are conducted at the target frequency in cycle-accurate RTL simulations using QuestaSim 2023.4. Switching activities are extracted from post-layout simulations, and used for power estimation in PrimeTime, assuming typical operating conditions of 25 °C and 0.8 V supply voltage.

A. Performance Evaluation

To evaluate the benefits of the COPIFT method and ISA extensions, we implement a set of mixed integer and FP workloads with diverse characteristics, extracted from two different domains:

- Hit and miss Monte Carlo integration methods [11], evaluating two different integration problems and pseudo-random number generators. Integer instructions are typically employed in pseudo-random number generation, while the integration is performed in double-precision FP arithmetic.
- Transcendental function evaluation on a vector of single-precision FP numbers. Reference implementations are taken from the GNU C Library [12] v2.40, and involve integer instructions for bit-manipulation and double-precision FP arithmetic to evaluate approximating polynomials.

The latter in particular, applied to the exponential function, is the main component of softmax operations, which consume a considerable fraction of cycles in modern Large Language Models (LLMs) [13].

We implement Snitch-optimized RV32G-compliant baseline codes and COPIFT-accelerated variants for each kernel, compiled using a custom toolchain for Snitch based on LLVM 18.1.4 with −O3 optimization.

Table I lists all of the evaluated kernels, with their unique characteristics. As the table shows, the number of integer and FP instructions can vary as a result of applying the COPIFT method, as e.g. integer load-stores are introduced in Step 4 and FP load-stores are eliminated in Step 6. These easily measurable kernel characteristics can be used to estimate the speedup potential of the COPIFT method. In fact, assuming similar IPCs in the integer and FP threads, the speedup S can be approximated as a function of the number of integer and FP instructions:

$$S \coloneqq \frac{t_{\text{int}}^{\text{base}} + t_{\text{fp}}^{\text{base}}}{\max(t_{\text{int}}^{\text{copift}}, t_{\text{fp}}^{\text{copift}})} \approx \frac{n_{\text{int}}^{\text{base}} + n_{\text{fp}}^{\text{base}}}{\max(n_{\text{int}}^{\text{copift}}, n_{\text{fp}}^{\text{copift}})} = S' \quad (1)$$

Similarly, we can approximate the IPC improvement I:

$$I \coloneqq S * \frac{n_{\text{int}}^{\text{copift}} + n_{\text{fp}}^{\text{copift}}}{n_{\text{int}}^{\text{base}} + n_{\text{fp}}^{\text{base}}} \approx \frac{n_{\text{int}}^{\text{copift}} + n_{\text{fp}}^{\text{copift}}}{\max(n_{\text{int}}^{\text{copift}}, n_{\text{fp}}^{\text{copift}})} = I' \quad (2)$$

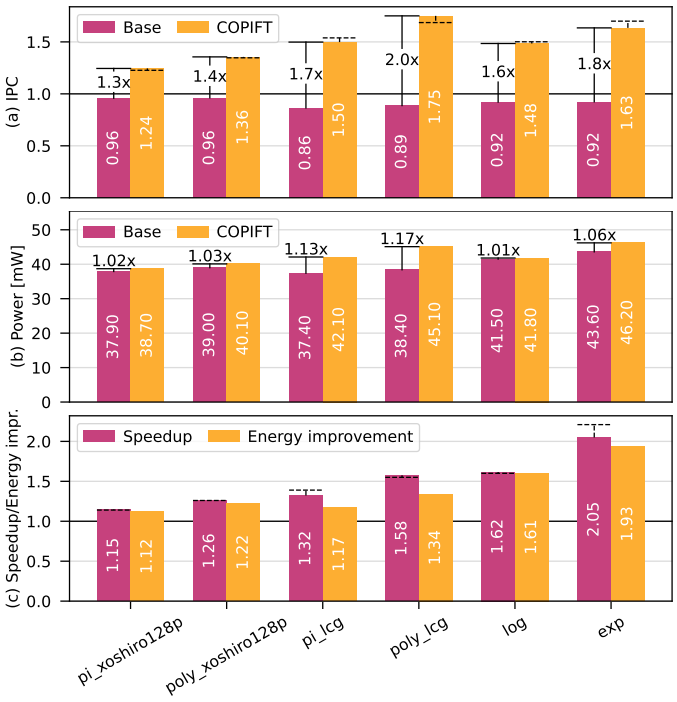

Fig. 2: Comparison of various metrics between COPIFT and baseline codes. Dashed lines indicate expected values: (a) the IPC derived from I' and (c) the speedup S'.

If the number of instructions does not differ significantly between the two code variants, we can further approximate the speedup as a function of the number of instructions in the original implementation alone:

$$S' \approx \frac{n_{\text{int}}^{\text{base}} + n_{\text{fp}}^{\text{base}}}{\max(n_{\text{int}}^{\text{base}}, n_{\text{fp}}^{\text{base}})} \overset{2}{=} 1 + \frac{\min(n_{\text{int}}^{\text{base}}, n_{\text{fp}}^{\text{base}})}{\max(n_{\text{int}}^{\text{base}}, n_{\text{fp}}^{\text{base}})} = \\ = 1 + \text{TI} = S'' = I'' \quad (3)$$

Intuitively, this shows how the speedup approximately depends on the thread imbalance (TI), as defined above.

Figure 2a compares the IPC of a steady-state iteration in the two implementations, for all kernels ordered by increasing expected speedup S'. We observe a significant geomean IPC improvement of 1.62×, and a peak IPC of 1.75, as a demonstration of dual-issue performance. As hypothesized, the IPC improvement correlates with I'. The deviations observed in the `poly_lcg` and `pi_lcg` kernels are due to the hypothesis made in Equation (1) being invalid. In fact, both benchmarks present stalls in the Pseudo-Random Number (PRN) generation with the Linear Congruential Generator (LCG), which are due to structural hazards on the register file's writeback port, and could not be eliminated by unrolling. These stalls effectively balance out the execution times of the integer and FP threads in the `poly_lcg` kernel, leading to a near-ideal IPC improvement of 1.97×, while unbalancing the

[2]Using equality $a + b = \max(a, b) + \min(a, b)$

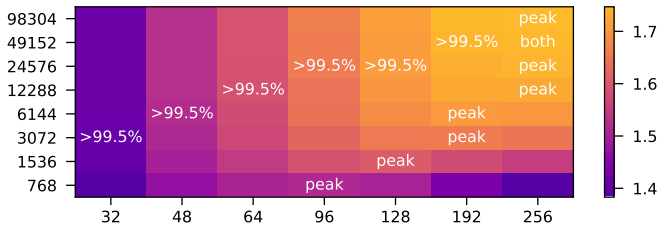

Fig. 3: IPC of the `poly_lcg` kernel for various problem and block sizes.

`pi_lcg` kernel. Finally, the `exp` kernel also shows a small deviation. This is due to the instruction overhead required to program the SSRs and switch buffers in every block iteration, which is not amortized as effectively on smaller blocks, as this kernel features.

To understand the impact of block size and problem size on performance, in Figure 3 we plot the IPC for various configurations of the `poly_lcg` kernel. As expected, IPC increases with problem size, as fixed prologue and epilogue overheads are amortized over a larger number of block iterations. Smaller blocks result in smaller prologue and epilogue overheads and a larger number of block iterations, for equal problem sizes, and can thus amortize these overheads more effectively. This trend is displayed in the ">99.5%" annotations, marking the smallest problem size which achieves >99.5% of the maximum IPC attainable with each block size. On the other hand, smaller blocks are less able to amortize overheads within the block, e.g. from SSR programming and switching buffers. As such, smaller block sizes feature lower maximum IPCs, when all other overheads are fully amortized. In this tradeoff, there exists an optimal block size per problem size, which we annotate with the "peak" labels. As the problem size increases, the peak shifts towards larger block sizes, up to the maximum size we can fit in L1 memory, reported in Table I. Finally, we note that, as we tend to amortize all overheads, the IPC converges to the steady-state IPC presented in Figure 2a. In the following discussions we will thus restrict our analysis to steady-state measurements.

Figure 2c shows how the IPC increase translates to improved kernel performance. Again, we observe a significant geomean speedup of 1.47×, with a peak 2.05× speedup on the `exp` kernel. The deviations from the expected speedup S' are a consequence of the same overheads affecting the IPC. Finally, we note that speedups greater than two are possible, as a result of additional optimizations, such as load-store elision with the SSRs, on top of dual-issue execution.

B. Energy Evaluation

Figure 2b compares the power consumption of the two implementations. The Monte Carlo benchmarks exhibit a lower base power consumption than their counterparts, due to the inactivity of the Direct Memory Access (DMA) engine and reduced L1 memory accesses. The increase in

power is consistently correlated with the IPC increase, with exception of the `log` and `exp` kernels. In fact, after separating the FP instructions, the integer loop bodies of these two kernels comprise less than 64 instructions, which entirely fit in Snitch's L0 I$. As a result, the I$ consumes significantly less power in the COPIFT implementations, which do not experience thrashing at the L0 level.

Ultimately, as the power consumption is dominated by constant components such as the clock network activity, we observe a maximum power increase of only 1.17×, and a geomean power increase of 1.07× over all kernels. As a result, COPIFT is still largely beneficial in overall energy terms, as shown in Figure 2c. The reduced execution time, resulting from dual-issue execution, outweighs the increase in power consumption, resulting in geomean energy savings of 1.37× on the measured benchmarks, and a peak 1.93× saving on the `exp` kernel.

IV. Related Work

To issue multiple instructions in parallel while preserving program correctness, multiple-issue processors must be able to identify dependencies within an instruction stream. Multiple-issue capabilities are often built into out-of-order processors, leveraging the facilities which enable out-of-order execution, such as reservation stations, register renaming and reorder buffers, which lead to high area and power overheads. On the other hand, in-order multiple-issue processors can be implemented in two flavours: statically-scheduled superscalar processors and VLIW processors [14]. In-order superscalar processors integrate logic to identify hazards between instructions in the issue packet and those in execution, while VLIW processors offload part of the job to the compiler, in charge of packing independent instructions into bundles of a predetermined size, at the cost of increased code size.

Few recent works in the literature look into the area- and energy-efficient design of dual-issue in-order RISC processors. All of these target dual-issue execution of arbitrary instruction pairs, with minor restrictions; as a consequence, they require a minimum of four read and two write (4R2W) ports into the RF. Lozano et al. [15] design a novel latency-optimized 4R2W-port SRAM-based RF implementation for soft FPGA cores, yet their implementation incurs a 4× cost in physical RAM blocks compared to the single-issue baseline, which also accounts for the majority of the +18% power increase. Similarly, Kra et al. [16] implement a dual-issue in-order RISC-V core based on CV32E40P, duplicating instruction decode, issue and execution stages and integrating a 5R3W-port RF with cross-forwarding support from all write to all read ports, for a total 60% area increase. Patsidis et al. [17] claim to further push the area and energy efficiency limits of dual-issue RISC-V cores, by restricting dual-issue to 16-bit compressed instructions, fitting within a single 32-bit instruction fetch port. They extend the RF with extra read ports, and a partitioned design to harvest the energy benefits from locality of reference to eight commonly-addressed registers by compressed instructions.

Wygrzvwalski et al. [18] present a pseudo dual-issue mechanism for small loop bodies, which resembles the Snitch implementation. A separate instruction buffer is allocated as a source of instructions for the second issue slot. Differently from Snitch, they rely on a banked RF design to prevent structural hazards on the RF ports, restricting parallel execution to pairs of instructions accessing different register banks. Conversely, Snitch targets pseudo dual-issue execution of integer and FP instructions, leveraging the separate RFs available by ISA design. Unfortunately, Wygrzvwalski's design is targeted to a specific application, limiting their investigation to a rather simple code featuring two independent threads operating in lockstep, without diving into the intricacies required to support more complex general-purpose scenarios.

In contrast to these works, we presented a novel methodology enabling dual-issue execution of mixed integer and FP instruction sequences in an area- and energy-efficient processor, with virtually no area overhead due to our extensions. This is possible by leveraging Snitch's SSR and FREP extensions, which extend beyond the scope of dual-issue execution, enabling the core's high FPU utilization.

V. Conclusion

In this work, we presented COPIFT, a generic methodology to enable sustained dual-issue execution of mixed integer and floating-point instruction sequences in Snitch, a state-of-the-art open-source RISC-V processor. We further developed a set of ISA extensions to broaden the range of applications which can leverage our methodology. To evaluate the benefits of COPIFT-enabled dual-issue execution, we implemented optimized RV32G baseline codes for a variety of mixed integer and floating-point workloads on Snitch, and compared these to COPIFT-optimized variants leveraging our ISA extensions. We measured speedups of 1.47× on average and a peak IPC of 1.75, proving COPIFT's effectiveness in enabling sustained dual-issue execution. We further compared the energy-efficiency of baseline and COPIFT-accelerated codes. Despite a small 1.07× average increase in power consumption, COPIFT proves beneficial in overall energy terms, resulting in 1.37× average energy savings on the measured benchmarks, and a peak 1.93× saving on the `exp` kernel, proving that effective dual-issue execution is possible on area- and energy-efficient in-order cores.

***Abstract*—As transistor scaling approaches sub-5nm technologies, power distribution networks (PDNs) in integrated circuits have grown increasingly complex, with billions to trillions of nodes. Simultaneously, reduced noise margins and increased power density necessitate more accurate and efficient power grid analysis. Traditional methods for solving large-scale PDNs, especially those requiring the solution of sparse linear systems, face significant challenges due to high computational costs. Although domain decomposition methods (DDM) allow for efficient parallel computation, the size of the dense global Schur complement grows excessively large as the number of partitions increases, limiting scalability and imposing substantial computational burdens. This paper introduces an efficient parallel nested domain decomposition solver that incorporates a parallel Schur complement computation strategy and intermediate Schur complement to address these challenges. Experimental results demonstrate that by introducing an intermediate Schur complement, the size of the global Schur complement is significantly reduced, achieving an average 1.70× speedup in computation, which results in a 1.30× speedup for the entire solver compared to the conventional DDM parallel solver.**

I. Introduction

As Moore's law drives transistor scaling to its limits, power distribution networks (PDNs) in integrated circuits have grown increasingly complex, encompassing billions to even trillions of nodes in sub-5nm technologies [1], [2]. Meanwhile, reduced noise margins, now as low as tens of millivolts due to lower supply voltages, and rising power density [3], [4] have made accurate and efficient power grid analysis more critical than ever. However, the computational demands of analyzing large-scale PDNs significantly hinder design efficiency and iteration speed. Consequently, enhancing the efficiency of power grid analysis methods has become a pivotal research focus.

Power grid analysis typically involves solving large-scale symmetric positive definite (SPD) linear systems, which can be addressed using direct or iterative solvers. Direct methods, such as Cholesky and LU decomposition [5], [6], provide exact solutions but are limited by high memory requirements, making them unsuitable for scalability on a single machine. Iterative methods, including Krylov subspace techniques [7], algebraic multigrid approaches [8], and graph spectral sparsification approaches [9], [10] offer better memory efficiency but often face stability and convergence challenges if preconditioners are not selected appropriately.

The rise of parallel computing technology has brought domain decomposition methods (DDM) to the forefront as a powerful approach for large-scale power grid analysis [11], [12]. These methods, which rely on graph partitioning, enable the division of PDN into smaller subdomains that can be processed in parallel, significantly improving computational efficiency. However, DDM relies on the Schur complement matrix. **Forming and solving the dense global Schur complement matrix can be even more demanding than directly solving the original system** [13], [14]**.** This challenge involves two main aspects:

- Calculating the local Schur complement for each subdomain is inherently complex and resource-demanding due to intricate interdependencies.
- While current computational resources are capable of handling many subdomains, excessive partitioning increases the size of the dense global Schur complement, making this large matrix challenging to parallelize and ultimately diminishing computational efficiency.

To overcome the above challenges, this paper introduces **an efficient parallel nested domain decomposition solver** specifically for power grid analysis, focusing on accelerating the formation of the local Schur complement, reducing the size of the global Schur complement matrix and addressing the limited parallelizability at the top level to ensure better scalability and resource utilization. This solver integrates multiple parallelization strategies to tackle the challenges associated with solving large-scale sparse linear systems, optimizing Schur complement matrix computation, and providing a comprehensive solution to enhance computational efficiency. The main contributions are as follows:

- **A parallel method for forming the Schur complement.** In this method, the nodes to be eliminated are divided into segments and processed in parallel, utilizing DDM to partition and solve in parallel blocks.
- **An intermediate Schur complement matrix to reduce the size of the dense global Schur complement.** This intermediate matrix can be naturally solved in parallel, further optimizing the overall process and improving computation and resource utilization.
- **A new solver that exploits the above optimizations to achieve higher scalability.** This solver overcomes the scalability limitations of conventional DDM solver, which struggles to achieve significant speedup as the number of partitions increases beyond a certain threshold.

Experimental results demonstrate that by introducing an intermediate Schur complement, the overall size of the global Schur complement is significantly reduced, effectively overcoming the limitations of traditional DDM. The intermediate Schur complement is well-suited for parallel computation, enabling task distribution to the intermediate layer and achieving a 1.70× speedup, which leads to our solver outperforming the conventional DDM solver with a 1.30× speedup. Furthermore, it achieves an 8.44× speedup over the CKTSO parallel solver and an 8.36× speedup over the CHOLMOD-based serial direct solver when utilizing 32 threads.

II. Background and Motivation

A. Introduction to DDM for Power Grid Analysis

DDM is a parallel method for solving large linear systems of the form $Gv = b$, particularly effective in PDN analysis [11], [12]. It partitions the PDN into subdomains by linking the coefficient matrix to an undirected graph and applying the Schur complement to enhance computational efficiency. Each subdomain contains internal nodes (fully within the subdomain) and interface nodes (shared between subdomains), forming a block sparse matrix that supports efficient parallel processing. The structure of the block sparse matrix is as follows:

$$\begin{bmatrix} \boldsymbol{A}_1 & \boldsymbol{B}_1 & O & O & \cdots & O & O \\ \boldsymbol{B}_1^T & \boldsymbol{D}_1 & O & E_{1,2} & \cdots & O & E_{1,m} \\ O & O & \boldsymbol{A}_2 & \boldsymbol{B}_2 & \cdots & O & O \\ O & E_{1,2}^T & \boldsymbol{B}_2^T & \boldsymbol{D}_2 & \cdots & O & E_{2,m} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ O & O & O & O & \cdots & \boldsymbol{A}_m & \boldsymbol{B}_m \\ O & E_{1,m}^T & O & E_{2,m}^T & \cdots & \boldsymbol{B}_m^T & \boldsymbol{D}_m \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ x_2 \\ y_2 \\ \vdots \\ x_m \\ y_m \end{bmatrix} = \begin{bmatrix} f_1 \\ g_1 \\ f_2 \\ g_2 \\ \vdots \\ f_m \\ g_m \end{bmatrix} \quad (1)$$

where A_i, B_i, and D_i represent the connections within the i-th subdomain, and $E_{i,j}$ represents the interactions between the i-th and j-th subdomains.

DDM works by first eliminating internal nodes using the Schur complement, as in Eq. (2)-(4), reducing the problem to a smaller system involving only interface nodes, which is given by Eq. (5). This reduction makes the problem more suitable for parallel computation by decreasing both the size and complexity of the system. Once the interface nodes are solved, the internal nodes can then be calculated using Eq. (6).

$$\begin{bmatrix} P_i A_i P_i^T & P_i B_i \\ B_i^T P_i^T & D_i \end{bmatrix} = \begin{bmatrix} L_{i,11} & O \\ L_{i,21} & L_{i,22} \end{bmatrix} \begin{bmatrix} L_{i,11}^T & L_{i,21}^T \\ O & L_{i,22}^T \end{bmatrix} \quad (2)$$

$$\widetilde{D_i} = D_i - B_i^T A_i^{-1} B_i = L_{i,22} L_{i,22}^T \quad (3)$$

$$\widetilde{g_i} = g_i - B_i^T A_i^{-1} f_i = g_i - L_{i,21} L_{i,11}^{-1} P_i f_i \quad (4)$$

$$\begin{bmatrix} \widetilde{D_1} & E_{1,2} & \cdots & E_{1,m} \\ E_{1,2}^T & \widetilde{D_2} & \cdots & E_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ E_{1,m}^T & E_{2,m}^T & \cdots & \widetilde{D_m} \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_m \end{bmatrix} = \begin{bmatrix} \widetilde{g_1} \\ \widetilde{g_2} \\ \vdots \\ \widetilde{g_m} \end{bmatrix} \quad (5)$$

$$A_i x_i = f_i - B_i y_i \quad (6)$$

B. Motivation

For conventional DDM, challenges remain in managing the cost of constructing and solving the dense global Schur complement and handling subdomain dependencies. In large-scale parallel computing, circuits are divided into small blocks, with the effects varying by partition count:

- **Fewer partitions:** Fewer partitions lead to longer local Schur complement calculations. *Larger sub-blocks require more time to compute*, limiting the advantages of parallel computing.
- **Too many partitions:** Numerous partitions can make top-level computation time significant, *potentially dominating the entire process*. The increased overhead for managing the global Schur complement reduces the benefits of parallel computing.

TABLE I: Breakdown time comparison for DDM solver.

Thread	2		4		8		16		32	
Case	T_{loc}	T_{top}	T_{loc}	T_{top}	T_{loc}	T_{top}	T_{loc}	T_{top}	T_{loc}	T_{top}
ibmpg8	10.5	0.01	4.03	0.40	2.53	1.65	1.88	3.62	1.38	2.95

thupg2	82.6	0.87	53.1	6.90	25.3	15.7	12.5	22.3	7.95	25.6
thupg3	101	1.16	63.2	9.60	41.8	21.1	17.7	30.0	11.2	29.6
thupg4	154	2.11	91.2	11.3	51.2	25.9	23.5	46.1	16.5	55.7
thupg5	216	3.11	129	31.0	72.8	42.1	45.3	73.2	23.4	100

Table I shows the relationship between top-level computation time and the number of partitions. **With fewer partitions**, the time for local Schur complement calculations, T_{loc}, becomes too long. **With more partitions**, the top-level computation time, T_{top}, becomes dominant. This occurs because the global Schur complement size becomes too large and cannot be efficiently parallelized. Thus, traditional DDM has faced scalability challenges, often struggling to achieve speedup when the number of partitions increases beyond a certain point, as solving the dense global Schur complement tends to dominate the computation time. However, **modern hardware supports a significantly higher number of processes and threads, offering opportunities for enhanced parallelism.**

III. Proposed Method

This section presents our parallel computing framework for scalable power grid analysis. We first introduce a parallel method for computing the Schur complement, which is then integrated to form a nested DDM approach. This nested structure enhances scalability and computational efficiency, making it ideal for analyzing large-scale power grid systems.

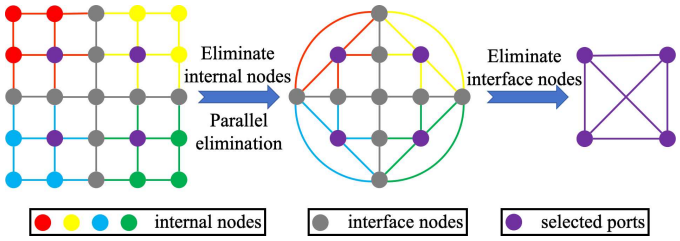
A. Parallel Schur Complement Computation

Forming the Schur complement is closely related to Gaussian elimination. This process simplifies the network by eliminating certain nodes and reducing conductances to equivalent values at the selected ports. By applying Gaussian elimination to the conductance matrix, electrical connections between

nodes are combined into effective conductances at key ports, resulting in a simplified version of the system that preserves its essential electrical behavior.

The DDM also facilitates forming the Schur complement. In this approach, we first identify selected ports and non-port nodes, then apply a graph partitioning tool like METIS [15] to classify nodes. To achieve balanced computation, higher weights are assigned to selected ports, allowing an even distribution across blocks. Afterward, non-port nodes are further divided into internal and interface nodes within each subdomain. This categorization aids in the elimination process and organizes the system into a block-structured format, which is optimized for parallel computation.

Within each subdomain, internal nodes, along with their associated interface nodes and selected ports, are initially extracted to facilitate efficient parallel processing. Subsequently, the internal nodes are eliminated parallelly, producing a streamlined structure for further computations. Finally, interface nodes are removed, yielding the Schur complement corresponding to the selected ports. To clarify this process, Fig. 1 uses edge-based partitioning to depict the steps involved.



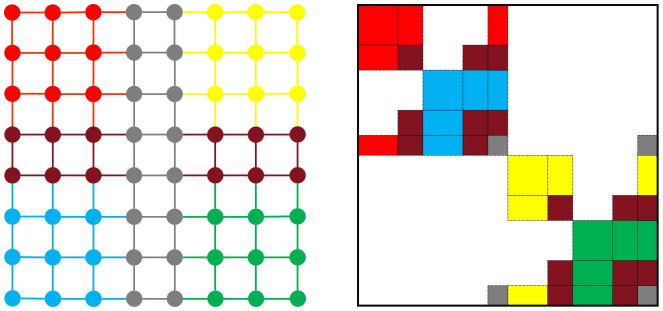


Fig. 1: Flow of parallel Schur complement computation.

This parallel Schur complement approach is not only effective for power grid analysis but can also be applied in scenarios where full-stack PDN simulation is unnecessary. For instance, in machine learning-based methods that predict supply noise [16]–[18]), selected ports can represent locations of worst-case noise. Our proposed parallel Schur complement method enables efficient computation of the noise at these critical locations.

B. Nested DDM for Power Grid Analysis

In conventional DDM for power grid analysis, the system is initially divided into m subdomains. As the number of subdomains increases (i.e., m becomes very large), the size of the global Schur complement matrix grows significantly, resulting in a dense matrix that is difficult to solve in parallel. To mitigate this, we apply a nested decomposition approach to the PDN, including the following steps.

Partitioning to construct nested DDM form matrix. The original matrix G can be transformed into the nested DDM form through a two-step graph partitioning process. First, the nodes corresponding to the entire matrix are partitioned to form the outer subdomains. Then the outer internal nodes within each outer subdomain are subdivided into inner interface nodes and inner internal nodes. This process classifies nodes into three types: *outer interface nodes* (e.g., gray nodes in Fig. 2), *inner interface nodes* (e.g., brown nodes in Fig. 2), and *inner internal nodes* (e.g., other colors in Fig. 2). After applying the corresponding permutation matrix, the transformed matrix takes the final form presented in Eq. (7).

(a) Graph (b) Matrix

Fig. 2: Graph partitioning to nested DDM: node colors in the graph (left) correspond to the sub-matrix block colors in the matrix (right).

For inner nodes, the matrices $A_{11}, \ldots, A_{pq}$ represent the inner internal nodes within the $p \times q$ inner subdomains, while $D_{11}, \ldots, D_{pq}$ correspond to the inner interface nodes. The matrix B_{ij} captures the interactions between the inner internal nodes and the inner interface nodes in the ij-th inner subdomain, while $E_{ij,st}$ describes the couplings between the inner interface nodes of the ij-th and st-th inner subdomains. The vectors f_{ij} and g_{ij} denote the right-hand side values associated with the inner internal nodes and inner interface nodes of the ij-th inner subdomain, respectively.

For outer interface nodes and their couplings, the matrix R_i represents the interactions among the outer interface nodes within the i-th outer subdomain. The matrix P_{ij} captures the coupling between the outer interface nodes of the i-th outer subdomain and the inner internal nodes of the ij-th inner subdomain, while Q_{ij} represents the coupling between the outer interface nodes of the i-th outer subdomain and the inner interface nodes of the ij-th inner subdomain. Additionally, $F_{i,j}$ characterizes the couplings between the outer interface nodes of the i-th and j-th outer subdomains. Finally, h_i refers to the right-hand side values associated with the outer interface nodes of the i-th outer subdomain.

Next step is to eliminate inner internal nodes.

1. Extract submatrices A_{ij}, B_{ij}, D_{ij}, P_{ij}, Q_{ij}, R_i, along with the right-hand sides f_{ij}, g_{ij}, and h_i parallelly for inner internal nodes, inner interface nodes, and related outer interface nodes, as shown in Eq. (7) within each inner subdomain.

2. Form matrices parallelly for inner interface nodes:

$$\widetilde{D_{ij}} = D_{ij} - B_{ij}^T A_{ij}^{-1} B_{ij} \tag{8}$$

3. Form matrices parallelly for outer interface nodes:

$$\widetilde{R_i} = R_i - \sum_{j=1}^{q} P_{ij}^T A_{ij}^{-1} P_{ij} \tag{9}$$

4. Form coupling matrices parallelly between inner and outer interface nodes:

$$\widetilde{Q_{ij}} = Q_{ij} - B_{ij}^T A_{ij}^{-1} P_{ij} \tag{10}$$

$$\begin{bmatrix} \boldsymbol{A_{11}} & \boldsymbol{B_{11}} & \cdots & O & O & P_{11} & \cdots & O & O & \cdots & O & O & O \\ \boldsymbol{B_{11}^T} & \boldsymbol{D_{11}} & \cdots & O & E_{11,1q} & Q_{11} & \cdots & O & O & \cdots & O & O & O \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ O & O & \cdots & \boldsymbol{A_{1q}} & \boldsymbol{B_{1q}} & P_{1q} & \cdots & O & O & \cdots & O & O & O \\ O & E_{11,1q}^T & \cdots & \boldsymbol{B_{1q}^T} & \boldsymbol{D_{1q}} & Q_{1q} & \cdots & O & O & \cdots & O & O & O \\ P_{11}^T & Q_{11}^T & \cdots & P_{1q}^T & Q_{1q}^T & R_1 & \cdots & O & O & \cdots & O & O & F_{1,p} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ O & O & \cdots & O & O & O & \cdots & \boldsymbol{A_{p1}} & \boldsymbol{B_{p1}} & \cdots & O & O & P_{p1} \\ O & O & \cdots & O & O & O & \cdots & \boldsymbol{B_{p1}^T} & \boldsymbol{D_{p1}} & \cdots & O & E_{p1,pq} & Q_{p1} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ O & O & \cdots & O & O & O & \cdots & O & O & \cdots & \boldsymbol{A_{pq}} & \boldsymbol{B_{pq}} & P_{pq} \\ O & O & \cdots & O & O & O & \cdots & O & E_{p1,pq}^T & \cdots & \boldsymbol{B_{pq}^T} & \boldsymbol{D_{pq}} & Q_{pq} \\ O & O & \cdots & O & O & F_{1,p}^T & \cdots & P_{p1}^T & Q_{p1}^T & \cdots & P_{pq}^T & Q_{pq}^T & R_p \end{bmatrix} \begin{bmatrix} x_{11} \\ y_{11} \\ \vdots \\ x_{1q} \\ y_{1q} \\ z_1 \\ \vdots \\ x_{p1} \\ y_{p1} \\ \vdots \\ x_{pq} \\ y_{pq} \\ z_p \end{bmatrix} = \begin{bmatrix} f_{11} \\ g_{11} \\ \vdots \\ f_{1q} \\ g_{1q} \\ h_1 \\ \vdots \\ f_{p1} \\ g_{p1} \\ \vdots \\ f_{pq} \\ g_{pq} \\ h_p \end{bmatrix} \tag{7}$$

5. Form right-hand sides parallelly for inner interface nodes:

$$\widetilde{g_{ij}} = g_{ij} - B_{ij}^T A_{ij}^{-1} f_{ij} \tag{11}$$

6. Form right-hand sides parallelly for outer interface nodes:

$$\widetilde{h_i} = h_i - \sum_{j=1}^{q} P_{ij}^T A_{ij}^{-1} f_{ij} \tag{12}$$

Therefore the intermidiate Schur complement is formed. Eq. (7) is condensed by removing the inner internal nodes through Gaussian elimination into a compact form, resulting in the intermediate Schur complement matrix, ready for further computations:

$$\begin{bmatrix} \widetilde{D_{11}} & \cdots & E_{11,1q} & \widetilde{Q_{11}} & \cdots & O & \cdots & O & O \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots \\ E_{11,1q}^T & \cdots & \widetilde{D_{1q}} & \widetilde{Q_{1q}} & \cdots & O & \cdots & O & O \\ \widetilde{Q_{11}}^T & \cdots & \widetilde{Q_{1q}}^T & \widetilde{R_1} & \cdots & O & \cdots & O & F_{1,p} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots \\ O & \cdots & O & O & \cdots & \widetilde{D_{p1}} & \cdots & E_{p1,pq} & \widetilde{Q_{p1}} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots \\ O & \cdots & O & O & \cdots & E_{p1,pq}^T & \cdots & \widetilde{D_{pq}} & \widetilde{Q_{pq}} \\ O & \cdots & O & F_{1,p}^T & \cdots & \widetilde{Q_{p1}}^T & \cdots & \widetilde{Q_{pq}}^T & \widetilde{R_p} \end{bmatrix} \begin{bmatrix} y_{11} \\ \vdots \\ y_{1q} \\ z_1 \\ \vdots \\ y_{p1} \\ \vdots \\ y_{pq} \\ z_p \end{bmatrix} = \begin{bmatrix} \widetilde{g_{11}} \\ \vdots \\ \widetilde{g_{1q}} \\ \widetilde{h_1} \\ \vdots \\ \widetilde{g_{p1}} \\ \vdots \\ \widetilde{g_{pq}} \\ \widetilde{h_p} \end{bmatrix} \tag{13}$$

Then, eliminate inner inerface nodes.

1. Extract submatrices $\widetilde{U_i}$, $\widetilde{V_i}$ and right-hand sides $\widetilde{g_i}$, $\widetilde{h_i}$ parallelly for inner and outer interface nodes in Eq. (13) within each outer subdomain:

$$\widetilde{U_i} = \begin{bmatrix} \widetilde{D_{i1}} & E_{i1,i2} & \cdots & E_{i1,iq} \\ E_{i1,i2}^T & \widetilde{D_{i2}} & \cdots & E_{i2,iq} \\ \vdots & \vdots & \ddots & \vdots \\ E_{i1,iq}^T & E_{i2,iq}^T & \cdots & \widetilde{D_{iq}} \end{bmatrix} \tag{14}$$

$$\widetilde{V_i} = \begin{bmatrix} \widetilde{Q_{i1}^T} & \widetilde{Q_{i2}^T} & \cdots & \widetilde{Q_{iq}^T} \end{bmatrix}^T, \quad \widetilde{g_i} = \begin{bmatrix} \widetilde{g_{i1}^T} & \widetilde{g_{i2}^T} & \cdots & \widetilde{g_{iq}^T} \end{bmatrix}^T \tag{15}$$

2. Form matrices parallelly for outer interface nodes:

$$\widetilde{\widetilde{R_i}} = \widetilde{R_i} - \widetilde{V_i}^T \widetilde{U_i}^{-1} \widetilde{V_i} \tag{16}$$

3. Form right-hand sides parallelly for outer interface nodes:

$$\widetilde{\widetilde{h_i}} = \widetilde{h_i} - \widetilde{V_i}^T \widetilde{U_i}^{-1} \widetilde{g_i} \tag{17}$$

And form the global Schur complement. The process of eliminating the inner internal and interface nodes employs the proposed parallel Schur complement computation method, ultimately resulting in the Schur complement for the selected ports (i.e., the outer interface nodes):

$$\begin{bmatrix} \widetilde{\widetilde{R_1}} & F_{1,2} & \cdots & F_{1,p} \\ F_{1,2}^T & \widetilde{\widetilde{R_2}} & \cdots & F_{2,p} \\ \vdots & \vdots & \ddots & \vdots \\ F_{1,p}^T & F_{2,p}^T & \cdots & \widetilde{\widetilde{R_p}} \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \\ \vdots \\ z_p \end{bmatrix} = \begin{bmatrix} \widetilde{\widetilde{h_1}} \\ \widetilde{\widetilde{h_2}} \\ \vdots \\ \widetilde{\widetilde{h_p}} \end{bmatrix} \tag{18}$$

Last step is solution process. The solution to Eq. (7) begins with Eq. (18) to determine the outer interface unknowns z_i. Next, the subsequent equations are used to find the inner interface unknowns y_{ij}, and finally, solving the second equation below yields the inner internal unknowns x_{ij}:

$$\begin{bmatrix} \widetilde{D_{i1}} & E_{i1,i2} & \cdots & E_{i1,iq} \\ E_{i1,i2}^T & \widetilde{D_{i2}} & \cdots & E_{i2,iq} \\ \vdots & \vdots & \ddots & \vdots \\ E_{i1,iq}^T & E_{i2,iq}^T & \cdots & \widetilde{D_{iq}} \end{bmatrix} \begin{bmatrix} y_{i1} \\ y_{i2} \\ \vdots \\ y_{iq} \end{bmatrix} = \begin{bmatrix} \widetilde{g_{i1}} - \widetilde{Q_{i1}} z_i \\ \widetilde{g_{i2}} - \widetilde{Q_{i2}} z_i \\ \vdots \\ \widetilde{g_{iq}} - \widetilde{Q_{iq}} z_i \end{bmatrix} \tag{19}$$

$$A_{ij} x_{ij} = f_{ij} - B_{ij} y_{ij} - P_{ij} z_i \tag{20}$$

Combining the above derivations, the Laplacian matrix $Gv = b$ is solved with nested DDM as in Algorithm 1.

C. The Overall Framework

Building on the optimizations outlined above, the overall framework of our proposed solver is presented in Algorithm 1, which consists of three stages:

- First, the PDN is divided into p outer subdomains, and then each outer subdomain is further subdivided into q inner subdomains, creating local grids labeled as $11 \sim pq$, where $m = p \times q$. This hierarchical strategy significantly reduces the size of the top-level problem by introducing an intermediate Schur complement, which, while still dense, is more suitable for parallel computation.

- Next, the local grids $i1 \sim iq$ within each outer subdomain i are used to construct the middle grid i through the computation of the Schur complement, which consolidates the conductance of most nodes onto specific nodes. The p middle grids are then combined through further node elimination to form the top grid. The solution process starts with solving the top grid, and its solution is then used to solve the p middle grids.
- Finally, the solutions of the middle grids are back-substituted into their respective local grid, as illustrated in Fig. 3.

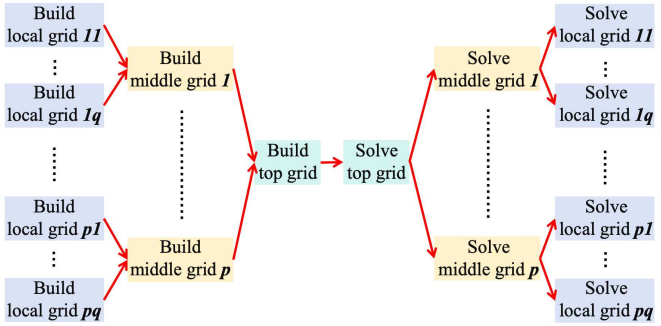

Fig. 3: Flow of the proposed nested DDM approach.

Efficient Elimination. In the local layer, instead of solving Eq. (8)-(12) individually, we concatenate A_{ij}, B_{ij}, D_{ij}, P_{ij}, Q_{ij}, and R_i into a unified matrix. This approach enables only a single factorization to yield the result, as shown in Eq. (2). To eliminate submatrix A_{ij}, techniques such as matrix reordering can be employed to reorganize the A_{ij}, thereby reducing fill-ins during factorization. Matrix reordering techniques can also be used in the middle layer when solving Eq. (16)-(17).

Maximizing Multithreading Efficiency. For the inner subdomains, each thread processes an individual submatrix. In the intermediate layer, only p tasks can be evidently parallelized, as described in Eq. (16)–(17) and (19). Therefore, q threads are used to solve each task. For the top layer, however, there are no obvious parallelization opportunities, as there is only one task, as indicated in Eq. (18). In this case, $p \times q$ threads are used to solve the single task.

IV. Experimental Results

Our proposed framework, implemented in C++ and compiled with GCC 9.4.0 using the -O3 optimization flag, utilizes METIS [15] for graph partitioning and CHOLMOD direct solver [5] with Intel MKL [19] for matrix factorization. We test on the IBMPG [20] and THUPG [21] benchmarks and compare our method with three state-of-the-art solvers, the CHOLMOD-based serial solver, the CKTSO parallel solver [6], and the conventional DDM parallel solver. Although CHOLMOD supports multithreading, our experiments show no significant performance improvement in the parallel version, so we compare the serial version's execution time. All experiments are conducted on a Linux server with two Intel Xeon Silver 4210R CPUs and 128GB of RAM.

Algorithm 1 Proposed parallel solver with nested DDM

Input: Initial matrix G, number of outer subdomains p, number of inner subdomains q.
Output: Solution x_{ij}, y_{ij}, and z_i of Eq. (7).

```
Perform initial graph partitioning on G to generate p outer subdomains, resulting in outer interface nodes and outer internal nodes.
for each of the p outer subdomains in parallel do
    Partition the outer internal nodes into q inner subdomains, resulting in inner interface nodes and inner internal nodes.
end for
for each of the p × q inner subdomains in parallel do
    Build the local grid using inner internal nodes, inner interface nodes, and corresponding outer interface nodes.
    Eliminate inner internal nodes via Eq. (8)-(12).
end for
for each of the p outer subdomains in parallel do
    Build the middle grid, resulting in Eq. (13).
    Eliminate inner interface nodes using Eq. (16)-(17).
end for
Build the global grid, resulting in Eq. (18).
Solve the global grid for z_i using Eq. (18).
for each of the p outer subdomains in parallel do
    Solve the middle grid for y_ij using Eq. (19).
end for
for each of the p × q inner subdomains in parallel do
    Solve the local grid for x_ij using Eq. (20).
end for
```

A. Results on DC Analysis of Power Grids

Table II provides the comparison results between the proposed nested DDM parallel solver and three other solvers. For DDM, the circuit matrix is divided into $p \times q$ subdomains, while nested DDM divides it into p outer subdomains, each with q inner subdomains. Optimal performance is observed with the divisions 2×2, 2×4, 2×8, and 4×8, which are used in Table II. Here, T_{loc}, T_{mid}, T_{top} and T represent the computation time for inner subdomains, intermediate Schur complement, global Schur complement and overall execution, respectively. T_{mt} is the total time for the intermediate and global Schur complements. The speedup ratios Sp_1, Sp_2, and Sp_3 indicate performance improvements over the CHOLMOD, CKTSO, and conventional DDM parallel solver, respectively.

It can be seen from Table II that our framework achieves an average 8.36× speedup compared to the CHOLMOD-

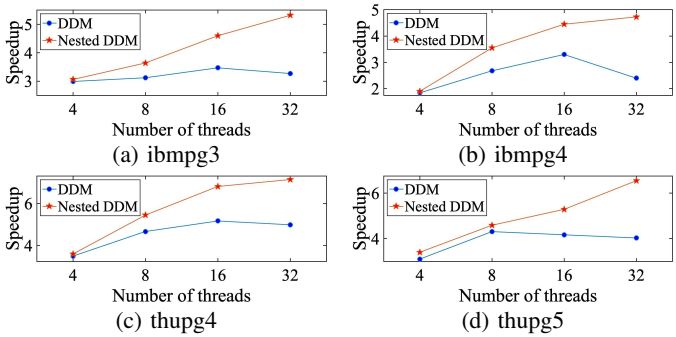

Fig. 4: Speedup comparison of DDM and nested DDM parallel solver over CHOLMOD-based serial solver.

based serial solver utilizing 32 threads, due to multi-level domain decomposition that enhances parallelism by breaking the problem into smaller independent subproblems. Compared to the CKTSO parallel solver, it achieves an average speedup of 8.44× in total runtime, owing to the more structured and sparsely connected nature of power grids. In comparison to the DDM parallel solver, our approach achieves a 1.70× speedup in solving the global Schur complement. This is due to the introduction of an intermediate Schur complement, which enables additional parallelism by redistributing top-level task to the intermediate layer in nested DDM. The improvement is evident when comparing T_{top} in DDM with T_{mt} in nested DDM. As a result, our method provides a 1.30× total runtime speedup over the DDM parallel solver.

To highlight the superior scalability of our framework compared to conventional DDM, we compare the two parallel solvers. As shown in Fig. 4, the nested DDM approach exhibits significantly better scalability with an increasing number of threads, while DDM's performance plateaus early due to inefficiencies in handling the large, dense global Schur complement.

B. Evaluation of parallel Schur complement computation

We further demonstrate the effectiveness of our proposed parallel method for computing the Schur complement using two power grid cases. In these examples, the red nodes represent the selected ports predicted to experience the highest worst-case noise, for which the Schur complement must be computed. The remaining nodes are eliminated to produce an equivalent conductance matrix for the selected ports (i.e., the key points we need to focus on). As shown in Fig. 5, our partition-based parallel computation method achieves significant performance improvements, with speedups of 6.73× and 11.6× when using 32 threads. The method is applicable to PDNs with various grid shapes, and its parallel efficiency depends on the initial partitioning. Fewer interface nodes (e.g., 750 × 31 in Case 2 compared to 3000 × 10 in Case 1 for 32 threads) generally result in higher parallel efficiency.

(a) Case 1 (b) Case 2

Fig. 5: Comparison of speedup in DDM for Schur complement computation across different grid shapes.

V. Conclusion

In this paper, we have presented an efficient parallel nested domain decomposition solver for power grid analysis, aimed at enhancing the scalability of the traditional DDM parallel solver. By introducing a parallel method for computing the Schur complement and integrating it with conventional DDM, we effectively addresses the challenges of managing the large, dense global Schur complement and the computational complexity inherent in large-scale PDNs. Our results demonstrate that the proposed method not only accelerates the solution process but also optimizes resource utilization, making it highly suitable for modern IC design.

AutoPower: Automated Few-Shot Architecture-Level Power Modeling by Power Group Decoupling

Qijun Zhang, Yao Lu, Mengming Li, Zhiyao Xie*
Hong Kong University of Science and Technology
{qzhangcs, yludf, mengming.li}@connect.ust.hk, eezhiyao@ust.hk

***Abstract*—Power efficiency is a critical design objective in modern CPU design. Architects need a fast yet accurate architecture-level power evaluation tool to perform early-stage power estimation. However, traditional analytical architecture-level power models are inaccurate. The recently proposed machine learning (ML)-based architecture-level power model requires sufficient data from known configurations for training, making it unrealistic.**

In this work, we propose AutoPower targeting fully automated architecture-level power modeling with limited known design configurations. We have two key observations: (1) The clock and SRAM dominate the power consumption of the processor, and (2) The clock and SRAM power correlate with structural information available at the architecture level. Based on these two observations, we propose the power group decoupling in AutoPower. First, AutoPower decouples across power groups to build individual power models for each group. Second, AutoPower designs power models by further decoupling the model into multiple sub-models within each power group. In our experiments, AutoPower can achieve a low mean absolute percentage error (MAPE) of 4.36% and a high R^2 of 0.96 even with only two known configurations for training. This is 5% lower in MAPE and 0.09 higher in R^2 compared with McPAT-Calib, the representative ML-based power model.

I. Introduction

Power efficiency is a critical design objective in modern CPU design, and its optimization relies on efficient power evaluation. However, as the complexity of processors keeps scaling up, standard VLSI power evaluation flow requires increasing time. The standard power evaluation flow goes through RTL implementation, RTL simulation, logic synthesis, and power simulation [1]. Completing such a power evaluation flow can take weeks, seriously hindering early microarchitecture optimization and design space exploration. Architects need a fast yet accurate architecture-level power evaluation to support the early optimization of CPU microarchitecture.

Analytical Power Model: Classical architecture-level power models such as McPAT [2] and Wattch [3] are analytical models [4] designed by engineers for a specific type of processor[1]. However, as processor architecture keeps updating, the analytical power model can hardly reflect the design of new processors. As mentioned in many studies [4]–[6], directly applying McPAT on the new generation of CPUs incurs unacceptable errors [4]. Therefore, it is usually necessary to modify McPAT for each target architecture, requiring huge engineering effort and time overhead.

Machine learning (ML)-based Power Models: In recent years, ML-based architecture-level power models [6], [7] are trained to predict the CPU power consumption based on hardware parameters and event parameters. However, training an accurate ML-based model *requires a large number of samples with golden power labels*. In practice, it is time-consuming to go through a standard power evaluation flow to collect golden power labels. More importantly, the number of available configurations is also limited. Therefore, these data-hungry ML-based models are not applicable in real engineering scenarios. Some recent ML works [4] proposed to reduce required training data by unifying analytical models and ML-based models. However, [4] relies on analytical resource functions, which are design-dependent and heavily based on architect expertise. Therefore, there is still a lack of a fully automatic power modeling method that only requires limited known design configurations for training.

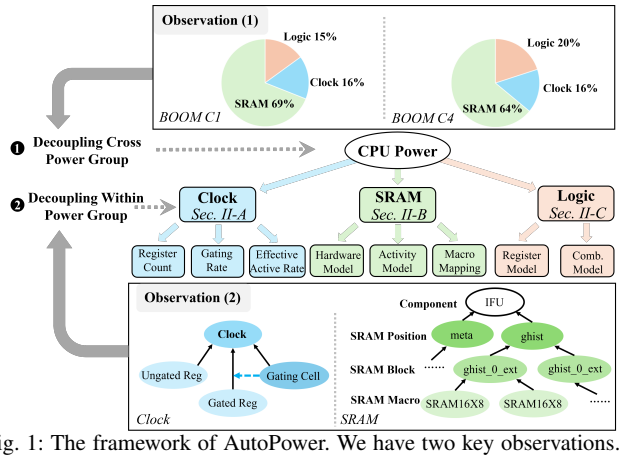

Fig. 1: The framework of AutoPower. We have two key observations. (1) Clock and SRAM dominate the power consumption. (2) Clock and SRAM power correlate with structural information available at the architecture level. Based on these observations, AutoPower decouples the power modeling across different power groups and further decouples the power model for each power group into multiple sub-models.

Goal: This work proposes our new solution named AutoPower[2], achieving both *fully automatic* and *few-shot* architecture-level power modeling, 1) *Fully automatic*: The power modeling method does not require any engineer-defined design-specific analytical power model. 2) *Few-shot*: The model can achieve high accuracy with very limited known configurations for training. As illustrated in Fig. 1. Our solution is initially based on two key observations:

- **Observation 1: Clock and SRAM dominate total power consumption.** The clock and SRAM dominate the power consumption of the processor. Observation 1 in Fig. 1 shows power percentage of each power group of RISC-V BOOM CPU [8] measured at layout stage. It demonstrates that the clock and SRAM dominate the power consumption of the processor.
- **Observation 2: Clock and SRAM power correlate with structural information available at the architecture level.**. (1) Clock power mainly depends on clock pins in registers and clock gating information. The number of registers and the percentage of registers with clock gating are predictable even at the architecture level. (2) SRAM in processors usually follows a four-level hierarchy from top to bottom: component, SRAM Position, SRAM Block, and SRAM Macro. Many design components have some SRAM Positions that will be filled

[2]It is open-sourced at https://github.com/hkust-zhiyao/AutoPower

by SRAM-dominated structures (e.g., tables and queues). Each SRAM Position consists of multiple SRAM Blocks that will be defined in RTL implementations. SRAM Block is built up with SRAM Macros supported by technology node library (i.e., SRAM compiler).

Power Group Decoupling in AutoPower: (1) Motivated by our 1st observation, AutoPower decouples the power models across power groups, building individual power modeling methods for different power groups including clock, SRAM, and logic. (2) Motivated by our 2nd observation, within each power group, AutoPower further decouples the modeling into multiple sub-models based on our observed unique pattern of each power group.

AutoPower adopts innovative power modeling methods for each power group as shown in Fig. 1. (1) For the clock, AutoPower is the first architectural power model that explicitly considers *clock gating*, an indispensable optimization that significantly reduces clock power. Based on the structure of clock power, it proposes to decouple the clock power modeling into the prediction of register count, gating rate, and our pre-defined effective active rate. (2) For SRAM, AutoPower estimates the power based on our proposed hierarchy with a top-down approach. AutoPower transfers the feature from components to SRAM Position, then applies the hardware model and activity model to estimate hardware information and read/write frequency at the SRAM Block level, and finally combines SRAM Macro hardware information and read/write frequency with macro-level mapping. (3) For the logic power, AutoPower decouples it into register power (without clock pins) and combinational logic power, with different modeling methods.

Contributions: Our contributions are summarized below.

- We propose a new architecture-level power modeling framework, AutoPower, that decouples the power model across power groups and within each power group. It requires no design-specific engineer expertise and achieves high accuracy with only a few training samples (i.e., few-shot learning).
- AutoPower proposes innovative power models for each power group: 1) For clock power, AutoPower considers the clock gating technology and decouples the model based on the structure of clock power. 2) For SRAM power, AutoPower estimates the SRAM Macro information and read/write frequency based on our proposed four-level hierarchy. 3) For logic power, AutoPower adopts decoupled power for combinational logic and register power respectively.
- We evaluate AutoPower based on 15 out-of-order RISC-V CPUs with different configurations and 8 workloads. AutoPower achieves a low MAPE of 4.36% and a high R^2 of 0.96 on average only using two known configurations for training. It achieves 5% lower MAPE and 0.09 higher R^2 compared with representative prior works.

II. Methodology

AutoPower decouples the modeling into different power groups including clock power, SRAM power, and logic power. Within each power group, AutoPower further decouples the power models into multiple simple sub-models based on the specific structural information of each power group.

As an architecture-level power model, AutoPower only takes hardware parameters and event parameters as input to calculate the power consumption of the processor. Hardware parameters denoted as H are the parameters to determine the processor configurations, such as DecodeWidth and ICacheWay. Event parameters denoted as E are the information collected from architecture-level performance simulators, by simulating a workload with a certain CPU configuration, for example, the number of cache misses and branch mispredictions.

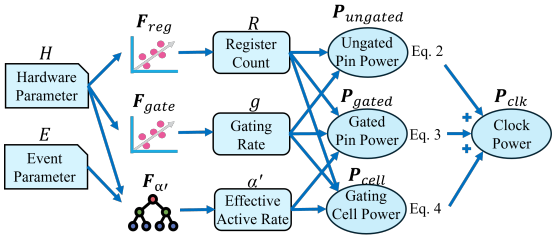

Fig. 2: The clock power includes the power of clock pins in the ungated register (Ungated Pin Power), the power of clock pins in the gated register (Gated Pin Power), and the power of clock gating cells (Gating Cell Power). These three parts can be modeled with the register count, gating rate, and effective active rate, which are estimated by ML models.

We introduce our model for clock power (Sec. II-A), SRAM power (Sec. II-B), and remaining logic power (Sec. II-C) in this section.

A. Power Model for Clock

Clock consumes a significant percentage of power, as shown in Fig. 1. We devote a customized power modeling method for the clock-related power. Such clock-related power is dominated by the internal power of the clock pins in registers. Clock gating is one of the most effective techniques for optimizing clock power, utilizing the clock gating cells to gate the clock of the register. Therefore, AutoPower takes the effect of clock gating into account.

Fig. 2 illustrates our clock power model, which decouples the clock power into the power of clock pins in the ungated register (Ungated Pin Power), the power of clock pins in the gated register (Gated Pin Power), and the power of clock gating cells (Gating Cell Power). To accurately model these three parts of the clock power, we further decouple them into formulations represented by register count, gating rate, and effective active rate. Therefore, ML models only require estimating these three values, which have simpler correlations with hardware parameters and event parameters.

Formulation of Clock Power: The clock power of a processor with the clock gating technique consists of the register clock pin power and the power of clock gating cells. The register clock pin power includes the power of clock pins in the ungated register (ungated pin power) and the power of clock pins in the gated register (gated pin power). Denoting the clock power as P_{clk}, ungated pin power as P_{ungated}, gated pin power as P_{gated}, and the power of clock gating cell as P_{cell}, the clock power can be formulated below,

$$P_{\text{clk}} = P_{\text{ungated}} + P_{\text{gated}} + P_{\text{cell}} \tag{1}$$

We further decouple the power of each part. To formulate it, we denote the number of registers as R, the ratio between registers and clock gating cells as r, the percentage of gated registers as g, the clock pin power per register with active clock as p_{reg}, the pin power of latch in clock gating cell as p_{latch}, and the average active rate across all gated registers as α. We formulate P_{ungated}, P_{gated}, and P_{cell} below,

$$P_{\text{ungated}} = R * (1 - g) * p_{\text{reg}} \tag{2}$$

$$P_{\text{gated}} = \alpha * R * g * p_{\text{reg}} \tag{3}$$

$$P_{\text{cell}} = r * R * g * p_{\text{latch}} \tag{4}$$

(1) For the ungated pin power P_{ungated} in Eq. 2, the clock pin keeps active for every cycle, regardless of the workload that is executed on the processor. Therefore, the power is the multiplication between the number of ungated registers $R * (1 - g)$ and the clock pin power per register with active clock p_{reg}. (2) For the gated pin power in Eq. 3, because of the clock gating, the clock pin can be

inactive for some cycles. Therefore, the active rate α should be considered. (3) For the power of the clock gating cell in Eq. 4, it is difficult to estimate all of these factors accurately at the architecture level. However, in processors, the number of clock gating cells is approximately proportional to the number of gated registers. Besides, the negligible effect of the toggling of its control signal and the number of registers connected with its output clock can be ignored under the architecture-level power modeling scenarios. Therefore, the power can be formulated as Eq. 4.

Putting them together, Eq. 1 can be expressed as below,

$$\begin{aligned} P_{\text{clk}} =& R\,(1-g)\,p_{\text{reg}} + \alpha R\,g\,p_{\text{reg}} + r\,R\,g\,p_{\text{latch}} \\ =& R\,(1-g)\,p_{\text{reg}} + \alpha\,R\,g\,p_{\text{reg}}\,(1 + r\,p_{\text{latch}}\,/\,p_{\text{reg}}) \end{aligned} \tag{5}$$

The reason why we do not directly estimate the number of ungated registers and the number of gated registers is that the clock gating is performed with the logic synthesis tools, which is difficult to predict at the architecture level. In contrast, estimating the total number of registers R and the gating rate g can be easier.

To facilitate the ML-based prediction, we further simplify $\alpha * (1 + rp_{\text{latch}}/p_{\text{reg}})$ as an effective active rate α',

$$\alpha' = \alpha * (1 + r\,p_{\text{latch}}\,/\,p_{\text{reg}}) \tag{6}$$

then Eq. 5 can be finalized as below,

$$P_{\text{clk}} = R\,(1-g)\,p_{\text{reg}} + \alpha' R\,g \tag{7}$$

In Eq. 7, P_{reg} can be looked up from the library file of the technology node adopted for the VLSI flow. Therefore, we totally require three prediction models. (1) register count prediction model $\boldsymbol{F}_{\text{reg}}$ to predict R, (2) gating rate prediction model $\boldsymbol{F}_{\text{gate}}$ to predict g, and (3) effective active rate prediction model $\boldsymbol{F}_{\boldsymbol{\alpha'}}$ to predict α'.

Prediction Model: We formulate the three prediction models below,

$$R = \boldsymbol{F}_{\text{reg}}(H), \quad g = \boldsymbol{F}_{\text{gate}}(H), \quad \alpha' = \boldsymbol{F}_{\boldsymbol{\alpha'}}(H, E) \tag{8}$$

Register count and gating rate of a processor are determined after logic synthesis regardless of workload executed. Therefore, register count prediction model and gating rate prediction model only take hardware parameters of the component as input features. We adopt ML models to learn the correlation. Because the correlation is usually simple and we do not have sufficient samples for training, we adopt the linear model with L2 normalization as our ML model. To collect labels for training, we can collect the number of registers and the number of gated registers from the netlists of known configurations.

Different from register count and gating rate, the active rate α depends on both configuration and workload executed, which is the same case for the effective active rate α'. Therefore, the effective active rate prediction model takes both the hardware parameters and the event parameters as input features. We also adopt the ML model to learn the correlation. In contrast to the register count and gating rate prediction where the correlation is relatively simple, this correlation can be relatively complex. Besides, samples on known configurations for training can be more than the register count and gating rate because we can get multiple samples on a configuration by executing different workloads. Therefore, we adopt a relatively advanced ML model, XGBoost [9], to capture the complex correlation.

B. Power Model for SRAM

SRAM plays an important role in modern processors as the backbone of several tables, such as the history table in branch predictor and the metadata table in IFU, and caches. Its high power consumption is caused by expensive SRAM access. To estimate the SRAM power, we propose to explore the general hierarchy of SRAM in modern CPUs. Our model targets to estimate the SRAM power based on the SRAM Macro information, including the type, number, and read/write frequency. Then the SRAM power can be accurately estimated with the technology node library. Our SRAM power model mainly consists of (1) a scaling-pattern-based hardware model to estimate the number and shape of SRAM Blocks, (2) an activity model to predict the read/write frequency of SRAM Block, and (3) a macro-level mapping model to map the SRAM Block level information to SRAM Macro level.

SRAM Hierarchy: As shown in Fig. 3(a), we propose to model the SRAM power following our proposed general four-layer hierarchy with a top-down approach:

Component → SRAM Position → SRAM Block → SRAM Macro

SRAM Position: At the architecture level, some components include one or more *SRAM Position* that are built from SRAM and serve different functionalities. For example, in IFU, the Fetch Target Queue has two SRAM Positions: 1) ghist, the SRAM structure for the queue; 2) meta, the SRAM structure to store some other metadata.

SRAM Block: At the RTL design level, to build up an SRAM Position, one or multiple identical *SRAM Block* will be used to implement a single- or multi-bank structure. SRAM Block is a logical SRAM with the shape and type required for building SRAM Position. It is the lowest-level layer that is visible to microarchitecture and independent of the support of the adopted technology node library. For example, as shown in Fig. 3(a), the *ghist* consists of multiple SRAM Blocks called ghist_0_ext.

SRAM Macro: At the VLSI implementation level, *SRAM Macro* is the macro supported by the adopted technology node library. Memory compiler in the technology node library cannot generate memory macros with arbitrary shapes. Therefore, the SRAM Block with an unsupported shape should be built up with multiple SRAM Macro supported by the memory compiler. This step is microarchitecture-invisible and is a part of the VLSI flow, where the VLSI flow usually adopts an automatic script to generate a plan to build up each input SRAM Block with the supported SRAM Macros.

Power Model Overview: For the ultimate calculation of the SRAM power, we (1) transfer the feature from the Component to the SRAM Position, (2) propose a hardware model and activity model to estimate the hardware information and read/write frequency for the SRAM Block based on the feature of SRAM Position, and (3) then propose macro-level mapping to transform the SRAM Block level estimation to the SRAM Macro level for ultimate power calculation.

Information at the SRAM Position Level: Similar to the Component, the SRAM Position is also visible at the architecture level. Therefore, the information at the SRAM Position level includes the hardware parameter H and event parameter E of its component.

SRAM Block Hardware Model: The hardware model takes the hardware parameter of an SRAM Position as input to estimate the hardware information at the SRAM Block level, including the width, depth, and count of SRAM Blocks to build the SRAM Position.

The estimation is challenging because input information only includes high-level hardware parameters for SRAM Position. With our observation of SRAM scaling in processors, we propose a scaling-pattern-based hardware model for estimation.

Our insight is that the scaling of SRAM Blocks with respect to hardware parameters H mainly follows two general patterns: (1) Capacity scaling, the total SRAM capacity scales linearly with a hardware parameter, and (2) Throughput scaling, the width or

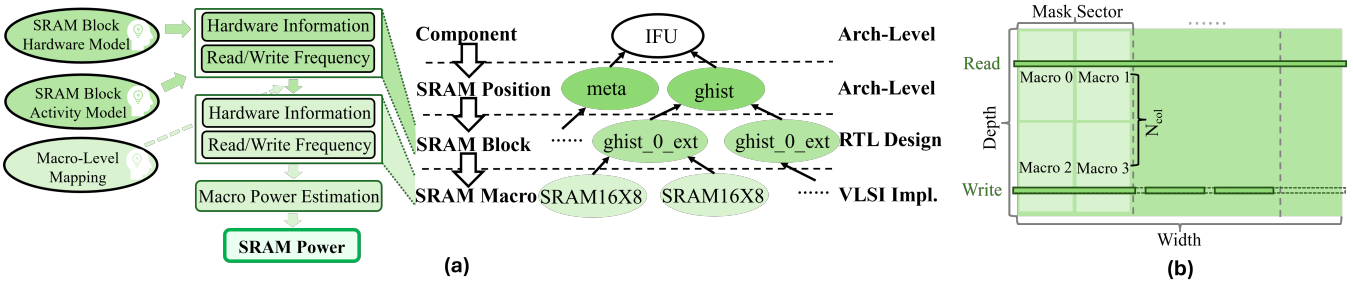

Fig. 3: (a) SRAM power model follows a top-down four-level SRAM hierarchy of processor. For each SRAM Position in a component, SRAM Block hardware model estimates hardware information of SRAM Blocks, and SRAM Block activity model estimates read/write frequency of SRAM Blocks. Based on the estimation, macro-level mapping calculates hardware information and read/write frequency of SRAM Macros, then SRAM Power can be estimated. (b) Illustration of macro-level mapping. It shows the relation between SRAM Block read/write and SRAM Macro read/write.

Training Config	Hardware Parameter			Block Information		
	FetchWidth	DecodeWidth	FetchBufferEntry	width	depth	count
C1	4	1	5	120	8	1
C15	8	5	40	240	40	1

TABLE I: The metadata table example for SRAM Block hardware model. It includes two known configurations C1 and C15 for training.

number of SRAM blocks scales linearly with a hardware parameter to provide more throughput. Based on the two scaling patterns, we can automatically infer the number and shape of SRAM Block even with limited known configurations during training.

The core of our hardware model is to detect which specific hardware parameters the throughput or capacity linearly scales with and scaling coefficient. Based on the information, we can get formulations of width, depth, and count of the SRAM Block.

To detect these hardware parameters, the model tries all hardware parameter combinations to fit a directly proportional function based on known configurations for training and selects the best combination with minimal error. We take the metadata table (meta) in IFU as an example. The hardware parameters of the metadata table include FetchWidth, DecodeWidth, and FetchBufferEntry. Table I shows the hardware parameters and SRAM Block information of two known configurations for training. The hardware parameter combinations include {FetchWidth}, {DecodeWidth}, {FetchBufferEntry}, {FetchWidth, DecodeWidth}, {FetchWidth, FetchBufferEntry}, {DecodeWidth, FetchBufferEntry}, and {FetchWidth, DecodeWidth, FetchBufferEntry}. The model checks each combination by fitting a directly proportional function and gets its error. For example, when checking if the capacity scales with {FetchWidth, DecodeWidth}, the model fits the function below,

$$\text{Capacity} = k * \text{FetchWidth} * \text{DecodeWidth}$$

The capacities, calculated by width * depth * count, of known configurations are 120 * 8 * 1 = 1920 bit and 240 * 40 * 1 = 19200 bit, the FetchWidth * DecodeWidth are 4 * 1 = 4 and 8 * 5 = 40. Therefore, the model can get the k as 240 and the error on two configurations for training as 0. This indicates the capacity scales linearly with FetchWidth and DecodeWidth, and results in the formulation of capacity as below,

$$\text{Capacity} = 240 * \text{FetchWidth} * \text{DecodeWidth}$$

Similarly, we can get the formulation of throughput and width,

$$\text{Throughput} = 30 * \text{FetchWidth}, \quad \text{Width} = 30 * \text{FetchWidth}$$

Because count is the throughput divided by width, and depth is the capacity divided by throughput, we can get the formulation of count and depth,

$$\text{Count} = 1, \quad \text{Depth} = 8 * \text{DecodeWidth}$$

Based on the formulation of width, depth, and count, we can estimate the SRAM Block information with only the hardware parameters.

The reason why we do not directly fit the width, depth, and count is that these three values usually do not scale linearly with hardware parameters in many SRAM Positions such as the table of ROB.

SRAM Block Activity Model: The activity model takes the hardware and event parameters of the SRAM Position as input to estimate the average read/write frequency of the SRAM Blocks.

Because the factors that determine the read/write frequency are complex, we utilize an ML model for the activity model. The input feature includes three parts: (1) hardware parameters of the SRAM Position, (2) event parameters of the SRAM Position, and (3) program-level features that are independent of microarchitecture, such as the number of branch instructions. All prior works do not take the program-level features into consideration. However, we find that the inaccurate performance simulator is one of the root causes of the low accuracy of the ML-based power model, therefore, some microarchitecture-independent features that are not affected by the performance simulator should be taken into account to improve the model accuracy. To collect the labels, we extract the traces of the read and write enable signals in RTL simulation to calculate the read and write frequency. The ML model we utilized is XGBoost [9].

Macro-Level Mapping: Macro-level mapping takes the hardware information and average read/write frequency of the SRAM Block as input to calculate the hardware information and read/write frequency of SRAM Macro. Hardware information of SRAM Macro includes the shape and count of required SRAM Macros to build SRAM Block.

The hardware mapping takes the SRAM Block shape (i.e. width and depth) as input to calculate the shape and count of SRAM Macros to build up the SRAM Blocks. The mapping rule is a part of VLSI flow such as BOOM VLSI flow [8]. It is available and unchanged for all processors implemented with the same VLSI flow. Therefore, given the estimated SRAM Block information, we can use the rule to get the shape and count of SRAM Macros.

To map the read and write frequency to the SRAM Macro level, we carefully analyze the building up of SRAM Block from SRAM Macro and result in a formulation to estimate the SRAM Macro level activity. Fig. 3(b) illustrates the activity of SRAM Macros when an SRAM Block read or write is triggered. When reading the SRAM Block, only the row of SRAM Macros that correspond to the address will be read. Therefore, the average read frequency of SRAM Macro f^R_{macro} is that of SRAM Block f^R_{block} divided by the number of SRAM Macros used to form a column denoted as N_{col}.

Different from the reading, when writing the SRAM Block, because of the masking adopted for writing, only the SRAM Macros that correspond to a valid mask sector will be written. To get a unified formulation for the read and write, we define "one write" to SRAM Block as a write to SRAM Block with all masks valid. For example, if an SRAM Block has two mask sectors, a write to this SRAM Block has one mask valid and another invalid, we will record it as

0.5 write. This will be taken into consideration when collecting the labels of write frequency for SRAM Block. Denoting the average read and write frequency per SRAM Macro as f^R_{macro} and f^W_{macro} and that per SRAM Block as f^R_{block} and f^W_{block}, based on the analysis in Fig. 3(b), the macro-level mapping can be formulated below,

$$f^R_{\text{macro}} = f^R_{\text{block}}/N_{\text{col}}, \quad f^W_{\text{macro}} = f^W_{\text{block}}/N_{\text{col}} \tag{9}$$

Ultimate SRAM Power Calculated at the Macro Level: With the number and types of SRAM Macros and the read and write frequency, we can estimate the SRAM power given the read and write power, denoted as P_{R} and P_{W} looked up from the technology node library. The toggling of address and data pins also has power consumption, but it only has a small contribution to the SRAM power compared with the read and write. Therefore, it can be approximately regarded as a constant. Denoting the SRAM power as P_{SRAM} and power caused by the toggling of address and data pins as C, we formulate the SRAM power as below,

$$P_{\text{SRAM}} = f^R_{\text{macro}} * P_{\text{R}} + f^W_{\text{macro}} * P_{\text{W}} + C \tag{10}$$

where C can be estimated based on the golden power of an SRAM Block collected from power simulation.

C. Power Model for Logic

AutoPower models the logic power by estimating the register power and combinational logic power individually.

Power Model for Register: The register power is the power of registers excluding its clock pin. Our register power model includes a hardware model and an activity model.

In detail, hardware model $\boldsymbol{F}_{\text{reg}}$ takes hardware parameters H as input features and golden number of registers as labels. The activity model $\boldsymbol{F}_{\text{act}}$ takes both hardware parameters H and event parameters E of the component as input features. The active rate label is P_{reg}/R. The register power is the multiplication of $\boldsymbol{F}_{\text{reg}}$ and $\boldsymbol{F}_{\text{act}}$,

$$P_{\text{reg}} = \boldsymbol{F}_{\text{reg}}(H) * \boldsymbol{F}_{\text{act}}(H, E) \tag{11}$$

Power Model for Combinational Logic: Estimating the power consumption of the combinational logic is challenging. Compared with the clock, the SRAM, and the register, the pattern of combinational logic power is more complex. Besides, the combinational logic has a variety of cell types with different power characteristics, incurring the difficulty of decoupling.

Therefore, compared with directly decoupling along physical information, we build a combinational logic power model that decouples the power into a stable power and a variation. The stable power is the power value that can reflect the general combinational logic characteristics from the power aspect, where we adopt the average power across all workloads in the fixed benchmarks for training. It is a purely hardware-related model, only depending on hardware parameters. The variation is the ratio between combinational logic power and stable power, which represents workload-specific information.

In detail, the stable model $\boldsymbol{F}_{\text{sta}}$ is trained based on the average combinational power across all workloads P_{sta}, with the hardware parameters as input features. The variation model $\boldsymbol{F}_{\text{var}}$ takes both hardware parameters and event parameters as the input features and the ratio between power and the stable power $P_{\text{comb}}/P_{\text{sta}}$ as labels. The combinational logic power prediction can be formulated as below,

$$P_{\text{comb}} = \boldsymbol{F}_{\text{sta}}(H) * \boldsymbol{F}_{\text{var}}(H, E) \tag{12}$$

Hardware Parameter	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10	C11	C12	C13	C14	C15

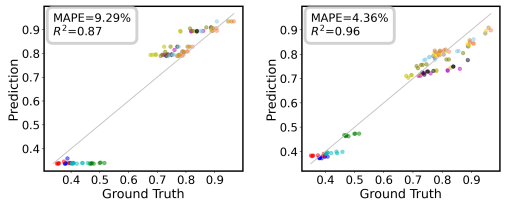
III. Experimental Results

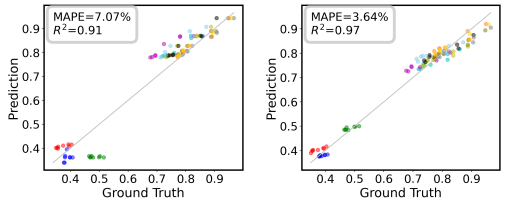
A. Experiment Setup



In our experiment, we adopt Chipyard [10] v1.8.1 to generate RTL code. We utilize RISC-V BOOM CPU [8] with 15 configurations with different scales for evaluation, as shown in Table II. Table III lists the hardware parameters for each component. We have eight workloads from riscv-tests [11] for evaluation, including dhrystone, median, multiply, qsort, rsort, towers, spmv, and vvadd.

We performed RTL simulation, logic synthesis, and power simulation with Synopsys VCS® [12], Synopsis Design Compiler® [13], and PrimePower [1] respectively. Our VLSI flow is based on TSMC 40nm standard cell library and associated Memory Compiler to generate SRAM. To collect event parameters, we utilize gem5 [14] as our performance simulator.

B. Power Prediction Results



1) Summary of Baseline Methods: We compare AutoPower with the state-of-the-art architecture-level automatic power modeling method McPAT-Calib [6] as our baseline. Besides McPAT-Calib, we also include an extra baseline for the ablation study, McPAT-Calib + Component. McPAT-Calib + Component adopts the McPAT-Calib as a building block and builds power models for each component respectively. We select XGBoost [9] as the ML model adopted in McPAT-Calib and McPAT-Calib + Component, as it is the best ML model reported by McPAT-Calib [6].

2) End-to-End Power Model Accuracy: Fig. 4 and 5 visualize the comparison between AutoPower with our baseline method, McPAT-Calib, and the ablation study, McPAT-Calib + Component, when only 2 and 3 configurations are known for training when building the power model. Each point represents a configuration with a workload, points with the same configuration are in the same color. The comparisons demonstrate that AutoPower can consistently outperform McPAT-Calib. Under the two scenarios, AutoPower can achieve the highest R^2 of 0.96 and 0.97, which is 0.07 higher on average than McPAT-Calib with R^2 of 0.87 and 0.91. AutoPower can also achieve the lowest MAPE of 4.36% and 3.64%, which is 4.2% lower on average than McPAT-Calib with MAPE of 9.29% and 7.07%. This superiority is achieved by the suitable decoupling of AutoPower. Fig. 6 shows the comparison results when comparing AutoPower

(a) McPAT-Calib (b) AutoPower

Fig. 4: Accuracy Comparison with 2 configurations for training.

(a) McPAT-Calib (b) AutoPower

Fig. 5: Accuracy comparison with 3 configurations for training.

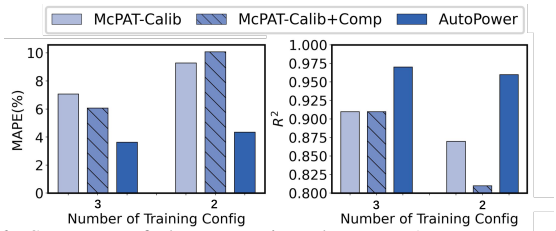


Fig. 6: Summary of the comparison between AutoPower and other methods under different numbers of known configurations for training. "Comp" stands for Component.

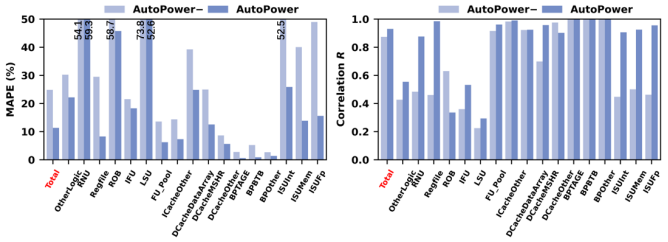

Fig. 7: Detailed comparison of clock power prediction between AutoPower− that directly utilizes the ML model and the AutoPower.

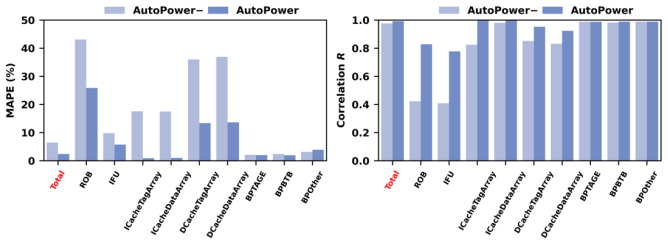

Fig. 8: Detailed comparison of SRAM power prediction between AutoPower− that directly utilizes the ML model and the AutoPower.

with the extra baseline McPAT-Calib + Component. It demonstrates that AutoPower can also outperform McPAT-Calib + Component consistently. This ablation study further verifies that power group decoupling is critical for accurate power estimation.

3) Clock Model Accuracy: To demonstrate the superiority of the AutoPower compared with directly applying the ML model for each power group, we provide another baseline, AutoPower−. It only decouples the model across different power groups and only directly adopts the ML model for the estimation of each power group.

Fig. 7 shows the prediction accuracy for the clock power and the comparison with AutoPower−. It demonstrates that our proposed clock power model can surpass AutoPower− which directly estimates the clock power for most components. Clock power prediction is challenging because of the lack of RTL-level information. Fig. 7 also shows that, with our proposed clock power modeling method, even with limited features and limited training data, AutoPower can still achieve a relatively low MAPE of 11.37% and a high correlation coefficient R of 0.93 with 2 known configurations for training.

Large Workload	Max Power Error (%)			Min Power Error (%)			Average Error (%)		
	C2	C3	C4	C2	C3	C4	C2	C3	C4
GEMM	7.7	9.9	8.1	10.2	11.6	14.9	3.5	2.3	11.0
SPMM	10.6	13.3	14.1	14.7	18.8	20.7	2.0	3.5	8.7

TABLE IV: Summary of fine-grained time-based power trace prediction results for large workloads with millions of cycles. It shows the percentage errors for maximal power, minimal power, and the average time-based power prediction error.

The high accuracy of clock power is contributed by the accurate prediction of each sub-model. The prediction of the number of registers R and gating rate g can achieve a low MAPE on average with 6.93% with 2 known configurations.

4) SRAM Model Accuracy: Fig. 8 shows prediction accuracy for SRAM power and comparison with AutoPower−. The results demonstrate that SRAM power model in AutoPower can achieve a higher accuracy compared with AutoPower− for most components. It can achieve high accuracy even if only the architecture-level information is available, with a low MAPE of 7.60% and a high correlation coefficient R of 0.94, under 2 known configurations.

Such a high accuracy benefits from the accurate estimation of the number of macros and the read/write frequency. Especially, with our insight based on the scaling pattern of SRAM in processor designs, our hardware model can accurately predict the SRAM Block hardware information with a nearly 0 MAPE, and then it can accurately model the SRAM Macro with the rule from VLSI flow.

5) Time-Based Power Trace Prediction for Large Workloads: Besides average power, fine-grained time-based power trace prediction is also critical for modern processor design. However, because of the fine-grained information required for prediction, architecture-level power trace prediction is challenging.

We adopt two large workloads with millions of cycles, GEMM and SPMM, as our target workloads for time-based power trace prediction. The length of the time step is 50 cycles. The model is trained based on only two known configurations. Table. IV shows the accuracy when applied to the C2, C3, and C4. It demonstrates that, even for fine-grained time-based power trace prediction, our model trained on two known configurations can still achieve a low MAPE without tuning on additional time-based power trace data.

IV. Conclusion

In this work, we propose AutoPower targeting fully automated architecture-level power modeling with limited known design configurations. It decouples the modeling into different power groups and further decouples the power models into multiple simple sub-models based on the specific structural information of each power group. AutoPower lowers the data requirement barrier, which is a compelling addition to architects' toolbox.

***Abstract*—The fast-rising demand for wireless bandwidth [1] requires rapid evolution of high-performance baseband processing infrastructure. Programmable many-core processors for software-defined radio (SDR) have emerged as high-performance baseband processing engines, offering the flexibility required to capture evolving wireless standards and technologies [2]–[4]. This trend must be supported by a design framework enabling functional validation and end-to-end performance analysis of SDR hardware within realistic radio environment models. We propose a static binary translation based simulator augmented with a fast, approximate timing model of the hardware and coupled to wireless channel models to simulate the most performance-critical physical layer functions implemented in software on a many (1024) RISC-V cores cluster customized for SDR. Our framework simulates the detection of a 5G OFDM-symbol on a server-class processor in 9.5s-3min, on a single thread, depending on the input MIMO size (three orders of magnitude faster than RTL simulation). The simulation is easily parallelized to 128 threads with 73-121× speedup compared to a single thread.**

***Index Terms*—RISC-V, SDR, 5G, 6G, SBT.**

I. Introduction

The worldwide demand for more wireless subscriptions (8.5 billion in 2023) and network data traffic (145EB in Q1-2024) [1] fostered the development of new Radio-Access-Networks (RAN) technologies. The Massive Multiple Input Multiple Output (MIMO) paradigm ratified by 3rd Generation Partnership Project (3GPP) Release-17 [5] gained momentum and will extend to more users and antennas in the upcoming 6th Generation (6G) releases [6]. Alongside increased performance requirements, channel traffic characteristics will also change, resulting in a dynamic range from a few kBs for a voice call to GBs for high-quality multimedia [7].

The flexibility required to address demanding worst-case specifications and wide operation ranges can be obtained by implementing the MIMO processing workload on programmable cores, an approach known as Software Defined Radio (SDR). Multi-core and many-core systems promise high performance on SDR 5th Generation (5G) workloads at the edge, implementing the full Physical Layer (PHY) on basestations (BSs) [2]–[4]. Additionally, the RISC-V Instruction Set Architecture (ISA) emerged as a powerful domain-specialization tool to fight back the energy-efficiency loss of instruction processors vs. custom hardware, enabling the co-design of efficiency-boosting processors features and domain-specific instruction extensions [3], [4].

Evaluating the algorithmic (functional) performance of software running on SDR-hardware and its execution performance under varying network traffic, spatial topology, and transmission channel conditions is critical to the design of future BSs. To this purpose, a model of the SDR receivers must be simulated as Device Under Test (DUT) in an end-to-end (E2E) transmission, matching the following requirements: deterministic behavior, flexibility to evolving standards, and awareness of timing to synchronize with other elements of the processing chain [7]. Additionally, a fast simulation framework is needed to evaluate the receiver performance via extensive numerical Monte Carlo (MC) simulation.

TABLE I
Simulation methods for SDR baseband hardware.

	Device	Freq.	Speed	Design Effort	Multi-Core
[8], [9] RTL	-	-	↓	↓	✗
[10] TLM	Intel Core2	3.00GHz	↑	↑	✗
[11] FPGA	XCZU28DR	128MHz	↑	↓	✗
[2] FPGA	ZCU102	120MHz	↑	↑	✓
Ours SBT	AMD EPYC-7742	3.25GHz	↑	↓	✓

Table I summarizes different options to include SDR hard-

ware as DUT in an E2E wireless transmission testbench. Event-based (e.g., QuestaSim [12]) and compiled (e.g., Verilator [13]) Register Transfer Level (RTL) simulators, require low effort to directly simulate Hardware Description Language (HDL) code of baseband receivers [8], [9], [14]. Unfortunately, they are too slow for MC simulation of complex workloads. Transaction Level Modeling (TLM) in SystemC allows the creation of detailed virtual prototypes of entire digital systems [10] and can also be used for the simulation of RF analog transceivers [15]–[17]. However, TLM simulations are limited in speed for the sequential execution of SystemC processes managed by a centralized kernel [18] and require long compilation time, constraining design iterations. Field Programmable Gate Array (FPGA) [2], [11] or Application Specific Integrated Circuit (ASIC) prototyping can not be used to implement a fast hardware-software co-design loop, because it requires a fully designed system and can be used only late in the design process. In the case of complex baseband many-core receivers, the prototyping on FPGA also requires considerable design effort. High Level Synthesis (HLS) tools, such as Python Productivity for Zynq (PYNQ) [11], are used to emulate small dataflows on FPGA, but the approach does not extend to many-core baseband processors with hundreds of processing elements. Moreover, implementing multi-core systems on FPGA must trade off limited hardware resources and operating frequencies, as clearly shown by the implementation of 36 RI5CY cores on Xilinx XCVU9, presented in [2].

This paper proposes a lightweight Static Binary Translation (SBT) based framework to simulate SDR many-core programmable transceivers based on the RISC-V ISA. Our simulator can be connected to channel models for extensive MC analysis and is easily parallelized on Commercial Off The Shelf (COTS) multi-core servers. The following contributions quantify these claims:

- We propose the open-source[1] SBT-based simulator Banshee [19] for deterministic and instruction accurate emulation of many-core transceivers. The simulator is connected to wireless channel models [20] for E2E MC analysis of the receiver performance. As a challenging benchmark, we emulate the 1024 independent instruction streams of the open-source[2] programmable TeraPool-SDR [3] on a 128-cores AMD EPYC-7742 server.
- We demonstrate fast design space exploration on the Minimum Mean Squared Error (MMSE) detection in different arithmetic precisions. A single thread of the 128-core AMD EPYC-7742 server simulates the detection of an Orthogonal Frequency Division Multiplexing (OFDM) symbol in $<$ 3min, depending on the MIMO size. A small 4x4 input only requires 9.5s, compared to 13h:44min for RTL simulation of the same binary (Questasim-2022.3). Independent symbols are easily parallelized, with 73-121$\times$ speedup, compared to a single thread.
- We show that augmenting the SBT-based simulator with an approximate timing model of the hardware offers first-order estimates of the receiver processing time, with 30% average error over the measured RTL cycle-count for different MMSE implementations and MIMO sizes.

Running MMSE detection with a speedup over RTL simulation exceeding 1000$\times$, the developed framework enables fast MC analysis of programmable baseband transceivers.

[2]https://github.com/pulp-platform/mempool

II. Many-Core SDR Architecture

TeraPool [3], the largest shared-memory many-core cluster for SDR presented in the open literature, is a challenging simulation benchmark: emulating its 1024 independent instruction streams, diverse ISA, and large hierarchical interconnect is time-consuming in RTL simulation and would require consistent modeling effort in TLM. Moreover, TeraPool's open-source RTL design enables comparisons with cycle-accurate simulation.

The TeraPool architecture, illustrated in Figure 1, features *Snitch* processing elements that support the RV32IMAF ISA. The single-stage core decodes instructions and executes the RV32I ISA, excluding load&stores. Other instructions are offloaded to co-processing functional units, including a Load&Store Unit (LSU), an Integer Processing Unit (IPU) for integer multiplication and division, and a Floating Point Unit (FPU) implementing the *zfinx* and *zhinx* extensions [21].

Snitch's functional units also implement custom integer and Floating Point (FP) RISC-V extensions for Digital Signal Processing (DSP). The *Xpulpimg* set includes post-increment load&stores, Multiply and Accumulates (MACs), and Single Instruction Multiple Data (SIMD) compute and data-shuffling operations on 8b-16b integer types. The *Smallfloat* and *Minifloat* sets [22], [23] include SIMD operations on FP 8b-16b types, widening-dotproduct (wDotp) with 8b-16b operands and 16b-32b accumulators, and complex 16b FP MAC.

The base of TeraPool's hierarchical design is the *Tile*, where 8 cores share 32 KiB of scratchpad memory with 1-cycle access latency and 4 KiB of I$. The cores access the scratchpad of other Tiles via shared ports to the cluster interconnects. One 8x8 crossbar connects 8 Tiles in the *SubGroup* hierarchy. Three 8x8 crossbars connect Tiles of the SubGroup to Tiles of 3 other SubGroups in the *Group* hierarchy. Three 32x32 crossbars connect the Tiles of a Group to Tiles in 3 other Groups, summing up to 128 Tiles and 4 MiB of scratchpad in a Cluster. Pipeline stages at hierarchy boundaries configure non-uniform memory access (less than 9 cycles without contentions). A cluster-level AXI interconnect and a Direct Memory Access (DMA) engine allow explicit data transfers from L2 memory.

III. Co-simulation of DUT with TX-Channel

We describe a wireless E2E MIMO transmission and the developed framework for co-simulation of the transmission channel model and of the RISC-V DUT.

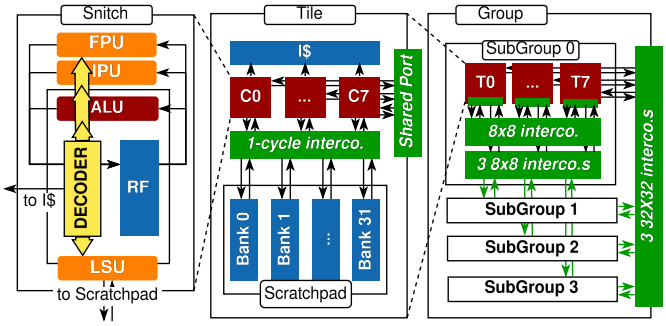

Fig. 1. Snitch core, Tile, SubGroup, and Group of TeraPool.

A. End-to-end MIMO wireless transmission

MIMO is a key enabling technology for 5G and beyond networks, where the BS is equipped with N_{RX} antenna elements, which receive signals from N_{TX} user equipments (UEs). During uplink, the transmission bit sequence maps to a Quadrature-Amplitude Modulation (QAM) constellation, and blocks of QAM-symbols are transmitted through the channel on N_{SC} OFDM subcarriers, namely an OFDM-symbol [5]. At the BS, the detection algorithm uses channel state information (CSI) to estimate the transmitted QAM-symbols. The BS processes a Transmission Time Interval (TTI) with 14 OFDM-symbols in <1ms. The evolution from 5G to 6G will increase in the N_{SC}, N_{TX}, and N_{RX}, affecting the Key Performance Indicators (KPIs) of DSP detection algorithms as well as their hardware implementation.

We therefore identify MIMO detection as a reference application to prove the capabilities of our co-simulation approach. We implement the MMSE detector, which offers optimal performance for transmission through a Additive White Gaussian Noise (AWGN) channel, on the target SDR-hardware.

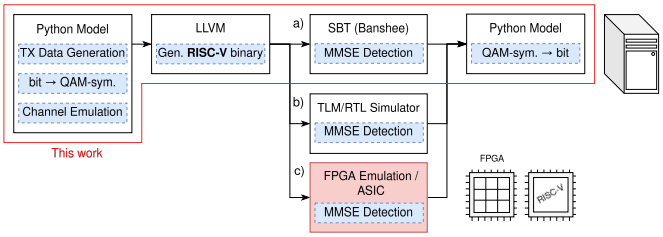

Fig. 2. Different approaches to add RISC-V hardware in the loop of a telecommunication application: c) execution on prototype ASIC, emulation on FPGA, b) cycle-accurate RTL/TLM simulation and a) simulation on Banshee.

B. Simulation of the MIMO wireless transmission

The proposed framework and flow are described in Figure 2. A Python model of the MIMO transmission based on [20] runs on the simulation host. The model includes bit-sequence transmission generation for different users, QAM-symbol mapping, and wireless channel emulation. It also implements a double-precision reference of the detection MMSE algorithm.

The SDR hardware running MMSE processing is simulated on Banshee, an open-source LLVM-based binary translator for instruction-accurate emulation of multi-core systems. The simulation flow in Banshee is divided into two phases. During *translation*, Banshee converts a RISC-V binary into LLVM Intermediate Representation (IR) via SBT. The generated IR references to Banshee runtime functions to keep track of the emulated device state. LLVM optimizes and translates the IR into host code. During *emulation*, Banshee maps the translated code to multiple threads on the host platform for each hardware thread of the emulated RISC-V multi-core.

Besides offering an instruction-accurate simulation of the host and taking advantage of fully parallel execution, Banshee assigns a static latency to each instruction to estimate the program runtime. To model outstanding instruction execution, Banshee implements a scoreboard that keeps track of the Read After Write (RAW) dependencies between instructions. This feature allows a fast software performance estimation by accounting for instruction stalls caused by long-latency instructions such as loads&stores.

We modified Banshee to translate *zfinx*, *zhix*, *Smallfloat*, and *Minifloat* FP extensions, which compute on operands in the integer register file, as specified in [21]. The latency of FP instructions is also annotated in the simulator for first-order estimation on the emulated code runtime.

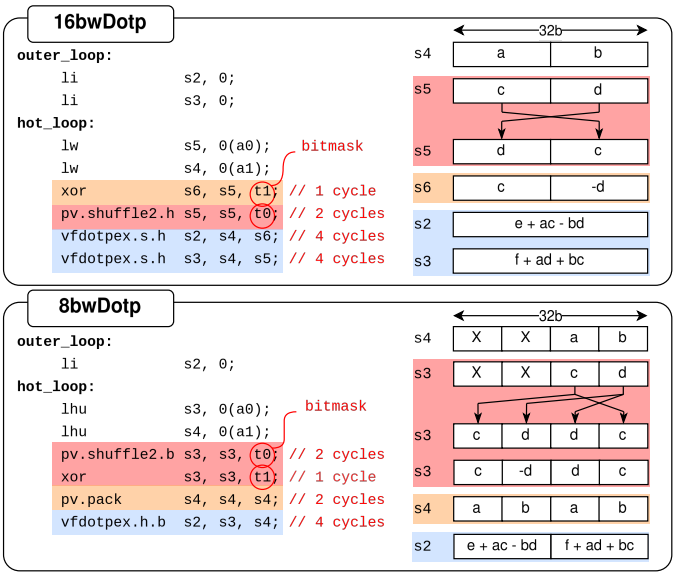

Fig. 3. Execution of the complex MAC in different arithmetic precisions using *Smallfloat* and *Xpulpimg* instruction sets.

IV. Software-defined MMSE on TeraPool

This section describes the SDR implementation of a MMSE detector on TeraPool. Given y the received signal, $\hat{H}$ and σ an estimation of the channel and noise at the BS, and $\hat{x}$ the detected signal, the analytical MMSE detector is:

$$\hat{x}_i = (\hat{H}_i{}^H \hat{H}_i + \sigma_i^2 I)^{-1} \hat{H}_i{}^H y_i \quad \forall i \in [1, N_{SC}] \qquad (1)$$

The operator in Equation (1) requires a matrix inversion. Given $G = (\hat{H}^H \hat{H} + \sigma^2 I)$ and $z = \hat{H}^H y$, we decompose $G = L^H L$ in its lower and upper triangular components, using the Cholesky algorithm. The linear system $G\hat{x} = z$ is solved by

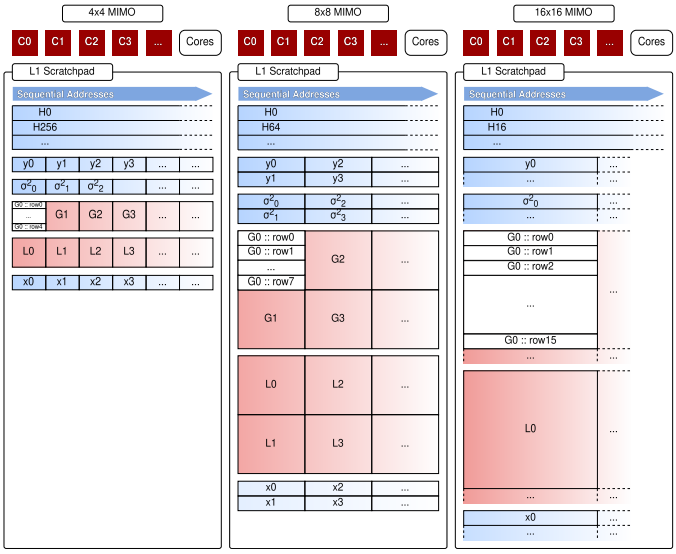

Fig. 4. Implementation of parallel MIMO-MMSE on the TeraPool many-core cluster for different sizes of the MIMO problem.

inverting two lower triangular matrices $\hat{x} = L^{-1}\left((L^H)^{-1}z\right)$. This reduces the overall arithmetic complexity of the inversion, as described in [24]. The MMSE detection then requires four operators: the Hermitian of the channel, the Matrix Vector Multiplication (MVM) between the complex-conjugate of the channel and the received symbol, the Cholesky decomposition, and the solution of a triangular system.

TeraPool has a *fork-join* type programming model (common trait of many-core clusters). In the *fork* phase of the program, each core executes an independent instruction stream in parallel. The *join* phase consists of a synchronization barrier: cores wait for each other before executing the next parallel section.

In an OFDM transmission a different MMSE problem must be solved for each subcarrier of the transmission spectrum. In the parallel execution on TeraPool, the kernels of MMSE are implemented for a single Snitch core, and an independent MMSE problem is then distributed in parallel to each core. The single-core MMSE is implemented in different arithmetic precisions, as this is a key exploration parameter for trading off functional accuracy with execution speed and energy.

1) 16bHalf: uses the RISCV *zhinx* set. We load 16b words. A complex MAC requires four `fmadd.h` instructions.

2) 16bwDotp: uses the wDotp extension of the *Smallfloat* set, with 32b accumulation. We load 32b words, and we use two wDotps and a SIMD `shuffle` instruction from *Xpulpimg* set to implement the complex MAC, as described in Figure 3.

3) 16bCDotp: uses the complex dotproduct operation. The multiplication internal precision is 32b, and real-imaginary accumulators are in 16b, fitting a 32b word.

4) 8bQuarter: uses *Smallfloat* 1b sign, 4b exponent, 2b mantissa FP format. After the execution of the $\hat{H}^H\hat{H}$ matrix product and of the $\hat{H}^H y$ MVM, we cast the outputs to 16b to solve the $G\hat{x} = z$ linear system in higher numerical precision.

5) 8bwDotp: uses *Smallfloat* wDotp for the matrix products and the MVM, with accumulators in 16b. A complex MAC requires a wDotp instruction and a SIMD `shuffle` instruction from the *Xpulpimg* set, as described in Figure 3. The linear system is solved in 16b precision.

For the parallel execution, each core runs an independent MMSE problem (1024 in total). The operands are allocated in the shared memory of TeraPool to reduce the cores' contentions to shared interconnect resources [25]. In Figure 4, we represent TeraPool cores and the corresponding input-outputs of independent MIMO problems. The elements of vectors in Equation (1) (y, σ^2, $\hat{x}$, and $\hat{H}$, flattened to a one-dimension array in row-major order) lay in consecutive addresses of L1. This matches the allocation of data in L2 and does not require relocating elements after explicit DMA transfers to L1. On the contrary, intermediate outputs of the computation L matrix and G matrix have rows on different memory rows. This keeps the data local to the processing cores. For example, in the 4x4 MIMO, each core sends requests to different banks, fetching y, σ^2, $\hat{x}$, and G, and in the 32x32 MIMO only 8 cores contend for the same scratchpad banks.

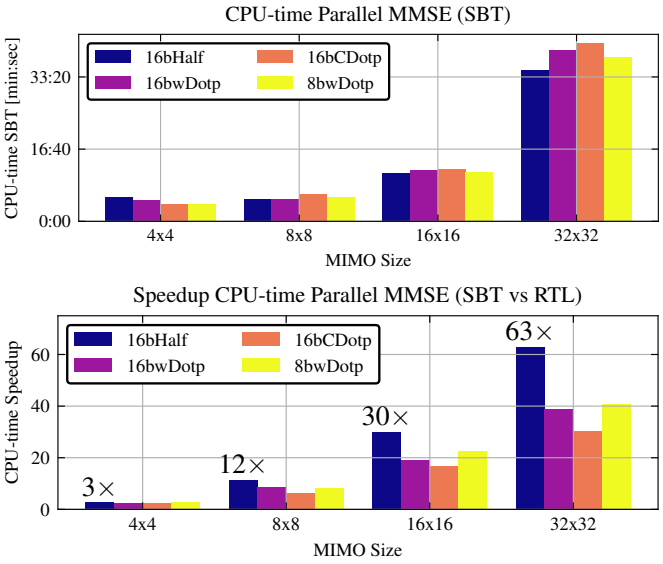

Fig. 5. Parallel MMSE in different precisions and input sizes: speedup on 128-cores AMD EPYC-7742 of multi-thread Banshee simulation against single-thread RTL simulation with QuestaSim-2022.3.

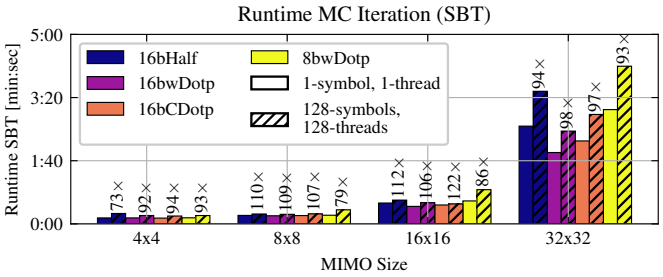

Fig. 6. Batched execution on a Snitch of $N_{SC} = 1638$ MMSE problems of an OFDM-symbol: single-thread runtime of Banshee simulation and multi-thread simulation of independent symbols with corresponding speedup, on a 128-cores AMD EPYC-7742 server.

V. BER & Runtime Analysis

This section explains how SBT can be used for fast design-space exploration of MMSE in different arithmetic precisions. It presents Banshee runtime, then shows how to measure the KPIs of software-defined MIMO applications.

A. Simulator runtime performance

We execute 1024 MMSE problems in parallel on 1024 TeraPool cores. We simulate a total of 1024 independent instruction streams. The experiment runs on a 128-CPUs COTS server processor at 3.25GHz (AMD EPYC-7742). Each CPU has 32MiB L3-cache and shares 1TB of system memory. We compare the total CPU-time of a multi-thread Banshee simulation with the CPU-time of a single-thread RTL simulation (Questasim-2022.3 being intrinsically single-threaded). For multi-thread, we average the results of 10 independent runs to filter the effect of competing processes on the server. Figure 5 shows the runtime (top) and speedup (bottom) results: the total CPU-time for a Banshee call amounts to average $<$ 35min, while the average wall-clock runtime is $<$ 2min:45s, over all the input sizes. Comparing CPU-times, Banshee simulation is up to 63$\times$ faster than single-thread QuestaSim-2022.3 RTL simulation. Comparing wall-clock runtimes, Banshee multi-thread simulation is up to 1582$\times$ faster than single thread RTL simulation.

To speed up the simulation, the MC simulation of independent MMSE problems is batched on a single TeraPool core. We consider a New Radio (NR) transmission in a 50MHz bandwidth, with $N_{SC} = 1638$, 30kHz subcarrier spacing, and 0.5ms TTI duration. We simulate a MC iteration, consisting of $N_{SC} = 1638$ MMSE problems running on a single Snitch, with a single AMD EPYC-7742 thread. The maximum speed for a single-threaded Banshee simulation of a single Snitch is 3.57 Million Instructions Per Second (MIPS). The runtime in Figure 6, shows $<$ 3min per MC iteration, and down to 9.44s for an input 4x4 MIMO, compared to 13h:44min required by RTL simulation of the same binary (5237$\times$ faster).

Independent OFDM symbols can be easily parallelized over the 128 cores of the server. Figure 6 shows the runtime with 128 active threads and the speedup compared to a single thread. We measure 12.5s-4min:10s simulation runtime per 128 MC iterations, depending on the MIMO size and arithmetic precision: 73-121$\times$ speedup compared to single-thread execution. The achieved simulation throughput is fully compatible with a fast HW-in-the-loop exploration of the E2E 5G application under exam.

B. MMSE cycle-count on TeraPool

Figure 7 reports the cycle-count of the complete parallel *16bHalf* MMSE application, measured by RTL simulation in QuestaSim-2022.3. The cycle-accurate RTL simulation gives precise information on the speedup of lower arithmetic precisions compared to *16bHalf*. SIMDs reduce the total number of instructions issued. In particular, for a 32x32 input, the ratio between instructions issues in the *16bHalf* compared to *16bwDotp*, *16bCDotp*, and *8bwDotp* corresponds to 1.15$\times$, 1.84$\times$, and 1.37$\times$. These values are slightly smaller than the measured speedup (1.29$\times$, 1.86$\times$, 1.38$\times$): requiring fewer loads, compared to *16bHalf*, SIMD instructions also reduce the stalls from contentions in the shared interconnect.

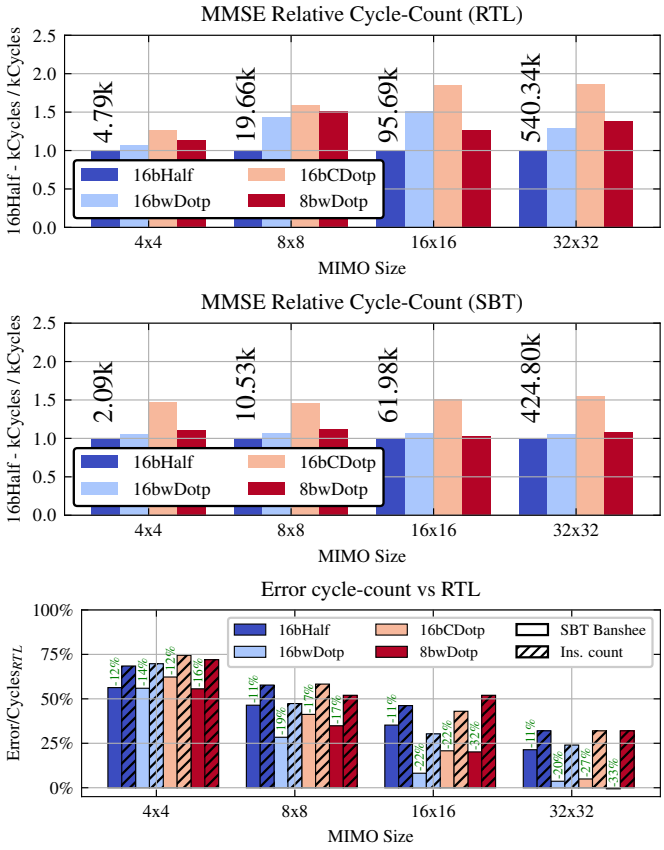

Fig. 7. Parallel implementation of the MMSE in different precisions for various sizes of MIMO. Error between the cycles measured by RTL simulation with QuestaSim-2022.3 and estimated by Banshee or by counting instructions.

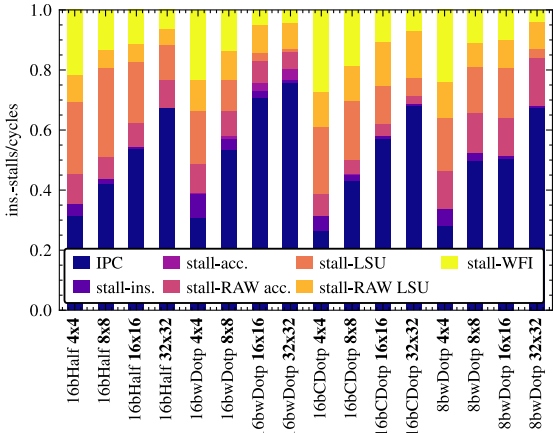

Fig. 8. Breakdown of instructions and architectural stalls over the cycle-count. Result of cycle-accurate experiments in QuestaSim-2022.3.

The breakdown of instructions and stalls over the cycle count for different arithmetic precisions and input problem sizes is in Figure 8. We measure few *stall-ins.* for I$ refill and

stall-acc., occurring when the pipelines of Snitch functional units are full. Loops are unrolled to minimize RAW stalls, with increasing benefits at higher problem sizes. The amount of stalls due to contentions in the interconnect (*stall-LSU*) is the highest for the low arithmetic intensity *16bHalf* application. Finally, *stall-WFI* refers to the time spent by cores idling at the synchronization during the fork-join MMSE application.

Figure 7 reports a comparison between the cycle count measured by RTL simulation, the cycle count estimated by Banshee, and a rough estimation based on the instruction count. Privileging multi-thread fast simulation of parallel programs on the host, Banshee omits priorities between loads&stores targeting the same memory bank or Tiles' shared-ports to interconnects, as well as priorities between atomic memory operations, used to implement synchronization barriers. Modeling these effects would require expensive synchronization between hardware threads or computationally heavy statistical models. Our approximate solution, oriented to simulation speed, is conservative in assigning statically to all the transactions the largest memory access latency without contentions (9 cycles).

On average, we obtain 30% error compared to RTL simulation cycle-count. The largest errors measured (20-62%) correspond to the *16bHalf* implementation, which loads&stores separately the real-imaginary parts of the operands (twice the number of memory operations, compared to other kernels). Small MIMO problems with large synchronization overhead are more affected by the permissive latency modeling of atomics. Nevertheless, in this unfavorable case, Banshee obtains 12-16% improvement (in green) on the rough estimation considering the instruction count only. For a large 32x32 MIMO input, the error of Banshee is only 0.6-20%.

Despite the cycle performance over-estimation, in Figure 7 we note that measuring the cycle count in Banshee does not invalidate the key insight on the speedup of SIMD implementations, compared to *16bHalf*. The values measured for 32x32 inputs, 1.05×, 1.54×, 1.07×, confirm *16bCDotp* as the fastest option, followed by *8bwDotp* and *16bwDotp*. The tool is useful for rough estimations of the E2E cycle count. Targeting an open-source DUT facilitates further calibration and reduction of performance over-estimation based on RTL simulations results.

C. BER extraction via fast MC simulation

A classic telecommunications KPI is the Bit Error Rate (BER), which measures the ratio of bit errors compared to the original transmitted bit sequence. We compute the BER of the MMSE implemented on TeraPool simulating MC iterations with Banshee and leveraging its bit-true functional modeling accuracy. For different input Signal to Noise Ratio (SNR), we iterate to a target error count. We explored the performance of the MMSE detector in different arithmetic precisions according to three variables: MIMO problem size, bit-sequence modulation, and wireless channel type.

The input bit-sequence maps to different QAM constellations. In Figure 9, we compare the BER vs. SNR, obtained for a 4x4 or a 32x32 MMSE problem with 16QAM and a 64QAM modulation. We observe the *16bHalf*, *16bwDotp*, and *16bCDotp* implementations achieving the same results as the *64bDouble* Python model. The *8b* implementations both suffer the truncation of results precision before the *16b* matrix inversion, corresponding to a 10× loss at 18dB.

In Figure 10, we examine the BER of the receiver, assuming a flat-fading Rayleigh channel. While the AWGN channel assumes zero attenuation and interference from other transmitters, the Rayleigh channel considers the effects of multi-path fading and models a 5G-MIMO transmission more closely. The MC co-simulation of TeraPool and the wireless channel gives immediate feedback on the performance of low-bit arithmetic precision RISC-V extensions on the full wireless application: only the *16bwDotp* and *16bCDotp* implementations follow the performance of the *64bDouble* golden model. The fast co-simulation approach revealed the benefits of accumulating in *32b* (*16bwDotp*), or execution of the complex MAC in *32b* internal precision (*16bCDotp*).

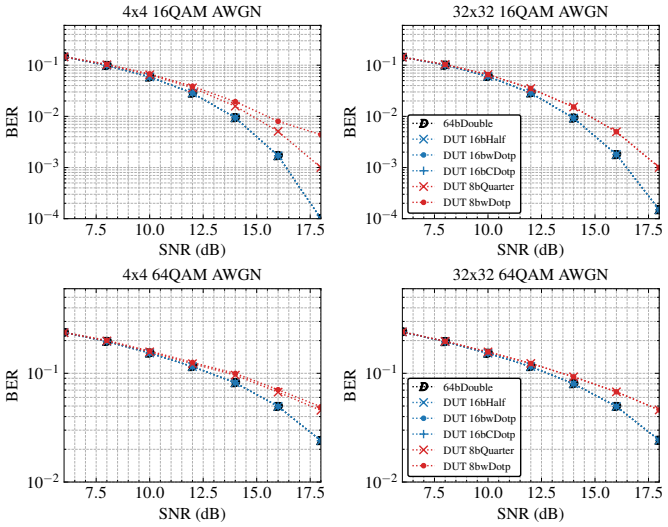

Fig. 9. BER for 16QAM and 64QAM modulation, AWGN channel.

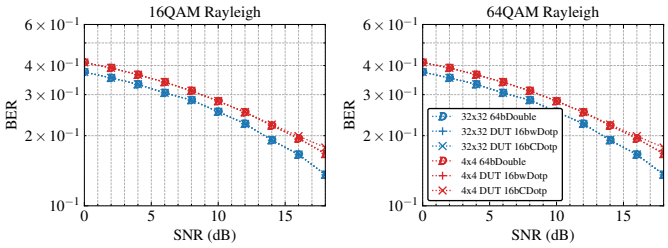

Fig. 10. BER for 16QAM and 64QAM modulation, Rayleigh channel.

VI. Conclusions

This work presented an open-source SBT-based lightweight simulator coupled to wireless channel models to extract the E2E performance of RISC-V SDR-transceivers. The simulation framework fulfills the requisites [7] to model BS programmable receivers in large-scale RAN testbed. SBT offers

fast, functional modeling of SDR workloads on the open-source TeraPool 1024-core cluster, accounting for the low-bit precision of the hardware. It enables fast design space exploration of E2E 5G transmissions, considering different modulation schemes and wireless channels: MMSE on a 5G OFDM-symbol is simulated in only 9.5s-3min, depending on the input MIMO size, three orders of magnitude faster than RTL simulation. Independent symbols are parallelized on up to 128 threads of a COTS server with 73-121$\times$ speedup compared to single-thread simulation. The translation approach is agnostic of the algorithm used, which makes the method flexible to an evolving telecommunication standard. Finally, augmenting the simulator with a simple hardware timing model gives first-order estimates of the runtime on the DUT, with only 30% average error, for different MIMO sizes. The fully open-sourced RTL of the DUT ease further calibration and reduction of the performance over-estimation.

***Abstract*—Linear-response time-dependent Density Functional Theory (LR-TDDFT) is a widely used method for accurately predicting the excited-state properties of physical systems. Previous works have attempted to accelerate LR-TDDFT using heterogeneous systems such as GPUs, FPGAs, and the Sunway architecture. However, a major drawback of these approaches is the constant data movement between host memory and the memory of the heterogeneous systems, which results in substantial *data movement overhead*. Moreover, these works focus primarily on optimizing the compute-intensive portions of LR-TDDFT, despite the fact that the calculation steps are fundamentally *memory-bound*.**

To address these challenges, we propose NDFT, a Near-Data Density Functional Theory framework. Specifically, we design a novel task partitioning and scheduling mechanism to offload each part of LR-TDDFT to the most suitable computing units within a CPU-NDP system. Additionally, we implement a hardware/software co-optimization of a critical kernel in LR-TDDFT to further enhance performance on the CPU-NDP system. Our results show that NDFT achieves performance improvements of 5.2x and 2.5x over CPU and GPU baselines, respectively, on a large physical system.

***Index Terms*—Near-Data Processing, Density Functional Theory, Workload Scheduling, Hardware/Software Co-Design**

I. Introduction

First-principle calculations, also known as *ab initio* methods, predict the properties of materials by solving the electronic motion equations derived from the fundamental principles of quantum mechanics. Among these methods, density functional theory (DFT) is widely used to determine the ground-state properties of systems by focusing on electron density rather than wavefunctions. Building on DFT, **linear response time-dependent density functional theory (LR-TDDFT)** is particularly notable for its ability to accurately describe the excited states of complex systems. LR-TDDFT is extensively applied in material analysis, condensed matter physics, and quantum chemistry. However, it often encounters significant computational challenges, including high execution time, memory complexity, and frequent data accesses, which can easily lead to memory bottlenecks. Given the crucial role of LR-TDDFT in scientific research and the computational challenges it presents, exploring optimization techniques for this method has become a prominent topic in the field of high-performance computing.

Recent studies have tried to accelerate LR-TDDFT calculations using heterogeneous systems such as graphics processing units (GPUs) [20] and the Sunway architecture [22]. These architectures leverage parallel processing capabilities to execute a large number of computations simultaneously, significantly speeding up the *compute-intensive* aspects of the software. However, executing LR-TDDFT on these systems requires frequent data transfers between main memory and local memory. This overhead from this data movement can negate the performance gains achieved by heterogeneous architectures, leading to a phenomenon known as the data movement bottleneck.

Near-data processing (NDP) is a promising solution to this bottleneck in modern computing systems. By positioning computing units closer to the main memory, the NDP mechanism reduces the overhead associated with data access [28]. With recent advancements in memory technology [1]–[4], [6], [9]–[11], [13] and the growing demand from data-intensive applications [6], [7], the near-memory computing paradigm has become increasingly feasible [14], [17].

However, effectively harnessing the potential of NDP systems to accelerate LR-TDDFT calculations presents several key challenges. First, NDP systems typically operate alongside CPU systems, forming a CPU-NDP system. For LR-TDDFT calculations, which involve both compute-intensive and memory-intensive kernels, such systems require a precise scheduling and partitioning scheme to ensure efficient execution. Second, in the pseudopotential computation of LR-TDDFT (see Section III-B), each process stores its copy of the data in memory, leading to significant redundancy given the large number of NDP cores and corresponding processes. Therefore, we need to rethink the data organization of pseudopotential in the NDP scenario to mitigate this issue.

To address these challenges, **our goal** in this work is to design a partitioning and scheduling mechanism specifically tailored for DFT calculations to achieve better performance, along with a hardware/software co-design solution that optimizes the data organization and memory access in the pseudopotential calculations.

This paper makes the following key contributions:

- We conduct a detailed study of the computation and memory characteristics in the LR-TDDFT application, identifying the key performance bottlenecks in its execution and

*Equal contribution, listed alphabetically
†Corresponding Author

determining LR-TDDFT as a promising application for NDP systems.

- We design NDFT, a near-data density functional theory calculation framework, featuring a novel workload partitioning and scheduling mechanism, along with a hardware/software co-design based on a CPU-NDP heterogeneous architecture.
- We evaluate NDFT across physical systems of varying sizes and compare it with CPU and GPU baselines. The results show that NDFT achieves a performance speedup of 5.2x and 2.5x over CPU and GPU baselines on a large physical system.

II. Background

A. LR-TDDFT

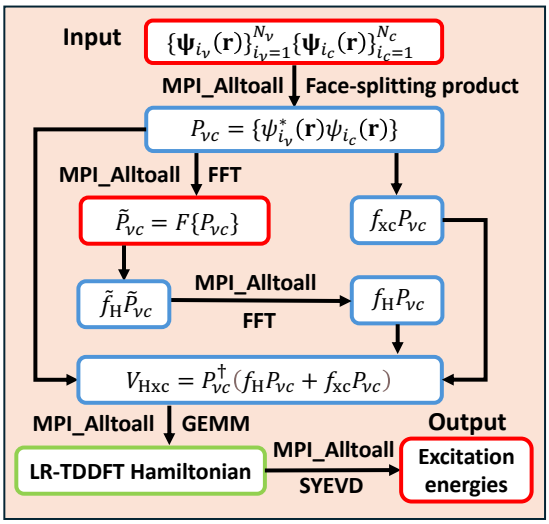

Fig. 1. Computation flowchart of LR-TDDFT. $\psi_{i_v}(\mathbf{r})$ and $\psi_{i_c}(\mathbf{r})$ stand for the valence and conduction orbitals in real space $(\{\mathbf{r_i}\}_{i=1}^{N_r}$.

LR-TDDFT [30] is a widely used computational method for studying the excited-state properties of molecules and solids in condensed matter physics, computational chemistry, and materials science. In recent years, advancements in both computational hardware and numerical algorithms have significantly improved the scalability and performance of LR-TDDFT, enabling its application to large and complex physical systems [26], [33]. As shown in Figure 1, the computation of LR-TDDFT involves several major operations: (1) fast Fourier transform (**FFT**), (2) face-splitting product, i.e., **point-to-point multiplication** between two vectors, (3) general matrix multiplications (**GEMM**), (4) **MPI_Alltoall** between all processes to transpose data, and (5) diagonalization (**SYEVD**).

Due to its scientific significance, numerous prior works have focused on accelerating the *computation-intensive* aspects of LR-TDDFT using heterogeneous architectures, such as GPUs [20], [34], the Sunway supercomputer [21], [22], and field-programmable gate arrays (FPGAs) [29]. However, accelerating LR-TDDFT on these heterogeneous architectures presents two major problems: (1) These approaches primarily target the *compute-intensive* components, neglecting the *memory-intensive* parts, which constitute a significant portion of LR-TDDFT's overall execution time; (2) Executing kernels on heterogeneous architectures requires frequent data transfers between the host device's memory and the memory of the heterogeneous device, resulting in substantial bottlenecks.

B. NDP Architecture

The fundamental idea of NDP is to place computing logic close to where data resides, offering significant potential for improving the performance of *memory-intensive applications*. NDP can be implemented by integrating processing logic within DRAM banks [1], [13], in the logic layer of 3D-stacked memory [2], [6], [10], or within the buffer chip of DDR-DIMMs [3], [4], [9], [11]. As shown in Figure 2, in such architectures, the bottom-most layer, known as the logic layer, can be equipped with **wimpy cores** that perform simple, parallelizable tasks close to the data. These cores leverage the high internal bandwidth and low data movement latency of the memory stacks to improve efficiency. Typical 3D-stacked NDP systems, such as Hybrid Memory Cube (HMC) [8] and High Bandwidth Memory (HBM) [18], [19], consist of multiple memory stacks interconnected in a memory network. By bringing computation closer to the data, NDP systems take advantage of the high bandwidth within the memory structure and reduce data access latency.

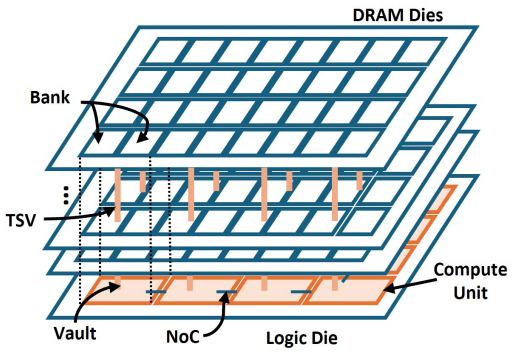

Fig. 2. An example of 3D-stacked memory.

C. CPU-NDP Hybrid Execution

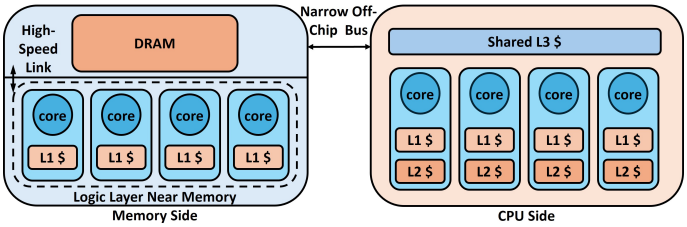

Fig. 3. A high-level CPU-NDP architecture.

In a typical configuration, NDP cores operate alongside CPU cores within a computing system, forming what we refer to as the CPU-NDP architecture in this paper, as illustrated in Figure 3. This architecture includes two types of computing units: the CPU, which excels at complex, compute-intensive tasks but suffers from high-latency and low-bandwidth memory access, and the NDP cores, which are more numerous and benefit from lower-latency, higher-bandwidth memory access, but feature simpler logic. Thus, CPU cores are suitable for *compute-intensive* workloads, while NDP cores handle

memory-intensive tasks more efficiently. In such systems, a key challenge is determining which code regions of a program should be offloaded to NDP for optimal performance. Several prior works have attempted to solve this problem [12], [23], [35]. However, none of these approaches have been applied to exploit the performance potential of DFT applications in CPU-NDP systems.

III. Motivational Study

In this section, we conduct a detailed study on several key characteristics of LR-TDDFT, aiming to identify the key bottlenecks in CPU-NDP hybrid execution and demonstrate its potential for performance improvement on CPU-NDP heterogeneous architecture.

A. LR-TDDFT kernel characteristics

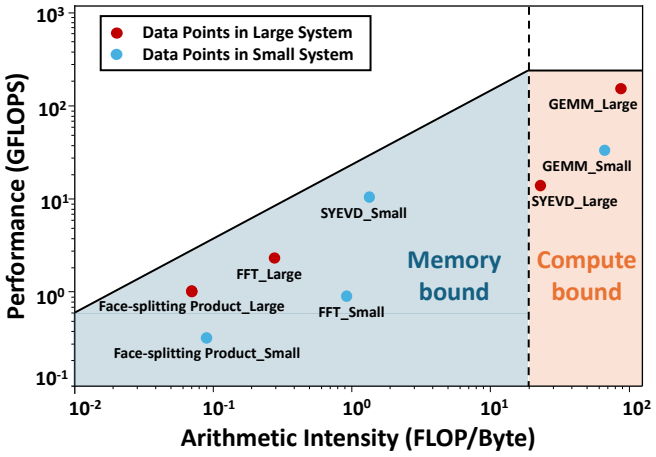

Fig. 4. Roofline model analysis of LR-TDDFT kernels across two different system sizes.

We analyze the performance characteristics of representative kernels in LR-TDDFT calculations on the Roofline model, as introduced in Section II-A, using two different physical system sizes: Si_64 (small system) and Si_1024 (large system). The Roofline model [36] integrates floating-point operations (FLOPs) and arithmetic intensity (AI) to assess the computational and memory characteristics of a given kernel. We use Intel VTune Profiler [16] for the analysis, with system configurations described in Section V. From the results shown in Figure 4, we make three key observations: (1) LR-TDDFT calculations are fundamentally **memory-bound**: most computing kernels in LR-TDDFT fall within the memory-bound region, and the MPI_Alltoall operations used in LR-TDDFT introduce a large amount of irregular memory accesses [22]. (2) Different kernels in LR-TDDFT calculations exhibit distinct compute-bound or memory-bound characteristics: FFT kernels are memory-bound, while GEMM kernels are compute-bound across different physical system sizes. (3) The compute- or memory-bound nature of LR-TDDFT kernels depends on the system size: for large physical systems, the SYEVD operation is compute-bound, whereas, for small systems, SYEVD is memory-bound; GEMM becomes more compute-bound as the system size increases.

Based on these observations, we conclude that LR-TDDFT is well-suited for CPU-NDP acceleration due to its diverse kernel characteristics. To fully leverage the strengths of both CPU and NDP cores, the system requires an intelligent scheduling mechanism that can dynamically allocate tasks to the appropriate computing units based on their characteristics. For example, memory-bound kernels such as FFT could benefit from execution on NDP units optimized for memory access, while compute-bound kernels like GEMM and SYEVD (in large systems) would perform better on CPU cores, which excel at handling complex computations. However, designing a precise task scheduling framework for LR-TDDFT in a CPU-NDP system is not trivial, as it faces two main challenges: (1) It must account not only for the suitability between kernels and computing units but also for the *data movement overhead* between the two types of computing units. The data required by the kernels must also be scheduled accordingly to the appropriate execution units. (2) The selection of offloading granularity, ranging from fine-grained instructions to basic blocks or entire kernels, requires careful consideration.

B. Analysis of pseudopotential calculations

Pseudopotentials are commonly used in DFT calculations to simplify the treatment of inner electrons, as the outer valence electrons primarily determine an atom's physical and chemical properties. In LR-TDDFT, pseudopotentials simulate the influence of the atomic nucleus and inner electrons. During this procedure, each wavefunction is updated based on the pseudopotential information associated with each atom. In a multi-process execution, each process must maintain a complete copy of the pseudopotential information in its memory space. However, in systems with numerous cores, such as NDP architectures [12], [32], these redundant data copies can lead to significant memory inefficiency.

TABLE I
Memory Footprint of Pseudopotentials in CPU and NDP Systems

Memory Footprint	size (GB)	Percentage (%)
NDP in Small system	4.43	6.92
CPU in Small system	1.84	2.88
NDP in Large system	35.3	55.15
CPU in Large system	13.8	21.56

We profile the memory footprint during LR-TDDFT calculations on typical NDP and CPU systems using two physical systems of different scales, where the NDP system and the CPU system are isolated. The configuration is detailed in Section V. As shown in Table I, our observations are as follows: (1) In the small physical system, the memory footprint of pseudopotentials in NDP execution occupies 6.92% of the system memory, which is 140.2% higher than that in CPU execution; (2) In the large physical system, the memory footprint reaches 55.15%, representing an increase of 155.7% compared to CPU execution. We conclude that the large number of NDP cores leads to an increase in parallel processes, resulting in pseudopotentials consuming a significant amount of memory space. Moreover, in more complex physical systems, the traditional

per-process pseudopotential approach causes an out-of-memory (OOM) problem. Therefore, optimizing the data structure of pseudopotential information in memory is critical to reducing the substantial memory footprint in the CPU-NDP architecture.

IV. NDFT Design

In this section, we elaborate on the design of NDFT, aiming to maximize the performance potential of the CPU-NDP system for DFT calculations. This includes a novel workload partitioning and scheduling mechanism, which is introduced in Section IV-A, as well as a hardware/software co-design strategy to better orchestrate an important computational scheme in LR-TDDFT calculations, which is covered in Section IV-B and IV-C, respectively.

A. Workload Partition and Scheduling

1) Offload Granularity: To provide a better offloading granularity for LR-TDDFT, it is crucial to understand the costs associated with scheduling contiguous code segments to different computing units. We identify two primary sources of overhead: (1) The *data transfer overhead*, which arises from maintaining the consistency of data across two computing units. This overhead is proportional to the amount of data that needs to be transferred. (2) The *context switch overhead*, which involves synchronizing the context (e.g., register values) between threads on different units, is a constant time cost.

In this work, we choose *function-level* offloading granularity based on two key observations: (1) Dividing the program into too many small segments introduces significant offloading overhead. (2) Most functions in LR-TDDFT exhibit consistent compute/memory characteristics throughout their execution. For example, GEMM and FFT maintain the same computing and memory access patterns across the entire function.

2) Cost-Aware Offloading mechanism: To fully leverage the performance benefits of a heterogeneous CPU-NDP system, we design a kernel offloading mechanism in NDFT based on a static code analyzer (SCA) [15], [25]. The SCA analyzes the intrinsic properties of a given code segment, such as estimated execution time, memory access patterns, and instruction dependencies. These insights help inform decisions on whether each code segment is compute- or memory-bound, and provide an estimation of the data transfer overhead when scheduling different code segments across CPU and NDP units. In this work, we leverage the SCA to profile the compute and memory intensity of each function and use this information, along with a cost model that accounts for the overhead of scheduling between CPU and NDP cores, to formulate a cost-aware offloading mechanism.

$$\text{Scheduling Overhead} = \sum_{i \in \text{NDP}} \sum_{j \in \text{CPU}} (DT(i,j) + CXT) \quad (1)$$

By evaluating the suitability of each function for execution on either CPU or NDP cores, the SCA allows us to determine whether it is more efficient to offload the function to the NDP or retain it on the CPU. The overall scheduling strategy then incorporates the scheduling overhead, as shown in (1), which is defined as the sum of data transfer (DT) overhead and context switch (CXT) overhead between the CPU and NDP cores. This approach enables a cost-aware offloading mechanism that balances the performance gains from offloading with the associated overheads, optimizing the performance of the heterogeneous system.

B. Optimization of Pseudopotential Algorithm

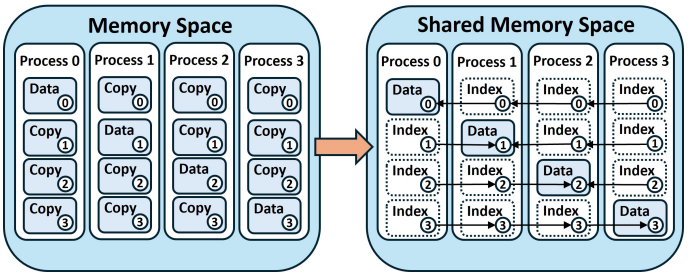

Fig. 5. The data structure optimization to eliminate the data redundancy of pseudopotential.

To reduce the memory footprint in LR-TDDFT and enhance the scalability for large physical systems, we propose an optimization based on an improved pseudopotential data structure. As shown in Figure 5, each process stores **only a portion of the pseudopotentials**, along with indices pointing to the pseudopotentials in other processes, accessing the shared data via these indices. Compared to the original approach, our optimization enables seamless data sharing between processes, significantly reducing the memory footprint and making LR-TDDFT more suitable for our CPU-NDP heterogeneous design.

In our optimization, we reduce the memory overhead of each process by addressing the complexity of each atom's pseudopotential data, which includes arrays of integers and double-precision floating-point matrices, through the design of a **shared block** to efficiently manage and share this information. This data structure facilitates unified management of pseudopotential data and simplifies data sharing. As shown in Algorithm 1, the highlighted gray section represents the main optimization of the algorithm: (1) In lines 7-9, the algorithm reorganizes the pseudopotential information of each atom into a shared block and writes it into shared memory. (2) In line 13, the algorithm retrieves the addresses of pseudopotential data in shared memory based on the distribution of the shared block. (3) In line 19, the algorithm accesses the data from shared memory for wavefunction updating.

Although this approach significantly reduces memory usage, it introduces the need for inter-process data communication, leading to some performance overhead. We design a novel shared memory hardware structure to mitigate this overhead, detailed in Section IV-C.

C. Shared Memory Design for Pseudopotential

As we improve the data structure of the pseudopotential in each process, data communication is needed to synchronize the pseudopotential. To mitigate this overhead, we design shared memory based on scratchpad memory (SPM) for processes to share the pseudopotential information within the same stack, and a hierarchical communication scheme to manage the communication between the shared memory of different stacks.

Algorithm 1 Pseudopotential Algorithm in LR-TDDFT, with the gray background highlighting our optimizations.

Input: Pseudopotential
Output: Wavefunction updated using pseudopotential

```
1:  for each local atom do
2:      calculate pseudopotential
3:  end for
4:  for each global atom do
5:      if this process holds the information then
6:          for each atom's pseudopotential do
7:              calculate the data size
8:              allocate a continuous space in shared memory
9:              write local pseudopotential information as
                a block into shared memory
10:         end for
11:     else
12:         for each shared memory block do
13:             obtain the address of the shared block
14:         end for
15:     end if
16: end for
17: for each local wavefunction do

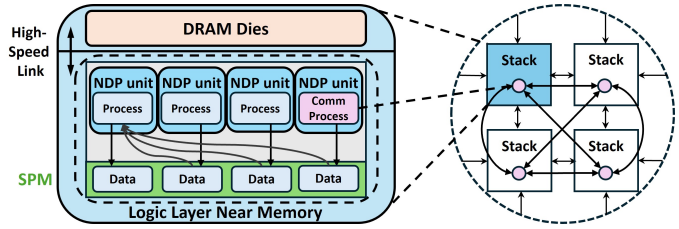

Fig. 6. Shared Memory Hardware Design and Hierarchical Communication Scheme. Green color highlights the shared memory architecture.

SPM-based Shared Memory. The left part of Figure 6 shows our shared memory hardware design. We design an SPM in the logic layer of each memory stack to enable the shared memory functionality. The processes within the same stack can access local pseudopotentials and also access the pseudopotentials of other processes in SPM-based shared memory. The high read/write speed and low access cost of SPM [5] allow these processes to efficiently access pseudopotentials, avoiding the expensive memory access in DRAM.

In addition, we develop a set of communication APIs to support shared memory functionality. As shown in Table II, these APIs implement multiple synchronization semantics, providing the flexibility and comprehensiveness needed for essential communication primitives. For example, `NDFT_Alloc_Shared` enables NDP units to allocate memory for pseudopotential data in `sharedBL`. The function's parameters include the pseudopotential data (`pseu_info`) and the NDP unit ID (`stID* id`), and it returns a `sharedBL`. The definition of `sharedBL` corresponds to the shared block introduced in Section IV-B. We also design primitives such as `NDFT_Read` and `NDFT_Write` to facilitate reading and writing pseudopotentials within the shared block. By managing pseudopotentials with SPM-based shared memory, our design reduces communication overhead between NDP units within the same stack. To further enhance scalability, we implement a hierarchical communication scheme.

TABLE II
PROGRAMMING INTERFACES OF NDFT

NDFT's Message Programming Interface(i.e., API)
sharedBL NDFT_Alloc_Shared (Var* pseu_info, stID* id);
void NDFT_Read (sharedBL* data, void* address, int length);
void NDFT_Write (sharedBL* data, void* address, int length);
void NDFT_Read_Remote (sharedBL* data, void* address, int length, stID* source_id, stID* dest_id);
void NDFT_Write_Remote (sharedBL* data, void* address, int length, stID* source_id, stID* dest_id);
void NDFT_Broadcast (sharedBL* data);
.....

Hierarchical Communication Scheme. For pseudopotential data communication between different stacks, we designate one NDP unit per stack as a communication arbiter, which runs a *comm process* (indicated in pink in Figure 6) to manage inter-stack communication. When a process requests data from another stack via `NDFT_Read_Remote`, it submits the request to the *comm process* within its own stack. The `dest_id` parameter specifies the stack ID from which the data is needed. After exchanging data with the communication process of the destination stack, the local *communication process* writes the data into shared memory and returns the index to the requesting process. This hierarchical design acts as a filter, maximizing intra-stack communication and only transmitting essential data across stacks, thereby reducing overall communication overhead.

V. EVALUATION METHODOLOGY

System model. We implement NDFT in zsim [31], a fast and accurate Pin-based simulator, and use Ramulator [24] as the memory simulator. Table III summarizes the NDFT's CPU-NDP system configurations.

TABLE III
CPU-NDP SYSTEM CONFIGURATION

CPU	8 General purpose core; 3 GHz, 4-way superscalar; 32 KB L1I/D, 256 KB L2, 2 MB L3
NDP	8 NDP units per stack, 2GHz, in order; 64 GB in total, 512 MB per unit; 2 GHz, 2 cores per NDP unit, 32KB L1I/D Shared Memory: 16 KB per core, 256 KB per stack
Memory	HBM2, 4 × 4 stacks in mesh, 8 channels per stack; 128-bit bus width, 1000Mhz, 64 GB capacity

Baseline Architectures. We compare NDFT with two baselines: (1) CPU: 2 CPUs of Intel Xeon E5-2695@2.40 GHz, 12 cores per socket, with 64 GB DDR4 memory; (2) GPU: 2 GPUs of NVIDIA V100 in DGX-1 server.

Physical Systems. We use various crystal silicon systems with 16, 32, 64 (small system), 128, 256, 1024 (large system), and 2048 silicon atoms, denoted as Si_16, Si_32, Si_64, Si_128, Si_256, Si_1024, and Si_2048, respectively.

VI. Evaluation Result

A. Performance Analysis on Execution Time

Figure 7 shows the performance on CPU, GPU, and NDFT, along with the time distribution across different kernels in 2 different sizes of physical systems. The execution time breakdown includes the execution time of FFT, point-point multiplication, Global Communication (Global Comm) phase, SYEVD, etc. The NDFT design includes the additional *scheduling* overhead between CPU and NDP, as mentioned in Section IV-A. We compare NDFT with both GPU and CPU baselines, and obtain the following evaluation results:

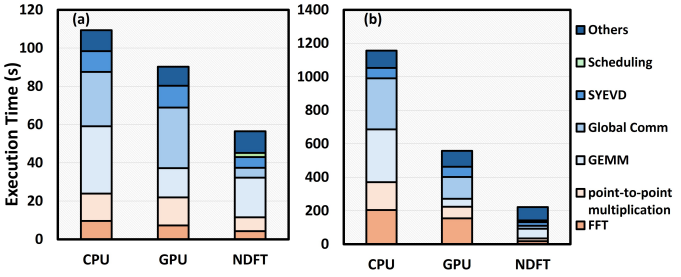

Fig. 7. Performance comparison between CPU, GPU, and NDFT design using a small physical system (a) and a large physical system (b).

Comparison with CPU. (1) Despite the scheduling overhead, NDFT achieves 1.9x and 5.2x speedups in small and large physical systems, respectively, thanks to our scheduling mechanism and software/hardware co-design. (2) The performance of memory-intensive kernels is significantly improved; for example, FFT achieves an 11.2x speedup in the large system, while the Face-splitting Product achieves a 1.99x speedup in the small system.

Comparison with GPU. (1) NDFT achieves 1.6x and 2.5x speedups compared to the GPU baseline in small and large physical systems, respectively. (2) While compute-bound kernels like GEMM on the GPU outperform those on NDFT by 35.9% and 22.2% in the two physical systems, respectively, memory-bound kernels show significant improvements with NDFT, achieving 2.1x and 5.2x speedups in the small and large physical systems, respectively.

Other Discussion. (1) The scheduling overhead accounts for only 3.8% and 4.9% in small and large physical systems, respectively, demonstrating that NDFT's scheduling strategy carefully keeps this overhead minimal while improving kernel performance. (2) We study the memory footprint of pseudopotential information in NDFT. We observe that, in the large physical system, NDFT reduces memory footprint by 57.8% compared to NDP in Table I, bringing it close to CPU execution (1.08x). Global Comm only increases by 3.2% over the GPU baseline, showing that NDFT's hardware/software co-design resolves the OOM issue in NDP systems with low communication overhead.

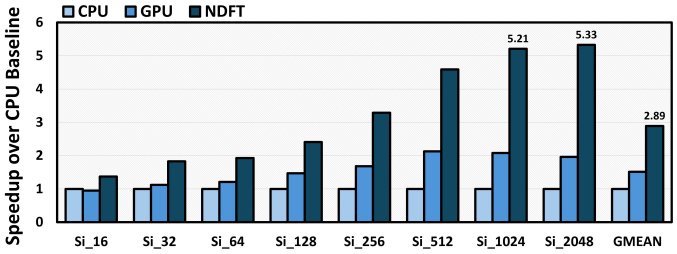

Fig. 8. Speedup provided by NDFT, GPU over CPU baseline in several physical system scales.

B. Scalability Analysis

To explore NDFT's performance across different physical system scales, we conduct a study ranging from Si_16 to Si_2048. Figure 8 demonstrates that as the size of the physical system increases, NDFT's performance advantage becomes more pronounced (up to 5.33x speedup in Si_2048). We conclude that NDFT improves the performance of LR-TDDFT calculations in most cases, showing NDFT's great potential for addressing large-scale computational problems in the field of high-performance computing.

VII. Related Work

To our knowledge, NDFT is the first work to accelerate DFT calculations through optimizations of a general NDP architecture. A prior work [27] proposes a heterogeneous approach focused on alleviating data movement bottlenecks in quantum chemistry simulations based on *ab initio* methods. That work analyzes two specific components—FFT and time-consuming loops—proposing a custom hardware design tailored to these kernels. In contrast, NDFT emphasizes task scheduling and hardware-software co-design, offering a more comprehensive solution within general-purpose NDP-CPU heterogeneous systems, thereby providing greater applicability and scalability.

VIII. Conclusion

In this work, we propose NDFT, a Near-Data Density Functional Theory framework to address performance bottlenecks in LR-TDDFT calculations on CPU-NDP heterogeneous systems. NDFT involves a task partitioning and scheduling mechanism that efficiently assigns memory- and compute-bound kernels, minimizing data movement and fully leveraging CPU-NDP heterogeneous architectures, and a hardware-software co-design optimizing memory access for pseudopotential calculations, solving OOM issues in NDP systems. Evaluations show speedups of 5.2x and 2.5x over CPU and GPU baselines in a large physical system, as well as NDFT's scalability across different system sizes.

***Abstract*—Many verification methods have been proposed to detect microarchitectural information leakage in response to the surge of security breaches in hardware designs. These sophisticated efforts have gone a long way toward preventing attackers from breaking the system's confidentiality. However, each approach has its own set of weaknesses: it may not be scalable enough, exhaustive enough, flexible enough to meet changing requirements or fit well into existing verification flows.**

We propose FastPath, a hybrid verification methodology that combines the efficiency of simulation with the exhaustive nature of formal verification. FastPath employs a structural analysis framework to automate the method further. Our experimental results compare FastPath to a state-of-the-art formal approach, showing a significant reduction in manual effort while achieving the same level of exhaustive confidence. We also discovered and contributed a fix for a previously unknown leak of internal operands in cv32e40s, a RISC-V processor intended for security applications.

***Index Terms*—Hardware Security, Information Flow Tracking, Simulation, Formal Verification, Data-Oblivious Computing.**

I. Introduction

A seemingly endless flood of timing side channel attacks [1], [2], [3], [4], [5] severely disrupted the view of hardware as a root of trust. This necessitates rethinking architectures and fortifying them to meet ever-changing security requirements. In response, software and hardware communities are actively proposing novel mitigation techniques [6], [7], [8], [9], [10], [11] to address these requirements.

Most countermeasures against microarchitectural timing side channels demand that specific basic hardware operations are *data-oblivious*. Data-obliviousness requires these hardware primitives to process data without any measurable data-dependent side effects, e.g., the operation's timing must be independent of its inputs. A prominent software paradigm, called *Constant-Time Programming* [12], [8], [13], assumes that simple instructions, such as an addition, do not leak data via timing side channels. More complex instructions, such as a division or floating point operations, are assumed to be data-dependent and replaced with data-oblivious primitives [14]. Making matters worse, whether an instruction is data-oblivious or not depends on the underlying microarchitecture. Intel [15], ARM [16] and RISC-V [17] have therefore added ways to refine the instruction set architecture (ISA) with information about the data-obliviousness of individual instructions.

However, recent insights [18], [5] have shown that, despite these precautions, sophisticated optimizations in modern processors can invalidate these assumptions. Chen et al. [5] exploit an optimization feature of recent Apple devices, called data memory-dependent prefetcher, to attack constant-time cryptographic routines by tricking the prefetcher into misinterpreting secret data as addresses. This attack demonstrates that it is insufficient to simply assume a certain behavior of the hardware layer. Instead, it is necessary to provide *exhaustive* security guarantees upon which software countermeasures can be built.

As part of the effort to restore trust in hardware, we propose FastPath, a hybrid security verification approach. The method exhaustively verifies *non-interference* [19], [20] properties, e.g., the property that confidential information does not leak into publicly visible states of the system. In this paper, we specifically verify that hardware operates in a data-oblivious manner. However, FastPath is not limited to this threat model.

The key observation behind FastPath is that recent formal methods [21], [22] achieve high scalability through a *semantic partitioning* of the computational problem. Rather than partitioning the design *structurally* into paths to be checked formally, these methods logically decompose the global proof problem. While the new techniques scale even to complex out-of-order processors, deriving this logical partitioning can require a considerable amount of manual refinement.

With FastPath, we identify and leverage a unique synergy between these formal methods and simulation-based security verification: simulating a design with Information Flow Tracking (IFT) [23] efficiently derives the bulk of the problem partitioning required by the formal methods, eliminating most manual effort. Formal verification, on the other hand, complements the weakness of simulation in finding subtle leaks in corner-case scenarios. To round out our hybrid approach, FastPath employs static structural analysis to detect when simulation and formal are not necessary and to generate property templates when they are needed. This novel way of combining these methods creates a highly automated and scalable, yet exhaustive verification approach.

In summary, this paper makes the following contributions:

- We propose FastPath, a hybrid verification approach for hardware security that leverages the complementary nature of simulation and formal methods (Sec. IV). Instead of combining the two approaches in a straightforward way by applying a formal analysis to certain paths not covered during simulation, our method uses a global property formulation and a seamless communication of intermediate results between the different methods.
- We integrate a structural analysis and IFT framework called HyperFlow Graph (HFG) [24] (Sec. III-A) into FastPath. The structural information can be used to exclude trivial cases where no syntactic information flow paths exist and to generate templates for the formal properties.
- We apply FastPath to a variety of accelerator and processor designs (Sec. V) and compare the manual effort with a formal-only approach [22]. Our case studies show a 36% to 100% reduction in manual refinement. In an experiment with the cv32e40s [25] processor, FastPath was able to detect a previously unknown leak of internal operands.

*Both authors contributed equally to this research.

II. Threat Model

FastPath verifies *non-interference* properties [19], [20]. *Non-interference* divides the system into *high*-security and *low*-security domains and can be used to model a variety of different threat models. Confidentiality, for example, requires that information never leak from *high* to *low*. For the purposes of this paper, we adopt the threat model and definitions from [22]. In particular, we consider a hardware system that processes confidential input data. The attacker exploits violations of data-obliviousness in the hardware and observes any data-dependent side-effect, i.e., any deviation in the control behavior caused by the values of the operands being processed. This is usually reflected in a difference in timing, resulting in different values at the control related output of the system. Note that our method is not limited to this threat model and can be extended to other attack scenarios.

Our threat model is described more precisely as follows: We model a hardware system as a standard Mealy-type Finite-State Machine (FSM) $M = (I, O, S, S_0, \delta, \lambda)$, where we denote sets of input symbols I, output symbols O, states S, and initial states $S_0 \subseteq S$. The state transition function is given by $\delta : S \times I \mapsto S$ and the output function is given by $\lambda : S \times I \mapsto O$. In addition, we denote the set of Register-Transfer Level (RTL) input signals by X, output signals by Y, and state signals by Z. We partition the set of input signals X (output signals Y) into disjoint sets of control inputs X_C (control outputs Y_C) and data inputs X_D (data outputs Y_D). In this threat model, as described in previous works [26], [22], [27], [28], the system processes the *high*-security data inputs X_D, while the attacker is able to observe the *low*-security control outputs Y_C. If a data-dependent control behavior is observed, such as a different timing of a handshake signal (e.g., `valid`), an attacker can infer information about the data being processed. This breaks confidentiality and can, for example, severely weaken encryption techniques. This security threat is eliminated if the design is proven to be *data-oblivious*.

Definition 1 (*Data-Obliviousness*)**.** A hardware module is called *data-oblivious* if, under a set of system-level constraints, the sequence of values at its control outputs Y_C is uniquely determined by the sequence of values at its control inputs X_C. In other words, its control inputs X_D have no influence on its control outputs Y_C.

Data-obliviousness of hardware designs is the verification target pursued throughout this paper.

III. Background

A. HyperFlow Graph

A HyperFlow Graph (HFG) [24], [29] is a graph-based intermediate representation which models how information flows in a hardware design. Derived automatically from a static analysis of RTL code, an HFG $G(N, E)$ contains a set of nodes N and a set of directed, labeled edges E. An HFG node $n_x \in N$ represents a unique hierarchical design signal `sig_x`. An HFG edge $e(ui, n_s, n_d, C) \in E$ represents a flow scenario in which information flows, explicitly or implicitly, from a source signal `sig_s` to a destination signal `sig_d`. Each edge can be precisely mapped to an originating RTL code construct. If the originating code construct has no guarding conditions ($C = \emptyset$), then the flow is always "active". Otherwise, the flow is only active if all guarding conditions $c \in C$ are simultaneously satisfied. Note that multiple edges are allowed between two nodes so each edge also has a unique identifier ui.

HFGs enable a variety of queries that produce security-relevant information. In this work, we primarily utilize the HFG path query $q(n_s, n_d)$ which returns a set of HFG paths P where each path $p \in P$ comprises a finite sequence of HFG edges $p = (e_1, \ldots, e_k)$ that could *potentially* enable information flow from the source signal `sig_s` to the destination signal `sig_d`. Emphasis is placed on the *potential* nature of the returned HFG paths due to the possibility for false positives. By design, the static analysis employed in the HFG construction process is intended to enable speed and scalability, but this comes at the price of producing an over-approximation of the information flow in the system. This means that the HFG path query can produce false positives but it will never produce false negatives. In other words, if there are no HFG paths ($P = \emptyset$) connecting the source signal `sig_s` to the destination signal `sig_d`, then it is guaranteed that the source signal `sig_s` cannot influence or leak information to the destination signal `sig_d`. However, if there are any HFG paths ($P \neq \emptyset$), then each path $p \in P$ has the potential to be an unrealizable sequence of design states (a false positive) and no guarantees on signal influence can be made without further analysis. As discussed in Sec. IV, our hybrid verification strategy employs simulation-based IFT and formal verification to address this issue.

B. Information Flow Tracking

Hardware Information Flow Tracking (IFT) [23] is a powerful verification strategy that allows designers to reason about information movement through a hardware design. Hardware IFT properties can be used to verify trace and hyperproperties related to confidentiality, integrity, and availability. These properties can specify where, when, and how information should or should not flow from source signals to destination signals, with relatively few operators and expressions. IFT properties can be written as assertions using the no-flow operator (`=/=>`) as follows: {`src_sigs`} `=/=>` {`dst_sigs`}. Hardware IFT tools determine whether the hardware adheres to the properties.

In simulation-based IFT, a given design is instrumented with additional logic (i.e., an IFT circuit) that tracks information flow by calculating and updating security labels (e.g., HIGH and LOW). An IFT-enhanced simulation produces a simulation trace with functional values and security labels for all signals. All design signals are initially labeled LOW, except for the source signals from which information is being tracked, which are labeled HIGH. Throughout the simulation, the IFT circuit updates signal label values considering the functional values from the simulation testbench and security labels. Any signal that starts with a LOW label and eventually reaches a HIGH label has received information from a source signal, i.e., the source signal is affecting it.

The ability to determine signal influence from merely tainting a source signal as HIGH is extremely valuable when dealing with large, complex designs. However, IFT-enhanced simulations are completely dependent on the underlying testbench to produce a property-relevant information flow. As a result, IFT properties that could be falsified may not be falsified due to an insufficient testbench. FastPath overcomes issues related to exhaustiveness via its formal verification step (Sec. IV).

C. Unique Program Execution Checking

Unique Program Execution Checking (UPEC) [21] is a formal verification methodology to exhaustively detect the propagation of confidential (or malicious) information at the RTL. The approach was originally created to detect transient execution side channel (TES) attacks, but has since been extended to cover a variety of different threat models. According to our threat model (see Sec. II), we focus on UPEC for data-independent timing (UPEC-DIT) [22].

UPEC is based on a technique called Interval Property Checking (IPC) [30] and uses a 2-safety computational model, i.e., the design under verification (DUV) is instantiated twice. At the start of the proof, each signal is initialized with the same value as its counterpart in the other instance. The only discrepancy between both instances is the information to be tracked, usually a proprietary secret that should not be revealed to the attacker. Any malicious information flow is detected by following the propagation of this difference through the system. In addition, IPC allows the equal initial state to be *symbolic*, and thus implicitly models every possible history of the system. Therefore, UPEC can "fast-forward" to the point where the propagation occurs, allowing scalability to complex systems.

UPEC-DIT is a variant of UPEC that can exhaustively verify the data-obliviousness of hardware systems according to Def. 1. In its computational model, the control inputs X_C are constrained to be equal between the two instances, while the data inputs X_D remain unconstrained. Also, both instances start from the same symbolic state. UPEC-DIT then verifies that for any arbitrarily long sequence of inputs, the control outputs Y_C of the two instances never diverge, certifying that the control behavior is independent of the processed data. The approach achieves scalability by an iterative partitioning of the internal state-holding signals based on counterexamples. Every signal declared as data is allowed to assume different values in the following iteration of the algorithm, thus implicitly modeling any previous propagation path. This process is repeated until a malicious propagation is found, or until a fixed point is reached where no new propagation occurs.

The exhaustive nature of UPEC allows to provide formal security guarantees, and thus achieve a much higher level of confidence compared to simulation-based approaches. However, the iterative manual inspection of counterexamples can be tedious and requires a certain level of design and verification expertise. In FastPath, we offload a majority of the manual work to fully-automated structural analysis and IFT-based simulation. We then leverage the intermediate simulation results to perform a UPEC-based proof, achieving the same level of exhaustiveness as the original approach combined with an improved scalability.

IV. Methodology

Fig. 1 gives an overview of FastPath. FastPath has three main steps: structural analysis based on the HFG [24], efficient bug hunting with IFT-enhanced simulation [23], and exhaustive formal verification based on UPEC-DIT [22]. We start with the RTL description of the DUV and a security specification that defines what data is considered confidential. This paper focuses on data-dependent side effects (as described in Sec. II), but the proposed methodology can also be extended to other threat models. We assume an attacker is able to measure the timing of a system by observing control-related outputs, e.g., by monitoring the signals of a bus.

Our goal is to exhaustively verify (with as little manual inspection as possible) that sensitive data inputs (X_D) do not affect the control behavior of the system (Y_C). In addition, by inspecting violations of data-obliviousness, FastPath systematically derives a set of software constraints under which the hardware is guaranteed to operate in a data-oblivious manner. The verified hardware, in combination with these derived restrictions for the software, forms a root of trust for the higher levels of the system stack.

A. Structural Analysis

The first step is to create an HFG of the design. Because this process considers only structural information, it is easily scalable to complex systems. The HFG serves two primary purposes. First, it is a starting point for the other two approaches, providing structural information that can be used to generate property templates or speed up proofs with optimizations such as cone-of-influence reduction. Second, we can leverage it to skip the proof procedure in trivial cases. There can be no information flow if there is no structural connection between sensitive data inputs X_D and publicly visible control outputs Y_C. This may be the case if the design is largely data-oriented and does not implement complex control behavior (cf. Sec. V). In particular, FastPath terminates early if

$$\forall n_x \in X_D, \forall n_y \in Y_C : q(n_x, n_y) = \emptyset$$

where $q(n_x, n_y)$ is an HFG path query (cf. Sec. III-A).

In many cases, however, structural connections exist, but the design still operates data-independently in the given application scenario. For example, data-dependent instructions are explicitly avoided in constant-time programming. Even though they are never used, the functionality of these instructions is still implemented, creating a structural path through which information could flow. Another example of such an application scenario is the limited functionality of an unprivileged user. Structural analysis alone is not sophisticated enough to account for such usage restrictions. Therefore, we need to be able to verify a system's data-obliviousness under a given set of software constraints.

B. IFT-Enhanced Simulation

In the next step, an IFT-enhanced simulation of the design is performed. This can be done using any existing testbench or random simulation approach. We seek to verify the following IFT property:

$$X_D \; =/=> \; Y_C$$

At the start of the simulation, all sensitive data inputs X_D are tainted (labels are set to HIGH), and the labels of the remaining signals are set to LOW. If any control output $y_c \in Y_C$ has its labels transition from LOW to HIGH, this constitutes a counterexample and indicates that it is influenced by the sensitive data.

In the case of a counterexample, the verification engineer must investigate the root cause. The counterexample may represent a scenario that contradicts the given application scenario. In this case, the setup must be adjusted, usually by introducing constraints on the simulation or restricting the flow policy, and the simulation is restarted. However, if an actual security problem is found, the leakage must be fixed in the RTL design, and the methodology starts over.

The main advantage of running an IFT-enhanced simulation is the ease of setup and the efficiency of debugging. Given a stimulus source and an interface partitioning (cf. Sec. II), no manual effort is required to run the simulation. In addition, each counterexample shows a complete propagation path from data input to control output, starting from reset. This avoids false alarms and makes root cause analysis easier than in a formal approach where the counterexamples may start from an arbitrary run-time state. However, if a signal does not become tainted during simulation, this does not mean that no information can flow into that signal. It only indicates that there is no information flow for the scenarios exercised by the testbench. Subtle corner-case scenarios can easily be missed, which often happens in the presence of unknown vulnerabilities. Therefore, FastPath uses formal verification to ensure that data cannot propagate further than what was found by simulation.

Definition 2 (*Untainted State Signals*)**.** For a given design with an input partitioning $X = X_D \cup X_C$ and a given testbench, we define

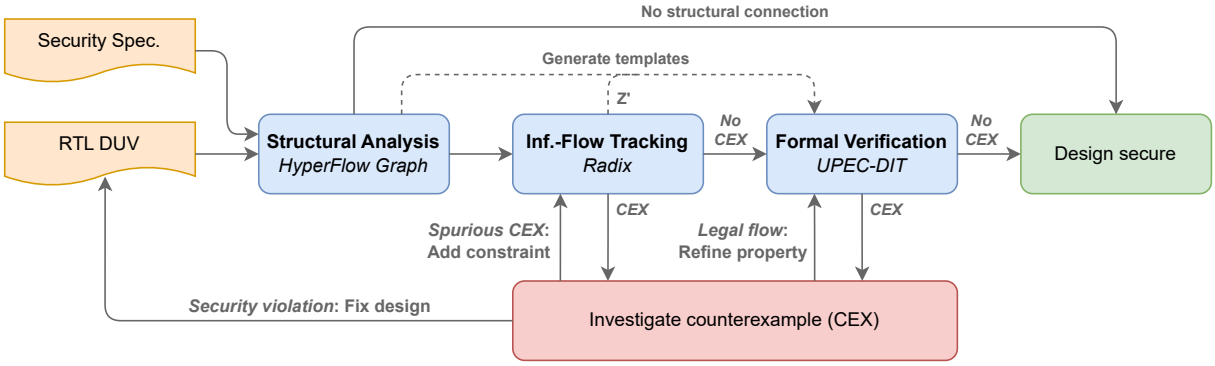

Fig. 1. The FastPath Verification Flow determines if the RTL design adheres to the security specification. FastPath uses a three-step process to efficiently compute counterexamples and update the specification with new constraints and property refinements. The output is a security violation that must be fixed in the design, or a guarantee that the design is secure.

the subset of all state-holding signals Z that have not been influenced by X_D during simulation as the set of untainted state signals $Z' \subseteq Z$.

Def. 2 describes the set of signals Z' whose labels remained LOW during simulation. The goal of the subsequent formal step is to verify that Z' constitutes a semantic partitioning of the computational problem. In particular, FastPath formally verifies by inductive reasoning that no sequence of inputs to the design exists for which a state variable $z' \in Z'$ becomes tainted. Hence, no taint can reach any output $y_c \in Y_C$, which means that X_D never influences the attacker-observable control outputs Y_C.

Finally, we emphasize that FastPath does not require sophisticated testbenches to achieve significant efficiency improvements. Because the formal step catches any remaining leaks, the verification engineer does not have to worry about missing corner cases during simulation. In addition, refinements to the IFT flow policy can be applied without worrying about over-constraining the policy.

C. Unique Program Execution Checking (UPEC)

In the final step, we apply an inductive UPEC-DIT [22] property to achieve exhaustive coverage. In the original UPEC-DIT approach, the verification engineer is required to manually inspect *every* propagation originating from the data inputs X_D. This process can be tedious, especially for large data-driven designs, as most propagation alerts are legal, but still require the verification engineer to manually remove the newly reached signal from consideration. In this work, however, we already possess knowledge about possible propagation paths. We use it to skip most of the manual steps of the UPEC-DIT procedure by jumping directly to the, potentially final, inductive step.

```
1 UPEC-DIT(Z', Y_C):
2 assume:
3   at t:              two_safety_eq(Z')
4   during [t, t+1]: software_constraints()
5 prove:
6   at t+1:            two_safety_eq(Z')
7   during [t, t+1]: two_safety_eq(Y_C)
```

Listing 1. Generalized UPEC-DIT interval property

At the end of the IFT-simulation, the set of all untainted state signals Z' is returned to the HFG analysis. Using the structural information, the HFG stage then generates both the 2-safety computational model (see Sec. III-C) and the verification framework. The key formal property is shown in Lst. 1. It employs the following macros:

- *two_safety_eq*(A) specifies that all signals of the given set A are equal between the two instances of the computational model. We use this macro in both the assumption and commitment parts of the property to verify that, when considering all previous propagation paths, no further information flow is possible.
- *software_constraints*() specifies the given usage constraints under which the system operates data-obliviously. These are inherited from the simulation, but may need to be extended if new violations are found using the formal property (see below). However, this did not happen in our experiments.

In case the property check fails, the verification engineer must examine the returned counterexample and identify the root cause. If the counterexample shows a security vulnerability, the design must be fixed and FastPath starts over. If the counterexample shows a scenario which violates data-obliviousness, but can be prevented with a software constraint, we update *software_constraints*(). After adding such a new software constraint, we backtrack to the simulation step (Sec. IV-B), since a new constraint may increase the set of untainted state signals Z'. If a spurious counterexample is found (i.e., an unreachable scenario caused by the symbolic initial state), we refine the property with an invariant (see [22]). Finally, if the counterexample shows a legal data propagation (that was missed by IFT-simulation), we refine the property by removing the corresponding signal from Z'. After refining the property, we simply repeat the formal property check.

If the property is verified successfully, it means that the resulting Z' is a partitioning of the problem and will never be affected by the data inputs X_D under the derived constraints. This results in a fixed point where no control output Y_C is ever influenced by confidential data X_D, and our system is thus data-oblivious according to Def. 1.

V. Experiments

We conducted experiments on a diverse set of designs, including various accelerators and processors. Table I gives an overview of our experiments. All experiments are available in our GitHub repository [31]. We used Cycuity's Radix-S tool [32] for IFT simulation and Siemens EDA's OneSpin 360 tool [33] for formal verification.

For each experiment, we show:

- The result of the analysis. In particular, we report whether the design operates data-obliviously either always (*True*), only

Design	Data-Oblivious	Method	State Size		Data Prop. Found		Manual Inspections		
			Signals	Bits	IFT	+ UPEC	Original [22]	FastPath	Reduction (%)
SHA512	True	HFG	37	2162	–	–	33	0	100.0
AES (opencores)	True	HFG	24	554	–	–	19	0	100.0
AES (secworks)	True	HFG	26	2470	–	–	11	0	100.0
CVA6-DIV	Constrained	UPEC	15	217	10	10	12	3	75.0
FWRISCV-MDS	Constrained	UPEC	13	331	5	8	9	4	55.5
ZipCPU-DIV	False	IFT	14	142	14	–	9	1	88.8
cv32e40s	Constrained	UPEC	471	5624	16	17	30	19	36.6
BOOM	Constrained	UPEC	5340	41948	163	177	185	24	87.0

TABLE I
CASE STUDIES

under certain, reasonable software constraints (*Constrained*), or not at all (*False*). FastPath systematically finds such constraints under which the hardware operates data-obliviously. In our experiments, we also performed a more fine-grained analysis that considers a propagation path for each combination $(x_D, y_C) \in X_D \times Y_C$ of a data input x_D and a control output y_C. For some of the designs, we present these results in more detail in the text below, highlighting interesting findings.

- The step in the FastPath methodology at which the experiment becomes complete, whether by simple structural proof using the HFG (Sec. IV-A), by finding a security issue using IFT simulation (Sec. IV-B), or by exhaustive formal verification using UPEC-DIT (Sec. IV-C).
- The number of state-holding word-level signals and the total number of bits consumed by these signals.
- The number of signals influenced by the data inputs. In particular, we present how many propagations were found by IFT alone and how many were found after employing formal verification, i.e., UPEC-DIT. If the method terminates earlier, e.g., due to a structural proof by the HFG, this step is not required.
- Finally, we measure the amount of manual signal inspection required. We count the number of divergent signals, i.e., signals with different values in the two instances of the 2-safety UPEC model, that are found in counterexamples during the execution of FastPath and require manual inspection. Counterexamples that cause the IFT flow policy to be updated or a constraint or an invariant [21] to be created are also counted. We compare this value to the manual effort of the formal-only approach presented in [22].

A. Cryptographic Accelerators

We analyzed three different crypto-accelerators, one implementing the Secure Hash Algorithm (SHA) [34] and the other two implementing the Advanced Encryption Standard (AES) [35], [36]. We investigated whether any plaintext or key input could affect the control behavior of the system.

Our proposed methodology was able to prove the data obliviousness of all designs through a simple structural analysis using the HFG. The HFG showed that there is no path, implicit or explicit, starting from any of the data inputs X_D to any of the control outputs Y_C. While the absence of such a path is not trivially guaranteed, it can be expected because the round-based nature of the underlying algorithms makes a data dependency very unlikely.

The ability to perform structural analysis trivializes these proofs by eliminating the need for simulation or formal verification. As a result, no manual effort is required beyond the initial annotation of the interface. In contrast, the original UPEC-DIT method [22], for the SHA accelerator, requires a manual inspection of 33 signals influenced by X_D before reaching a fixed point.

B. Division Modules

We verified three division modules taken from processor designs. A structural path between X_D and Y_C exists for all designs, which means that structural analysis alone is not sufficient to verify data-obliviousness.

For the division unit of the ZipCPU [37] project, IFT simulation detected several data dependencies, such as an early termination for a divisor of zero. Since there is no reasonable software constraint under which the design operates data-obliviously, there is no need to proceed to the formal analysis.

The *Featherweight RISC-V* [38] processor employs a single module for multi-cycle multiplication, division and shifting. Using a random pattern testbench, IFT simulation was able to confirm the findings of [22] that the timing of shift operations is dependent on the shift amount. We introduced a constraint to exclude shifting, rerun the simulation and generated formal properties based on the untainted signals Z'. In the formal step, UPEC was able to detect three additional data propagations that were missed due to the simplicity of the testbench. After refining the formal property, FastPath verified that the design can operate data-obliviously if the software satisfies the constraint derived by our method (no shifting).

We also verified a hardened version of the CVA6 division unit taken from [39]. It implements security labels that indicate whether operands are public or confidential. Division timing is dynamically optimized to depend only on public information, but to perform better than worst-case latency. We taint the operands according to their labels, i.e., whenever they are confidential. In this experiment, the IFT simulation reported a false counterexample due to an overly conservative flow policy. In FastPath, however, we do not have to worry about restricting the IFT policy, since the formal step catches any missing propagation paths. In addition, two invariants were required to verify the security mechanism of this design.

C. In-Order Processor

We applied FastPath to cv32e40s [25], a RISC-V processor intended for security applications. It implements a variety of security mechanisms, including a data-independent timing (*data_ind_timing*) mode that ensures that normally variable-time instructions execute with a fixed latency. Some special cases, such as misaligned memory accesses, are excluded. Our results confirm the expectation that CSR accesses, jumps and branches can still influence the control behavior of the system even when in *data_ind_timting* mode. Load and store instructions that access more than a single byte can cause misalignment and thus affect control. In contrast, as intended, the latency

of division instructions becomes constant when the *data_ind_timing* mode is active.

However, FastPath was able to identify another, previously unknown, leakage affecting the operands of *all* instruction types. The method detected that the operands residing in the pipeline buffer of the ID-EX stage are always visible on the primary interface to the data memory, regardless of whether a memory access is taking place. Even if the corresponding validity signal is deasserted, the core still interprets the operands as address and data and passes them on to the outputs. Any IP, faulty or malicious, that does not comply with the protocol, can easily obtain information about internal computations, rendering security mechanisms such as *data_ind_timing* obsolete. We reported the vulnerability and worked with the processor development team to contribute a fix.

We used a fairly rudimentary testbench in our experiment, yet the IFT simulation was able to find almost all data propagations. The only missed state signal was inside the multiplier and is only tainted during MULH instructions. The formal step of FastPath showed a counterexample for this signal. In this experiment, most manual inspections involved deriving constraints for non-oblivious instructions, or writing invariants.

D. Out-of-Order Processor

Finally, to demonstrate its efficiency and scalability, we apply FastPath to the Berkeley Out-of-Order Machine (BOOM) [40] and compare the manual effort with the results of [22]. We confirm their findings regarding the data-obliviousness of certain instructions.

BOOM implements a sophisticated floating point (FP) pipeline, resulting in a large number of signals in the data path. Using a simple testbench, FastPath identifies the vast majority of these signals, as well as non-oblivious instructions, via IFT simulation. This reduces the manual effort of the formal step to corner cases, such as special cases for FP computations, and greatly reduces the overall manual effort for verifying the most complex design in our benchmark suite.

E. Discussion - Runtime and Manual Effort

IFT-simulation and formal property checking produce counterexamples that provide violations of the specified and desired security behavior as described in the security properties. These counterexamples require a manual analysis, during which the verification engineer must determine whether the counterexample describes a scenario that violates the intended design behavior. In other words, the verification engineer must determine if the security properties correctly describe the threat model. Property specification is challenging, and analyzing the counterexamples often provides cases where the properties must be refined. This analysis may take a considerable amount of time, depending on the verification engineer's design knowledge, the design's complexity, and the complexity of the counterexample at hand. For this reason, we use the number of signals that must be inspected manually as a metric for the verification effort. The manual inspection time is hard to quantify but can take weeks to months [21] for the designs considered in this work. As shown in Table I, compared to previous work, FastPath is able to significantly reduce the time spent manually examining counterexamples and thus the overall verification effort.

We observe a reduction of manual effort between 36% and 100%. The smallest reduction is obtained for the cv32e40s processor. This can be explained by the fact that this processor contains a relatively small data path but a complex control structure interweaved with several security features. This results in a comparably large number of counterexamples that lead to invariants or restrictions needed for security-aware software development. Remarkably, for BOOM, by far the largest and most labor-intensive design examined in this work, an 86% reduction of manual effort was achieved. In contrast to cv32e40s, BOOM employs a much larger and more sophisticated data path. In spite of its complex control for instruction scheduling, our hybrid approach is particularly effective because it clearly separates control from data path. Overall, our experiments demonstrate the immense promise of FastPath for increasing productivity in complex design projects.

Tool runtime is an important aspect when assessing the scalability of a verification approach. For FastPath, however, these runtimes were negligible. Running a single IFT-simulation, including the extraction of all tainted signals from the simulation trace, took 1–2 minutes. In the formal step, the initial design elaboration in the formal model checker took around 5 minutes for the most complex experiment. Afterward, a single check of the formal property (Lst. 1) finished in less than 10 seconds by merit of the symbolic initial state. Hence, tool runtime contributes only a small fraction to FastPath's verification time.

VI. Related Work

FastPath combines simulation and formal verification in the context of hardware security. Previous work exploring synergies between the two techniques, such as [41], has mostly attempted to improve simulation efficiency and coverage with formal methods. Consequently, such approaches inherit the limitation of simulation techniques and cannot provide formal guarantees. But there are also efforts in the other direction, i.e., the use of random simulation to improve formal approaches, such as in [42]. However, none of these methods address hardware security issues.

Significant efforts [43], [26], [22], [44], [27], [28], [45] have been made to detect leakage of confidential operands through timing or other microarchitectural side effects. Clepsydra [43] instruments an RTL design with IFT logic to discover timing flows through either simulation or formal verification. UPEC-DIT [22] relies on standard SystemVerilog Assertions (SVA) properties to detect data-dependent side-effects in the microarchitecture. While the symbolic initial state of the approach allows for a very high scalability, its main drawback lies in the considerable manual refinement effort (cf. Sec. V). More recent formal methods take a different approach [27], [28], [45], but have not been shown to scale to complex systems. We believe that also these methods could benefit from a hybrid approach along the lines proposed in this paper.

VII. Conclusion

FastPath is a hybrid verification methodology that leverages the complementary strengths of structural analysis, IFT-simulation, and formal verification to produce exhaustive security guarantees for data-oblivious architectures. FastPath uses a global formulation that automatically transfers intermediate results between the three verification techniques. The key benefit of FastPath is a drastic reduction of manual effort, achieved by combining the efficiency of simulation with the exhaustiveness of formal methods. In our case studies on functional units, FastPath was able to verify (or disprove) data-obliviousness with little to no manual interaction. Furthermore, especially for complex systems with intensive data paths like BOOM, FastPath offers unique scalability both in terms of runtime and manual effort. Thus, FastPath provides a tremendous reduction in security verification effort since the manual inspection dominates the overall verification time. Our future work aims at exploring the synergies of the proposed method for different threat models.

***Abstract*—Federating heterogeneous models on edge devices with diverse resource constraints has been a notable trend in recent years. Compared to traditional federated learning (FL) that assumes an identical model architecture to cooperate, model-heterogeneous FL is more practical and flexible since the model can be customized to satisfy the deployment requirement. Unfortunately, no prior work ever dives into the existing model-heterogeneous FL algorithms under the practical edge device constraints and provides quantitative analysis on various data scenarios and metrics, which motivates us to rethink and re-evaluate this paradigm. In our work, we construct the first system platform PracMHBench to evaluate model-heterogeneous FL on practical constraints of edge devices, where diverse model heterogeneity algorithms are classified and tested on multiple data tasks and metrics. Based on the platform, we perform extensive experiments on these algorithms under the different edge constraints to observe their applicability and the corresponding heterogeneity pattern.**

***Index Terms*—Federated Learning, Platform, Model Heterogeneity**

I. Introduction

Federated learning (FL) is empowering multiple real-world applications such as Google's Keyboard [1] and medical image analysis [2], whose key idea is to employ a set of personal clients to collaboratively train a deep learning model with the orchestration of a central server. In recent years, conducting FL among edge devices has become a noteworthy trend [3], [4]. Under this condition, the typical FL assumption with respect to keeping an identical model architecture is hard to hold since edge devices are usually resource-constrained.

The research community has recognized this issue and introduced the concept of *Model-Heterogeneous Federated Learning (MHFL)* [5]. In this context, each client maintains a model that accounts for the device's resource constraints, and the federated learning process operates among these heterogeneous models. MHFL can offer the following benefits: (1) For resource-constrained devices, MHFL provides the flexibility to adaptively conduct FL under diverse resource constraints (e.g., computation, communication, and memory) by adjusting the model size. (2) For individual edge users with distinctive preferences, MHFL allows them to customize the model's structure and size. Overall, MHFL is well-suited for deployment on various edge devices.

In the past few years, a large number of papers have been published to improve the performance of MHFL [6], [7]. After exploration, we find that all of them are based on simple configurations (i.e., using the proportion of the original model to satisfy device constraints). However, they do not consider real-world device constraints. As shown in Table I, on two real edge devices (Jetson Nano, Jetson Orin NX), models generated by different heterogeneous methods with the same proportion exhibit significant differences in terms of various resources, particularly for the computational cost (training time) and the memory usage. Therefore, *we argue that the current comparisons of model-heterogeneous federated learning methods are not fair, and the community should rethink and re-evaluate model-heterogeneous federated learning under practical device constraints*.

To gain a fair and comprehensive performance comparison of diverse model-heterogeneous mechanisms for real-world constraints of edge devices, we construct the first system platform **PracMHBench**. PracMHBench defines three representative heterogeneity levels, each of which includes several corresponding MHFL algorithms. The platform also contains multiple model architectures and metrics, which are evaluated on various data tasks, spanning from computer vision (CV), natural language processing (NLP), and human activity recognition (HAR). Based on the benchmark, PracMHBench further build three typical edge-side constraint cases, which we call *computation-limited MHFL, communication-limited MHFL, and memory-limited MHFL*, and conducts experiments on them. For each limitation setting, we create it based on the collected statistics of practical edge devices, such that the results can benefit and guide the MHFL deployment in real-world resource-constrained scenarios.

Based on PracMHBench, we first perform extensive experiments on different model-heterogeneous algorithms under the specific device constraint to demystify the performance on different data tasks. Next, in terms of our evaluated metrics, we analyze the pattern of different heterogeneity algorithms and levels, aiming to explore the most suitable strategy for different resource-constrained scenarios. Finally, through the experiments, we summarize several insightful observations and conclusions (details in Section V).

This paper makes the following contributions:

- We construct a system platform PracMHBench to characterize and evaluate diverse model-heterogeneous algorithms under the practical resource-constrained edge devices. To the best of our knowledge, this is the first work that delves into the deployment of MHFL on real-world scenarios [1].
- We perform extensive experiments on PracMHBench with different heterogeneity levels and device constraints, and the results reveal a comprehensive landscape of current MHFL algorithms from a real system perspective.
- Based on the experiments, we summarize the insightful observations and practical implications that can benefit the practitioners and researchers targeting resource-constrained MHFL systems.

II. Background and Related Work

Model Heterogeneity in Federated Learning. In recent years, Federated learning (FL) tailored for massive edge devices has garnered unprecedented attention [3], [4], [8]–[10]. Unlike traditional federated learning that only focuses on algorithm performance, federated learning in such scenarios pays more attention to the characteristics of heterogeneous devices. For example, training VGG16 requires over 8GB memory with a batch size of 8 [11], making it hard to

deploy for many edge devices. The research community has proposed *model-heterogeneous federated learning (MHFL)* to address the issue. The primary aim is to enable each device to customize its model size while ensuring federation with other devices.

Achieving MHFL encompasses two categories of state-of-the-art techniques. The first category is sub-model partial aggregation [5], [6], [12]. Its fundamental idea involves extracting sub-models from a large model that adheres to the memory constraints of devices, followed by weight aggregation based on the positional information of neurons. The second category employs knowledge distillation to achieve federated aggregation [7], [13]–[15]. Its primary pipeline involves: (1) The server leverages a public dataset to compute the output logits of each model and performs logits aggregation; (2) The server sends the aggregated logits back to each client, thereby enabling them as the teacher model for the distillation process. While MHFL has been extensively studied, its level of heterogeneity and the performance of various methods under different real device constraints have not been thoroughly explored. Our work aims to fill this gap by constructing a comprehensive and practical platform for MHFL in resource-constrained edge systems.

FL Platforms. Benchmarking and evaluating the performance of FL is essential for practitioners to understand and employ associated algorithms and configurations effectively. At present, there are two main categories of platforms for FL. The first category comprises general FL platforms, which primarily aim to comprehensively assess the performance of various FL algorithms under different conditions [16]–[18]. The second category consists of specific FL platforms, tailored for in-depth exploration of certain characteristics within FL systems [19]–[21]. For example, to assess the data heterogeneity, Li *et al.* [20] proposed a comprehensive data partitioning strategy to cover typical non-IID (non-independently and identically distributed) data cases and evaluated existing FL algorithms under such settings. Furthermore, Yang *et al.* [21] developed an FL platform to explore the impact of heterogeneity on performance, particularly focusing on hardware and state heterogeneity. In our study, we pay more attention to the impact of *model heterogeneity* on FL performance and the practice of conducting diverse heterogeneous methods on resource-constrained edge devices, which is fundamentally different from previous research efforts.

III. BENCHMARK CONSTRUCTION

PracMHBench is a platform aimed to characterize and evaluate diverse model heterogeneity algorithms on practical resource-constrained devices. In this section, we first describe its benchmark construction in detail. The concrete statistics are shown in Table II.

Model Heterogeneity Levels. Due to diverse resource constraint conditions, various clients in federated learning may equip models with different capacities or architectures. In our PracMHBench, we define and categorize the model heterogeneity mechanism in an FL system into three levels (as shown in Figure 2):

- *Width Heterogeneity*, where the models employed by clients share the same topology while exhibiting differences in the number of channels in each layer, resulting in heterogeneous models with various widths.
- *Depth Heterogeneity*, where the model topology employed by clients is also identical and the difference lies in the number of layers, which can be considered as the depth-level heterogeneity.
- *Topology Heterogeneity*, where clients employ models with entirely different topologies. For example, an FL system may consist of diverse model architectures, such as ResNet [22], EfficientNet [23], MobileNet [24], and GoogleLeNet [25], in order to satisfy various user preferences and requirements.

Representative Heterogeneous Algorithms. In terms of the aforementioned heterogeneity levels, we select several heterogeneous algorithms for each level to represent its performance. Specifically, for *width heterogeneity*, we adopt Fjord [12], SHeteroFL [5] and FedRolex [6], whose key settings are allocating sub-models with different widths to clients before conducting specifically designed federation schemes. In the case of *depth heterogeneity*, we select FeDepth [26], InclusiveFL [27] and DepthFL [28], which achieves depth scaling by pruning one or more of the top layers of the global model. Towards *topology heterogeneity*, FedProto [7] and Fed-ET [14] are used to conduct FL with the help of knowledge distillation among these heterogeneous architectures.

Data Tasks. In our platform, we target three areas: computer vision (CV), natural language processing (NLP), and human activity recognition (HAR), each of which is evaluated by two representative datasets. For CV, we utilize CIFAR-10 and CIFAR100 [29]. For NLP, we employ AG-News [30] and Stack-OverFlow [31], and for HAR, we choose HAR-BOX [32] and UCI-HAR [33].

Model Architectures. To evaluate the different levels of model heterogeneity, we select various model architectures for experiments. For width and depth heterogeneity, we follow the settings outlined in related works [5], [6], conducting experiments using four different widths/depths (100%, 75%, 50%, 25%) of the ResNet-101 [22] on the CIFAR-100 dataset [29] and MobileNetV2 [24] on CIFAR-10 dataset [29]. Additionally, for NLP tasks, we employ a customized transformer model [34] on AG-news and ALBERT [35] on Stack Overflow. We partition them into various dimensions to meet different definitions of heterogeneity. For HAR tasks, we employ customized CNNs following the previous work [36] and partition it into various dimensions to meet different definitions of heterogeneity. Regarding topology heterogeneity, we conduct experiments using two model families with distinctive architectures on CV tasks, including the ResNet Family [22] (ResNet-18, ResNet-34, ResNet-50, ResNet-101) on CIFAR-100 [29], and the MobileNet Family [24] (MobileNetV2, MobileNetV3 small, MobileNetV3 large) on CIFAR-10 [29]. Considering NLP models, we choose the ALBERT Family [35] (ALBERT base, ALBERT large, ALBERT xxlarge) on Stack Overflow [31]. Additionally, we modified the structure of the customized CNNs for HAR tasks.

Evaluated Metrics. To provide a comprehensive evaluation, PracMHBench adopts the following four metrics: (i) *Global accuracy*, where we maintain a global dataset and the final federated model is evaluated on it. (ii) *Time-to-accuracy*, which is defined as the wall

clock time for training a deep learning model to reach a pre-set accuracy, aiming at measuring the training speed. (iii) *Stability*, where we record the accuracy of each device and compute the variance among them to show the stability for various heterogeneous models. (iv) *Effectiveness*, where we compare the final accuracy of MHFL algorithms with a simple resource-aware homogeneous baseline (i.e., training the smallest homogeneous model across all heterogeneous devices). The effectiveness is measured by the accuracy improvement. Our goal is to test whether heterogeneous models are actually needed (i.e., whether the improvement is greater than zero) and the benefit of conducting MHFL (i.e., the improvement value).

IV. PRACTICAL DEVICE CONSTRAINTS

Given the above benchmark settings, we then manually build three typical resource-constrained cases based on real-world device properties (enumerated in Table III). As illustrated in Figure 3, we first build a model pool, where various deep learning models in the literature are measured and we pick out the suitable one in terms of the heterogeneity level and resource constraint. Our principle for selecting models from the model pool is to keep the constraint consistent for all methods to ensure fairness. In the following subsections, we describe each resource limitation on MHFL in detail. Note that for each specific limitation, other resources remain identical.

A. Case I: Computation-Limited MHFL

Description. Limited computing power means that different devices may demonstrate varying levels of computational constraints. As shown in Table I, there exists a significant difference in computing power among real edge devices, leading to distinctive training speed. Under this condition, we define *Computation-Limited MHFL* as follows:

Definition IV.1. (Computation-Limited MHFL). *Given the various computing capabilities of practical edge devices, the goal of computation-limited MHFL is to adapt the model size of its original version to ensure a same model training speed among devices for synchronous aggregation.*

Setting. To achieve such a scenario, we follow the IMA dataset settings [21], where they collected status from more than 1,000 devices (e.g., Samsung Note 10, Nexus 6, and Redmi Note 8) and recorded the real computational capabilities of these devices. We used the computing power of the IMA dataset to build the computation-limited scenarios. Specifically, we assign the diverse computational capabilities in the IMA dataset to the clients of the federated learning system as their training constraint, and select corresponding suitable models of different heterogeneity levels for each client from the model pool, with the help of the statistics of the training time for various models, which is provided by an AI Benchmark on various devices [37]. This helps ensure roughly equivalent training times for each device and achieve synchronous aggregation under a fixed submission deadline.

B. Case II: Communication-Limited MHFL

Description. The limited communication bandwidth indicates that the speed of uploading/downloading model parameters is affected by the actual device hardware and network environment. In an FL system, a client with small communication bandwidth may spend a lot of time for uploading or downloading model parameters, resulting in its inability to upload model parameters in time for aggregation. The *Communication-Limited MHFL* can be defined as follows:

Definition IV.2. (Communication-Limited MHFL). *Given the various communication bandwidth of different devices, the goal of communication-limited MHFL is to adjust the model size of its original version to ensure a same uploading/downloading speed among devices for synchronous aggregation.*

Setting. In the case of communication constraints, we control the communication time of each round in the federated learning system to a certain time (e.g., 200s) based on the real network bandwidth information provided by the IMA dataset. We then select appropriate models and corresponding quantities from the model pool to deploy different heterogeneity levels. Note that the parameter sizes corresponding to the various models under the different methods vary, and thus the model proportion of different sizes in the different methods also varies.

C. Case III: Memory-Limited MHFL

Description. Unlike the above, limited memory capacity focuses more on the actual memory requirements of training each model on different devices. Limited memory may have a direct impact on whether a client can conduct training and changing the model size can directly satisfy a specific memory limit. In this case, we define *Memory-Limited MHFL* as follows:

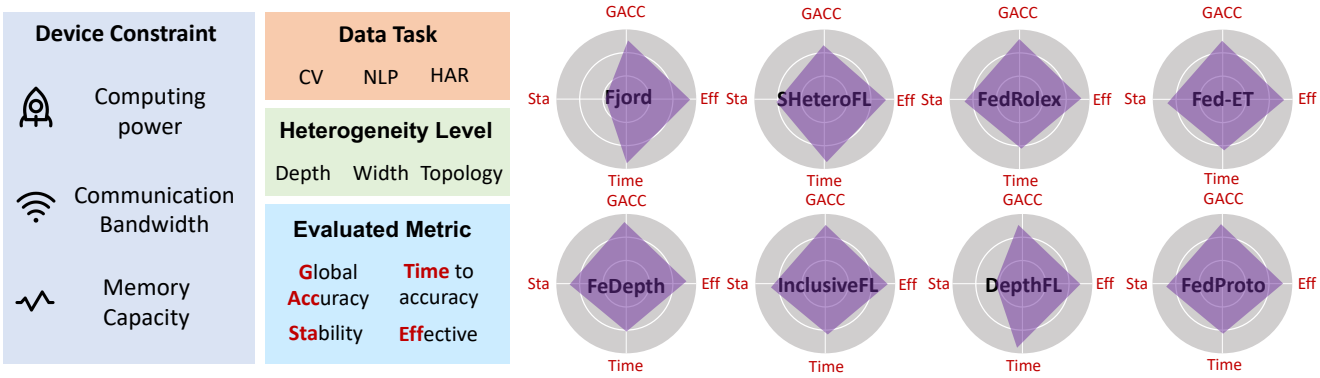

Fig. 1. Evaluation track of our platform PracMHBench. Here the information in radar charts is just for demonstration. The concrete performance will be compared in the subsequent experiments.

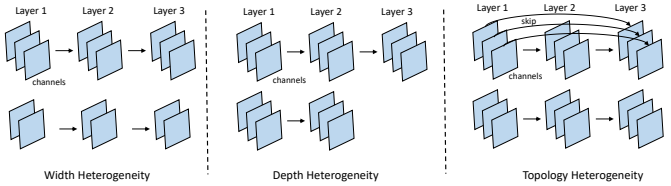

Fig. 2. Demonstration of different heterogeneity levels. Here 'skip' denotes the skip connection used in ResNets.

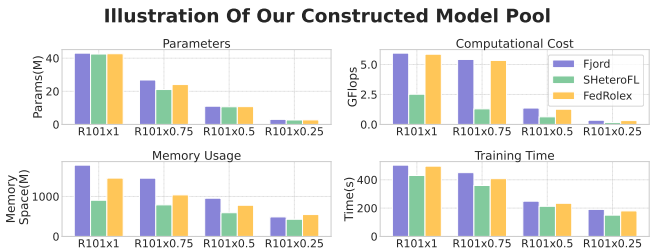

Fig. 3. Illustration of our constructed model pool. We use the tested system statistics (e.g., Parameters, GFlops) for three algorithms on Jetson Orin NX as an example. 'R' refers to ResNet.

Definition IV.3. (Memory-Limited MHFL). *Given the various memory capacity of different devices, the goal of memory-limited MHFL is to change the model size of its original version to ensure available local training for completing FL.*

Setting. We choose three typical GPU memory sizes of real devices: 16GB (e.g., Jetson Orin nx), 4GB (e.g., Jetson tx2 nx), and no GPU (e.g., Raspberry Pi). We then conduct experiments on real devices to observe whether the models in the model pool can be trained for federated learning. The largest trainable model is assigned to the client for meeting the corresponding memory size. In addition, the client proportion of different memory sizes is determined by the real-world proportion distribution depicted in [38].

V. Evaluation and Analysis

Based on PracMHBench, we perform extensive experiments and analyze the results. The theme of this measurement is to quantitatively understand the performance discrepancy of different heterogeneity algorithms. As shown in Figure 1, the evaluation track includes: (1) selecting a targeted resource constraint; (2) conducting experiments on a variety of data tasks for different heterogeneity levels and algorithms; (3) recording and comparing the performance based on the evaluated metrics. In the following parts, we will describe the results of each resource constraint in detail. Note that some methods are not compatible with NLP tasks, and thus we omit the corresponding results. In addition, for the memory-limited scenario, we only focus on large CNN models (i.e., Resnet-101) and Transformer models (i.e., ALBERT) since most of the current edge devices can hold small models for HAR tasks.

Specifically, for CIFAR10, CIFAR100 and AG-News, we adopt IID (Independent and Identically Distributed) partition. For Stack Overflow, HAR-BOX and UCI-HAR, the dataset is partitioned over user IDs, making the dataset naturally non-IID distributed. The number of clients for CIFAR10, CIFAR100, AG-News, Stack-OverFlow, HAR-BOX, and UCI-HAR is 100, 100, 50, 500, 100, 30. The sampling ratio is 10%. All of the experiments are conducted for 1000 federated rounds to ensure convergence. Finally, we run each experiment 3 times and average them as the reported results.

A. Results on Computation-Limited MHFL

Global accuracy and time-to-accuracy. The top row of Figure 4 shows the comprehensive results of global accuracy and time-to-accuracy. From the figure, we can observe that: (1) Overall, SHeteroFL and DepthFL achieve better performance on both global accuracy and time-to-accuracy. Regardless of the type of the data tasks, these two methods ensure relative superiority while Fjord and FedProto consistently exhibit the poorest performance across all data tasks. This suggests that under the computational constraint, the method's performance is unrelated to the type of data. (2) Although the two top-performing methods belong to different heterogeneity levels, we find that all depth-level methods (i.e., FeDepth, InclusiveFL, DepthFL) demonstrate favorable outcomes. This implies that adjusting the model size based on depth is a suitable choice in this scenario.

Stability and effectiveness. The bottom row of Figure 4 demonstrates the performance of stability and effectiveness. The following observations can be drawn: (1) Different from global accuracy and time-to-accuracy, which can identify the best algorithm for all data tasks, achieving a simultaneous satisfaction of stability and effectiveness is challenging on most datasets except for CIFAR-10, where FeDepth can be considered the best performer, which means that we can enhance the performance across nearly all devices. For other datasets, these two metrics tend to exhibit a trade-off, meaning that as stability increases, effectiveness tends to decrease. (2) For different heterogeneous levels, their performance on these two metrics does not follow any specific pattern and varies according to the differences in datasets.

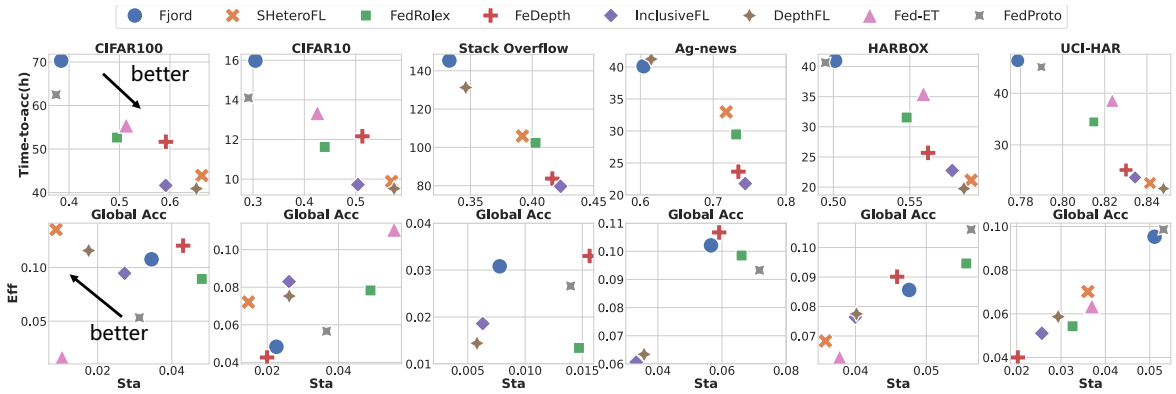

Fig. 4. Results on computation-limited MHFL. The top row refers to the comprehensive performance of global accuracy and time-to-accuracy. The bottom row represents the performance of stability and effectiveness.

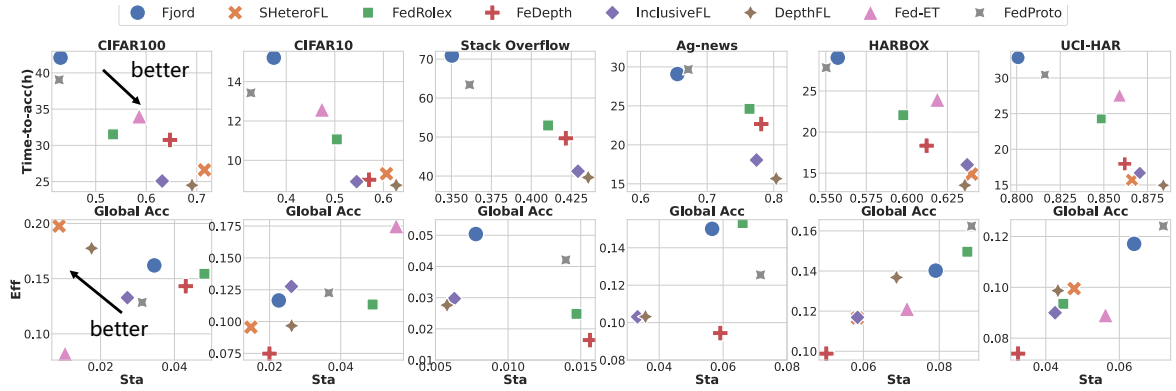

Fig. 5. Results on communication-limited MHFL.

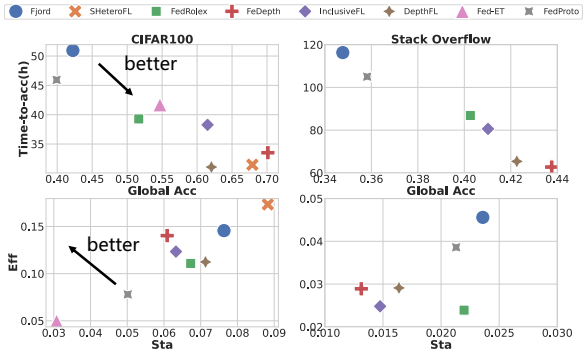

Fig. 6. Results on memory-limited MHFL.

> **Observation**: *In computation-limited MHFL, the superiority in terms of global accuracy and training speed remains a consistent pattern regardless of changes in data tasks. Among them, the methods belonging to the depth-level heterogeneity are relatively better than others. However, there is no one-size-fits-all algorithm that can achieve a desirable trade-off between the stability and effectiveness on diverse data tasks.*

B. Results on Communication-Limited MHFL

Global accuracy and time-to-accuracy. The top row of Figure 5 shows the comprehensive comparison. We can draw the following conclusions: (1) Similar to the scenario of computational constraints, under communication bandwidth constraints, SHeteroFL and DepthFL still perform optimally, and this conclusion remains consistent in all data tasks. Besides, depth-level methods outperform other baselines. This indicates that the extent of changes in model size due to computational and communication constraints is not significant. Thus, the overall superiority of various model-heterogeneous algorithms remains unchanged. (2) Although the performance ranking has not changed, there is still a noticeable variation in the training speed gap among different methods. For example, on the Stack Overflow dataset, under the communication bandwidth constraint, the gap of time-to-accuracy (i.e., training speed) is significantly smaller than it is in the computational constraint (roughly 2X). On other datasets, the conclusion also holds. We believe this is because the communication constraint is more related to the size of the model parameters, which better aligns with the original design principle of the algorithms (i.e., controlling the proportion of model size). Therefore, each method can essentially follow the original settings, and the fluctuation in training speed will not be too significant compared to the computational constraint, which not only considers the model parameters but also takes into account the computational capabilities of different devices.

Stability and effectiveness. As depicted in the bottom row of Figure 5, we record the stability and effectiveness performance under the communication limitation. We can see that: (1) At a high level, it is hard to figure out which algorithm can simultaneously ensure stability and effectiveness across all data tasks. In other words, these two metrics do not follow any specific pattern. (2) We discovered that heterogeneous methods at the depth level perform poorly in terms of effectiveness. The reason may be twofold: on the one hand, architectures related to depth itself exhibit good performance (with high global accuracy as mentioned in the figure); on the other hand, as stated above, the communication constraint does not differ significantly from proportional splitting. Therefore, the overall state aligns well with the original design of the corresponding paper. Therefore, the improvement after heterogeneity is not as pronounced.

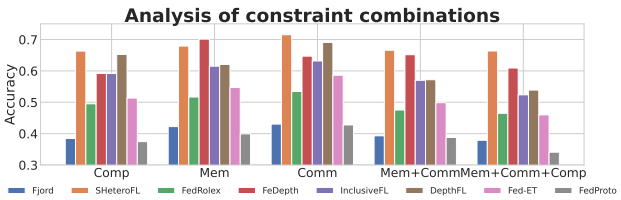

Fig. 7. Analysis of constraint combinations.

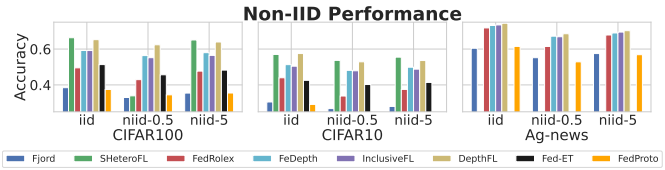

Fig. 8. Non-iid performance on the computation-limited scenario. Here '0.5' and '5' are the alpha of the non-iid dirichlet partition.

> **Observation**: *Communication-Limited MHFL somewhat resembles the proportional splitting in existing literature, as it pays more attention to the number of model parameters. Therefore, the gaps among various algorithms, especially in terms of training speed, are not significant. Additionally, compared to other heterogeneous levels, although depth-level heterogeneity still holds an advantage in global accuracy and training speed, the performance improvement (i.e., effectiveness) brought by heterogeneity is relatively limited.*

C. Results on Memory-Limited MHFL

Global accuracy and time-to-accuracy. Figure 6 shows the results. From the top row, the following phenomenon is noticeable: We *surprisingly* find that DepthFL, which performs well in the above two constraints, no longer exhibits superiority. Its global accuracy has significantly decreased, falling below the previously comparable SHeteroFL and inferior FeDepth. We attribute this to the fact that DepthFL itself requires a substantial amount of memory (shown in Table I). When memory is constrained, DepthFL needs to drastically reduce its size, leading to a decrease in performance. Instead, although FeDepth does not perform well under the computational and communication constraints, its small memory footprint (shown in Table I) allows it to accommodate larger models in this scenario, resulting in better performance.

Stability and effectiveness. We show the results at the bottom of Figure 6. From the figure, we find the following interesting observation: Compared to the two scenarios mentioned above, there is not much variation in the effectiveness trends of different algorithms. However, the conclusion regarding stability is almost reversed. For instance, in the case of CIFAR100, SHeteroFL exhibits the highest stability under the computation and communication constraints. However, for the memory constraint, its stability becomes the lowest among all methods. For Stack Overflow, Fjord demonstrates relatively high stability under the first two scenarios, but faced with memory limitations, its stability jumps to the lowest. We attribute this phenomenon to the significant difference between model parameters and actual device memory usage (as shown in Table I). Therefore, under the memory constraint, the model size of many methods may undergo substantial changes, leading to unstable performance.

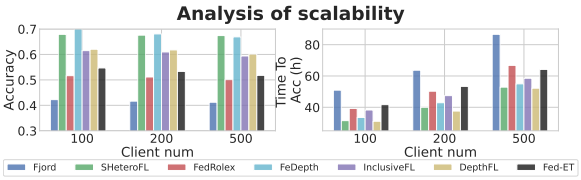

Fig. 9. Analysis of scalability.

> **Observation**: *In practical memory-constrained scenarios, the performance of global accuracy and training speed, apart from the influence of heterogeneous levels and the methods themselves, is significantly affected by the actual memory footprint occupied by the models of different methods. Moreover, it does not exhibit a strong correlation with the types of data tasks. Additionally, concerning the stability, although it remains challenging to identify specific patterns, its trends are precisely opposite to the conclusions drawn under the computation and communication constraints.*

D. Other Analysis

Analysis of constraint combinations. Here we test two types of combinations: communication+memory limited FL and computation+communication+memory limited FL on the CIFAR-100 dataset. Figure 7 demonstrates the accuracy results.We can observe that: Under the combination of communication+memory, the performance of all methods decreases compared with the single restriction and SHeteroFL performs best when various constraints are combined together due to its excellent partitioning method. SHeteroFL's slimmable partition method is well controlled in terms of calculation volume, memory consumption and communication volume, making it more adaptable to various restricted environments.

Analysis of Non-IID Performance. Figure 8 show the results of computational constraints under the non-iid scenario. From the figure, we can observe that although non-iid will degrade the performance, the conclusion is not changed, which means that existing algorithms is robust to the non-iid scenario.

Analysis of scalability. To demonstrate the scalability, here we conduct an experiment to evaluate the convergence-related metrics of various methods with different client numbers on the memory-limited MHFL setting and the CIFAR-100 dataset. As shown in Figure 9, scaling up leads to a decline in convergence performance, including both convergence effectiveness and speed. Among these methods, the width-level heterogeneity demonstrates relatively smaller performance losses, indicating better scalability.

VI. Conclusion

In this work, we construct the first comprehensive platform for MHFL on practical resource constraints and conduct extensive measurements to quantitatively evaluate their performance. The results help reveal a complete landscape among diverse model heterogeneity levels and algorithms on real-edge devices. Based on the results, we summarize strong observations and implications that can be useful to FL developers and researchers of resource-constrained federated systems.

***Abstract*—This paper presents BPUFuzzer, a fuzz testing tool for detecting branching transient execution vulnerabilities in CPU RTL design. BPUFuzzer addresses two key challenges: generating testcases that capture complex control flows, and extracting essential data from vast hardware states to guide testcase selection. Utilizing a control flow graph-based testcase generation strategy with anomaly detection and employing fitness and coverage metrics, BPUFuzzer works on testcases that cover broader program flows and deliberately selects testcases to discover transient execution vulnerabilities effectively. When applied on RISC-V Boom v3, BPUFuzzer uncovered more Spectre types than the state-of-the-arts, including a previously unidentified variant, named Spectre-LOOP.**

I. Introduction

Transient execution vulnerabilities are a significant hardware security issue in modern CPUs. Attacks like Spectre [1] and Meltdown [2], along with their variants [3]–[11], severely impact the reliability of processor hardware. The majority of these vulnerabilities are caused by the malicious exploitation of the branch prediction unit (BPU), which is a commonly implemented microarchitecture in modern processors designed to optimize pipeline performance by predicting control flow changes thus preventing pipeline stalls [12]. The discovery of these vulnerabilities and their variants has raised new concerns about processor security, as these microarchitecture-based issues cannot be easily fixed by vendors and pose serious threats to information system security.

Recent advancements have been made in the automated detection of transient execution vulnerabilities. Several approaches [13]–[17] focus on testing limited code snippets based on prior knowledge, without addressing a broad range of code patterns. SpecDoctor [18] generates testcases without prior knowledge but imposes constraints that prevent loop generation in its implementation. Furthermore, it lacks coverage feedback mechanisms specific to transient execution vulnerabilities, limiting its ability to detect issues arising from complex hardware states. Moreover, current techniques limit their vulnerabilities detection without in-depth analysis of complex BPU behaviors. Detecting vulnerabilities within BPU poses two significant challenges. First, since the combination of branch instructions that can change the BPU state is very diverse, covering a broad range of control flow patterns is difficult. Second, it is challenging to efficiently search for testcases that tend to trigger transient execution from numerous testcase patterns corresponding to complex BPU states.

In this paper, we present BPUFuzzer, a pre-silicon fuzz testing tool designed to address these challenges and effectively detect branching transient execution vulnerabilities. In order to capture complex control flow patterns, we propose an effective testcase generation and validation method based on control flow graph (CFG). In addition, we propose effective fitness and coverage functions to guide testcase selection, innovatively taking into account the states of the Reorder Buffer (RoB) and the Branch Prediction Unit (BPU). This approach extends fitness and coverage metrics to the microarchitectural component level, improving vulnerability detection efficiency. Through BPUFuzzer testing, we identified a new transient execution pattern, termed the loop pattern, which can manifest as a new Spectre variant called Spectre-Loop. The main contributions of our work are:

- We propose a CFG-based testcase generation that encompasses all possible program control flows, including loop types that were not addressed in previous work.
- We propose an effective feedback method on fuzz testing to guide testcase selection. It significantly enhances the efficiency of uncovering transient execution vulnerabilities in complex hardware designs.
- The proposed fuzz tool successfully identified a new Spectre variant called Spectre-loop on Boom v3 CPU. Experiments also demonstrate that BPUFuzzer uncovers more Spectre types than previous work.

II. Related Work

The automated detection of transient execution vulnerabilities has gained significant attention. Prior work, such as Medusa [13], uses authenticated PoC snippets as test seeds. SpecFuzz [14] simulates branch misprediction in security-sensitive libraries. Absynthe [15] and Osiris [16] focus on finding specific side-channels. These approaches mainly test limited code snippets based on prior knowledge, rather than covering a broad range of code patterns and hardware states. Furthermore, these frameworks test only on post-silicon CPUs, limiting their ability to identify potential transient execution leaks in the pre-silicon design phase before the processor is taped out. In pre-silicon RTL-stage research, Introspectre [17] uses predefined code gadgets with a focus on meltdown-type vulnerabilities. DifuzzRTL [19] and SIGFuzz [20] apply a

*Corresponding author: dan@hit.edu.cn

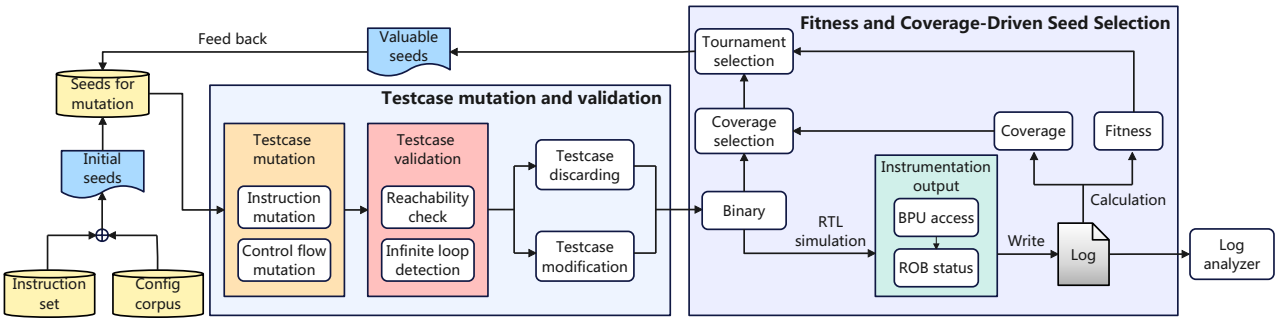

Fig. 1: Overview of BPUFuzzer

coverage based on control signals that drive the muxes to find CPU bugs and side channels. They focus on register states and ignore microarchitecture states, which is essential for transient execution. So their coverage definitions are unsuitable for detecting transient execution vulnerabilities. WhisperFuzz [21] focuses on timing behaviors changing by triggering different microarchitectural state transitions. In contrast, BPUFuzzer in-depth studies the states of microarchitectural components, including BPU and RoB. The coverage metrics formed by these states are used to search for testcases tend to trigger branching transient execution, significantly improving the efficiency of detecting vulnerabilities. SpecDoctor [18] generates testcases using CFG construction. To avoid invalid testcases in implementation, it enforces constraints that prevent loop generation. However, loop is an important control flow transfer pattern. Moreover, it does not provide coverage feedback mechanisms, limits its detection from complex hardware states. In contrast, BPUFuzzer is capable of discovering transient execution caused by any control flow transfer. Moreover, BPUFuzzer tailored coverage and fitness metrics optimized for transient execution. Owing to these two improvements, BPUFuzzer surpasses previous work in both the scope and efficiency of detecting transient execution vulnerabilities.

III. Overview of BPUFuzzer

In this section, we present an overview of the architecture of our transient execution vulnerability fuzz testing tool, BPUFuzzer. We consider the following threat model which aligns with the mainstream studies in discovering transient execution vulnerabilities such as Spectre and Meltdown:

(1) The attacker is a user without privilege, the victim is the privileged kernel. The attacker and the victim locate on the same logical core;

(2) The attacker can invoke the victim through system calls.

As shown in Figure 1, our tool includes two main modules to address the challenges outlined in Section I. The testcase mutation and validation module generates testcases for fuzz testing. To maximize the range of control flow patterns in testcase generation, We employ a modified CFG-based technique that includes instruction mutations and control flow mutations without any pattern constraints. A testcase validation submodule is also included to detect and avoid infinite loops. These methods enable us to produce a greater variety of control flow patterns compared with state-of-the-art tools.

The fitness and coverage-driven seed selection module select testcases with high tendency of transient execution and feed them back as seeds for mutation. Aimed at selecting valuable testcases efficiently, BPUFuzzer incorporates hardware information through instrumentation, including the status of BPU and RoB, which is closely related to transient execution. These pieces of information are logged and used to calculate the fitness function and testcase coverage. Specifically, testcases are first selected based on whether they cover new hardware states, as determined by coverage calculation, and then undergo tournament selection based on fitness value. Additionally, a log analyzer detects transient execution risks through the collected data and classifies them based on the originating microarchitectural component.

Sections IV and V will detail the working principles of the testcase mutation and validation module, as well as the fitness and coverage-driven seed selection module.

IV. Testcase Mutation and Validation

The testcase mutation and validation module aims to generate testcases that cover the maximum possible range of control flow patterns. This module consists of two components: mutation of instructions within a basic block and mutation of control flow instructions. To ensure that generated testcases maximize control flow coverage and execute to termination, a validation module checks each testcase after mutation.

A. Mutation Rule of a Basic Block

Figure 2 shows the structure of a basic block (BB) and all possible mutation behaviors. A BB must end with either a conditional or unconditional jump instruction, with no jump instructions allowed at any other position within the block. During mutation, various transformations may occur within the BB, including the insertion, removal, substitution of instructions, and modifications to jump instruction targets.

B. Control Flow Related Instructions on RISC-V

In RISC-V instruction sets, there are two types of instructions related to control flow transfer, unconditional jump instructions and conditional branch instructions, shown in Table I. A conditional branch adds two outgoing edges to the basic block in the CFG, while an unconditional jump only adds one outgoing edge.

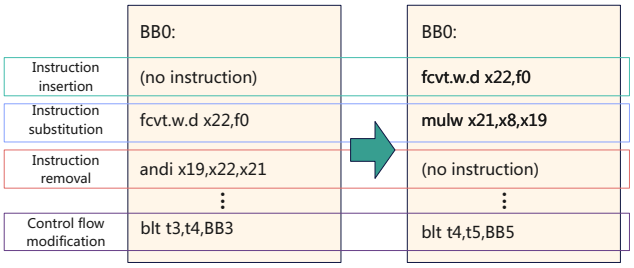

Fig. 2: Possible mutation operations on a basic block

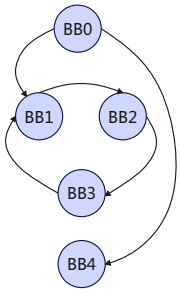
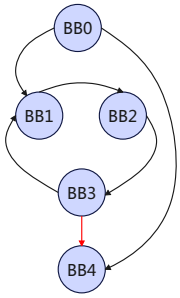
TABLE I: Control Flow Related RISC-V Instructions



Inst	Description
beq, rs1, rs2, imm	if(rs1 == rs2) PC += imm
bne, rs1, rs2, imm	if(rs1 != rs2) PC += imm
blt, rs1, rs2, imm	if(rs1 $<$ rs2) PC += imm
bge, rs1, rs2, imm	if(rs1 $\geq$ rs2) PC += imm
bltu, rs1, rs2, imm	if(rs1 $<$ rs2) PC += imm
bgeu, rs1, rs2, imm	if(rs1 $\geq$ rs2) PC += imm
jal, rd, imm	rd = PC+4; PC += imm
jalr, rd, rs1, imm	rd = PC+4; PC = rs1 + imm

C. Testcase Validation



To maximize coverage of flow transfer scenarios in CFG generation, we do not restrict jump or branch targets during mutation. However, arbitrary jump combinations may create infinite loops, so we apply a validation process to detect and correct invalid testcases.

All loops in a CFG have the potential to cause infinite loops. Based on the types of jumps at the end of the BBs of a loop, we classify the causes of infinite loops into the following categories:

- **Unconditional jumps**: In this type, all BBs within the loop end with unconditional jumps. Consequently, once the control flow enters such a loop, it becomes impossible to exit. An example of this situation is illustrated in Figure 3(a), once the control flow jumps from BB0 to BB1, it will never exit. We will refer to this type of testcase as type 1 testcase in the following discussion.

(a) Infinite loop caused by unconditional jumps

(b) Infinite loop caused by conditional branches that always branch in the same direction

Fig. 3: Two types of invalid testcases

- **Conditional jumps with fixed direction**: Although at least one BB within these loops end with conditional jumps that could theoretically allow for an exit, arbitrary mutation operations may cause the direction of the conditional jump to remain unchanged, resulting in an infinite loop. As shown in Figure 3(b), although theoretically the unconditional jump at the end of BB3 could jump to BB4, improper instruction mutation may causes the value comparison between the two source registers of BB3's conditional jump to remain unchanged, preventing the jump from BB3 to BB4 from ever occurring(illustrated with a red arrow) and thus forming an infinite loop. We will refer to this type as type 2 testcase.

Notation	Description
BB.jmpIns	Last jump instruction of basic block `BB`.
BB.jmpIns.name	Name of the instruction.
BB.jmpIns.rs1	Source register 1 of the jump instruction.
BB.jmpIns.rs2	Source register 2 of the jump instruction.
instruction.dest	Destination register of arithmetic & logical instructions.

TABLE II: Notations used in Algorithm 1.

Algorithm 1: Type 2 testcases modification

```
Input : BBs containing conditional jump instructions in a cycle
Output: Modified BBs
foreach BB in BBs do
    if BB.jmpIns.name in {blt, bge, bltu, bgeu} then
        Set BB.jmpIns.rs1 to t1;
        Set BB.jmpIns.rs2 to t2;
        foreach instruction in BB do
            if instruction.dest in {t1, t2} then
                Delete instruction;
        ▷ Adjust the two source registers according to their current states;
        Insert instruction slti t3, t1, t2;
        Insert instruction xor t4, t3, 1;
        Insert instruction slli t3, t3, 6;
        Insert instruction slli t4, t4, 6;
        Insert instruction add t1, t1, t3;
        Insert instruction add t2, t2, t4;
        Insert instruction addi t1, t1, -32;
        Insert instruction addi t2, t2, -32;
    if BB.jmpIns.name in {beq, bne} then
        Set BB.jmpIns.rs1 to zero;
        Set BB.jmpIns.rs2 to t2;
        foreach instruction in BB do
            if instruction.dest = t2 then
                Delete instruction;
        Insert instruction srli t2, 1;
```

To identify and correct the two types of invalid testcases mentioned above, we employed a two-phase detection and modification approach after each round of mutation.

- **Discarding type 1 testcases**: We verify that all basic blocks reachable from the starting BB can also reach the terminating BB, any testcase that fails to meet this criterion will be discarded. Thus the type 1 invalid testcase can be avoided.

- **Modifying type 2 testcases**: After all type 1 testcases are discarded, each rest cycle in generated CFGs contains at least one conditional jump. In order to allow the direction of conditional jumps to change, we implement the following two measures: (I) Inserting instructions to adjust the two source registers according to their current states. For blt, bge, $bltu$ and $bgeu$, if the value of register a exceeds that of register b, we add instructions to reduce the value in register a and increase the value in register b, and vice versa. For bne and beq, since the probability of two 32-bit numbers being equal is extremely low, we implemented a specific approach: one source register is set to special zero register defined in RV32I [22], which always holds the value zero, while the other register is initialized with a non-zero value. Additionally, we insert a logical right shift instruction, consequently, the values in the two registers are always unequal initially, but after a finite number of loops, they will become equal. (II) Ensuring that no other instructions within the loop modify the contents of registers related to the jump. We deleted all instructions modifying any of the two resource registers before we insert the above instructions. The implementation can be found in Algorithm 1. The notations used in it are defined in Table II.

V. Fitness and Coverage-Driven Seed Selection

In this section, we present our implementation of the coverage and fitness functions and how they enhance our fuzz tool's ability to select more effective testcases.

A. Hardware Instrumentation

We collect essential microarchitectural data during the hardware instrumentation phase. The data that is interested is collected based on our study of the branching transient execution. The specific microarchitectural details are listed in Table III. We primarily gather information on BPU access and RoB status, which clearly reveals the behavior of transient execution and distinguishes them from normal program execution.

B. Design of Fitness Function and Coverage

Using the data in Table III, we designed a fitness function to estimate the likelihood of a testcase mutating into one that triggers transient execution. Additionally, we developed a coverage metric to efficiently search for testcases that tend to trigger transient execution from numerous testcase patterns corresponding to complex BPU states.

The formula of the fitness function is as follows:

$$fitness = mispredict_count \times weight + btb_hit_count \quad (1)$$

The fitness function is a weighted sum of the misprediction count in the RoB and the BTB hit count. The misprediction count plays a critical role in triggering transient execution, while the BTB hit count is associated with the attacker's training phase in vulnerabilities like Spectre and its variants. In our testcase selection, greater emphasis is placed on the misprediction count, which is assigned a larger weight.

TABLE III: Hardware instrumentation information summary

uArch Comp.	Instrumentation Output	Description
RoB	mispredict_pc	The program counter of the mispredicted branch instruction.
	mispredict_ins_code	The instruction code of the mispredicted branch instruction.
	mispredict_target_addr	Mispredicted target address.
	mispredict_count	Total count of mispredictions.
BTB	wbtb_clock	Clock count when writing BTB.
	wbtb_bank_sel	Selection of bank when writing BTB, part of BTB index rule.
	wbtb_meta_bank_sel	Selection of bank when writing BTB meta data(tag and type), part of BTB index rule.
	wbtb_way	Selection of way when writing BTB, part of BTB index rule.
	wbtb_set	Selection of set when writing BTB, part of BTB index rule.
	wbtb_branch_offset	Offset of the branch ,i.e.target_pc-current_pc
	wbtb_branch_type	Type of branch instruction, i.e.conditional/unconditional
	wbtb_branch_tag	Tag associated with the branch, i.e. part of PC
	btb_hit_count	Count of BTB hits.
	btb_hit_set	The hit BTB set.
uBTB	ubtb_hit_count	Count of uBTB hits.
	ubtb_hit_tag	Tag in hit uBTB entry.
LOOP	loop_hit_count	Count of LOOP hits.
	loop_hit_set	Set of hit LOOP entry.
TAGE	tage_hit_count	Count of TAGE hits.
	tage_hit_table_idx	Index of hit TAGE table.
	tage_counter_count	Count of TAGE 3-bit counter.

For coverage, since each control flow transfer affects BTB states, we incorporate several branch prediction-related values into our coverage metric, which is shown in Algorithm 2.

In transient execution exploitation, the prediction training and triggering rely on the branch/jump instructions with specific instruction addresses, jump directions and target addresses. These values are stored in BTB and BTB meta table. To analyze these behaviors, we extract the relevant information and hash each corresponding piece of data in the log to generate binary feature values ($t.btb$, $t.btb_meta$). $t.btb$ represents the features of jump directions and target addresses, while $t.btb_meta$ represents the features of instruction addresses. If there is a new feature value, there is a control flow transfer instruction whose address or target address has changed. It may bring new transient execution possibility, reflected in an increase in test coverage.

Based on our fitness function and coverage, we select testcases to enhance defect detection effectiveness. First, we prioritize testcases that generate new coverage. If a testcase

Algorithm 2: Coverage Calculation

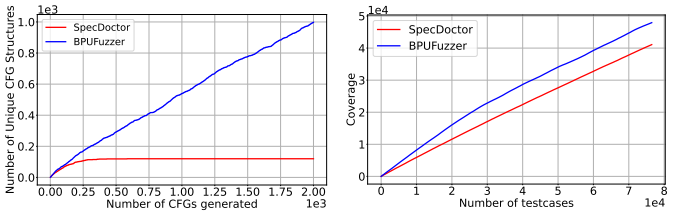
Input : A set of testcase and their logs
Output: whether the testcase is a new coverage

```
cov_list = empty set;
cov_sum = 0;
foreach t in test_case_set do
    t.btb = 0;
    t.btb_meta = 0;
    foreach line in test_case.log do
        btb_info = wbtb_set + wbtb_way +
          wbtb_branch_offset + wbtb_bank_sel;
        meta_info = wbtb_set + wbtb_way +
          wbtb_branch_tag + wbtb_branch_type +
          wbtb_meta_bank_sel;
        t.btb = t.btb xor btb_info;
        t.btb_meta = t.btb_meta xor meta_info;
    if (t.btb,t.btb_meta) not in cov_list then
        cov_list.insert(t.btb,t.btb_meta);
        t.coverage = true;
        cov_sum += 1;
    else
        t.coverage = false;
```

generates new coverage, it is added to the candidate set, while those without new coverage have a 5% probability of being included to prevent local optima. All testcases in the candidate set then undergo a tournament selection based on the fitness to form the next generation of testcases. This approach ensures that testing progressively covers more hardware states and that testcases increasingly tend to produce transient execution. The discovery of a new Spectre variant, called Spectre-Loop (detailed in Section VII), is owed to this methodology.

VI. Evaluation of BPUFuzzer

In this section, we present experiments that demonstrate the advantage of our proposed BPUFuzzer in terms of testcase generation pattern, coverage and vulnerability detection. We compare them with existing state-of-the-art tool, SpecDoctor.



A. Experiment Setup

RISC-V CPU under test. We evaluated BPUFuzzer on the open-source out-of-order RISC-V CPU: Boom V3 [23]. It supports RV64G ISA which includes supervisor level instructions and user level instructions. It contains the out-of-order microarchitectural units including RoB and branch predictors.

Fuzz testing environment. We evaluated BPUFuzzer with a RTL simulator called Chipyard [24]. It is a modified Verilator simulator designed for Boom RISC-V CPU. All the fuzzing experiments are conducted on a machine equipped with an Intel(R) Xeon(R) E5-2670 v3 CPU at 2.30GHz with 64GB of RAM, which runs Ubuntu 22.04 LTS.

B. Testcase Generation Pattern

In section IV, we propose a testcase mutation and validation method designed to cover diverse control flow transfer patterns, corresponding to mutually non-isomorphic control flow graphs [25]. We verify the number of patterns generated and compare it with SpecDoctor.

(a) comparison of testcase pattern with SpecDoctor (b) comparison of test coverage with SpecDoctor

Fig. 4: Comparison with SpecDoctor

In Figure 4(a), we applied a basic block limit of 6 in the testcase generation process for both our tool and SpecDoctor. In SpecDoctor, basic blocks are connected by conditional jump instructions, and each block can only link to subsequent blocks, preventing loop structures. Under these constraints, SpecDoctor can generate only 120 unique testcase patterns, equivalent to 5 factorial. In contrast, our tool produces a greater variety of control flow transfer patterns, including testcases with loops that execute successfully.

C. Coverage

In Section V, we introduced a fitness function and coverage design based on microarchitectural state to guide testcase selection and mutation, and conducted a comparative experiment with SpecDoctor in Figure 4(b). Using the same hardware setup and the same testcase limit of 76,000, we tested on both tools respectively. SpecDoctor generated 34,916 testcases that do not generate new hardware states, which is unprofitable for transient execution detection. BPUFuzzer covered 6,846 more hardware states than SpecDoctor, leading by 16.7% in coverage. We also ran BPUFuzzer with and without coverage feedback under the same hardware setup for 40 hours. With coverage feedback, BPUFuzzer identified an average of 12.89 testcases with transient execution risks per minute, compared to 11.26 testcases per minute without coverage feedback. This represents a 14.5% improvement in transient execution detection efficiency, highlighting the benefits of coverage feedback.

D. Vulnerability Detection

We ran BPUFuzzer and SpecDoctor under the same hardware setup for a week and classified found vulnerability types following previous research [12]. The found vulnerability types comparison is shown in Table IV. BPUFuzzer successfully detected transient execution in micro BTB and LOOP while SpecDoctor do not.

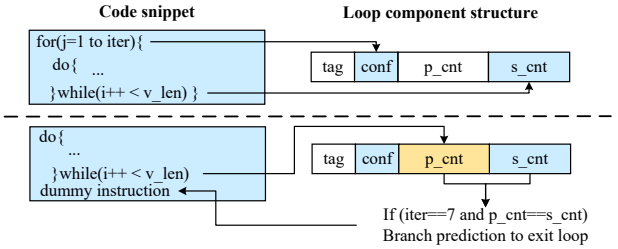
In Boom v3, micro BTB is a prediction unit that stores local target addresses. It utilizes a fully-associative index method and only works when the corresponding BTB entry is empty. Spectre_uBTB needs to train the micro BTB while clearing the BTB entries. It requires the precise coordination of branch instructions in a wider range of instruction addresses than Spectre_BTB. However, the range of instruction addresses is relatively limited in SpecDoctor, makes it incapable of generating this vulnerability type.

TABLE IV: Found vulnerabilities summary and comparison with SpecDoctor

Category	Name	Description	BPUFuzzer	SpecDoctor
Bound Check Bypass	Spectre_BIM_IP	Exploitation of Bi-Modal Table.	✓	✓
	Spectre_uBTB_IP	Exploitation of micro BTB.	✓	×
	Spectre_TAGE_IP	Exploitation of TAGE.	✓	✓
	Spectre_TAGE_OP	Exploitation of TAGE with Table entry collision.	✓	✓
	Spectre_Loop_IP	Exploitation of Loop.	✓	×
	Spectre_Loop_OP	Exploitation of Loop with Table entry collision.	✓	×
Branch Target Injection	Spectre_uBTB_IP	Exploitation of micro BTB.	✓	×
	Spectre_BTB_IP	Exploitation of BTB.	✓	✓

VII. New Finding of BPUFuzzer: Spectre-Loop

During our analyzing on experiment results, we found some vulnerabilities have significantly large btb_hit_count in their fitness value. Through our further analysis, We found that they all have a loop structure. We eventually confirmed that they exploited a loop prediction optimization mechanism in Boom v3 and formed a new Spectre variant, termed Spectre-Loop.



A. Details of Spectre-Loop

Figure 5(a) describes the working mechanism of LOOP, which predicts long loop exit timing of up to 1024. LOOP table has 4 parts: tag derived from the instruction's PC, is used to identify matching entries in the table. $iter$ is a three-bit saturating counter records times the loop is executed as a whole. p_cnt represents the present count of times the loop body has entered the pipeline during loop iteration, and it is updated each time the loop body enters the pipeline. s_cnt records the sum number of iterations after the loop code has fully completed execution. When the loop code runs again, if $iter$ reaches the threshold and p_cnt equals s_cnt, the prediction will indicate a loop exit. In summary, It is a prediction mechanism triggered by a loop code structure, this control flow pattern is not included in the testcase generation implementation of SpecDoctor. Thus SpecDoctor unable to detect transient execution caused by this prediction mechanism.

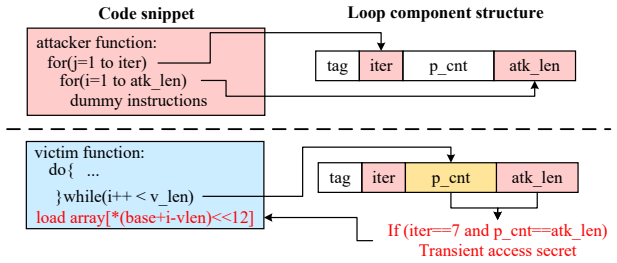


Figure 5(b) demonstrates the attack flow of spectre-loop. First, in the attacker phase, the loop is executed multiple times to train the s_cnt to the value atk_len. Then, in the trigger phase, the loop predict loop exit early after executing atk_len times. During speculative execution, this results in a transient out-of-bounds access on the offset of $atk_len - v_len$ (with $atk_len < v_len$). By controlling atk_len, an attacker can bypass the bound check and transiently access arbitrary locations, enabling access to specific secret data. The attacker can subsequently recover the transiently accessed secret data using a simple flush+reload technique.

B. Analysis of Spectre-Loop

Spectre-Loop successfully retrieved the secret of 1,024 bits with the error rate under 0.01%. Each bit leakage cost 220k clock cycles on the Chipyard simulator. The leakage rate is 4.9 Kb/s assuming a CPU clock rate of 1GHz.

(a) loop prediction optimization mechanism

(b) attack scenario of spectre-loop

Fig. 5: Loop prediction mechanism & Process of Spectre-loop

VIII. Conclusion

In this paper, we propose a pre-silicon fuzz testing tool, BPUFuzzer, to detect transient execution vulnerabilities. We propose a novel modified CFG-based test case generation method that outperforms all existing approaches in generating a broader range of control flow patterns, particularly by incorporating loop patterns that have not been considered in any prior work. Additionally, We develop novel coverage and fitness metrics tailored to the characteristics of transient execution, significantly enhancing the efficiency in detecting transient execution vulnerabilities. Finally, BPUFuzzer finds a newly discovered Spectre variant, termed Spectre-Loop, which exploits a previously overlooked prediction mechanism to perform a Bounds Check Bypass attack.

***Abstract*—Point-based point cloud neural networks (PNNs) have shown remarkable accuracy in various applications. However, the performance of PNNs is usually limited on resource-constrained edge devices. This paper presents Point-CIM, an efficient Compute-in-Memory (CIM) based accelerator for PNNs, with software and hardware co-optimization. A reconfigurable CIM unit, which exploits the inherent zero-bit-skipping capability of CIM array, is designed to efficiently process Multiply-Accumulate (MAC) operations on decomposed feature data with high bit sparsity. A Voxel-Morton-sorted Partitioning (VMP) method combined with Channel-wise Minimum (CM) base point selection is proposed to improve the decomposition bit sparsity further and reduce the hardware implementation overhead. Additionally, a detailed Bit-level Truncation Quantization (BTQ) method is proposed to directly compress the bit-width of the offset without incurring any additional hardware overhead. Based on this decomposition method, a Pre-decomposition (PD) data movement strategy is employed to reduce data transfers of intermediate features between the on-chip buffer and CIM array. Extensive evaluation experiments on multiple datasets show that Point-CIM achieves an average speedup of 1.69× to 9.63×, and 3.11× to 17.32× improvement in energy efficiency, compared to state-of-the-art accelerators and general-purpose processors.**

***Index Terms*—compute-in-memory, accelerator, point neural network, bit truncation**

I. Introduction

3D point cloud data captured by LIDAR sensors or RGB cameras can accurately model the shape and surface characteristics of objects and environments. Unlike 2D pixels, 3D point cloud data is inherently unstructured and contains spatial positioning information, making its data processing and analysis complex and demanding. To address the challenges, Point-based PNNs, like PointNet [1] and PointNet++ [2], have been proposed to learn embedding features from raw points directly.

PointNet++, an extension of PointNet, specializes in capturing local structures and hierarchical features of 3D point clouds. Due to its promising performance, PointNet++ has become the foundational architecture for most Point-based PNNs [3]–[5]. Although Point-based PNNs show excellent accuracy, their heavy computational demands limit their deployment in resource-constrained edge devices. To tackle this problem, various software-hardware co-optimization methods have been proposed to improve the hardware efficiency. Most previous works [6]–[8] mainly focus on optimizing the farthest point sampling (FPS) and neighbor search stages, whereas the feature learning stage, typically executed by multi-layer perceptron (MLP), receives less attention. However, this stage

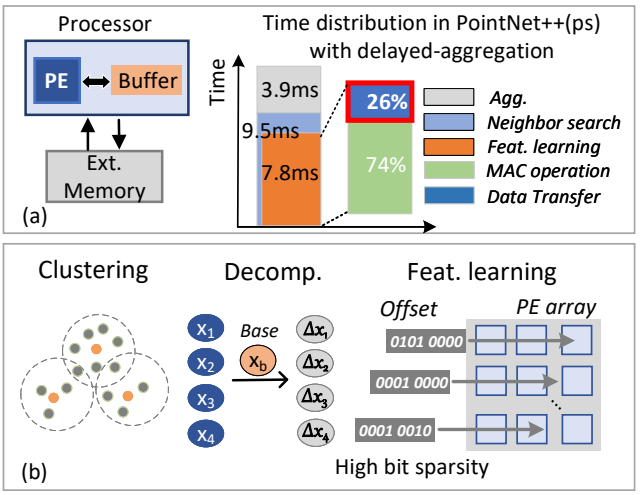

Fig. 1. (a) Time distribution in the point cloud processing task [9]; (b) overview of decomposition-based method.

takes more than half of the computation time of the PointNet++ executed on GPUs (Fig. 1(a)). Recently, several works revealed that the computation efficiency could be improved by exploiting the similarity in the features of points in closer spatial proximity [10]–[12]. As illustrated in Fig. 1(b), this insight allows for the decomposition of feature data into base and offset. The offset contains a higher proportion of zero-value bits and has a more concentrated distribution, enabling a further reduction in redundant computations of offset data. To fully convert this software optimization to real hardware performance improvement, customized processing units are designed to support zero-skipping operations and distribution statistics analysis for dynamic precision quantization on offsets [11], [12]. While previous works focus on the acceleration of MAC operations, the massive data movements also introduce substantial latency during the feature learning stage. As shown in Fig. 1(a), data transfer between the external memory and the processing units accounts for 26% of the processing time during the feature learning stage (tested on Nvidia Jetson TX2 [13]), which limits further improvement in the accelerator throughput.

Compute-in-memory (CIM) has emerged as a promising solution for data-centric applications to reduce the data movements [14]. By integrating the computation units into memory units and employing a weight stationary dataflow for MAC

operations, CIM avoids the data transfer of weight parameters, thus enhancing both the speed and energy efficiency of accelerators. Additionally, as the MAC operations in the CIM array are generally done in a digit-decomposed manner with binary inputs, zero-bits in the inputs are encoded as 0V and thus consume no energy [15]. In other words, CIM inherently supports zero-skipping operations without requiring any extra specialized designs in terms of energy consumption. Consequently, the energy efficiency of CIM-based accelerators is highly sensitive to the bit sparsity of inputs. On the other hand, the latency of the MAC operations are proportional to the bit-width of input data, which is directly affected by the quantization method. Furthermore, although the weight transfers are eliminated, there is still data movement of intermediate features on-chip. The latency and energy consumption caused by it remain significant overheads that cannot be overlooked [16].

To address the aforementioned problems and fully utilize the hardware advantages of CIM, we propose Point-CIM, an efficient CIM-based accelerator for PNNs. Software-hardware co-optimization techniques have been applied to improve the efficiency of Point-CIM. Our key contributions can be summarized as follows:

- We propose a reconfigurable CIM-based processing unit to support MAC operations on decomposed inputs with high bit sparsity. Two different modes are designed to process base and offset calculations, respectively. To further improve the hardware performance, a Pre-decomposition (PD) dataflow is employed to reduce data transfers of intermediate feature results on chip.
- We introduce a Voxel-Morton-sorted Partitioning (VMP) method combined with Channel-wise Minimum (CM) base point selection to ensure positive offset values and maintain high bit sparsity, which benefits the subsequent CIM computing scheme. Additionally, we introduce a detailed Bit-level Truncation Quantization (BTQ) method, designed to directly compress the bit-width of the offset without incurring any additional hardware overhead.
- Evaluated on various datasets, Point-CIM can achieve an average speedup ranging from $1.69\times$ to $9.63\times$, along with $3.11\times$ to $17.32\times$ improvement in energy efficiency, compared to state-of-the-art accelerators and general-purpose processors.

II. Background

A. Point-based Point Cloud Neural Networks

Point-based PNNs typically consist of several Set Abstraction (SA) layers in serial. Each SA layer is composed of FPS, neighbor search, and feature learning stages. Firstly, FPS is applied to select a subset of points that represents the overall structure of the point cloud. Next, the neighbor search groups neighboring points around each sampled point. Finally, MLP layers are performed to extract the local feature within each group during the feature learning stage.

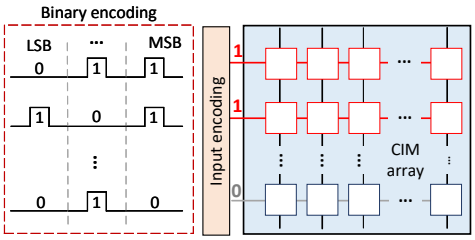

Fig. 2. The binary input encoding process for CIM.

Given an FPS-sampled point x_i and its neighboring group $\mathcal{N}(x_i)$, the final output of each SA layer is determined by

$$y_i = \max_{1 \le j \le J} \sigma(w \cdot (x_i^{(j)} - x_i))$$

where w represents the weights, $x_i^{(j)}$ denotes the j-th neighboring point in $\mathcal{N}(x_i)$, and $\sigma(\cdot)$ is the activation function (e.g. ReLU).

B. Feature Similarity in Close Spatial Proximity

Several previous works [10]–[12] have observed that points located near each other in space tend to share similar geometric features. This property can be leveraged to decompose features into two components: a base and an offset. For points within the same cluster, denoted as $x_c^k \in \mathcal{C}(x_c)$. They share a common base point x_c, with each point can be represented as:

$$x_c^k = x_c + (x_c^k - x_c) = x_c + \Delta x^k$$

where Δx^k represents the offset value of each point in this cluster. After this decomposition, the convolutional operation can be transformed into:

$$w \cdot x_c^k = w \cdot x_c + w \cdot \Delta x^k$$

which offers three advantages in theory. Firstly, since all points within the same cluster share a common base, the convolutional result of the base point $w \cdot x_c$ can be reused for all points of this cluster. Secondly, points that are close in space often show strong feature similarity, meaning that the offset Δx^k tends to have a more concentrated distribution. This allows Δx^k to be quantized with lower precision. Thirdly, the effective bits of each value are reduced greatly, which enables reduce redundant computations by skipping unnecessary zero-bit calculations.

C. CIM-based CNN accelerator

To tackle the memory wall bottleneck, researchers have introduced the in-memory computing paradigm, where computations are conducted directly within the memory array [17]–[19]. In CIM, the weight parameters are mapped into the crossbar memory array. As illustrated in Fig. 2, to perform MAC operations, the input vector is usually encoded into a binary sequence, with positive numbers represented in their original form and negative numbers in two's complement. Zero volts and power supply voltages are used to represent

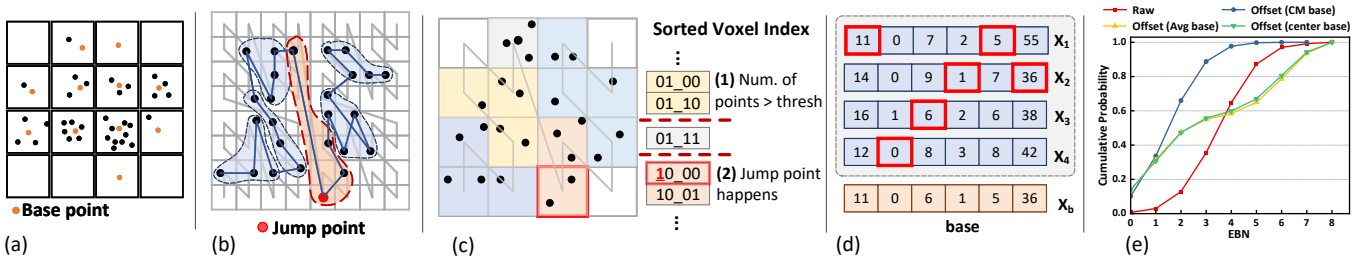

Fig. 3. (a) Uniform voxel partition method; (b) morton-sorted partition method; (c) Voxel-Morton-sorted Partition method (take a 2D space with Morton encoding using 2 MSBs as an example); (d) Channel-wise Minimum base point selection; (e) CDF of EBN for raw data and offsets in SA1 of PointNet++(m) with different base types.

logic "0" and "1", respectively. The "0" input bits, in terms of 0V, do not contribute any current, consuming no energy cost. Accordingly, the CIM paradigm can naturally support skip zero bits of the input and the energy efficiency of the CIM-based accelerators is significantly affected by the bit sparsity of input series.

III. Methodology

This section discusses the software-hardware co-design techniques adopted for Point-CIM. In this section, all models' weights and activations are originally quantized to 8 bits. Additionally, two definitions need to be clarified:

- Effective Bit Number (EBN): This refers to the number of bits equal to "1" in a fixed-point value, representing the sparsity of the value at the bit level. Lower EBN means higher bit-level sparsity.
- Effective Bit Length (EBL): This refers to the valid bit length of a fixed-point value from the highest non-zero bit to the least significant bit (LSB).

As an example, for an 8-bit fixed-point number $00101010_{(2)}$, the EBN is 3, and the EBL is 6.

A. Partitioning Method and Base Point selection

Before decomposing the features, it is necessary to partition the 3D space into clusters of spatially proximate points. GDPCA [11] partitions the 3D space into uniformly distributed, fixed-size voxels. However, the number of points within each voxel may vary greatly, leading to significant workload imbalances, as shown in Fig. 3(a). To balance the size of the clusters, MoC [12] utilizes Morton code to encode and sort the coordinates of all points. All points are partitioned into uniform regions with fixed intervals. However, as shown in Fig. 3(b), the jump points usually reflect huge changes in spatial location, which will be clustered into wrong groups with uniform partitions. Additionally, for tasks with large input sizes, the significant number of points poses challenges for sorting circuits. For example, in the S3DIS dataset [20], each input contains 4096 points. To balance the computing efficiency and accuracy performance, a Voxel-Morton-sorted Partitioning (VMP) method is proposed in this work.

Voxel-Morton-sorted Partitioning (VMP) method. As shown in Fig. 3(c). Instead of encoding the full precision

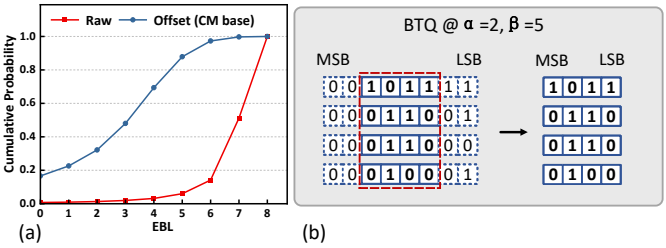

Fig. 4. (a) CDF of EBL for raw data and offsets in SA1 of PointNet++(m); (b) Bit-level Truncation Quantization method (Take $\alpha = 2$ and $\beta = 5$ for example).

of coordinates, we only encode the first 3 MSBs of each coordinate with Morton code (e.g. [101xxx, 001xxx, 010xxx] is encoded as 001_100_011). In this way, the 3D space with xyz dimension will be partitioned into uniform 512 ($8 \times 8 \times 8$) voxels with index encoded with 9 bits. Consequently, we only need to sort 512 blocks, rather than all points. The partitioning is conducted based on two principles: (1) the total number of each partition's points exceeds the workload threshold; (2) an index jump occurs. In our setting, the workload threshold is defined as the ratio of the number of points to the number of partitions. The jump point is identified when the 3rd MSB of the voxel index flips, indicating a location jump in space. As a result, points from different voxels around jump point will not be encoded to the same partition. Inside each voxel, the points are grouped by storage ordering with loose locality constraints.

Channel-wise Minimum (CM) Base Point. The base point of the decomposition can be decided in different ways. GDPCA [11] takes the point nearest to the center of each voxel (Center base), while MoC [12] takes the average of features in each group (Avg base). The former suffers from the overhead of distance calculation, while the latter may lead to nearly symmetric offsets around zero. For performing CIM operations, the inputs are encoded in 2's complement format. Thus, near-zero negative values for offsets (e.g. -1, -2) in this format contain lots of "1" bits (yellow line in Fig. 3(e)), rapidly reducing the bit sparsity of offset data and increasing the energy cost of in-memory computing. To address this issue, the base point is defined as a vector of channel-wise minimum feature values across different data points within the same partition, ensuring that all offsets are positive (Fig.

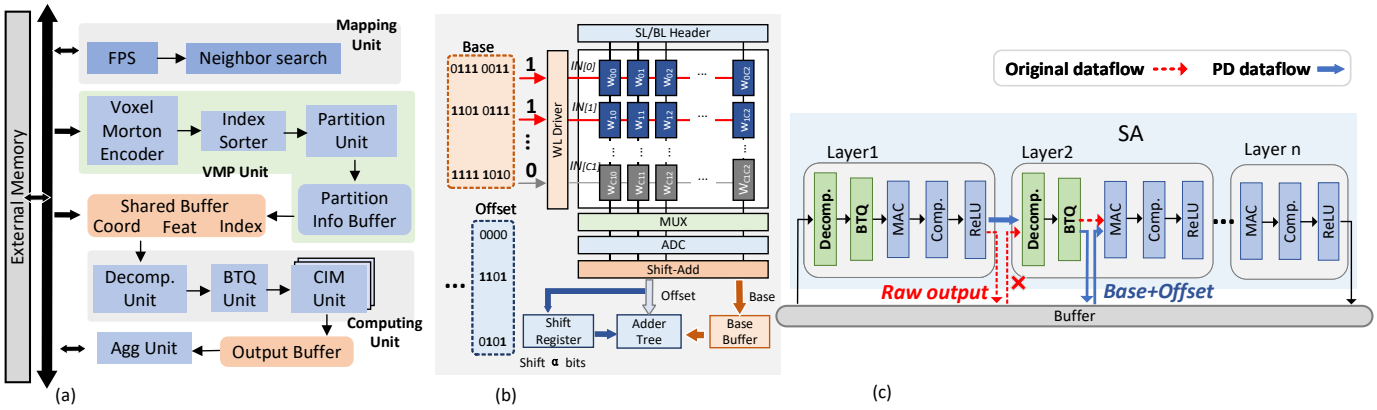

Fig. 5. (a) Architecture Overview; (b) hardware design for CIM computing unit; (c) Pre-decomposition dataflow

3(d)). Since all vectors within one partition exhibit strong similarity in value distributions along the channel axis, there is no need to worry about the base point being a zero vector. The performance of the proposed partitioning and base point selection methods are evaluated by analyzing the Cumulative Distribution Function (CDF) of EBN for bases and offsets in Fig. 3(e). It can be observed that the offsets using CM base point exhibit much higher bit sparsity, compared to raw data, as well as the offsets using the Avg and Center base, which will improve the energy efficiency of CIM computing unit.

B. Bit-level Truncation Quantization

While EBN impacts the energy efficiency of CIM operations, EBL decides the total computing cycles. As shown in Fig. 4(a), the EBL of raw data primarily ranges from 7 to 8 bits (red line) for SA1, which means 7 to 8 computing cycles are needed for bit-serial inputs. On the other hand, the EBL of offset data is considerably less, typically ranging from 4 to 6 bits. Based on this observation and DNN's tolerance for small noise, we introduce the Bit-level Truncation Quantization (BTQ). We truncate the high and low redundant bits of the input data in a real-time fashion. As shown in Fig. 4(b), for a complete 8-bit input offset from decomposition, we only keep the $\alpha_{th} \sim \beta_{th}$ bits for further computation, where α and β are configurable by the CIM macro.

IV. Hardware Design

A. Architecture Overview

As shown in Fig. 5(a), Point-CIM mainly consists of five parts: Mapping Unit, Voxel-Morton Partitioning (VMP) Unit, Shared Input Buffer, Computing Unit, and Aggregation (Agg) Unit. The Mapping Unit supports the FPS and Neighbor search operations for selecting centroid points and finding neighboring points, respectively. In the VMP unit, the Voxel-Morton Encoder interleaves only the 3 MSBs of binary representations of the three coordinates values for each point, dividing the whole space into $8 \times 8 \times 8$ voxels. The Index Sorter will sort all voxel indexes. Then, the Partition Unit will gather voxels according to two principles to generate final partitions. The shared buffer stores the index info, feature data, 3D coordinates, as well as morton-encoded indices. The main computations of feature learning are performed at the Computing Unit, which contains CIM macros for MAC operations and specific digital units for decomposition and BTQ. A global Agg Unit is employed to generate the final output from neighboring information and all points' features. The dataflow for feature learning on-chip will be discussed later.

B. Reconfigurable CIM Computing Units

The CIM macro (Fig. 5(b)) of Point-CIM can operate in two modes: Base Mode and Offset Mode. In the base mode, high-precision inputs are fed to CIM macro to generate the base partial sums. These partial sums are sent to the base buffer for temporary storage. In the offset mode, the offset inputs with a shorter bit-width are applied to the same CIM macro, allowing them to be processed with fewer computing cycles. The precision of inputs is configured by controlling the number of cycles for CIM operation. The shift-add units inside the CIM macro are designed to support the input bit-width of the base. Due to the BTQ, the scales of base and inputs are different for the same cycles. Thus, to recover the MAC results between the weights and original inputs, the offset partial sums need to be aligned with the base partial sums. This is done by a configurable shift register, where the base partial sums are shifted right by α bits (if the $\alpha - 1$ LSBs were truncated). The adder tree then combines the data from the base buffer and the shift register to produce the final output.

In our design, the CIM array is based on SRAM and is organized by tiles. Each tile has a memory size of 1024 × 1024, with each memory cell storing a single bit data. Each tile is further divided into PEs with size of 2×2, and each PE is subdivided into subarrays with size of 4×4. Each subarray has a memory size of 128×128 and is capable of conducting basic MAC operations. The 6-bit SAR-ADC is employed at array level.

C. Pre-decomposition Dataflow

For the layer-by-layer operations of the feature learning stage, the intermediate features generated after the activation

function are sent back to the on-chip buffer for temporary storage. As the chip size scales up, this data movement could lead to significant hardware overhead. To mitigate this, we propose a Pre-decomposition (PD) Dataflow, which shifts the decomposition and BTQ operation from the input of a certain layer to the output of the previous layer. As shown in Fig. 5(c), the network for feature learning consists of multiple layers of perceptrons, with the last layer followed by aggregation and max-pooling operations. In the original dataflow, the decomposition and BTQ are applied on the inputs of each layer and then fed into the MAC units for further processing. The raw outputs of each layer are sent back to the buffer for temporal storage and used as the inputs of the next layer later. In this dataflow, the raw data transmitted are in full precision. In the PD dataflow, the intermediate data between perceptron layers inside the same block are decomposed and BTQed before being sent back to the buffer. In this way, the bases are transferred in full precision and offsets in reduced precision, enabling reducing total transmitted bits. Consequently, the overhead in data transfer between buffer and CIM array can be mitigated significantly. For the last layer in the SA, as the raw data has to be applied to the Agg unit and Maxpool unit, the decomposition and BTQ for the next layer could not be applied in advance.

V. Evaluation

A. Experimental Setup

Algorithmic Setup. To evaluate our design, we select the representative Point-based model, PointNet++, and assess its performance across three datasets, as shown in Table I. All models are implemented using PyTorch and trained to reach state-of-the-art performance. Subsequently, the models were retrained using the delayed-aggregation method [9]. Finally, all models were quantized to 8-bit weights and 8-bit activations. The accuracy performance of all models is compared in Table II.

Hardware Setup. For the feature learning stage, the hardware performance for MLP-related computations is evaluated using the Neurosim framework [16], [21]. NeuroSim is an open-source simulator that can build the CIM architecture with traced inputs from real networks to evaluate the overall hardware performance. Other components, such as the Mapping Unit and Agg Unit, are directly adopted from GDPCA [11].

Baseline. To evaluate the accuracy impact and hardware performance improvement of Point-CIM, we choose the 8-bit quantized model as the accuracy baseline. Additionally, we adopt three types of platforms as hardware baselines, including CPU (Intel Xeon Gold 6226R), GPU (Tesla A100), and state-of-the-art ASICs (Mesorasi [9], PointAcc [22], GDPCA [11]).

B. Parameters Setting

The hardware design parameters are presented in Table III. Point-CIM is compared with several prior customized accelerators, which are all based on 40 nm technology node and operate at a frequency of 1 GHz. Point-CIM is implemented

TABLE I
EVALUATION BENCHMARKS

Application	Dataset	Model	Notation
Classification	ModelNet40 [23]	PointNet++ (SSG)	PointNet++(m)
Part Segmentation	ShapeNet [24]		PointNet++(ps)

TABLE II
Model Accuracy (%)

Dataset	Original Model	Delayed-Aggregation	w:8,a:8
ModelNet40	92.2	91.3	91.3
ShapeNet	85.2	84.6	84.4
S3DIS	54.3	54.6	53.7

*w:8 and a:8 mean the weight and activation are quantized with 8-bit precision.

TABLE III
Hardware Configurations

Chip	Mesorasi [9]	PointAcc [22]	GDPCA [11]	Point-CIM
Tech(nm)	40	40	40	45
Frequency(MHz)	1000	1000	1000	1000
Buffer(KB)	2048	776	2560	2048
Bandwidth (GB/s)	HBM	HBM	HBM	HBM
MACs	64×64 Systolic Array	64×64 Systolic Array	64×64 BSP Array	SRAM:4.4MB CIM Array

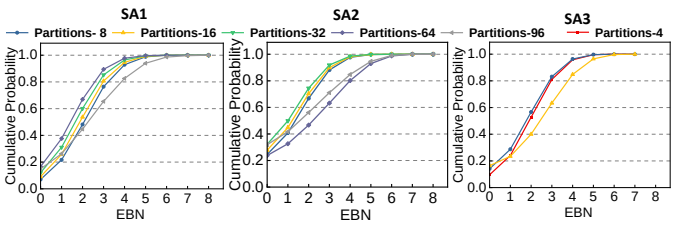

Fig. 6. CDF of EBN for offsets in SA1, SA2, and SA3 of PointNet++(m).

with 45 nm technode and operates at 1 GHz. Mesorasi and PointAcc utilize 64×64 systolic array MACs, while GDPCA introduces 64x64 BSP array MACs. Point-CIM employs an SRAM-based CIM architecture. The computational capability of the CIM architecture is evaluated based on the capacity of the SRAM, which should be able to store all weight parameters of models. In our experiment, we configured the CIM-SRAM with a capacity of 4.4 MB. All architectures utilize HBM memory with a bandwidth of 256 GB/s.

The number of partitions is a critical parameter that needs to be specified before experiments. In this section, we present the parameter setting for PointNet++(m) as an example. The same analytical process can be applied to other benchmarks to determine the optimal number of partitions. As shown in Fig. 6, when the number of partitions for SA1 is set to 64, EBN achieves the sparsest distribution. The optimal number of partitions for SA2 is 32; while for SA3, it is 8. These parameter settings align with the characteristics of PointNet++. As the depth increases, the number of points in each layer decreases, requiring fewe rpartitions.

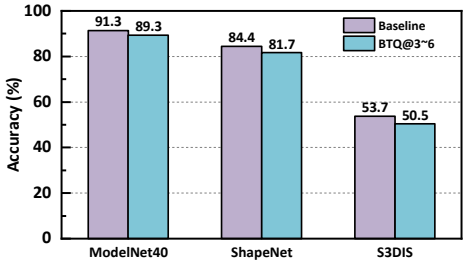

Fig. 7. The accuracy comparison between baseline models and models quantized with BTQ.

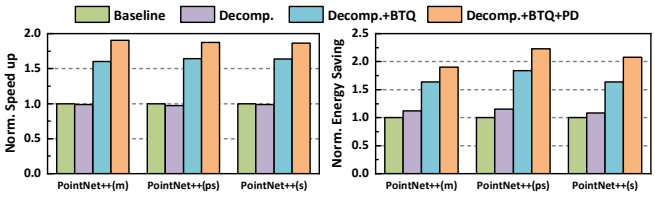

Fig. 8. The speedup and energy savings achieved by BTQ and PD dataflow are compared to the baseline model.

The configurable parameters α and β are set to be 3 and 6 according to case study, which means the 3rd to 6th bits of offsets are reserved for CIM operations.

C. Accuracy Analysis

To analyze the the impact of BTQ on inference accuracy of models, we compare the the accuracy between models quantized with BTQ and the baseline across three different datasets. As shown in Fig. 7, after BTQ, the accuracies decrease by 2.0%, 2.7%, and 3.2% across three datasets, respectively. The decreases in accuracy are within an acceptable range for our experiments.

D. Hardware Performance Analysis

Fig. 8 compares the speedup and energy savings in feature learning stage optimized with BTQ and PD dataflow against the baseline across three different models. After decomposition, Point-CIM achieves increases in energy efficiency by $1.12\times$, $1.15\times$, and $1.08\times$, respectively. This indicates that the offset values show much higher bit sparsity after decomposition and the CIM-based computing unit can handle inputs with high bit sparsity with higher energy efficiency. Furthermore, after applying BTQ, Point-CIM achieves improvements in energy efficiency by $1.64\times$, $1.84\times$, and $1.64\times$, respectively. Meanwhile, Point-CIM demonstrates speed-up enhancement of $1.61\times$, $1.64\times$, and $1.64\times$, respectively. At last, when both BTQ and PD dataflow are applied, energy savings increase by factors of $1.90\times$, $2.23\times$, and $2.07\times$, while speed-up is improved by $1.91\times$, $1.87\times$, and $1.86\times$, respectively. It suggests the effectiveness of PD dataflow in mitigating the transfer overhead of intermediate features.

Fig. 9 provides a comparative analysis of the normalized speedup and energy efficiency of Point-CIM relative to other hardware baseline on PointNet++(m). Specifically, Point-CIM

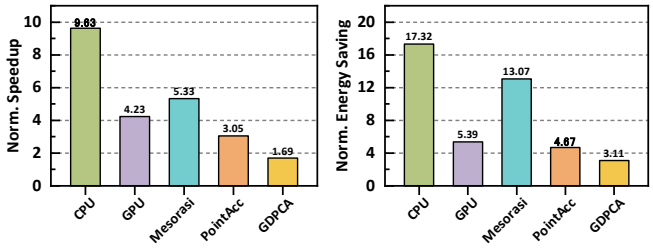

Fig. 9. The speedup and energy saving of Point-CIM over other platforms

achieves an average speedup of $9.63\times$, $4.23\times$, $5.33\times$, $3.05\times$, and $1.69\times$ over CPU, GPU, Mesorasi, PointAcc, and GDPCA, respectively. Moreover, Point-CIM shows notable improvements in energy efficiency, offering $17.32\times$, $5.39\times$, $13.07\times$, $4.67\times$, and $3.11\times$ higher energy savings compared to other platforms. These results highlight Point-CIM's superior performance in both computational speed and energy efficiency when compared to other hardware platforms.

VI. Conclusion

This paper presents Point-CIM, an efficient CIM-based accelerator for PNNs, with software and hardware co-optimization. A reconfigurable CIM unit is designed to efficiently process MAC operations on decomposed feature data with high bit sparsity. A novel VMP method combined with base point selection method is proposed to further improve the offset bit sparsity and reduce the hardware overhead. Additionally, a BTQ method is proposed to directly compress the bit-width of the offset without incurring any additional hardware overhead. To reduce data transfers of intermediate features between the on-chip buffer and CIM array, a PD data movement strategy is employed to optimize dataflow. Extensive experiments show that Point-CIM achieves an average speedup of $1.69\times$ to $9.63\times$, and $3.11\times$ to $17.32\times$ improvement in energy efficiency, compared to state-of-the-art accelerators and general-purpose processors.

HIVE: A High-Priority Victim Cache for Accelerating GPU Memory Accesses

Yuhan Tang, Jianmin Zhang*, Sheng Ma*, Tiejun Li*, Hanqing Li, Shengbai Luo, Jixuan Tang, Lizhou Wu
National University of Defense Technology, Changsha, China
{jmzhang, masheng, tjli}@nudt.edu.cn

***Abstract*—The victim cache was originally designed as a secondary cache to handle misses in the L1 data (L1D) cache in CPUs. However, this design is often sub-optimal for GPUs. Accessing the high-latency L1D cache and its victim cache can lead to significant latency overhead, severely degrading the performance of certain applications. We introduce *HIVE*, a high-priority victim cache designed to accelerate GPU memory accesses. HIVE handles memory requests first, before they reach the L1D cache. Our experimental results show that HIVE achieves an average performance improvement of 77.1% and 21.7% compared to the baseline and the state-of-the-art architecture, respectively.**

I. Introduction

Due to their powerful computing capacity and high energy efficiency, Graphics Processing Units (GPUs) are widely used in various applications, such as high-performance computing, machine learning and embedded systems. GPUs accelerate these applications by concurrently executing many warps, each consisting of a group of threads that execute the same instructions. For example, NVIDIA GPUs have supported up to 64 concurrent warps (2048 concurrent threads) within a single core since the Kepler architecture [1].

Unfortunately, a large number of warps can lead to severe performance degradation when GPUs execute memory-intensive applications [2]–[5]. One important reason for the performance degradation in these applications is that multiple warps sharing limited cache resources can cause severe cache contention [6], [7]. Although recent GPU architectures have larger L1D caches than previous generations, a single thread typically can access only tens of bytes in the L1D cache [8], [9].

Previous works have proposed using a victim cache to alleviate cache contention and achieve significant performance improvements in GPUs [7], [10]. In their designs, the function of the victim cache remains the same as in CPUs, acting as a secondary cache when a miss occurs in the L1D cache. However, we find that these designs are often sub-optimal for GPUs. This is due to two main reasons.

On the one hand, the L1D cache in GPUs exhibits higher miss rates, while evicted lines from the L1D cache have a high probability of being reused. This means that the number of memory requests that hit in the victim cache can approach or even exceed the number of requests that hit in the L1D cache. For example, we observe an average L1D cache miss rate of 63.7% in our evaluated GPU applications, and Oh et al. [7] also observe similar results. We also observe that most evaluated GPU applications exhibit a high probability (an average of 69.6%) of reusing evicted L1D cache lines (see Section II-B for more details). Therefore, the victim cache does not need to act as a supplement to the L1D cache.

On the other hand, GPUs use a unified architecture for the L1D cache and shared memory, or the L1D cache and texture cache, to save hardware overhead [1], [8], [9], [11]. However, this hardware architecture significantly increases the L1D hit latency. For example, the L1D hit latency is 32 cycles in the TU104 GPU and 82 cycles in the GP100 GPU [12]. We observe that some applications are susceptible to the cache access latency, and increasing cache latency can severely degrade performance (see Section II-C for more details). However, the conventional victim cache is a secondary cache for the L1D cache. This means that the victim cache has an even higher hit latency, which severely degrades the performance of latency-sensitive applications.

To this end, we propose ***HIVE***, a high-priority victim cache for accelerating GPU memory accesses. The key idea of HIVE is to prioritize using the victim cache rather than the L1D cache to handle memory requests, which means that the victim cache does not act as a supplement to the L1D cache. Doing so can improve performance because HIVE enables most memory requests to be fulfilled in the victim cache.

To implement HIVE, we insert an extra stage into the baseline pipeline, dedicated to handling memory accesses to the victim cache. This stage involves two hardware structures: the access controller and the victim cache tag array. The access controller is composed of set indexing logic and memory request queues: (1) the set indexing logic is responsible for calculating the victim cache set number based on the memory request address, and (2) the request queues buffer requests to access the victim cache, thereby avoiding the blocking of running warps from generating memory requests due to the limited number of requests that the tag array can handle simultaneously. The victim cache tag array is a traditional set-associative structure that stores tag information associated with the data array. To save hardware overhead, we use the method from the state-of-the-art architecture, Linebacker [7], reusing idle register files as the victim cache data array.

To improve the effectiveness of HIVE, we explore two optimization techniques on top of our basic design. First, we increase the effective capacity of the victim cache by employing a low-latency data compression technique. We find that a slight increase in hit latency in the high-priority victim cache due to data compression has almost no impact on performance. Second, We design a new replacement policy for the victim cache based on the LRU (Least Recently Used) algorithm, which minimizes the number of valid cache lines evicted.

To evaluate the effectiveness of HIVE, we measure the performance of various applications from different benchmark suites using the PTX mode in the AccelSim simulator [13]. Our experimental results show that HIVE achieves an average of 77.1% and 21.7% performance improvement compared to the baseline and the state-of-the-art architectures, respectively, with maximum improvements of 240.0% and 86.5%. As a trade-off, HIVE consumes 9.4% more power on average compared to the state-of-the-art architecture. However, HIVE can save an average of 17.4% in power consumption compared to the baseline architecture.

We make the following contributions:

- We propose HIVE, the first high-priority victim cache for accelerating GPU memory accesses. HIVE handles memory

*Corresponding authors.

requests first, before they reach the L1D cache. We have open-sourced our design code[1].

- We introduce two optimizations for HIVE: (1) increasing the effective capacity of the victim cache by using a low-latency data compression technique; (2) designing a cache replacement policy to minimize the number of valid cache lines evicted.
- We evaluate HIVE and show that it significantly improves performance and power efficiency, effectively outperforming the state-of-the-art across different GPU architectures.

II. BACKGROUND AND MOTIVATION

A. Baseline GPU Architecture

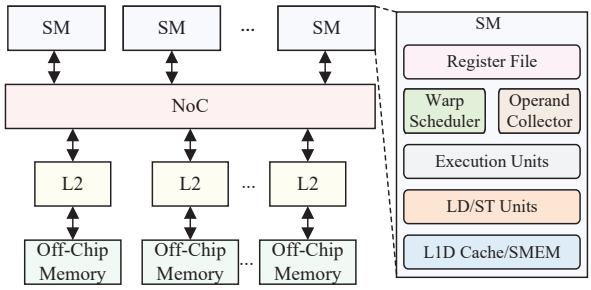

Fig. 1. Baseline GPU high-level organization.

GPU programming models allow the creation of thousands of threads that each execute the same code. NVIDIA's programming model groups threads into 32-element vectors called warps to improve efficiency. The threads in each warp execute in a SIMT (single instruction, multiple thread) fashion. In most programs, many warps map to a single GPU core, or streaming multiprocessor (SM) in NVIDIA's terminology [14].

Fig. 1 illustrates the high-level architecture of a baseline GPU. A GPU is composed of multiple SMs, in terms of the memory hierarchy, each of which contains a private register file, and a private, dynamically partitioned L1D cache and shared memory.

GPUs have very large register files to support a larger number of threads. Each active warp stores its architectural context in its own dedicated register file space. For example, NVIDIA GPUs have 256 kilobytes (KB) of register files per core across multiple generations [1], [8], [9], [11], [15]. However, this large register file is often underutilized [5], [7].

The L1D cache and shared memory (SMEM) share a unified on-chip memory space. The programmer specifies the capacity of software-managed shared memory, and the rest of the unified on-chip memory space is dedicated to the L1D cache, automatically [16]. Although recent GPU architectures have larger L1D caches than previous generations, a single thread typically can access only tens of bytes in the L1D cache [8], [9].

The GPU core accesses the memory-side shared L2 cache via the NoC in the case of an L1D cache miss. The L2 cache connects to off-chip memory, which is either HBM or GDDR [4]. Memory requests are expected to hit in the L1D cache to avoid the much longer latency of the L2 cache or off-chip memory accesses.

B. Capturing Lost Locality with Victim Cache

GPUs frequently evict cache lines that will be reused due to severe cache contention. To quantify the benefits of using a victim cache, we measure the L1D miss rates and the probability of evicted cache lines from the L1D cache being reused in various applications (details of simulations and applications can be found in Section IV).

[1]https://github.com/paper-account1/HIVE

Table I. The L1D miss rates (*Miss.*) and the probability (*Prob.*) of evicted cache lines being reused.

App.	Miss.(%)	Prob.(%)	App.	Miss.(%)	Prob.(%)
KM	99.7	75.3	FW	48.8	72.2
GM	6.3	54.1	MV	91.7	70.6
GMV	79.1	85.2	BC	8.6	77.6
BG	79.2	67.8	SN	63.2	69.4
MVT	79.1	64.4	BFS	80.9	59.3

Table I shows our results. We make two key observations. First, all evaluated applications exhibit a high probability (54.1% - 85.2%) of reusing evicted cache lines, indicating that a victim cache can be effectively used to capture lost data locality. Second, the L1D cache of most applications exhibits high miss rates (48.8% - 99.7%), except for GM and BC, indicating that most memory requests cannot be fulfilled in the L1D cache. We conclude that if a victim cache is used, the number of memory requests that hit in the victim cache can approach or even exceed the number of requests that hit in the L1D cache for most applications.

C. Motivation for a High-Priority Victim Cache

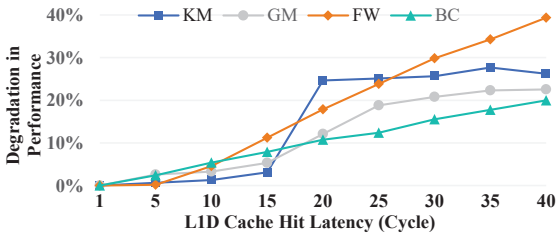

Fig. 2. Sensitivity of latency-sensitive applications to the L1D cache hit latency.

The increase in cache hit latency can significantly hurt the performance of some applications. We find that four out of ten evaluated applications experience a performance drop of over 20% when the L1D hit latency increases from 1 cycle to 40 cycles. We define these applications as latency-sensitive applications. Fig. 2 shows the sensitivity of latency-sensitive applications to the L1D cache hit latency. When the L1D cache latency increases to 40 cycles, the average performance drop of latency-sensitive applications is 27.0%.

The conventional victim cache was a secondary cache when a miss occurs in the L1D cache, which means that the hit latency of the victim cache includes the hit latency of the L1D cache. Even if memory requests hit in the victim cache, this latency overhead can severely degrade the performance of latency-sensitive applications.

Based on the above observations, it is natural to prioritize using a victim cache that does not act as a secondary cache to the L1D cache to handle memory requests. We refer to this victim cache as a high-priority victim cache. By doing so, most memory requests can be fulfilled in the victim cache, thereby accelerating overall memory accesses in GPUs.

III. DESIGN

In this section, we introduce HIVE, a high-priority victim cache designed to accelerate GPU memory accesses. HIVE handles memory requests first, before they reach the L1D cache.

A. Overall Architecture of HIVE

Fig. 3 outlines the key structures of the HIVE design. The gray parts indicate the baseline architecture, and the rest indicates the additional or modified parts required to support HIVE.

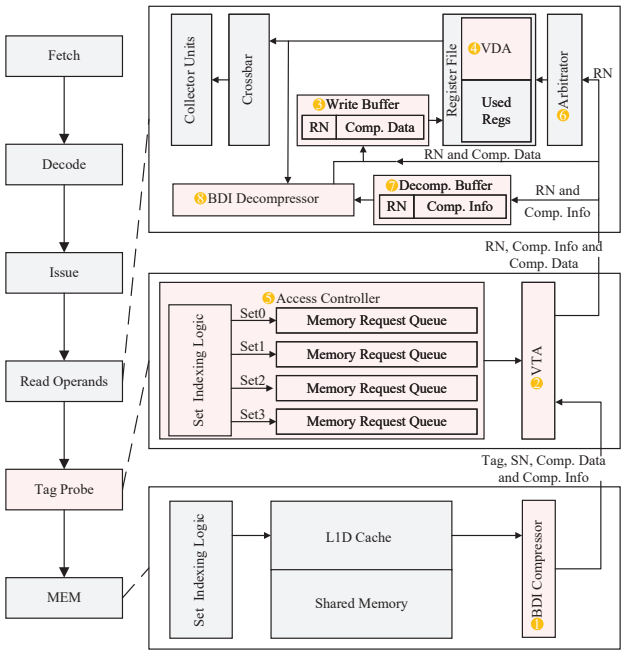

Fig. 3. Overall architecture of HIVE (*Comp. Info*: Compression Information, *Comp. Data*: Compressed Line, *RN*: Register Number, *SN*: Set Number).

To implement HIVE, we insert an extra stage, called the tag probe, into the baseline five-stage memory pipeline before the mem stage, dedicated to handling memory accesses to the victim cache. Compared to the baseline architecture, memory requests are generated in the tag probe stage, rather than in the mem stage, and these requests first arrive at the victim cache rather than the L1D cache.

The tag probe stage involves two hardware components: the Access Controller (❺) and the Victim Tag Array (VTA) (❷). Memory requests accessing the VTA first arrive at the access controller, where the set indexing logic calculates the set number based on the memory request address and then forwards the request to the corresponding memory request queue associated with the set number. A given request is dequeued as soon as the request's VTA set is ready to serve a new request. The VTA is a traditional set-associative structure that stores tag information associated with the data array. To save hardware overhead, HIVE uses the method from the state-of-the-art architecture, Linebacker [7], reusing idle register files as the victim cache data array (VDA) (❹). A warp register is 128 bytes, which is equal to the size of a physical cache line.

To improve the effectiveness of HIVE, we explore two optimization techniques: (1) cache lines evicted from the L1D cache are first compressed using the Base-Delta-Immediate (BDI) [17] Compressor (❶) and then stored in the victim cache, thus increasing the effective capacity of the victim cache; (2) we design a new replacement policy for the VTA based on the LRU algorithm, which minimizes the number of valid cache lines evicted.

B. Details of HIVE Implementation

BDI Compressor and Decompressor. HIVE exploits the BDI data compression technique [17] to increase the effective capacity of the victim cache. This is possible because a low-latency victim cache accelerates most memory accesses and leaves a "latency margin". As shown in Fig. 2, we observe that all latency-sensitive applications exhibit slight performance drops (up to 5.91%) when the increase in the hit latency is within 10 cycles, and only show significant performance drops when the hit latency exceeds 15 cycles. Therefore, we exploit a low-latency, high-compression-rate BDI algorithm from various compression algorithms to utilize this latency margin and increase the effective capacity of the victim cache.

The key idea of the BDI compression is that, for many cache lines, the values within a cache line have a low dynamic range - i.e., the differences between values stored within a cache line are small. The BDI compression algorithm chooses an 8-, 4-, or 2-byte *base*, divides the cache line into blocks of size equal to *base*, and represents each block as a *delta* (Δ) which is the difference of the value of the block from the *base* [18]. The compression logic consists of eight distinct compressor units: six units for different base sizes (8, 4 and 2 bytes) and Δ sizes (4, 2 and 1 bytes), and two units for zero and repeated value compression. Every compressor unit takes a 128-byte cache line as an input, and outputs whether or not this cache line can be compressed with this unit. If it can be, the unit outputs the compressed cache line. If multiple compression options are available for the cache line (e.g., 8-byte base 1-byte Δ and zero compression), the selection logic chooses the one with the smallest compressed cache line size. Note that all potential compressed sizes are known statically and described in Table II. All compressor units can operate in parallel.

Table II. BDI compression encoding. All sizes are in bytes.

Name	Base	Δ	Size	Enc.	Name	Base	Δ	Size	Enc.
Zeros	1	0	1	0000	Rep.Values	8	0	8	0001
Base8-Δ1	8	1	24	0010	Base8-Δ2	8	2	40	0011
Base8-Δ4	8	4	72	0100	Base4-Δ1	4	1	36	0101
Base4-Δ2	4	2	68	0110	Base2-Δ1	2	1	66	0111
NoCompr.	N/A	N/A	128	1111					

Based on prior works [18], [19], we model a 2-cycle compression latency and a 2-cycle decompression latency, with 0.192 nJ compressor access energy and 0.056 nJ decompressor access energy for BDI. For simplicity, we allow a warp register to store at most two compressed cache lines. Each compressed cache line requires 4 bits to store compression encoding and 6 bits to store the start segment, amounting to 10 bits of compression information.

VTA. The VTA is a classic set associative array with the same number of sets as the L1D cache. Each entry of the VTA maps one-to-one to a 128-byte warp register of the VDA. The baseline architecture has 2048 warp registers in total. If a tag hits in an entry at set A and way B, the warp register number (RN) associated with the compressed cache line is calculated as follows:

$$RN = OFFSET + A \times (\#WAYS) + B \quad (1)$$

OFFSET in the above equation is the value that is manually set. In this paper, we set OFFSET to 1024, allowing a maximum of 1024 idle warp registers to be reused as the VDA (i.e., RN 1024-2048). The VTA also includes a simple logic that calculates RN as shown in Equation 1.

Fig. 4 shows the entry layout in the VTA. Each entry contains two sub-entries because we allow each warp register to store at most two compressed cache lines. Each sub-entry consists of fields including the current request's tag, compression info (indicating how to decompress the compressed cache line), a valid bit (indicating if

the compressed cache line is valid), and LRU bits. Additionally, each entry has an active bit, which is set if the corresponding warp register is idle (determined at compile time).

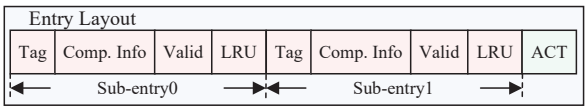

Fig. 4. VTA entry layout (*Comp. Info*: Compression Information, *ACT*: Active Bit).

We model the VTA using CACTI 6.5 [20] with a 22nm process. We observe that for a 256-way set-associative tag array with 4 sets, 1.877 ns (3 cycles) access latency and 0.041 nJ access energy are necessary for the configurations listed in Table III.

Replacement Policy. To reduce the number of valid compressed lines evicted from the victim cache, the VTA exploits a new cache replacement policy for the victim cache, as shown in Algorithm 1.

In the VTA, two sub-entries in a single entry map one-to-one to two compressed lines in a warp register. A compressed line is valid if the corresponding sub-entry in the VTA has its valid bit set. For any evicted line from the L1D cache to the victim cache, Algorithm 1 first avoids replacing an invalid sub-entry which could lead to the eviction of adjacent valid sub-entry.

For example, assume that a VTA entry stores an invalid sub-entry A and a valid sub-entry B. The sub-entry B is mapped to a compressed line of size 72 bytes. If a compressed cache line is evicted from the L1D cache and its size is 72 bytes, replacing the invalid sub-entry A will cause the valid sub-entry B to be evicted because the combined size of the two compressed cache lines will exceed 128 bytes. Algorithm 1 avoids this replacement.

Subsequently, Algorithm 1 attempts to find an entry with two invalid sub-entries and replaces one of them to store the information of the evicted compressed cache line. If no such entry is found, it finally uses the baseline LRU replacement policy.

Access Controller. The access controller contains two functional modules: the set indexing logic and the memory request queues. A memory request first arrives at the set indexing logic. To guarantee cache coherence, the VTA and the L1D cache use the same set indexing logic. The set indexing logic calculates the set number of the VTA for the memory request and forwards the request to the corresponding memory request queue.

The memory request queues buffer any request to the VTA, thereby avoiding the blocking of running warps from generating memory requests due to the limited number of requests that the tag array can handle simultaneously. A given request is dequeued as soon as the request's VTA set is ready to serve a new request. The number of memory request queues is equal to the number of sets in the VTA, as each set has a separate memory request queue. Similar to the L1D cache, the VTA can handle multiple requests per cycle from different memory request queues simultaneously.

Buffers. The write buffer for the register file (Write Buffer) (❸) holds compressed data waiting to be written into the register file, and the decompression buffer (Decomp. Buffer) (❼) holds the compression information needed for decompressing the compressed data. We evaluate the lengths of the write buffer and the decompression buffer from 1 to 20. We observe that a 1-entry write buffer and a 4-entry decompression buffer are sufficient to saturate performance.

Cache Coherence. The victim cache stores only the data evicted from the L1D cache, and the data evicted from the victim cache is directly discarded. When a store instruction is executed, HIVE searches the requested line in the victim cache. If the written line hits in the victim cache, the victim cache entry is invalidated, and the store data is sent directly to the L1D cache. The invalidated entry can be reused as a victim line later. When a cache line is evicted from the L1D cache, the evicted line is sent to both the victim cache and the next level of the memory hierarchy. The result of this cache policy is that the data in the victim cache is never dirty, and the L1D cache and the victim cache do not store data from the same memory address simultaneously.

Algorithm 1: VTA Replacement Policy

Input : *tag* denotes the tag of evicted cache line
set denotes the set number of evicted cache line
sz denotes the compressed size of evicted cache line
Output: *pos* denotes the position of the sub-entry to be replaced
way denotes the way of the sub-entry to be replaced

```
// i_0 denotes sub-entry0, and i_1 denotes sub-entry1
for i ∈ VTA[set] do
    if Valid(i_0) = false then
        if Valid(i_1) and (sz + Size(i_1) > 128B) then
            continue
        else
            return pos ← Pos(i_0), way ← Way(i)
    else if Valid(i_1) = false then
        if Valid(i_0) and (sz + Size(i_0) > 128B) then
            continue
        else
            return pos ← Pos(i_1), way ← Way(i)
if find_invalid (tag, set, sz) then
    pos, way ←invalid_replace (tag, set, sz)
else
    pos, way ←lru_replace (tag, set, sz)
return pos, way
```

C. HIVE Workflow

An evicted cache line is sent to the BDI Compressor (❶) for data compression. The compressor generates compression information during the compression, which is used to guide the decompressor to decompress the compressed data correctly. After compression, tag (*Tag*), set number (*SN*), compressed cache line (*Comp. Data*), and compression information (*Comp. Info*) are sent to the VTA (❷). The VTA stores tag and compression information for tag probing and decompression, respectively. Then, the VTA calculates the register number associated with the compressed cache line. The register number (*RN*) and the compressed cache line are sent to the Write Buffer (❸). Each buffer entry consists of a register number field and a compressed data field. When the port of the register file is free, the compressed cache line is written into the corresponding 128-byte warp register in the VDA (❹). The VDA is a set of statically unused warp registers whose numbers are determined after compile time.

A memory request from the core first arrives at the Access Controller (❺). The controller forwards the memory request to access the VTA (❷). Upon a tag miss, the request is sent to the L1D cache of the MEM stage. Upon a tag hit, if the request is a store, the store data is sent to the L1D cache, and the corresponding sub-entry in the VTA is cleared. Upon a tag hit, if the memory request is a load, the register number is sent to the Arbitrator (❻) for reading the compressed data, and the register number and the compression information are sent to the Decomp. Buffer (❼) for decompressing the compressed data. Each buffer entry consists of a register number field and a compression information field. When the compressed data from

the VDA is sent to the BDI Decompressor (❽), the decompression buffer forwards compression information to the BDI decompressor to indicate how to decompress the data correctly.

IV. Experimental Setup

We model and evaluate HIVE using AccelSim [13], a cycle-level simulator. AccelSim has two execution modes: PTX and SASS. To obtain the necessary cache data, we use the PTX mode in the AccelSim simulator. Table III shows the simulation parameters modeling our baseline. This Turing-like GPU configuration is similar to that used in a recent study [4]. We select 10 applications from six benchmark suites: Rodinia-3.1 [21], ISPASS [22], Polybench [23], Tango [24], Microbenchmark [13], and Pannotia [25]. The applications used in our study are shown in Table IV.

Table III. Baseline GPU configuration.

Parameter	Value
GPU Core Features	30 SIMT cores, 1.525GHz
Max Warps/SM	64 (2048 threads)
Warp Scheduling	4 GTO schedulers/SM
Register Files/SM	256KB, 16 banks
L1 Data Cache/SM	32/64KB 64/128-way L1 data cache, 4 banks, LRU, 128B cache line, access latency=38 cycles
L2 Cache	96KB/memory sub partition (6MB in total), access latency=198 cycles
Off-chip DRAM	RRD=3, RCD=12, RAS=28, RP=12, RC=40, CL=12, WR=10, access latency=298 cycles

Table IV. Evaluated applications.

App.	Abbr.	App.	Abbr.
kmeans [21]	KM	fw_block [25]	FW
gemm [23]	GM	spmv [25]	MV
gesummv [23]	GMV	bc [25]	BC
bicg [23]	BG	sn [24]	SN
mvt [23]	MVT	bfs [22]	BFS

We study GPU performance for four different architectures: (1) *BL*: the baseline system that models a GPU architecture with the parameters reported in Table III. (2) *LB*: the state-of-the-art architecture, Linebacker [7]. It dynamically throttles warps and utilizes idle register space as victim cache space. (3) *HIVE-Basic*: HIVE without BDI compressor and decompressor and using the baseline LRU replacement policy. (4) *HIVE-All*: the full design of HIVE. To provide a fair comparison, we require that HIVE and LB use the same maximum number of idle registers. To analyze the power consumption of HIVE, we use a modified version of AccelWattch [26] that is augmented with the VTA and BDI compressor/decompressor power models.

V. Evaluation

A. Performance

To study the effectiveness of HIVE in improving GPU performance, we measure instructions per cycle (IPC) on four architectures, namely *BL*, *LB*, *HIVE-Basic*, and *HIVE-All* (see Section IV for details of each evaluated architecture). Fig. 5 shows the results. The y-axis shows the IPC of evaluated applications (the higher the better). All results are normalized to the baseline (*BL*).

We make four key observations. First, *HIVE-All* improves GPU performance by an average of 77.1% and 21.7% over *BL* and *LB*, respectively, for all applications. Remarkably, *HIVE-All* shows the greatest performance improvement in GMV (240.0% and 86.5%) because GMV has sufficient idle registers that can be reused as victim cache space, and the compression algorithm effectively compresses the data. Additionally, although GM and BC exhibit lower L1D miss rates, they are latency-sensitive (see Section II-B and II-C), so HIVE still improves their performance compared to *BL* and *LB*.

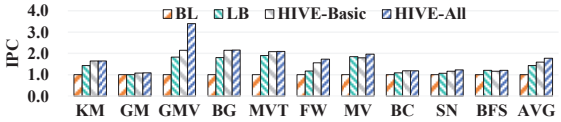

Fig. 5. Comparison of four GPU architectures' IPC (normalized to *BL*).

Second, *HIVE-Basic* improves performance by an average of 59.6% over *BL* by providing an extra on-chip cache and reducing access latency for most memory requests. Third, *HIVE-Basic* improves performance by an average of 11.2% over *LB* because it provides faster access to the victim cache. Fourth, *HIVE-All* improves performance by an average of 9.1% over *HIVE-Basic*, by utilizing data compression and exploiting a new replacement policy for the victim cache. We conclude that *HIVE-All* is highly effective at improving the performance of different applications.

B. Victim Cache Hit Rate

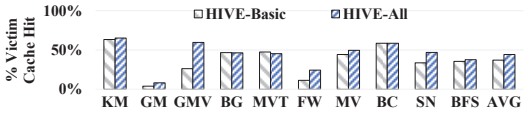

Fig. 6. Victim cache hit rates in *HIVE-Basic* and *HIVE-All*.

HIVE provides an extra cache to extend on-chip cache capacity, further reducing cache contention. We measure the victim cache hit rates for *HIVE-Basic* and *HIVE-All*. Fig. 6 shows our experimental results. We observe that the average hit rates for *HIVE-Basic* and *HIVE-All* are 37.1% and 44.2%, respectively, indicating that nearly half of the data evicted from the L1D cache can be reused in the victim cache. We also observe that *HIVE-All* improves hit rates by an average of 19.1% over *HIVE-Basic*, thanks to the BDI compression and the VTA replacement policy. We conclude that HIVE can effectively capture the lost data locality.

C. L2 Cache Traffic and Off-Chip Memory Traffic

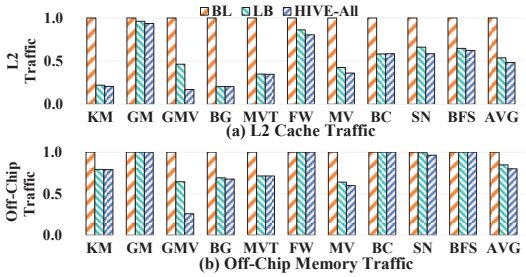

Fig. 7. L2 cache traffic and off-chip memory traffic in *BL*, *LB*, and *HIVE-All* (normalized to *BL*).

HIVE provides an extra victim cache and uses the BDI compression algorithm and the VTA replacement policy to increase the effective capacity of the victim cache, thereby effectively reducing access to the high-latency L2 cache and off-chip memory. We

compare the L2 cache traffic and the off-chip memory traffic of *HIVE-All* to those of *LB*. Fig. 7 shows our experimental results (normalized to the baseline (*BL*) architecture). *HIVE-All* reduces the L2 cache traffic and off-chip memory traffic by 51.7% and 20.0%, respectively, compared to the baseline. Compared to *LB*, *HIVE-All* reduces 12.0% more L2 cache traffic and 30.8% more off-chip memory traffic.

D. Overhead Analysis

We analyze the storage and power overheads of the additional hardware required by HIVE.

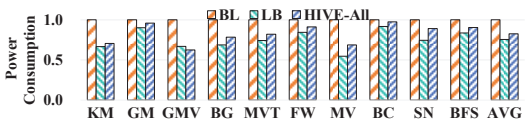

Fig. 8. Power consumption in *BL*, *LB* and *HIVE-All* (normalized to *BL*).

Storage Cost. HIVE has two main storage components: the VTA and the write buffer for the register file. The VTA is a 256-way set-associative tag array with 4 sets. Each entry in the VTA contains two sub-entries and one active bit. Each sub-entry contains 23-bit tag, 10-bit compression info, 1-bit valid, and 8-bit LRU. Consequently, the total size of the VTA is 10.625 KB. The write buffer has a 0.125 KB storage for compressed cache data. Overall, HIVE requires 10.75 KB of storage overhead, which accounts for 3.1% of the SM's storage.

Power Consumption. We measure the power consumption of *BL*, *LB*, and *HIVE-All*. Fig. 8 shows our experimental results (normalized to the baseline (*BL*) architecture). We observe that *HIVE-All* increases power consumption by an average of 9.4% compared to *LB*. However, *HIVE-All* significantly reduces power consumption by an average of 17.4% compared to the baseline. Both *HIVE-All* and *LB* reduce the L2 cache and the off-chip memory traffic compared to the baseline, but *HIVE-All* also increases register accesses and BDI compressor/decompressor accesses compared to *LB*.

Considering the experimental results in this section and the hardware cost estimation, we believe that HIVE is a cost-effective solution to improve performance on GPUs.

E. Sensitivity Study

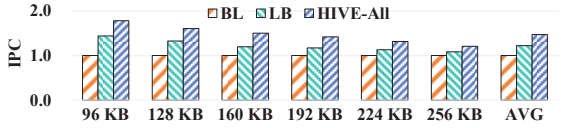

Fig. 9. Performance of varying unified memory space for the L1D cache and shared memory in *BL*, *LB*, and *HIVE-All* (all results are geometric mean values of the evaluated applications and normalized to *BL*).

Different GPU architectures have varying sizes of unified on-chip memory space for the L1D cache and shared memory [8], [15]. We explore the performance sensitivity by varying the unified on-chip memory space. We fixed the configurable shared memory capacity at 32/64 KB, with the exact size determined by the compiler. For example, if a kernel is configured with 32 KB of shared memory by the compiler in one architecture, the shared memory capacity for that kernel will still be configured as 32 KB by the compiler in other architectures. We measure the performance changes with the unified on-chip memory space for the L1D cache and shared memory set to 96 KB, 128 KB, 160 KB, 192 KB, 220 KB, and 256 KB.

Fig. 9 shows our results (normalized to the baseline (*BL*) architecture). We observe that *HIVE-All* improves performance by an average of 47.0% and 20.2% compared to the baseline and *LB*, respectively, across different unified memory space configurations. With the smallest capacity configuration (96 KB), *HIVE-All* shows 77.1% performance improvement while *LB* shows 43.6%. With the largest capacity configuration (256 KB), *HIVE-All* still outperforms *LB*. *HIVE-All* shows 20.8% performance improvement while *LB* shows 8.3%. We conclude that HIVE can be an efficient solution to improve cache efficiency across different GPU architectures.

VI. Related Work

The victim cache, proposed by [27], is placed in the refill path of an L1D cache and stores the cache lines evicted from the L1D cache in CPUs. Subsequently, there have been various studies based on the victim cache [7], [28], [29]. Differently, our proposed HIVE is more suitable for GPUs because it reduces the hit latency for most memory requests.

Data compression has already been explored in GPUs. [18], [30]–[32] explore data compression in register files [30], interconnect networks [31], and caches [18], [32]. To better utilize the latency margin provided by the high-priority victim cache, HIVE adopts a low-latency BDI compression algorithm, whose effectiveness in GPUs has been validated in [18].

The register file in GPUs is fairly large but often underutilized. To address this problem, prior works propose new techniques to utilize the register file efficiently. [2] proposes a new technique that reuses the core's on-chip memories, including register files, to extend the LLC capacity for a running memory-bound workload. [33] proposes a new compiler technique that explores TLP and registers allocation trade-off with the compile-time workload characteristic analysis.

Warp throttling techniques are introduced to reduce cache contention in GPUs [7], [34]–[36]. They require empirically setting some thresholds to decide whether to throttle. This means that for some applications, warp throttling can even hurt the performance. As explained in earlier sections, the closest work to HIVE is Linebacker [7], which simply reuses idle registers as a victim cache and employs warp throttling technology. However, Linebacker's victim cache is inherited from CPUs and is suboptimal for GPUs. In contrast, HIVE is suitable for GPUs. It reduces the hit latency for most memory requests and increases the effective capacity of the victim cache. Therefore, HIVE is expected to be more feasible and applicable to real practices.

VII. Conclusion

We propose HIVE, a high-priority victim cache for accelerating GPU memory accesses. The key idea of HIVE is to prioritize using the victim cache rather than the L1D cache to handle memory requests, meaning the victim cache does not act as a supplement to the L1D cache. Our experimental results show that HIVE can significantly improve GPU performance across various applications and different architectures.

***Abstract*—Logic synthesis tools are crucial to translate high-level descriptions into optimized gate-level netlists. However, complex optimization operations and operation configurations can cause synthesis faults. To address this, we propose MAGCS, a fault detection method using multi-agent reinforcement learning to dynamically refine optimization sequences. MAGCS consists of three components: a test program selector that applies feature extraction and cosine similarity to curate diverse test programs, an optimization selector using the A2C algorithm to adaptively adjust operations and configurations, and an optimization fault verifier performing equivalence checks to pinpoint optimization-induced faults. Using MAGCS, we identified 32 confirmed faults on Vivado and Yosys, all of which are resolved. MAGCS received recognition from the Vivado community for its significant contributions to tool improvement[1].**

***Index Terms*—Logic synthesis tools, optimization sequences, optimization faults**

I. Introduction

FPGA and ASIC are widely used in complex hardware system design such as communications and aerospace [1, 2]. In this process, logic synthesis is a critical step, which transforms high-level hardware description languages (e.g., Verilog and VHDL) into optimized gate-level netlists, to improve the performance and power efficiency of the design [3]. As shown in Fig. 1, the logic synthesis process typically consists of four main stages: Translation, Constrain, Logic Optimization, and Mapping, each involving specific optimization operations and configurations. By adjusting these operations and configurations, developers can create customized optimization sequences to achieve expression simplification, timing optimization, and efficient resource allocation. However, certain optimization sequences may produce unintended results or design errors, such as increased delays from timing optimizations and the unintended removal of critical logic during simplification. This risk is particularly concerning in safety-critical domains.

Fig. 2 is an example of circuit design code for FPGA and ASIC, which operates registers using the clock signal clk and generates a 768-bit output signal y. The logic synthesis uses Yosys with the sequence `opt_clean -purge; opt_expr -mux_bool; opt_dff -nodffe; opt_reduce -full; opt_demorgan`. In this sequence, `opt_clean` and `opt_expr` are optimization operations, while `purge` and `mux_bool` are their configurations. An error occurred when using the `opt_demorgan` operation (Fault ID: 4610[2]). As indicated in the log in Fig. 2(b), the error is caused by a zero input signal to the `$reduce_or` unit, which triggers a `std::out_of_range` exception. The error occurred at line 11: `reg79 <= (~reg67[(4'h8):(3'h5)]);` Due to an incorrect signal connection, the input size was mistakenly set to zero, leading to synthesis failure. The Yosys community resolved this issue through a fix (Pull Request ID: 4612[3]), as illustrated in Fig. 2(c). The fix involved modifying the *opt_demorgan.cc* optimization file. A conditional check was added at lines 43-44 to prevent further processing when the input signal is zero.

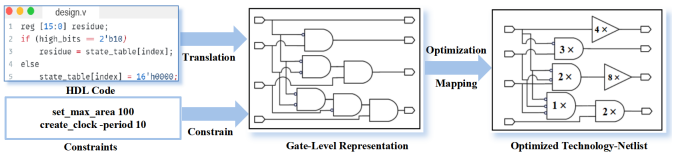

Fig. 1: Electronic Circuit Design - Logic Synthesis Flowchart.

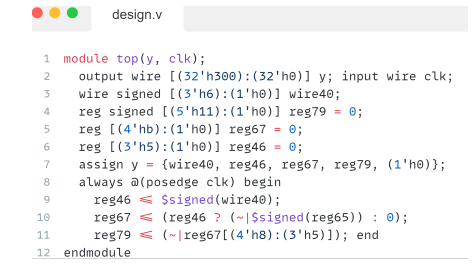
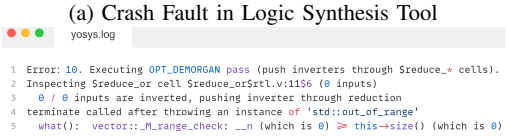


To identify faults in logic synthesis tools, several testing methods have been proposed [4, 5, 6, 7]. These methods typically rely on generators (e.g., Verismith and Vloghammer) to produce large numbers of Verilog files, which are then used as input (aka, test programs) to expose faults in synthesis tools. However, these methods often overlook the complexity introduced by user-defined optimization sequences. Methods like DeLoSo[8] address this by using heuristics to explore specific combinations of operations and parameter configurations that may trigger faults. However, DeLoSo lacks real-time adaptation based on feedback, limiting its exploration of broader optimization sequences. Additionally, DeLoSo relies on code generators to produce a single batch of test programs, which tend to exhibit similar structures within the batch, lacking sufficient diversity to comprehensively expose faults. Based on the current research landscape, fault detection in logic synthesis optimization faces two main challenges:

Challenge 1: Insufficient diversity in test programs. Fault detection relies on diverse test programs to thoroughly test the whole logic synthesis process. Limited variation among test programs restricts the ability of existing methods to reveal potential faults.



Challenge 2: Inadequate exploration of optimization sequences. Logic synthesis tools offer numerous optimization operations; for instance, Vivado has over 18 optimization operations, each with more than 10 possible operation configurations. Since only certain optimization sequences could be faulty, the vast search space of optimization sequences (e.g., over 10^{18+} for Vivado) makes exhaustive testing impractical.

To this end, we propose MAGCS, a multi-agent reinforcement learning-based method for detecting optimization faults in logic synthesis tools. To tackle the first challenge, MAGCS includes a test program selector component that uses circuit features to vectorize different test programs. MAGCS selects test programs with the greatest variability in terms of vector distances to ensure the

(b) Crash Fault Log Report

(c) Code Maintenance Patch

Fig. 2: Yosys Crash Fault (Fault ID: 4610)

diversity of test programs. To tackle the second challenge, MAGCS treats each optimization operation as an independent agent. MAGCS first determines the position of each optimization operation within the optimization sequence, then selects the corresponding operation configuration. Through multi-agent reinforcement learning, MAGCS dynamically adjusts the agents based on a reward function that prioritizes the fault detection ability of optimization sequences and minimizes equivalence check delays. MAGCS iteratively refines the optimization sequence to find optimal configurations for fault detection. Finally, an optimization fault verifier is used to determine if the optimized, synthesized design aligns with the intended functionality of the original design with equivalence check. If the equivalence is broken, an optimization fault could be found.

Experiments show that MAGCS outperforms baselines (i.e., DeLoSo, DynSwarm, and InitSwarm) in detecting optimization faults, with a fault detection rate 68.42% to 3100% higher than these methods. Over one month of testing on the commercial tool Vivado and the open-source tool Yosys, MAGCS identified 32 confirmed faults, demonstrating its effectiveness across different synthesis tools.

The contribution of this work includes: (1) the first multi-agent reinforcement learning-based approach for efficiently detecting optimization faults in logic synthesis tools; (2) 32 faults are found in Vivado and Yosys, all of which are confirmed and fixed; (3) the Vivado community acknowledges the value of our reported faults, recognizing our contribution to their tool improvement; (4) we have open-sourced MAGCS on Github[4].

II. RELATED WORK

Fault detection in logic synthesis tools is critical in FPGA and ASIC. Several automated testing frameworks have been proposed to generate diverse Verilog programs for fault detection. Herklotz et al. [4] developed Verismith, a tool that uses randomization techniques to generate complex Verilog programs for testing logic synthesis tools. Then, Vloghammer[5] was proposed, which can test the stability of Yosys. Ratchev et al.[6] developed VERGEN, which evaluates synthesis tool performance by generating structured random programs with specific design features. Thakur et al.[7] developed VeriGen, which uses template-based generation to test logic synthesis tools. While these approaches have been instrumental in fault detection, their primary focus is code generation; they cannot thoroughly explore faults arising from optimization sequences.

For optimization fault detection, Jiang et al. [8] proposed DeLoSo, which utilizes a heuristic method to explore optimization sequences that trigger faults in synthesis tool's optimization operations. However, DeLoSo faces limitations, such as being prone to local optima and not fully addressing test program diversity.

Overall, existing approaches lack thorough testing of optimization operations and operation configuration. This study effectively combines diverse optimization sequences with varied test programs to improve the effectiveness of fault detection.

III. MAGCS FRAMEWORK

To detect optimization faults in logic synthesis tools, we propose MAGCS, a multi-agent reinforcement learning-based fault detection method. As shown in Fig. 3, MAGCS has three core components to collaboratively select and validate optimization sequences.

A. Test Program Selector

To build a diverse and representative set of test programs, MAGCS employs a selection method based on feature extraction and similarity metrics. Given an initial set P of n_{seed} Verilog test programs, MAGCS represents each test program as a feature vector to encompass a diverse range of logic structures and timing characteristics.

Specifically, previous studies [9] have proposed five categories of features to represent a Verilog program, including

- *data processing and operations*, such as the number of arithmetic, logical, and comparison operators, which characterize data operation complexity;
- *data flow control and representation*, such as the number of assignment statements, variable declarations, and numerical representations, reflecting the synchronization and complexity of data flow;
- *structuring and modularization*, such as the number of module instantiation and declarations, describing the modular design traits of Verilog programs;
- *control flow and logic*, such as the number of conditional statements and loop control, which characterize the logical control and decision-making in Verilog programs;
- *abstraction and reuse*, such as the number of parameter definitions and scope identifiers, which capture the handling of parameterization and module reuse in Verilog programs.

We further add the sixth category of feature, namely *timing features*, which analyzes the characteristics of the timing behavior of hardware circuits, including the number of clock signals, flip-flops, edge-triggered logic, and non-blocking assignments in Verilog programs. These timing features are important for describing timing control in FPGA and ASIC designs, particularly in timing-sensitive circuits, enabling a more comprehensive characterization of Verilog program behavior.

Based on these features, MAGCS converts each test program p_i in P into a feature vector $F_i = [f_{i1}, f_{i2}, ..., f_{im}]$, where m represents the number of features. Each dimension in F_i is a quantified feature, e.g., f_{i1} counts the number of arithmetic operators in p_i, and f_{i2}

[4]https://github.com/MAGCS-method/MAGCS

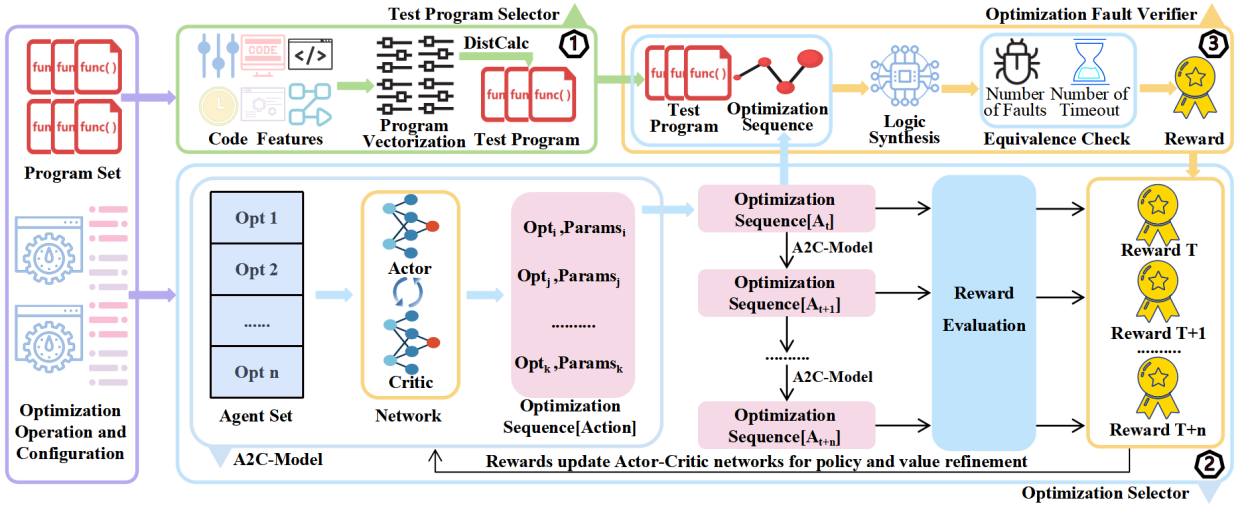

Fig. 3: The framework of MAGCS

is the number of logical operators in p_i. Once the feature vector is constructed, MAGCS normalizes each feature dimension j by:

$$\hat{f}_{ij} = \frac{f_{ij} - \min(f_{1j}, \ldots, f_{nj})}{\max(f_{1j}, \ldots, f_{nj}) - \min(f_{1j}, \ldots, f_{nj})} \quad (1)$$

where f_{ij} is the original feature value of test program p_i in dimension j, and $\min(f_{1j}, \ldots, f_{nj})$ and $\max(f_{1j}, \ldots, f_{nj})$ are the minimum and maximum values of dimension j across all n test programs.

After normalization, the feature vector of p_i is expressed as: $\hat{F}_i = [\hat{f}_{i1}, \hat{f}_{i2}, ..., \hat{f}_{im}]$. This normalization compresses the feature values of each dimension into the [0, 1] range, ensuring that all dimensions are on the same scale and avoiding bias.

Next, MAGCS uses cosine distance to measure the dissimilarity between test program features. Cosine distance reflects the angular difference between two feature vectors and is defined as: $d\left(\hat{F}_i, \hat{F}_j\right) = 1 - \frac{\hat{F}_i \hat{F}_j}{\left\|\hat{F}_i\right\| \left\|\hat{F}_j\right\|}$, where $\hat{F}_i \hat{F}_j$ is the inner product of the feature vectors, and $\left\|\hat{F}_i\right\|$ and $\left\|\hat{F}_j\right\|$ is the magnitudes of the vectors. A large $d\left(\hat{F}_i, \hat{F}_j\right)$ means two test programs are more dissimilar in the feature space.

To select a maximally diverse test program set P_{sel}, MAGCS employs a recursive greedy method. First, a test program p_1 is randomly selected from the initial set P to serve as the first program in P_{sel}. For each remaining test program $p_i \in P$, we compute the sum of its cosine distances to all already-selected programs in P_{sel}:

$$D\left(p_i\right) = \sum_{p_j \in P_{sel}} d\left(\hat{F}_i, \hat{F}_j\right) \quad (2)$$

Next, the test program p_k with the greatest dissimilarity to the current programs in P_{sel} is selected, satisfying the following condition:

$$p_k = \underset{p_i \in P / P_{sel}}{\arg\max}\ D\left(p_i\right) \quad (3)$$

Using this method, we iteratively build a diverse subset P_{sel} from P until it includes n_{sel} test programs. This method maximizes the diversity within the feature space, facilitating broader fault detection across various optimization scenarios in logic synthesis tools.

B. Optimization Selector

During the logic synthesis optimization process, the selection of optimization operations and their configurations creates a vast search space. For instance, in Yosys, commonly used optimization operations include `opt_expr`, `opt_clean`, `opt_merge`, `opt_muxtree`, and `opt_demorgan`. Each of them has various operation configuration. For example, `opt_expr` provides configurations such as `opt_expr -mux_bool` for converting Boolean expressions into multiplexers and `opt_expr -full` for applying comprehensive logic transformations. The execution order of these operations (i.e., the optimization sequence) directly affects the quality of the synthesis optimization.

To navigate this complex space, the optimization selector leverages a multi-agent reinforcement learning framework A2C [10] for optimizing the selection of operations and their configurations. In A2C, agents make decisions by selecting actions from an action space, which represents possible optimization operations and configurations, based on the current state of the system. The state space contains all relevant system information at a given time. By continuously learning from feedback rewards, agents optimize their decisions, identifying the best sequence of operations to improve fault detection. Let the state space S_t represent the optimization sequence and its corresponding operation configuration at a given time step t. S_t is composed of a set of optimization operations and their configurations:

$$S_t = \{(opt_{1,t}, params_{1,t}), \ldots (opt_{i,t}, params_{i,t}), ..., (opt_{n,t}, params_{n,t})\} \quad (4)$$

where $opt_{i,t}$ denotes the selection of the i-th optimization operation at time t, and $params_{i,t}$ represents its operation configuration. For instance, at time step t, the state might be:

$$S_t = \{(opt_expr, fine), (opt_clean, purge), (opt_merge, nomux)\} \quad (5)$$

The action space A defines the decisions that the agent can make at each time step. Each agent's actions include selecting the operation configuration of the current optimization operation as well as dynamically adjusting the order of these operations. Specifically, action $a_t \in A$ consists of two parts: $opt_{i,t+1}$, which selects the next optimization operation, and $params_{i,t+1}$, which specifies the configuration for $opt_{i,t+1}$. Hence, the action a_t is expressed as:

$$a_t = \{(opt_{i,t+1}, params_{i,t+1})\} \quad (6)$$

To guide the agent in selecting effective actions in this complex optimization space, we designed a reward function that maximizes the fault detection ability of each action a_t while minimizing unnecessary

equivalence check timeouts. Specifically, the reward function R for an action a_t is defined as:

$$R = \theta \cdot \frac{N_{fault}}{N_{fault}+1} - (1-\theta) \cdot \frac{N_{timeout}}{N_{timeout}+1} \tag{7}$$

where N_{fault} represents the number of faults detected when applying the current optimization sequence on all test programs in P_{sel}, and $N_{timeout}$ represents the number of timeouts encountered during equivalence check for the same sequence and test set. Parameter $\theta \in [0, 1]$ controls the balance between positive rewards and negative penalties. Detecting an optimization fault results in a positive reward, encouraging the agent to explore and find more faults, thereby improving the effectiveness of the optimization sequence. Timeouts during equivalence check are penalized because they delay verification of the design against the netlist and disrupt the overall testing process. By using timeouts as a negative reward, MAGCS reduces unnecessary delays to ensure test efficiency.

Our framework adopts an Actor-Critic (A2C) approach with two primary networks: a policy network (Actor) and a value network (Critic) [11]. The policy network learns to select optimization actions (operations and configurations) that maximize cumulative rewards, while the value network estimates the expected reward value of the current state to enhance decision accuracy.

At each time step t, the agent uses the policy network to select an optimization action a_t based on the current state s_t, specifying the next optimization operation and its configuration. Executing a_t generates a new state s_{t+1}, reflecting the updated sequence of optimization operations and configurations.

After each action, an immediate reward R is calculated, evaluating the optimization sequence based on detected faults and equivalence check timeouts. The critic network estimates the expected value of the state to guide further decisions. A2C iteratively refines the agent's policy, enabling effective selection of optimization operations and configurations. The objective is to maximize the cumulative discounted reward:

$$\max_{\omega} E\left[\sum_{t=0}^{T} \gamma^t R_t\right] \tag{8}$$

where ϖ is the policy network parameter, $\gamma \in [0, 1]$ is the discount factor that reduces the influence of rewards in future time steps, and R_t is the immediate reward at time step t. Based on prior studies [10, 11], we set ϖ to 0.001 and γ to 0.99.

Through iterative training, the agent gradually optimizes its strategy, making optimal decisions in the complex optimization space and maximizing the cumulative reward. The optimization selector continuously improves fault detection by dynamically adjusting the optimization operations and configurations, ensuring that each stage of testing delivers high fault detection capacity and efficiency.

C. Optimization Fault Verifier

After identifying each optimization sequence with the optimization selector, it is converted into optimization instructions applied to the design file—a Verilog or HDL circuit representation—during synthesis. In some cases, specific test programs and optimization sequences may cause unexpected synthesis terminations, as discussed in Fig. 2. This type of optimization fault indicates that certain operations or configurations within the optimization process contain issues, directly causing the synthesis to fail. Feedback on detected faults and timeouts from each sequence is then relayed back to the optimization selector, helping refine its strategy.

For optimization sequences that complete synthesis successfully, the system generates synthesis file and conducts equivalence check to ensure that the synthesized logic matches the original design's functionality. The equivalence check uses formal verification tools to convert both the original design and the synthesized files into comparable logic expressions, verifying whether their outputs match across all input conditions. Specifically, the core of the equivalence check is to ensure that the output logic of the source design L_{src} matches the synthesized design L_{syn} for all inputs x:

$$\forall x \in X, L_{src}(x) = L_{syn}(x) \tag{9}$$

Here, X represents the complete set of possible inputs. If under certain input conditions, $L_{src}(x) \neq L_{syn}(x)$, this indicates that a functional error occurred during the synthesis process.

By monitoring the synthesis process and conducting equivalence check, it is possible to determine whether the optimization sequence led to faults. If the synthesis process terminates unexpectedly or if the equivalence check fails, this signifies an issue with the optimization process. The optimization fault verifier ensures that any errors introduced during optimization are detected.

IV. EVALUATION

We evaluated the effectiveness of MAGCS by answering the following research questions (RQs): RQ1 – Effectiveness of MAGCS Compared to Baseline Methods, RQ2 – Impact of Parameter on MAGCS, and RQ3 – Effectiveness of MAGCS in Finding Real Faults.

A. Experimental Setup

Hardware Environment: Our experiments were conducted on an x86_64 computer running Ubuntu 18.04.01, equipped with an Intel Core i9-12900 CPU @ 2.80GHz with 24 cores and 128GB RAM.

Software and Test Program Generation: Our experiments employed two mainstream logic synthesis tools: the commercial tool Vivado (version 2024.1) and the open-source tool Yosys (version 0.41+126). We chose the latest versions, as they are more likely to contain recent fault fixes, which are particularly critical for developers [8]. To generate the initial test set P, we used Verismith [4] for its ability to produce diverse and complex Verilog programs essential for fault detection. Following configurations from prior studies [8], we generated an initial set of $n_{\text{seed}} = 200,000$ programs, from which a greedy method selected a diverse subset of $n_{\text{sel}} = 1,000$ programs.

Types of Errors: We identified four types of optimization faults: (1) Crash Fault: a crash during synthesis with specific optimization sequence; (2) Performance Fault: a hang or stall in the synthesis process; (3) Parsing Fault: errors in parsing the design files; and (4) Logic Fault: discrepancies between the synthesized and original design due to logic errors.

B. Baseline Methods and Testing Strategy

To assess the performance of MAGCS, we used nine methods for comparison. These methods are based on four basic methods, i.e., Default, InitSwarm, DynSwarm, and DeLoSo [8]. Each method has two steps, i.e., test program selection and optimization sequence generation. For test program selection, we employed two strategies: *Rand*, where 1,000 test programs are randomly selected from a pool of 200,000, and *Div*, where 1,000 diverse test programs are selected using the test program selector proposed in Section 3.1.

For optimization sequence generation, we have:

Default: Default optimization sequences in synthesis tools (e.g., opt-fast and opt-full in Yosys, and O1, O2, O3 in Vivado) are used.

InitSwarm: Using the default optimization operations in their fixed order, with only the operation configuration randomized.

TABLE I: Effectiveness of MAGCS in Fault Detection

Tools	Default		InitSwarm		DynSwarm		DeLoSo		MAGCS	MAGCS
	Rand	Div	Rand	Div	Rand	Div	Rand	Div	Rand	
Vivado	0	0	1	1	2	3	7	9	16	26
Yosys	0	0	0	1	1	1	2	3	3	6
Total	0	0	1	2	3	4	9	12	19	32

DynSwarm: The positions of optimization operations are randomly rearranged, and operation configurations are also randomly assigned.

DeLoSo: Genetic algorithm is used to explore optimization sequences by adjusting the positions of optimization operations and tuning their configurations, aiming to identify combinations that may trigger faults.

When combining the two steps, we have eight method variants, i.e., Default-Rand, Default-Div, InitSwarm-Rand, InitSwarm-Div, DynSwarm-Rand, DynSwarm-Div, DeLoSo-Rand, and DeLoSo-Div. For example, Default-Rand means that we use the default optimization sequence with the randomly selected 1,000 test programs to test synthesis tools. Additionally, we create a variant of MAGCS as the ninth baseline, i.e., *MAGCS-Rand*, where the test program selector in MAGCS is replace with the Rand strategy.

Each testing method was allocated a fixed runtime. During each iteration, methods like MAGCS dynamically generated new optimization sequences, while Default used predefined or randomized configurations. These optimization sequences were applied for logic synthesis. We analyzed both the synthesis process and checked for equivalence between the synthesized netlist and the original design to identify potential faults. When mismatches were detected, functional simulations were performed to gather more detailed data, enabling easier replication of the faults by the community.

For each detected fault, failed assertions and logs were analyzed to remove duplicates. The Verilog program that triggers the faults was incrementally reduced to its minimal form for reproduction. The simplified design, the triggering optimization sequence, and relevant error logs were submitted to the development team for verification as either new or known issues.

C. RQ1: Effectiveness of MAGCS and Baselines

To answer RQ1, we use MAGCS and nine baseline methods to test logic synthesis tools for over one month. This period includes Verilog test program generation, test case selection and optimization selector with each method, and fault verification. This evaluation period aligns with previous studies [8]. For the tests, we used the latest versions of Vivado (2024.1) and Yosys (0.41+126). We use two identical machines to run all methods.

As shown in TABLE I, MAGCS identified 26 faults in Vivado and 6 in Yosys, significantly outperforming other methods. In comparison, DeLoSo-Div found 9 faults in Vivado and 3 in Yosys, totaling 12. DynSwarm-Div detected 4 faults, while InitSwarm performed poorly. Default-Rand and Default-Div did not find any faults, as the default optimization sequence are typically extensively tested before release. MAGCS demonstrated superior fault detection ability across different tools by dynamically optimizing sequence combinations through multi-agent reinforcement learning.

We also used a Venn diagram to further analyze the differences between MAGCS and other baselines in fault detection. Since Default and InitSwarm-Rand did not detect any faults in the experiment, they were excluded from the Venn diagram. As shown in Fig. 4, the faults found by MAGCS is a superset of those found by other baselines. This indicates that MAGCS can both effectively select diverse test programs and explore a broader optimization configuration space, uncovering faults missed by other methods.

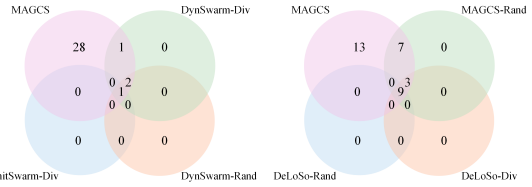

Fig. 4: Relationship of faults found by different methods.

TABLE II: Faults Detected by MAGCS with Different θ Values

Value of θ	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
Vivado Faults	1	2	4	3	7	8	11	13	11	9	5
Yosys Faults	0	1	1	1	2	3	4	4	3	1	1
Total	1	3	5	5	9	11	15	17	15	12	6

Conclusion: MAGCS is highly effective in detecting optimization faults in logic synthesis tools, surpassing baseline methods by triggering more optimization faults. The faults found by MAGCS form a superset of those detected by other baselines.

D. RQ2: Impact of Parameter on MAGCS

To answer RQ2, we explore a key parameter in MAGCS: the coefficient θ in the reward calculation formula (Equation 7). This coefficient balances the detection of optimization faults with the penalty for timeouts during equivalence check. In the experiment, the value of θ ranged from 0.0 to 1.0, with intervals of 0.1. Notably, when $\theta = 0.0$, the system only penalizes timeouts without incentivizing fault detection. In contrast, when $\theta = 1.0$, the system entirely ignores timeouts and focuses solely on the number of detected optimization faults.

As shown in TABLE II, we recorded the number of faults detected by MAGCS in Vivado and Yosys for varying values of θ. As θ increased from 0.0 to 0.7, the number of detected faults steadily rose. In this range, MAGCS prioritized fault detection, while allowing some timeouts, which helped reveal additional faults. However, as θ exceeded 0.7, the lack of penalty for timeouts began to interfere with testing, causing verification disruptions and fewer detected faults. At $\theta = 0.7$, MAGCS achieved the best balance between fault detection and time management, with high detection efficiency.

Conclusion: When θ is set to 0.7, MAGCS achieves the best performance in detecting optimization faults in logic synthesis tools.

E. RQ3: Effectiveness in Finding Real Faults

To answer RQ3, we used MAGCS to detect optimization faults in Vivado and Yosys. As shown in TABLE III, we have reported a total of 32 optimization faults to the Vivado and Yosys development teams or communities, including 16 crash faults, 11 performance issues, 1 parsing fault, and 4 logic faults. All reported faults have been confirmed. We also shared the details of these fault on GitHub. Below, we provide an example for each category of faults.

Crash Fault: Vivado Fault ID: 8jW2ngSAC[5] occurred due to improper resource scheduling during complex optimization operations. As shown in the crash log in Fig. 5, the crash happened while executing a synthesis task. The Vivado thread scheduling mechanism failed to properly manage multi-task loads, particularly for high-complexity tasks like hierarchy flattening and clock-gating conversion. The log indicates that the functions $HARTSWorker :: runJob()$ and $HARTSWorker :: runInternal()$ encountered synchronization issues during parallel task execution, leading to resource contention. Additionally, the $parallelListen()$ function failed to properly schedule parallel tasks, causing thread blocking and ultimately triggering the crash.

Logic Fault: Vivado Fault ID: 7AD9ZWSA1[6] is the inconsistency of simulation waveform between the original design and the synthesized netlist. At the 159ps timestamp in the waveform, as shown in the red box in Fig. 6, a clear discrepancy is evident. The first (correctly synthesized) netlist shows a value of 802, while the second (incorrectly synthesized) netlist shows a value of 800. This significant behavioral inconsistency issue arose in the module responsible for logic optimization during synthesis. Logic optimization failed to maintain the timing consistency of the design when dealing with certain synchronous or nested logic. Although subtle, this timing discrepancy can seriously cause the overall functionality of the circuit to fail, especially in high-speed designs.

Parsing Fault: Yosys Fault ID:4427[7], as shown in Fig. 7, indicates that Yosys failed to continue execution while generating the RTLIL representation due to an assertion failure. The assertion failure occurred at $frontend/ast/ast.cc : 855$, where $node- > bits == v$ failed. In this case, Yosys encountered a bit-width mismatch when generating the RTLIL representation for the modules top and

(b) Code Maintenance Patch

Fig. 8: Yosys Performance Fault (Fault ID: 4458)

$module282$. The error occurred in the frontend Abstract Syntax Tree parsing phase, where Yosys has a signal width mismatch during the conversion from Verilog program to RTLIL.

Performance Fault: Yosys Fault ID:4458[8] was triggered during logic synthesis optimization compilation. The hash table size exceeded the system's allowable limit, triggering a $std :: length_error$ exception, as shown in Fig. 8(a). This issue arose primarily because Yosys did not handle hash table size calculations properly when processing large design files, leading to rapid hash table expansion during optimization. As shown in Fig. 8(b), Yosys developers resolved this issue[9] by adjusting the hash table size calculation logic, using a larger prime number table to allocate hash table capacity. This ensured that the hash table would function correctly when handling large designs.

Conclusion: MAGCS demonstrates excellent capabilities in detecting optimization faults in logic synthesis tools. MAGCS successfully identifies 32 optimization faults, which are all confirmed and fixed.

V. Conclusion

Optimization faults in logic synthesis tools can critically impact hardware design accuracy and performance; therefore, effective fault detection is essential. We present MAGCS, a reinforcement learning-based multi-agent method to enhance fault detection in logic synthesis optimizations. Tested on Vivado and Yosys, MAGCS demonstrated high fault detection capabilities, finding 32 confirmed faults in both tools. The Vivado community acknowledged our fault reports, and shared a note of gratitude[10]: *"Thank you for reporting a series of Vivado synthesis issues and providing the related example designs. Most of the issues can be reproduced and have been reported to AMD's developers to improve our tool."*.

***Abstract*—Routability-driven global placement is a major challenge in modern VLSI physical design, for which mitigating routing congestion is a critical approach. Cell inflation can effectively address local routing congestion and is widely adopted, but with the issue of over-inflating or moving cells back into congested areas. Minimizing the congestion within a net bounding box is effective for alleviating global routing congestion, but the bounding box may be too large and contain congestion not contributed by the net. To address the first issue, we propose a momentum-based cell inflation technique that considers historical inflation ratios for mitigating local routing congestion. Then, we construct a differentiable global congestion function, developed from Poisson's equation, and introduce virtual standard cells onto two-pin nets to accurately guide net movements for mitigating global routing congestion. Furthermore, to improve pin accessibility, we adjust placement density around power and ground rails according to the routing congestion in global placement. The proposed techniques are integrated into an electrostatic-based global placement framework. Experiments on the ISPD 2015 contest benchmarks show that our framework achieves better routability results, with an average of 40% DRVs reduction and comparable wirelength and via count, compared to the leading routability-driven placer.**

***Index Terms*—routability-driven global placement, eliminating congestion, cell movement.**

I. Introduction

Ideally, placement and routing should be performed simultaneously in VLSI physical design. However, this is highly challenging due to their different problem nature and high computational complexity. Therefore, most studies follow the placement-then-routing flow and investigate ways to balance placement and routing to improve overall design efficiency [1, 2, 3, 4, 5]. With the rapid growth of design complexity and advances in process technology, routability has become a big issue in modern circuit design. Separation of placement and routing often leads to a large number of design rule violations after detailed routing. Therefore, routability-driven placement becomes critical. Optimizing a placement by considering routability can effectively address the routability and reduce the complexity in the later routing stage [3, 6, 7]. This work focuses on routability-driven global placement problem.

During global placement, the routability issue is complicated by diverse sources of routing congestion. As noted in [2], congestion can be divided into local routing congestion and global routing congestion. Fig. 1(a) shows both types of congestion. Local routing congestion occurs when there are too many cells in a given placement region, this congestion can be alleviated by relocating cells from the congested placement region. Global congestion occurs when too many nets traverse a G-cell, this congestion cannot be alleviated by moving cells out of the congested placement area, since there may be no cells in the congested region. Mitigating both types of congestion is a critical issue in routability-driven global placement.

Many strategies have been proposed to consider routability during the global placement stage. Cell inflation is an effective approach for mitigating local routing congestion. This approach usually utilizes a global router to create a routing congestion map and then applies cell inflation to artificially increase the density of congested areas, encouraging cell displacement from these regions [3, 5, 8]. One approach of cell inflation [3, 5] only considers the present congestion, when cells are moved to an uncongested area, these cells are not inflated, causing the cells to return to the previously congested areas inadvertently, and these areas may become congested again [9]. Another approach is inflating cells monotonically increasingly by considering historical inflation ratios [8]. This technique may lead to over-inflation even when cells have been moved away from the congested area. Therefore, to maximize the efficacy of cell inflation, it is crucial to design a dynamic cell inflation scheme by incorporating historical inflation ratios.

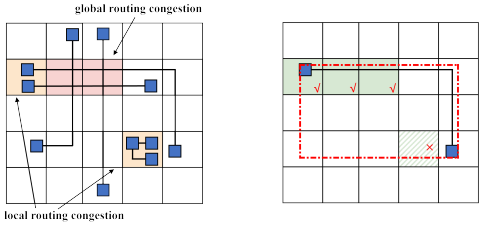

Fig. 1: (a) Local routing congestion and global routing congestion. (b) A net from (a); the red dashed box represents the bounding box (BB) of the net, the green area indicates routing congestion, and the congestion in the lower right corner is unrelated to the net.

To alleviate global routing congestion, it is an effective approach that adds a congestion penalty based on the bounding box (BB) of a net to the objective function of the global placement mathematical model. Within the deep learning framework, [4] leverages RUDY [10], PinRUDY and MacroRegion features, which are calculated based on BB, for forward propagation to generate a congestion map, followed by backpropagation to obtain routability-driven cell gradients. Nevertheless, RUDY treats all regions within the BB equally, overlooking the specific congestion situation. [6] introduces a congestion penalty for G-cell edges, minimizing the usage of G-cell edges based on nets' locations. Specifically, the congestion penalty involves every edge of G-cells surrounding the BB of a net, and the achieved effect is a reduction in the cells' distance within the net rather than direct congestion mitigation. [2] gives a BB-based congestion-aware net penalty model to reduce the net's overlap with congested areas. However, the BB may be too large and contain congestion that is not contributed by the net. For instance, as Fig. 1(b) illustrates, congestion within a net's BB may not be caused by the net itself, the lower right congested region stems from excess cell clustering, but [2] penalizes the net for this unrelated congestion.

In addition to local and global routing congestion, pin accessibility is another critical issue closely tied to routability. Existing methods

*Corresponding author: Wenxing Zhu, email: wxzhu@fzu.edu.cn.

[11, 12, 13] primarily optimize pin accessibility at the detailed placement stage, using local perturbations such as cell shifting, cell flipping, cell swapping, and cell replacement. However, pin accessibility has not been addressed at the global placement stage, which would be helpful for routability.

To address the above issues, we propose an analytical routability-driven global placement framework that includes net and multi-pin cell moving strategies, and a momentum-based cell inflation technique, which can simultaneously alleviate local and global routing congestion. Additionally, we consider optimizing pin accessibility during global placement to enhance routability further. The main contributions of this work are summarized as follows:

- We propose a differentiable congestion function developed from Poisson's equation and introduce virtual cells onto two-pin nets. The function is penalized into the global placement model for effectively guiding net movements to mitigate global routing congestion.
- A momentum-based cell inflation technique is developed to incorporate historical inflation ratios in calculating cells' current inflation ratios to mitigate local routing congestion more effectively.
- To improve pin accessibility, we adjust the placement density around power and ground rails during global placement, according to the routing congestion situation of the related region.
- We integrate the proposed techniques into an electrostatic global placement framework. Experiments on the ISPD 2015 detailed-routing-driven placement contest benchmarks demonstrate that our algorithm improves routability, achieving an average of 40% reduction in DRVs while maintaining comparable wirelength and via count, compared to the leading routability-driven placer Xplace-Route.

II. Analytical Global Placement

This section introduces the wirelength-driven analytical global placement problem, and presents our formulation of analytical routability-driven global placement problem.

A. Wirelength-Driven Global Placement

A circuit can be represented by a hypergraph $H = (V, E)$, where $V = \{v_1, v_2, \ldots, v_n\}$ denotes the set of cells, and $E = \{e_1, e_2, \ldots, e_r\}$ is the set of nets. The placement area is divided into a uniform grid of $m \times n$ bins $\mathbb{B}$. Then the wirelength-driven global placement problem can be formulated as

$$\begin{aligned} \min_{x,y} \quad & \sum_{e \in E} WL(e; x, y) \\ \text{s.t.} \quad & D_b(x, y) \le D_b, \quad \forall b \in \mathbb{B}, \end{aligned}$$

where $WL(e; x, y)$ is net e's wirelength, $D_b(x, y)$ is the density of bin b, and D_b represents the maximum allowable density of the bin.

The wirelength function $W(e; x, y)$ is often defined as the half-perimeter wirelength (HPWL). Direct minimization of HPWL in global placement is challenging due to its non-smoothness. In this work, we adopt the weighted average (WA) wirelength model [14] to approximate HPWL, the WA model in the x-direction is:

$$WA_{e_x} = \left(\sum_{i \in e} x_i e^{\frac{x_i}{\gamma}} \Big/ \sum_{i \in e} e^{\frac{x_i}{\gamma}} \right) - \left(\sum_{i \in e} x_i e^{-\frac{x_i}{\gamma}} \Big/ \sum_{i \in e} e^{-\frac{x_i}{\gamma}} \right).$$

The WA model iterates through the horizontal and vertical coordinates of each pin i in net e, producing a smooth wirelength function to approximate the HPWL, with γ controlling the degree of smoothness.

Electrostatics-based density [15] has inspired many state-of-the-art global placement algorithms [3, 16, 17]. This approach models each cell as a charged particle interacting within an electric field, where the field strength reflects cell density. High-density region creates a repulsive force, pushing cells toward lower-density region to achieve a balanced placement. Specifically, based on Gauss's law, ePlace [15] utilizes Poisson's equation with boundary and compatibility conditions to address cell density in placement optimization:

$$\begin{cases} \nabla \cdot \nabla \psi(x, y) = -\rho(x, y), & (x, y) \in R, \\ \mathbf{n} \cdot \nabla \psi(x, y) = 0, & (x, y) \in \partial R, \\ \iint_R \rho(x, y) = \iint_R \psi(x, y) = 0, \end{cases} \tag{1}$$

where R is the rectangular placement area, ∂R denotes its boundary, $\mathbf{n}$ is the outward normal vector of the region, ρ is the charge density, and ψ stands for the electric potential. The numerical solution of Poisson's Equation (1) can be found in [15].

Then, the wirelength-driven analytical global placement problem can be formulated as [3, 15, 16]:

$$\min_{x,y} \sum_{e \in E} WA_e(x, y) + \lambda_1 D(x, y), \tag{2}$$

where $D(x, y)$ is the electrostatic-based density penalty term, calculated by: $D(x, y) = \frac{1}{2} \sum_{i \in V} A_i \psi_i$, where A_i is the area of cell i, ψ_i is the electric potential of cell i. λ_1 is the weighting factor to balance the total wirelength and density penalty. Calculation of the electrostatic-based density gradient $\nabla D(x, y)$ can be found in [15].

B. Analytical Routability-Driven Global Placement

To address routability in global placement, we first introduce the definition of routing congestion. The 3D routing region is divided into a set of global routing cells (G-cells), denoted by $G_R \in \mathbb{R}^{R_r \times R_c \times L}$, here, R_r and R_c represent the row and column numbers of the routing grid, while L denotes the number of routing layers. Based on the G-cells, a congestion map C can be defined as [8]:

$$C_{m,n} = \max \left(\frac{\sum_{l=1}^{L} Dmd_{m,n,l}}{\sum_{l=1}^{L} Cap_{m,n,l}} - 1, 0 \right), \quad \forall (m, n) \in \mathbb{R}^{R_r \times R_c}, \tag{3}$$

where $C_{m,n}$ is the congestion value of the m-th row and n-th column of congestion map C. Dmd represents the routing demand map, which represents the total of wire demand and via demand, Cap refers to the routing capacity map.

To facilitate the establishment of the congestion model, we create a mapping of G-cells onto the 2D plane, which has the same dimension as the bins division. Let $Dmd_{m,n} = \sum_{l=1}^{L} Dmd_{m,n,l}$ and $Cap_{m,n} = \sum_{l=1}^{L} Cap_{m,n,l}$ represent the total routing demand and the total routing capacity of all layers' G-cells located at the m-th row and n-th column, respectively. Hereafter, any mention of G-cell refers to the 2D mapping. For routability-driven global placement, constraints are imposed into Equation (2) to ensure that the routing demand does not exceed its given routing capacity, and the routability-driven global placement problem is:

$$\begin{aligned} \min_{x,y} \quad & \sum_{e \in E} WA_e(x, y) + \lambda_1 D(x, y) \\ \text{s.t.} \quad & Dmd_{m,n} \le Cap_{m,n}, \quad \forall (m, n) \in \mathbb{R}^{R_r \times R_c}. \end{aligned} \tag{4}$$

Meeting the routing congestion constraints of Equation (4) is challenging, as routing demands frequently exceed available resources in certain regions, making routing congestion hard to alleviate. To handle this issue, we adopt the electric field model of ePlace [15], which enables moving cells away from high-density placement areas.

Analogous to [15], we apply the electric field model for routing congestion mitigation, using Poisson's equation to obtain an analytical solution for guiding the movement of cells away from high-congestion areas. To this aim, we take ρ in Equation (1) as

$$\rho_{m,n} = \frac{Dmd_{m,n}}{Cap_{m,n}}, \quad \forall (m, n) \in \mathbb{R}^{R_r \times R_c},$$

where $Dmd_{m,n}$ and $Cap_{m,n}$ are obtained by invoking the global router of [18]. Then, we solve Poisson's Equation (1) to obtain a solution, which is the electric potential for congestion, and calculate the related electrostatic-based congestion penalty term $C(x,y)$ by: $C(x,y) = \frac{1}{2}\sum_{i\in V'} A_i\psi_i$, where V' represents the set of multi-pin cells and virtual cells (for moving nets, detailed in Subsection III-A), A_i and ψ_i denote the area and electric potential of cell i, respectively. Then similar to Equation (2), the analytical routability-driven placement model can be established:

$$\min_{x,y} \quad \sum_{e\in E} WA_e(x,y) + \lambda_1 D(x,y) + \lambda_2 C(x,y), \tag{5}$$

where λ_2 is the weight for the congestion penalty term, which will be elaborated on in Subsection III-A. **The electrostatic-based congestion gradient $\nabla C(x,y)$ is computed with the method in [15]. However, it is not used directly as that of cell density, since the aim is mainly for moving nets to mitigate global routing congestion.** Updating $\nabla C(x,y)$ is detailed in Subsection III-A.

III. The Proposed Algorithm

This section details our proposed analytical routability-driven global placement framework for problem (5). Fig. 2 outlines the overall flow of the proposed algorithm. The red boxes indicate the technical points that we contribute.

In Fig. 2, we select power and ground (PG) rails based on the positions of macro blocks to prepare for the subsequent pin accessibility optimization. Then, we use the wirelength-diven global placer Xplace [16] to obtain an initial global placement result. Next, we proceed to the routability-driven global placement stage. We adopt the GPU-accelerated 3D Z-shape routing algorithm [18] to estimate routing congestion and generate a congestion map. This map is used for adjusting the cell inflation rate through our momentum-based cell inflation technique, and then we dynamically modify the local density using our pin accessibility adjustment technique. Next, the updated placement information is incorporated into the objective function of problem (5), which is subsequently solved using the Nesterov solver proposed in [15]. The routability-driven global placement is repeated until the $C(x,y)$ no longer decreases or the given number of iterations is reached. Lastly, the routability-driven legalization and detailed placement of Xplace-route [8] is adopted for the final placement.

In the following content of this section, we first introduce the congestion gradient update for mitigating global routing congestion in Subsection III-A. Then in Subsection III-B, we present the momentum-based cell inflation technique for mitigating local routing congestion. Finally, Subsection III-C discusses the pin accessibility optimization during the global placement stage.

A. Congestion Gradient Update

This subsection presents the congestion gradient update technique for the problem (5). As described earlier, congestion is generally categorized into local routing congestion, due to an excessive number of cells within an area covered by a routing grid, and global routing congestion, caused by high wiring density within a routing grid.

After adopting the GPU-accelerated 3D Z-shape routing algorithm [18] to estimate routing congestion and generate a congestion map, we can obtain the congestion penalty and cells' congestion gradient in problem (5). However, it would be insufficient to move the cells directly according to the congestion gradient generated by the electric field model as we do for the cell density, because a high congestion value is not only due to the excessive clustering of cells (local routing congestion, handled in Subsection III-B), but may also result

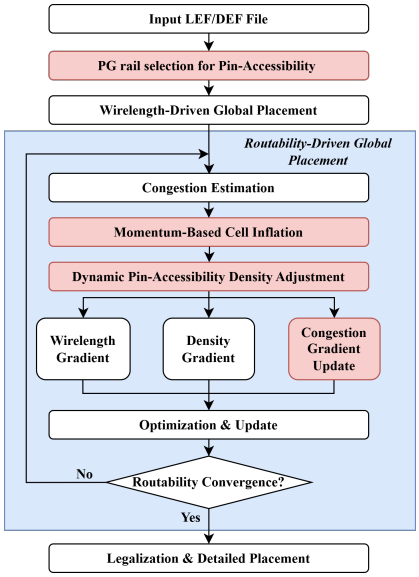

Fig. 2: Overview of our routability-driven global placement flow.

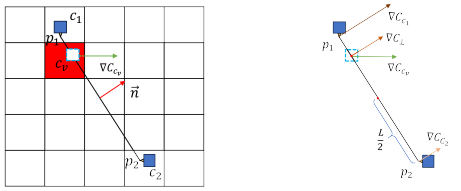
from a large number of nets covering the region (global routing congestion), as demonstrated in Fig. 1. In this subsection, we propose two strategies to mitigate global routing congestion.

Initially, We set the congestion gradient of all cells to 0, and then adjust them via the following approach. Firstly we update the congestion gradient for the two cells connected by a two-pin net, aiming to move the net. Then we update the congestion gradient for selected multi-pin cells.

1) Congestion Gradient Update for Two-Pin Net Moving: To mitigate global routing congestion, we propose a congestion gradient update algorithm for two-pin net moving. Since there is no routing information in the placement stage, the electric field force model only affects cells within the placement region, while generally ignoring net information. Therefore, to optimize routability for the nets, we introduce a virtual cell in every two-pin net, serving as a pivot point to guide the movement of the net.

For a two-pin net e with pins p_1 and p_2, as shown in Fig. 3(a), (x_1,y_1) and (x_2,y_2) are the positions of p_1 and p_2, respectively. Let c_1 and c_2 represent the cells to which these two pins belong. By connecting the pins p_1 and p_2, we get the segment $\widehat{p_1p_2}$. Then we determine the location of a virtual cell c_v with the same size as a standard cell for the two-pin net in a congested region.

Let l_x and l_y denote the width and height of a G-cell, respectively. We calculate (x_v,y_v) for c_v by the following equations:



$$k = \max\left(\left\lfloor\frac{|x_1-x_2|}{l_x}\right\rfloor, \left\lfloor\frac{|y_1-y_2|}{l_y}\right\rfloor\right), \tag{6}$$

$$(x_i,y_i) = (x_1,y_1) + \frac{i}{k+1}(x_2-x_1, y_2-y_1), \quad i\in[1,k], \tag{7}$$

$$(x_v,y_v) = \arg\max_{(x_i,y_i)} C_{m,n}, \quad m = \left\lfloor\frac{x_i}{l_x}\right\rfloor, n = \left\lfloor\frac{y_i}{l_y}\right\rfloor. \tag{8}$$

In Equation (6), we approximate the number k of G-cells traversed by the segment $\widehat{p_1p_2}$ by taking the maximum value between $\left\lfloor\frac{|x_1-x_2|}{l_x}\right\rfloor$ and $\left\lfloor\frac{|y_1-y_2|}{l_y}\right\rfloor$. Next we proportionally select k candidate points (x_i,y_i) on the segment in Equation (7). Then, we substitute the candidate points into the congestion map to select the candidate point with the maximum congestion value as (x_v,y_v) in Equation (8), where $C_{m,n}$ is given in Equation (3). At (x_v,y_v), a virtual cell c_v of the same size as a standard cell is created (shown in Fig. 3(a)).

Subsequently, we utilize the virtual cell c_v to calculate the con-

(a) (b)

Fig. 3: Congestion gradient for cells on a two-pin net. (a): c_1 and c_2 are two cells connected by the net with pins p_1 and p_2. $\vec{n}$ is the unit normal direction of the segment $\widehat{p_1p_2}$, oriented to form an acute angle with ∇C_{c_v}. The red region indicates the most congested region, where a virtual cell c_v is generated with the congestion gradient ∇C_{c_v}. (b): $\nabla C_\perp$ is ∇C_{c_v}'s projection onto $\vec{n}$. Then, ∇C_{c_1} and ∇C_{c_2} are updated so that they have the same direction as $\nabla C_\perp$.

gestion gradients for the cells c_1 and c_2, ensuring their connection net can be moved away from the high congestion region. Let $\vec{n}$ be the unit normal direction of the segment $\widehat{p_1p_2}$, and oriented to the direction with an acute angle with ∇C_{c_v}. Here, ∇C_{c_v} is the congestion electric field gradient experienced by the virtual cell c_v. We project ∇C_{c_v} onto $\vec{n}$ and get $\nabla C_\perp$, as shown in Fig. 3(b). This is the most efficient direction for the connecting net to leave the congested region. The final congestion gradient for the cells c_1 and c_2 is calculated as follows:

$$d_{iv} = \sqrt{(x_v - x_i)^2 + (y_v - y_i)^2},$$
$$\nabla C_{c_i} = \frac{L}{2d_{iv}} \nabla C_\perp, \tag{9}$$

where d_{iv} is the Euclidean distance between pin p_i and virtual cell c_v. $L = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$ is the segment length of $\widehat{p_1p_2}$.

In Equation (9), we use $\frac{L}{2}$ as a reference to control a cell's congestion gradient based on the distance between the cell and the virtual cell. A cell near the congested region receives a larger congestion gradient, while a cell far away from the congested region receives a smaller congestion gradient. This allows the cells to move away from highly congested routing regions more efficiently.

Algorithm 1 summarizes the pseudocode for the proposed net-driven cell congestion gradient calculation. First, we identify the maximum congestion point (x_v, y_v) along the segment connecting two pins (line 1) and create a virtual cell c_v (line 2). The congestion gradient ∇C_{c_v} of c_v is then obtained using the electric field model (line 3). Next, the straight-line distance L between the two pins is calculated, and a perpendicular vector $\vec{n}$ that forms an acute angle with the gradient ∇C_{c_v} is derived (lines 4-5). Finally, the congestion gradient of c_1 and c_2 is computed (lines 6-9).

2) Congestion Gradient Update for Multi-pin Cell: A multi-pin cell is connected to several other cells. A large number of nets are connected to multi-pin cells, and these cells often increase global routing congestion in areas where routing resources are already limited. To address this issue, we compute by Equation (1) the congestion gradient of **selected multi-pin cells**, and then update the gradient for moving these cells away from congested regions, thereby alleviating global routing congestion. The specific approach is presented as Algorithm 2.

In lines 3-6 of Algorithm 2, Algorithm 1 is executed to obtain the congestion gradient for each cell of the two-pin net. Lines 7-15 perform congestion gradient adjustments for selected multi-pin cells. Specifically, when the number of pins of a cell i is greater than the average number of pins $\bar{n}$ (line 1) and the congestion value of the G-cell under which the cell i's center position is located exceeds 0.7 (line 11), we adopt the congestion gradient of the cell by Equation (1) (line 12). Finally, the congestion gradient of all cells in net e is obtained by combining the congestion gradients produced by the two approaches (lines 16).

Algorithm 1: Cell Congestion Gradient Update for Two-Pin Net Moving

Input: Cells c_1, c_2, Pin positions p_1, p_2, Congestion map C;
Output: $CGrad^{net}$: Congestion gradient of cells c_1 and c_2.
1 $(x_v, y_v) \leftarrow$ find max congestion position by Equation (8);
2 $c_v \leftarrow$ create a virtual cell;
3 $\nabla C_{c_v} \leftarrow$ congestion gradient of c_v by Equation (1);
4 $L \leftarrow$ calculate distance between p_1 and p_2;
5 $\vec{n} \leftarrow$ the unit vector perpendicular to the segment connecting p_1 and p_2 and forming an acute angle with ∇C_{c_v};
6 **for** $i \in \{1, 2\}$ **do**
7 $\quad d_{iv} \leftarrow$ calculate distance between p_i and c_v;
8 $\quad \nabla C_\perp \leftarrow (\nabla C_{c_v} \cdot \vec{n}) \cdot \vec{n}$;
9 $\quad CGrad^{net}_{c_i} \leftarrow \frac{L}{2d_{iv}} \nabla C_\perp$;
10 **end**
11 **return** $CGrad^{net}$;

With Algorithm 2, the congestion gradient of all cells is obtained by traversing all nets of a circuit, and then the congestion gradient of each cell is the superposition of the congestion gradients returned to the cell by each of these nets.

Algorithm 2: Congestion Gradient Update for Cells on a Net

Input: Net e, the set of cells c_i of the net, pins $p_{i,j}$ of cell i, congestion map C;
Output: $CGrad$: Congestion gradient of cells c_i in net e.
1 $\bar{n} \leftarrow$ average number of pins of all cells;
2 $k \leftarrow$ number of pins in the net e;
3 $CGrad^{net} \leftarrow 0$;
4 **if** $k = 2$ **then**
5 $\quad$ Use Algorithm 1 to obtain $CGrad^{net}$;
6 **end**
7 $CGrad^{cell} \leftarrow 0$;
8 **foreach** c_i **do**
9 $\quad n \leftarrow$ the number of pins of cell c_i;
10 $\quad C_{c_i} \leftarrow$ the congestion value of the G-cell under which the cell c_i's center position is located;
11 $\quad$ **if** $n > \bar{n}$ *and* $C_{c_i} > 0.7$ **then**
12 $\quad\quad CGrad^{cell}_{c_i} \leftarrow$ congestion gradient of c_i by Equation (1);
13 $\quad$ **end**
14 $\quad CGrad^{cell} \leftarrow CGrad^{cell}_{c_i}$;
15 **end**
16 $CGrad \leftarrow CGrad^{net} + CGrad^{cell}$;
17 **return** $CGrad$;

3) The Weight of Congestion Penalty Term: In Section II-B, we established the analytical routability-driven global placement model (5), in which λ_2 is the congestion penalty weight. Here, it is set as:

$$\lambda_2 = \frac{2N_C}{N} \cdot \frac{||\nabla W(x,y)||_1}{||\nabla C(x,y)||_1}. \tag{10}$$

In Equation (10), λ_2 is obtained by the ratio of the L_1 norm of the wirelength gradient $\nabla W(x,y)$ to that of the congestion gradient $\nabla C(x,y)$, multiplied by an adjustment coefficient. Specifically, N_C is the total number of cells in congested regions, and N is the total number of cells. Using Equation (10), λ_2 is adjusted based on the current overall congestion during the iteration. When the number of cells in a congested area is big, λ_2 will be large, prioritizing con-

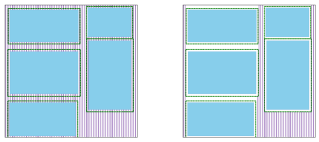
gestion optimization. Conversely, if congestion is low, λ_2 decreases, allowing for a greater emphasis on wirelength optimization.

B. Momentum-Based Cell Inflation

This subsection presents the momentum-based cell inflation technique for mitigating local routing congestion. Most cell inflation techniques primarily adjust cell's inflation rate based on the congestion information from the current iteration [3, 5]. They encounter the issue of moving a cell back into the original congested area when the cell is transited from the inflated state to the original state or over-inflated during the iteration. To address this issue, we incorporate the momentum technique into calculating the inflation rate. Our approach considers the historical inflation rate of a cell similar to NTUplace4dr [9] and a cell deflation mechanism to utilize available resources better. Once the inflation rate is determined, the cell size is proportionally inflated during density calculation, increasing the density of congested region. This provides a higher gradient to the cells in congested regions, prompting them to spread out the regions.

Specifically, the core formula is as follows:

$$\begin{aligned} r_i^t &= \min\left\{\max\left(r_i^{t-1}+\Delta r_i^t, r_{\min}\right), r_{\max}\right\}, \\ \Delta r_i^t &= \alpha \Delta r_i^{t-1} + (1-\alpha) s_i^t, \\ s_i^t &= \delta_i^t C_i^t, \end{aligned} \tag{11}$$



where r_i^t represents the inflation rate of cell i at the t-th ($t = 1, 2, 3, \dots$) iteration of cell inflation, and $r_i^0 = 1$. The r_{min}, $r_{\max}$, and α are user-specified values that provide an appropriate inflation rate for each cell, which are set to 0.9, 2.0, and 0.4 in this work respectively. Δr_i^t denotes the change value in the inflation rate, which is mainly affected by the inflation rate of all previous iterations, and $\Delta r_i^1 = C_i^1$. C_i^t is the congestion value of the G-cell under which cell i's center position is located at the t-th iteration of cell inflation. Moreover, in Equation (11), s_i^t is the congestion correction factor, which is determined by a decision parameter δ_i^t and the congestion value. δ_i^t is calculated by:

$$\delta_i^t = \begin{cases} -\left|\frac{C_i^{t-1}\bar{C}^t - C_i^t \bar{C}^{t-1}}{\bar{C}^{t-1}\bar{C}^t}\right|, & \text{if } C_i^t < \bar{C}^t \text{ and } C_i^{t-1} > \bar{C}^{t-1}; \\ 1, & \text{otherwise.} \end{cases} \tag{12}$$

In Equation (12), $\bar{C}^t$ is the average congestion value of all G-cells at the t-th cell inflation. If δ_i^t remains constant to 1, r_i^t will be monotonically increasing, meaning the inflation ratio of the cell will continue expanding even after it has been moved away from the congested region. This is unreasonable, so we introduce a cell deflation mechanism. When the congestion value C_i^t of cell i at the t-th iteration is lower than the average congestion value $\bar{C}^t$ of the t-th iteration, and the congestion value C_i^{t-1} of the $(t-1)$-th iteration is higher than the average value $\bar{C}^{t-1}$, we think that the cell has been moved away from a high congestion area to a low congestion area. At this time, a negative congestion correction factor is applied to the cell. We quantify the degree of cell deflation through the following approach. We calculate the ratio of $\bar{C}^t - C_i^t$ to the average congestion value $\bar{C}^t$, and then add the term $\frac{C_i^{t-1}-\bar{C}^{t-1}}{\bar{C}^{t-1}}$ to $\frac{\bar{C}^t - C_i^t}{\bar{C}^t}$ to get the absolute value $\left|\frac{C_i^{t-1}\bar{C}^t - C_i^t\bar{C}^{t-1}}{\bar{C}^{t-1}\bar{C}^t}\right|$, which represents the deflation strength of cell i, as shown in Equation (12).

C. Dynamic Pin-Accessibility Density Optimization

This subsection presents the dynamic pin-accessibility density optimization technique. Pin-accessibility is closely related to routability. Most work performs pin-accessibility optimization at detailed placement, in which local perturbations such as cell shifting, flipping, and swapping are used to optimize pin-accessibility [11, 12, 13]. These methods limit exploration space for pin-accessibility optimization. To improve solution quality, we consider pin accessibility optimization during global placement. As mentioned in Xplace-Route [8], during the placement process, cells on the M1 layer may move beneath the power grid rails on the M2 layer, making it difficult to connect the pins on these cells due to the constrained routing resources on M1. Xplace-Route [8] only adjusts cell density around PG rails before placement, while we focus on addressing pin accessibility throughout the entire global placement process. Our pin-accessibility algorithm is mainly divided into the following two steps:

(a) (b)

Fig. 4: PG rail selection for density adjustment in design matrix_mult_a [1], where the purple lines represent PG rails, the blue areas denote macro blocks and the green dashed line represents the expanded macro's bounding box. (a) presents all PG rails before PG rail selection. (b) gives the selected PG rails, the cell density of the related area will be adjusted.

1) PG rail selection for Pin-Accessibility: We find experimentally that, indiscriminately increasing the cell density of all regions covered by PG rails on the M2 layer is unreasonable. For example, the narrow region between macros are already highly congested, increasing the cell density around PG rails in the region would hinder cell spreading. Therefore, we perform a pre-processing step to identify regions where density can be adjusted effectively.

Specifically, we expand each macro's bounding box by 10%, and then project all bounding boxes and the PG rails onto the 2D plane, as shown in Fig. 4(a). These PG rails will be cut by the bounding boxes into some new PG rails. Then, we choose those PG rails whose length are at least 0.2 times the placement region's width (or height) in the horizontal (or vertical) direction, as shown in Fig. 4(b). The chosen PG rails are used for the next step of cell density adjustment.

2) Dynamic Pin-Accessibility Density Adjustment: Since multiple factors can affect congestion, it is impractical to focus only on the PG rails and ignore other factors. To reserve space for optimizing other factors and improve pin accessibility, we propose a precise density adjustment strategy concerning PG rails, aiming at enlarging density in congestion regions covered by the selected PG rails.

First, we evaluate the routing congestion on the area of the selected PG rails using the global router of [18]. Since we predefine the G-cell and bin to have the same dimension in Subsection II-B, we can map the congestion value of each G-cell to the corresponding bin at the same position. Then, **we selectively increase density only in highly congested bins**. This density adjustment dynamically adapts to congestion changes, preventing density increases across all selected PG rail areas and reserving space for further optimization.

Dynamic pin-accessibility-aware density primarily contains the original density D^{ori} and the M2-layer PG rails density D^{PG} (defined in Equation (13) and (14)). Cells located in the congested region covered by the selected PG rails will get a greater density gradient. This causes the cells at the region covered by congested PG rails to diffuse, reserving connection space for the pins in this area. The modified density D_b in bin b is: $D_b = D_b^{\text{ori}} + D_b^{PG}$, where

$$D_b^{\text{ori}} = \frac{1}{A_b}\sum_{i\in V} A_{c_i \cap b}, \qquad \forall b \in B, \tag{13}$$

$$D_b^{PG} = \frac{\eta_b(1+C_b)}{A_b}\sum_{i\in V_{PG}} A_{PG_i \cap b}, \qquad \forall b \in B. \tag{14}$$

* The DRV result of Xplace on superblue12 is not good, we exclude it from calculating its mean ratio to ensure a fair comparison of average ratios.
* Routing runtime may not reflect placement routability, as Innovus will end the detailed routing early if the placement has poor routability [8].

$$\eta_b = \begin{cases} 1, & \text{if } C_b > \bar{C}; \\ 0, & \text{otherwise.} \end{cases} \tag{15}$$

After adjusting the density map, we can calculate the density penalty in problem (5).

In the above Equations (13) and (14), $A_{c_i \cap b}$ represents the overlapping area between cell c_i and bin b, $A_{PG_i \cap b}$ represents the overlapping area between PG rail PG_i and bin b, and A_b represents the area of bin b. V is the set of cells, and V_{PG} is the set of selected PG rails during the PG rail selection process. C_b denotes the congestion value mapped at bin b, and $\bar{C}$ denotes the average congestion value across all bins. The PG rail density D_b^{PG} of bin b is controlled by the congestion value of bin b. As in Equation (15), if the congestion value C_b is higher than the average congestion value $\bar{C}$, the density increases with a weight of $1 + C_b$. This approach selectively increases the density in highly congested areas rather than adjusting the density in all regions where the selected PG rails cover, leaving additional space for other optimizations.

IV. Experimental Results

Our proposed framework is developed with PyTorch and CUDA, and deployed on the wirelength-driven global placer Xplace [16]. The experiments are performed on a Linux server with a 2.90GHz Intel Xeon CPU and a single Nvidia A800 GPU. The ISPD 2015 contest benchmarks [1] without fence-region constraints are used for the comprehensive evaluation and comparison.

We compare our analytical routability-driven global placement algorithm with Xplace [8] (without routability) and its routability-enhanced version Xplace-Route [8], a leading routability-driven placer. To ensure testing accuracy and maintaining the fairness of comparisons, the same version of the commercial tool Innovus [19] is used for global and detailed routing of the placement result by each compared placer. Specifically, we run each compared placer first and record the placement runtime (PT/s). Next, the placement result is input into Innovus to complete the global and detailed routing, and the post-routing results are recorded to measure routability. These results include detailed routing wirelength (DRWL/um), the number of DR vias (#DRVias), and the number of detailed routing violations (#DRVs). Moreover, we report the total routing runtime (RT/s). Table I lists the experimental results.

Table I shows that, our algorithm gains a significant improvement in routability compared to Xplace [8] and Xplace-Route [8]. Specifically, our algorithm achieves a 400% reduction in #DRVs compared to Xplace, meanwhile maintaining the same average DRWL and #DRVias. Compared to the leading routability-driven placer, Xplace-Route, our algorithm achieves a 40% reduction in #DRVs, while maintaining almost the same average DRWL and #DRVias.

TABLE II: Ablation Experiment.

Methods			DRWL/um	#DRVias	#DRVs
MCI	DC	DPA	Avg. Ratio	Avg. Ratio	Avg. Ratio
-	-	-	1.00	0.99	1.40
✓	-	-	0.99	0.99	1.27
✓	✓	-	1.00	1.00	1.12
✓	✓	✓	1.00	1.00	1.00

For the runtime, our algorithm spends $4.00\times$ and $1.59\times$ the total placement runtimes compared to Xplace and Xplace-Route, respectively. However, our algorithm's total global and detailed routing runtime is sped up by $1.37\times$ and $1.07\times$, compared to Xplace and Xplace-Route. These comparisons show that while our algorithm spends more time in placement to integrate routability techniques and reduce congestion, it ultimately reduces routing costs.

Further, we conduct ablation experiments to verify the effectiveness of our three techniques for alleviating routing congestion, with results shown in Table II. MCI refers to our algorithm with momentum-based cell inflation, DC to the algorithm with a differentiable congestion function, and DPA to the one with dynamic pin accessibility density adjustment. From the table, we observe that #DRVs decreases more as more techniques are applied, while the average DRWL and #DRVias remain nearly unchanged. This demonstrates that each technique improves routability without degrading wirelength or via count.

V. Conclusion

We have proposed an analytical framework for addressing routability in global placement. In this framework, a differentiable congestion function is developed by considering global routing congestion. Moreover, virtual cells in two-pin nets and selected multi-pin cells are introduced for guiding nets moving to mitigate global routing congestion. Furthermore, momentum-based cell inflation and dynamic pin-accessibility density optimization techniques are proposed for adjusting cell density to mitigate local routing congestion. Experimental results show that, our algorithm can effectively alleviate local and global routing congestion, improve routability significantly meanwhile maintaining comparable other metrics, compared to the leading routability-driven placer, Xplace-Route [8].

***Abstract*—K-nearest neighbor (kNN) search is a fundamental operation in various point cloud applications, such as autonomous driving. However, the heavy computational intensity and memory demands of kNN search pose significant challenges for efficient implementation, especially in resource-constrained scenarios. To address these challenges, we propose PICK, a processing-in-memory (PIM) architecture designed to accelerate kNN search in point cloud applications. PICK leverages bit-serial-based PIM (BS-PIM) and customized circuits to efficiently handle key operations of kNN search: distance calculation and top-k selection. The run-time off-chip access is eliminated thanks to the large on-chip memory. For distance calculation, we introduce a bit-width clipping technique to reduce the latency of bit-serial execution with negligible accuracy degradation, providing flexible trade-offs between performance and precision. Besides, we propose a filtering-and-selection strategy that realizes approximately constant time complexity for arbitrary values of k. Furthermore, a two-stage pipeline is implemented to parallelize distance calculation and top-k search, effectively hiding latency and improving throughput. According to our experiments, PICK achieves $4.17\times$ speedup and a $4.42\times$ energy saving over the state-of-the-art design.**

***Index Terms*—Processing-in-Memory, SRAM, KNN Search**

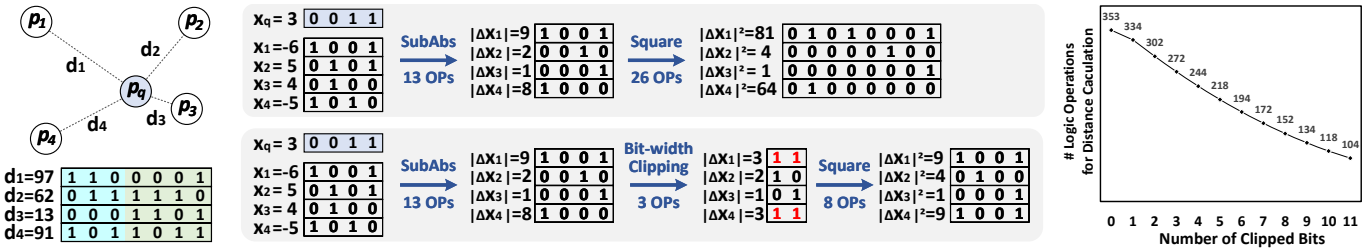
I. Introduction

Recent advancements in artificial intelligence have significantly driven the adoption of three-dimensional (3D) visual data, commonly known as point clouds. Generated by specialized sensors such as LiDAR [1], point clouds consist of sets of points representing the surfaces and properties of surrounding objects and environments. Their versatility has led to extensive use across various domains, including autonomous driving [2], robotics [3], and virtual reality [4]. These applications demand high accuracy while adhering to stringent performance constraints, such as low latency for real-time processing and minimal power consumption for edge deployments.

To meet these demands, significant research has focused on optimizing the *k-nearest neighbor* (kNN) search, a core operation in point cloud processing. KNN search identifies k closest reference points to a query point and underpins critical algorithms such as simultaneous localization and mapping (SLAM) [5], point registration [6], object recognition [7], and scene segmentation [8]. KNN search comprises two computationally intensive operators: *distance calculation* and *top-k search*, requiring extensive arithmetic computations and comparisons. Prior works [9], [10] have revealed that *kNN search can account for up to 80% of the latency in real-world point cloud applications*, primarily due to the computationally intensive nature of distance calculation and top-k search. Therefore, optimizing kNN search is crucial to improving the performance of point cloud applications, particularly in real-time and resource-constrained environments.

Recently, several kNN-specific accelerators [10]–[17] have been developed to enhance computational efficiency and reduce latency in point cloud applications. Partition-based techniques, *e.g.* kd-trees in QuickNN [11], octrees in ParallelNN [12] and SimDiff [14], hashing [15], and voxelization [16], have been explored to minimize computation and memory access. However, these methods often compromise accuracy (*e.g.*, 80% in [12]) and introduce preprocessing overhead. JUNO [13] exploits sparsity and locality to accelerate approximate neighbor search but cannot ensure full accuracy. BitNN [10] uses bit-serial computation and early termination to enhance efficiency but suffers from excessive on-chip and off-chip memory access, which accounts for over 35% of total energy consumption. Despite these advancements, challenges remain in *further reducing computation latency and memory access while preserving satisfactory accuracy*.

In this work, we propose PICK, a novel processing-in-SRAM architecture tailored to efficiently accelerate kNN search for point cloud applications. PICK leverages bit-serial-based PIM (BS-PIM) and custom computing modules to optimize the fundamental operations of kNN search, namely, distance calculation and top-k search. The *in-situ* bit-serial computing approach of BS-PIM minimizes on-chip data movement and simplifies circuit design, enabling sufficient on-chip memory to eliminate runtime off-chip memory access entirely.



Furthermore, to address the high latency of bit-serial algorithms [18], we introduce a bit-width clipping technique that reduces latency with negligible accuracy degradation, allowing flexible performance-accuracy trade-offs for diverse use cases. For top-k search, we design an efficient filtering-and-selection strategy that achieves approximately constant time complexity for arbitrary k. Additionally, a two-stage pipeline parallelizes distance calculation and top-k search, hiding latency and improving throughput. Extensive evaluations on real-world point cloud datasets demonstrate that PICK achieves a $4.17\times$ speedup and $4.42\times$ energy savings compared to the state-of-the-art accelerator BitNN [10]. The key contributions of this work are summarized as:

- We propose PICK, the first PIM-based architecture to accelerate the kNN search in point clouds. The highly parallelized and in-situ computing approach greatly accelerates the computation and reduces both on-chip and off-chip data movements.
- We propose a bit-width clipping method to reduce the latency and energy of distance calculation, with negligible accuracy loss.
- We propose a filtering-and-selection-based search method to efficiently perform top-k search for arbitrary values of k, enabling optimal performance across a wide range of application scenarios.
- By comparison, PICK achieves $4.17\times$ speedup and $4.42\times$ energy saving over the state-of-the-art accelerator BitNN.

II. Background

Point Cloud The point cloud is an unordered collection of discrete points, represented as $\mathbb{P} = \{\boldsymbol{p}_i\}$, where $\boldsymbol{p}_i = (x_i, y_i, z_i)$ specifies the Cartesian coordinates of the i-th point in the set $\mathbb{P}$. Typically, point clouds are continuously captured by specialized devices (*e.g.*, LiDAR and 3D scanner), enabling the perception and reconstruction of surrounding environments. Modern LiDAR sensors [19] can generate

(a) Example of 1-NN (b) Distance calculation without (top) and with (bottom) bit-width clipping (c) Reduction of operations

Fig. 1: **Motivation for bit-width clipping**. (a) Example of 1-NN (kNN with $k = 1$) search between a query point $\boldsymbol{p}_q$ and four reference points $\{\boldsymbol{p}_1, \boldsymbol{p}_2, \boldsymbol{p}_3, \boldsymbol{p}_4\}$, where $\boldsymbol{p}_3$ is identified nearest with a distance d_3 which can be accurately represented using only 4 bits (in green). (b) Comparison of distance calculation along the x-dimension, shown without (top) and with (bottom) bit-width clipping. Bit-width clipping reduces the number of bit-serial logic operations (OPs) and memory usage, while maintaining $\boldsymbol{p}_3$ as the nearest point. (c) As more bits are clipped (initially 16-bit), the distance calculation involves fewer logic operations, leading to a reduction in computational latency.

up to 460k points per frame at a frame rate of 20Hz (*i.e.*, 50ms per frame), delivering rich spatial information that underpins a wide range of applications. Recent point cloud datasets [20]–[23] cover diverse scenarios, including objects, indoor and outdoor environments, and geographic landscapes, further broadening the utility and applicability of point cloud data.

K-nearest-neighbor (kNN) search. The kNN search is an extensively employed algorithm to identify the top-k closest reference points to a given query point, in point cloud applications. This process consists of two primary operations: *distance calculation* and *top-k search*. The distance calculation computes the squared Euclidean distance between a reference point $\boldsymbol{p}_i = (x_i, y_i, z_i)$ and a given query point $\boldsymbol{p}_\mathrm{q} = (x_\mathrm{q}, y_\mathrm{q}, z_\mathrm{q})$, which can be expressed as $d = |x_i - x_\mathrm{q}|^2 + |y_i - y_\mathrm{q}|^2 + |z_i - z_\mathrm{q}|^2$. Once the distance d_i is calculated for each reference point $\boldsymbol{p}_i$ relative to the query point $\boldsymbol{p}_\mathrm{q}$, the top-$k$ search is performed to identify the k points with the shortest distances and retrieve corresponding indices as $\{i_1, i_2, \ldots, i_k\}$.

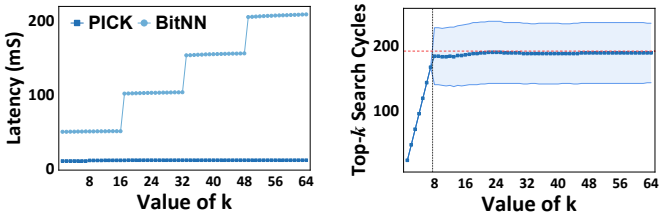
Bit-Serial-based Processing-in-Memory. Processing-in-memory (PIM) architectures [24]–[27] have been extensively investigated to accelerate various applications, offering reduced data movements and substantial computing parallelism. Bit-serial-based PIM (BS-PIM) is an extension of PIM that incorporates bit-serial algorithms [18], aiming to support general-purpose tasks. In bit-serial algorithms, multi-bit arithmetic functions (*e.g.*, addition, multiplication) are decomposed into multiple bit-wise logic operations (*e.g.*, `AND`, `OR`, `XOR`), which are executed sequentially over multiple cycles. To realize these operations efficiently, existing BS-PIM designs [28]–[32] employ bit-line computing technique [28] that enable parallel execution of bit-wise logic operations, and further extend support to arbitrary multi-bit arithmetic functions. In essence, BS-PIM facilitates *in-situ* scalar-vector [31] and vector-vector [29] arithmetic operations, making it a versatile architecture for diverse computational tasks.

III. Motivations

A. Minimizing Data Movements by Efficient PIM architecture

Problem. Memory access poses a significant bottleneck in optimizing kNN search, prominently impacting both latency and energy consumption. For instance, prior work [10] highlights that *non-continuous DRAM access accounts for over 80% of runtime* in QuickNN [11], while the on/off-chip data movements contribute to 35% of the energy consumption in BitNN [10]. To address these challenges, we propose to leverage PIM architecture to accelerate kNN search and minimize both on-chip and off-chip data movement.

Idea. Our approach incorporates customized computing circuits alongside the BS-PIM micro-architecture design from [28]–[31] to enable efficient in-memory kNN search. The large on-chip memory capacity in our design eliminates runtime off-chip memory access, while delicately optimized execution flows significantly reduce on-chip data movement and maximize computing parallelism. Furthermore, the bit-serial execution model inherent to BS-PIM facilitates energy-efficient *in-situ* arithmetic operations, thereby substantially lowering the energy consumption associated with kNN search.



B. Optimizing Distance Calculation through Bit-width Clipping

Problem. Bit-serial algorithms support a wide range of arithmetic functions, however, at the cost of high latency. For instance, an N-bit unsigned integer multiplication requires $(N^2 + 5N - 2)$ logic operations [30], *i.e.*, consuming 334 clock cycles for 16-bit data. Despite substantial throughput achieved through extensive computing parallelism, the execution latency of BS-PIM remains considerably higher than specialized digital circuits, particularly for distance calculation in kNN search. Reducing the bit-width of point cloud coordinates (x, y, z) can only marginally improve the latency since a minimum of 14-bit is required to maintain accuracy, as in BitNN [10].

Idea. We propose *bit-width clipping* to clip the bit-width precision of multiplications in distance calculation, thereby reducing operational cost and improving latency, with minimal impact on accuracy. This method leverages the observation that the *smallest distance, indicating the nearest point, can be precisely represented with fewer bits*. For example, in the 1-NN scenario shown in Fig. 1(a), the nearest reference point $\boldsymbol{p}_3$ to the query point $\boldsymbol{p}_q$ has a distance d_3=13, which can be accurately represented using only the lower four bits. Using additional bits to accurately represent distances $\{d_1, d_2, d_4\}$ is unnecessary for identifying the nearest point but incurs more latency and energy.

Therefore, we clip the bit-width of squaring (*i.e.*, multiplication) in distance calculation to reduce operations and memory usage. The top of Fig. 1(b) shows distance calculation along the x-dimension without bit-width clipping, where $|\Delta x_i|^2$ is obtained through subtraction (*i.e.*, addition in 2's complement) and absolute value computation, followed by square operation. In contrast, the bottom portion of Fig. 1(b) applies bit-width clipping, where the bit-width of $|\Delta x_i|$ is clipped from 4-bit to 2-bit, greatly simplifying the subsequent square operation. Note that, the values of $|\Delta x_1|$ and $|\Delta x_4|$ exceed the representable range of 2-bit and are re-mapped to 3 (*i.e.*, the maximum value in 2-bit), to ensure they remain farther from the query point. Bit-width clipping preserves the accuracy of the kNN result, as $|\Delta x_i|^2$ remains the smallest value, while reducing 28% bit-wise logic operations.

In practical usage, where bit-widths are typically higher, bit-width clipping yields even greater improvements. We select an initial bit-width of 16 based on our analysis of four real-world datasets in Table I.

(a) Latency on KITTI at different k (b) Top-k search cycles at different k

Fig. 2: **Performance analysis at different k.** (a) The latency of PICK and BitNN [10] on KITTI dataset [20] for various k values (clipping width is 6-bit). (b) The cycles required by PICK for top-k search at different k. The vertical dashed line ($k = 7.5$) marks the boundary of small and large k, the shadow indicates variation.

Fig. 1(c) presents the number of operations at each clipping width, where we can achieve 56% reduction in operations by clipping 8-bit, with negligible accuracy degradation as proved in Section V.

C. Efficient Filtering-and-Selection Search for Arbitrary K

Problem. In kNN, k varies significantly w.r.t. different applications. For instance, point registration [6] often uses 1-NN, while classification [33] and segmentation [34] tasks require $k \in [3, 64]$. This variability in k poses a challenge for existing accelerators to achieve optimal performance. For example, BitNN [10] includes 16 top-k units, which support searching 16 nearest points in parallel for each iteration. When $k = 64$, four iterations are required with 4× latency as plotted in Fig. 2a, while also claimed to negatively affect accuracy [10]. Increasing the number of top-k units can mitigate latency growth, but it incurs hardware overhead and leads to underutilization for small k. In summary, *efficient support of arbitrary k is yet absent*. As the countermeasure, we introduce *filtering-and-selection-based top-k search to efficiently support arbitrary k*.

Idea. We first propose a selection-based method to implement top-k search of distances through k iterations of min-search. In each iteration, the nearest point with the smallest distance is identified, continuing this process for k times to obtain the k closest points. Notably, previously identified points are excluded from subsequent searches. This approach is efficient when k is small but suffers from linearly increasing latency as k grows, as in Fig. 2b.

Therefore, for larger values of k, we propose a filtering-based method to improve efficiency. Specifically, we introduce a threshold t to filter the distances d_i, and count the number of points within this threshold ($d_i < t$), denoted as n. By selecting an appropriate threshold t that satisfies $n = k$, the n points within the threshold correspond exactly to the top-k nearest points. However, in practice, achieving an exact match is often challenging. Thus, we employ a fast bisection algorithm to dynamically adjust the threshold t, iteratively refining it until n is close to k, such that $|n-k| < m$, where m is a variable tolerance. Once this condition is met, the selection-based method finalizes the process by including or excluding points as necessary to ensure an exact match with k. The optimal value of m and the boundary that distinguishes small and large k are determined through explorations. In KITTI dataset [20], we select $k = 7.5$ as the boundary and $m = 4$. Consequently, arbitrary top-k searches are accurately achieved with nearly constant time complexity, as shown in Fig. 2.

IV. Architecture of PICK

A. Architecture Overview

The architecture of PICK is illustrated in Fig. 3, comprising multiple components designed to efficiently perform kNN search. The

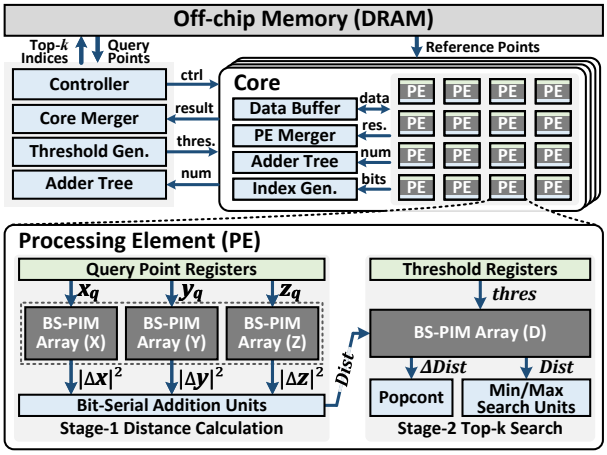


Fig. 3: **Overview of PICK architecture and dataflow.** The reference points are streamed from off-chip to the processing elements (PEs) of multiple cores for parallel computing. BS-PIM arrays cooperate with customized circuits to perform distance calculation and top-k search with a two-stage pipeline. The local search results are merged and the indices of the top-k nearest points are restored to the off-chip.

architecture features *multiple cores* dedicated to distance calculation and top-k search, a *core merger* for consolidating local search results from individual cores, a *threshold generator* and an *adder tree* for point filtering and counting (detailed in Section III-C), and a *controller* responsible for execution scheduling. Notably, the cores also function as on-chip storage for point cloud coordinates.

Core and PE. Each core integrates several key elements, including multiple processing elements (PEs), a data buffer with transposable access capabilities [28], a PE merger to aggregate search results from PEs, a local adder tree for point counting, and an index generator for retrieving the indices of searched points. At the core's foundation, the PE serves as the fundamental unit for kNN search. Each PE consists of four BS-PIM arrays dedicated to processing the x, y, and z dimensions, as well as distance computations. Additional components include registers for query points and thresholds, bit-serial-based units for arithmetic operations such as addition and min/max search, and a pop-count module for efficiently counting filtered points. This modular design ensures optimized performance and scalability for kNN search.

Dataflow of PICK, as annotated in Fig. 3, begins with point cloud data (coordinates) generated by sensors (*e.g.*, LiDAR) and stored in off-chip memory. Execution starts by streaming the reference points into the data buffers of multiple cores, where they are loaded into processing elements (PEs) in a transposed bit layout [28]. The reference points are stored in the BS-PIM arrays, while the coordinates of the query point are loaded into the PE registers.

Distance calculations for the x, y, and z dimensions are performed in parallel to compute $|\Delta x|^2$, $|\Delta y|^2$, and $|\Delta z|^2$, which are summed using bit-serial addition units and stored in the BS-PIM array dedicated to distance (Array D) for subsequent top-k search. For small values of k, the top-k nearest points are identified through k iterations of min-search, leveraging bit-serial min/max-search units, as detailed in Section III-C. For larger values of k, filtering is applied before selection, where distances are compared against a dynamical threshold, and the pop-count module counts the points within the threshold.

To optimize performance, a two-stage pipeline is employed to parallelize distance calculations and top-k search, to be described in Section IV-C. Since the number of reference points typically exceeds the capacity of a single PE, the data is distributed across multiple

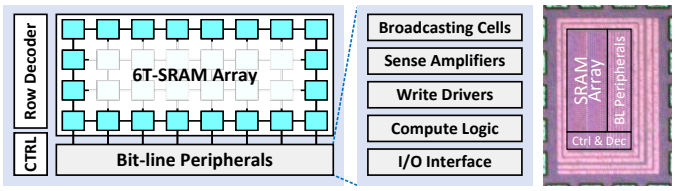

Fig. 4: **BS-PIM micro-architecture and micrograph of our demonstrated chip.** Parallel scalar/vector-vector bit-wise logic operations (AND, OR, XOR, and FA) are implemented utilizing bit-line computing technique [28] and integrated bit-line peripherals.

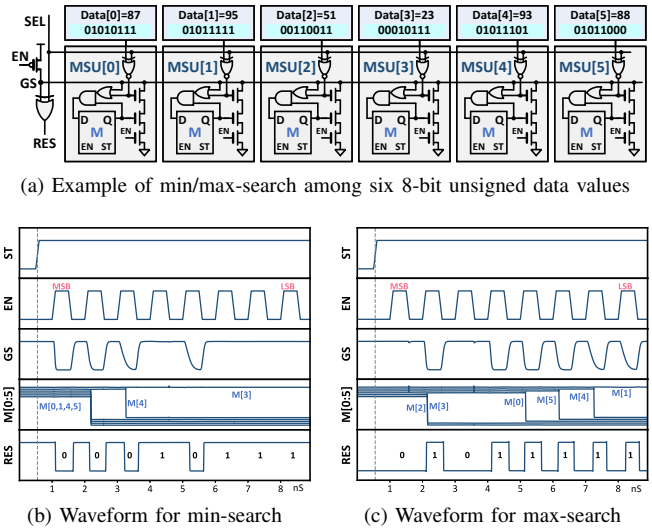
PEs and cores to enable parallel processing. Local search results, including values and indices, are hierarchically merged to produce the final result. Ultimately, the indices of the top-k nearest points are written back to off-chip memory.

B. Micro-architecture

1) BS-PIM Array: The micro-architecture of a single BS-PIM array, illustrated in Fig. 4, is designed to handle arithmetic operations (*e.g.*, addition, subtraction, multiplication) essential for kNN search. The circuit design of BS-PIM leverages optimizations from prior works [28]–[31], ensuring efficient and reliable performance.

At the core of the BS-PIM design is the 6T-SRAM array, which stores reference points or distances and enables parallel bit-wise logic operations (AND and NOR) through bit-line computing [28] and its associated bit-line peripherals. These peripherals are integral to both memory functionality and bit-serial computation. The broadcasting cells [31] facilitate the bit broadcasting of query points and distance thresholds, enabling concurrent scalar-vector arithmetic across all reference points and distances stored in the SRAM array.



Additional components include sense amplifiers and write drivers, which support memory read and write operations. Compute logic modules handle post-processing tasks such as bit-wise addition and multiplexing, while the I/O interface manages data input and output. These elements collectively ensure seamless integration of memory and computation within the BS-PIM array.

The demonstrated BS-PIM array, as depicted in Fig. 4, can execute the described computations at a maximum frequency of 1.35 GHz, making it a highly efficient and scalable solution for kNN search.

2) Min/Max-Search Units: The micro-architecture of the min/max-search units is depicted in Fig. 5a, which implements bit-serial-based vector-wise min/max search by iteratively comparing bits from the most significant bit (MSB) to the least significant bit (LSB) and conditionally updating the latch states (M). An example with six 8-bit unsigned integer values is shown in Fig. 5 to illustrate the procedure.

In each iteration, one bit from all data items is read as a bit vector, which is subsequently processed by the search units. This work specifically addresses the min/max-search of unsigned integers, as squared Euclidean distances are inherently non-negative. In this context, minimum and maximum values are distinguished by the concentration of '0' and '1' bits near the MSB, respectively. Therefore, *min-search can be treated as a max-search with input bits inverted*.

To accommodate this, we design max-search circuits and employ XNOR gates to invert input bits based on the SEL signal, as shown in Fig. 5a. When SEL is set to low, the circuit performs min-search, identifying Data[3] as the minimum value (Fig. 5b). Conversely, setting SEL to high enables max-search, identifying Data[1] as the maximum value (Fig. 5c). In PEs, the min/max-search process follows the same procedure but is executed with higher parallelism. Additionally, the index generator, as described in Fig. 3, converts

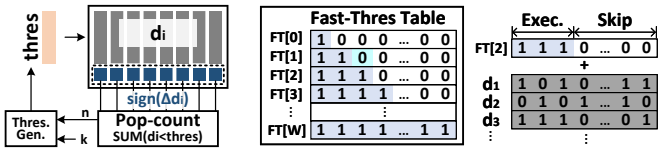
the latch bits (M) into an index using a priority encoder, enabling identification of the indices of the searched reference points.

C. Execution Flow

The execution flow of PICK follows the dataflow illustrated in Fig. 3, leveraging a two-stage pipeline to parallelize distance calculation and top-k search operations. The detailed implementation of these processes is outlined as follows.



1) Distance Calculation with Bit-width Clipping: The distance calculation determines the Euclidean distances between reference points and a given query point, incorporating bit-width clipping as described in Section III-B. The coordinates $(\boldsymbol{x}_i, \boldsymbol{y}_i, \boldsymbol{z}_i)$ of the reference points are stored as vectors in three BS-PIM arrays, utilizing a vertically aligned bit layout [28], as illustrated in Fig. 6. The query point coordinates are loaded into registers and broadcast to the BS-PIM arrays [31] for parallel computation.

Distance computation along each dimension involves three key bit-serial arithmetic functions, as shown in Fig. 6: subtraction and absolute value (SubAbs), bit-width clipping, and squaring. The implementation details of the bit-width clipping are provided in Algorithm 1. This technique introduces a complexity of $O(N)$, which simplifies the subsequent squaring operation, reducing its computational burden from $O(N^2)$. Finally, the summation of distance vectors across the x, y, and z dimensions is performed using bit-serial addition units, as depicted

Algorithm 1: Bit-serial-based Bit-width Clipping.

Input: A W-bit unsigned integer D; target bit-width W_c.

1: **for** each $i \in [W-1 : W_c+1]$ **do**
2: $\quad D[i] = OR(D[i], D[i-1])$
3: **for** each $i \in [0 : W_c]$ **do**
4: $\quad D[i] = OR(D[i], D[W_c])$
5: $D = D[0 : W_c]$

(a) Filtering-bases Search (b) Skip bit-serial addition with fast-thresholds

Fig. 7: **Illustration of filtering-based top-k search.** (a) The threshold is dynamically adjusted to make the number of points within the threshold approximates k. (b) Special thresholds (continuous '1's from MSB) are used to bypass the bit-serial additions of lower bits.

in Fig. 3. These addition units comprise digital 4-2 compressors and latches to achieve efficient accumulation of partial results.

2) Filtering-and-Selection-based Top-k Search: For small values of k, PICK performs top-k search by iteratively selecting the point with the smallest distance using min-search (Fig. 5b). To prevent previously selected points from being reconsidered in subsequent iterations, an additional bit is appended to the MSB of each reference point's distance. This bit acts as a mask, ensuring that selected points are assigned non-minimal distances and excluded from future searches.

For larger values of k, a filtering approach is employed to efficiently identify a subset of n points, where n approximates k within a predefined margin, such that $|n-k| < m$. The filtering-based top-k search process is depicted in Fig. 7a. During this process, the threshold generator produces a dynamic threshold value. The BS-PIM performs parallel bit-serial subtraction $\Delta d_i = (d_i - thres)$ and retains the sign bits. To simplify operations, negative thresholds are used, converting subtraction to addition in two's complement representation.

The pop-count unit sums the sign bits to determine the #points within the threshold ($d_i < thres$), denoted as n. Based on the comparison between n and k, the threshold generator adjusts the threshold iteratively: increasing $thres$ if $n < k$ or decreasing $thres$ if $n > k$. To accelerate threshold updates, a fast-threshold table is introduced, as shown in Fig. 7b. The table comprises threshold values consisting of continuous '1' bits starting from the MSB, enabling the system to bypass bit-serial additions for lower bits and save computational cycles. Thresholds from this table, denoted as *fast thresholds* (FT), are sequentially applied until $FT[x]$ results in $n < k$. Subsequently, thresholds are refined through binary approximation between $FT[x-1]$ and $FT[x]$, continuing until the condition $|n-k| < m$ is satisfied. Once the filtering phase concludes, the system applies either min-search (if $n < k$) or max-search (if $n > k$) to include or exclude the remaining $|n-k|$ reference points, finalizing the top-k search.

3) Pipeline Design: The pipeline of PICK is meticulously designed to optimize performance and maximize hardware utilization. Example pipeline and dataflow designs for distance calculation and top-k search are illustrated in Fig. 8. The operations are color-coded for clarity: memory read/write operations are marked in gray, while computational tasks are highlighted in green. The latency for distance calculation is constant, determined by the fixed bit-width and clipping width configurations. In contrast, the latency for the top-k search varies depending on the number of points processed, as shown in Fig. 2b.

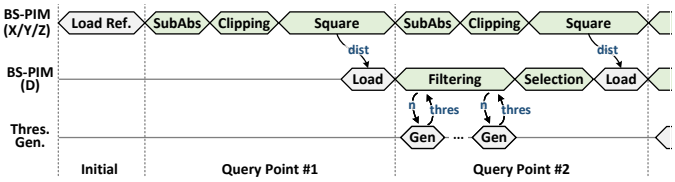


Fig. 8: **Pipeline design** of distance calculation and top-k search to hide latency and improve throughput.

TABLE I: Evaluation Benchmarks.

Dataset	Scenario	Sensor	Resolution	#Refer. Points	#Query Points
KITTI [20]	Outdoor	LiDAR	10^{-2}m	64k	64k
SONN [21]	Object	3D Scanner	10^{-4}m	64k	64k
S3DIS [22]	Indoor	3D Scanner	10^{-3}m	512k	512k
DALES [23]	Urban	LiDAR	10^{-2}m	512k	512k

V. Evaluation

A. Methodology

Benchmarks and Baselines. We construct evaluation benchmarks using four widely recognized real-world point cloud datasets, as summarized in Table I. These datasets encompass diverse application scenarios, including objects, indoor environments, outdoor settings, and urban landscapes, providing a comprehensive range of resolutions. The KITTI [20] and ScanObjectNN (SONN) [21] datasets represent smaller-scale scenarios, containing up to 64k points per frame. In contrast, S3DIS [22] and DALES [23] represent larger-scale environments, with up to 512k points per frame. Across all four datasets, the x, y, and z coordinates are encoded as 16-bit signed integers. For evaluation, we compare PICK against an RTX 3090 GPU (using PyG [35]) and prior kNN accelerators, including QuickNN [11], ParallelNN [12], and BitNN [10], which serve as our baselines.

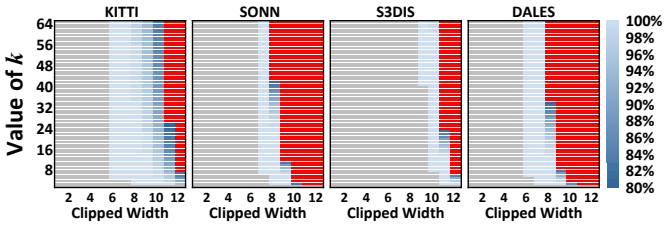
Implementations and Specifications. We implement PICK in 28nm technology and comprehensively validate its critical functionalities. The SRAM is generated using a commercial memory compiler and integrated with customized computing circuits using Virtuoso. For the data buffers supporting bit-layout transposition, we adopt the performance metrics reported in [30]. The digital circuits are implemented in Verilog and synthesized using Design Compiler. Architectural overheads, including data paths and memory organization, are modeled using NVSim [36], while off-chip memory access is evaluated with DRAMSim3 [37]. Hardware configurations and performance specifications are detailed in Table II, where PICK is evaluated in two configurations: small (S), optimized for smaller datasets (KITTI and SONN), and large (L), tailored for larger datasets (S3DIS and DALES). The hardware specifications are input into an in-house, cycle-level simulator to assess overall performance, where a PyTorch-based arithmetic library is developed to emulate hardware behaviors and evaluate accuracy, latency, and energy.

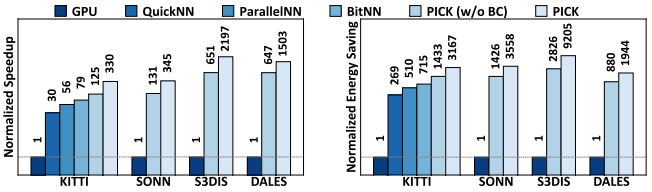
B. Experiment Results

Accuracy Analysis is conducted across four datasets with varying values of k (ranging from 1 to 64) and clipped bit-width (ranging from 1 to 12), to demonstrate that our proposed bit-width clipping method does not introduce noticeable accuracy degradation under appropriate configurations. The results are presented in Fig. 9, where accuracy below 80% is colored in red, while accuracy exceeding 99.9999998% (6σ, considered effectively error-free) is colored in gray. As evident from the results, maintaining accuracy for larger values of k requires more bits. However, for configurations clipping 5 bits on KITTI and DALES, 6 bits on SONN, and 8 bits on S3DIS, no noticeable accuracy loss is observed, even for 64-NN. These configurations

TABLE II: Hardware Configurations and Performance Specifications

Component	Configurations	Area (mm^2)	Power (mW)
PE	(96+18)kb BS-PIM, 512 parallelism	0.024	3.503
Core	32 PEs, 32kb Buffer, 16k parallelism	0.799	114.8
PICK(S)	4 Cores, 64k parallelism, 1GHz	3.293	463.7
PICK(L)	32 Cores, 512k parallelism, 1GHz	25.78	3677





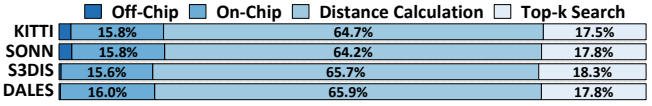


Fig. 9: **Accuracy map of PICK for varying values of k and clipped bit-width (initially 16-bit)**. Accuracy below 80% is filled in red, while accuracy exceeding 99.9999998% (6σ) is filled in gray.

(a) Normalized Speedup and Energy Saving

(b) Energy Breakdown of PICK

Fig. 10: **Normalized comparisons and energy breakdown of 5-NN search**. The bit-width clipping feature is disabled in PICK (w/o BC) to highlight the performance improvements.

achieve a significant reduction in the operational cost of distance calculation, ranging from 38% to 56%, as illustrated in Fig. 1(c).

Performance Analysis. Following prior works, we perform 5-NN searches on the four datasets to evaluate the performance of PICK, and compare it with GPU, QuickNN [11], ParallelNN [12], and BitNN [10]. The clipped bit-widths for the datasets are configured as $\{8,9,11,8\}$-bit, yielding accuracies of 99.38%, 99.94%, 99.73%, and 99.89%, respectively. To emphasize the effectiveness of our proposed bit-width clipping, we disable bit-width clipping in PICK (w/o BC). For fair comparisons, all non-GPU designs are normalized to the same power level. As shown in Fig. 10a, PICK achieves a 4.17× speedup and a 4.42× energy saving compared to the state-of-the-art design, BitNN, on the KITTI dataset. Furthermore, the bit-width clipping technique contributes to an additional 2.74× speedup and 2.54× energy savings. The energy breakdown, depicted in Fig. 10b, reveals that distance calculation and top-k search dominate the energy consumption. However, the costs of on-chip and off-chip data movements are minimized by the efficient PIM architecture and optimized execution flow, contributing to the overall efficiency.

Ablation Study. Fig. 11 presents the latency and energy scaling of PICK across different values of k, with bit-width clipping (BC), filtering-and-selection-based search (FSS), and fast-threshold (FT) individually disabled. For each value of k, the smallest clipping width is selected to maintain an accuracy above 99%. The stepwise jumps in the curves are primarily attributed to changes in the clipping width. Overall, BC demonstrates the most substantial impact on performance

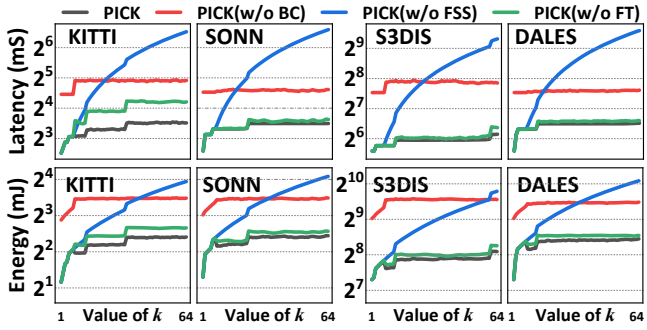

Fig. 11: **Latency and energy scaling** of PICK when disabling bit-width clipping (BC), filtering-and-selection-based search (FSS), and fast-threshold (FT), with accuracy constrained above 99%.

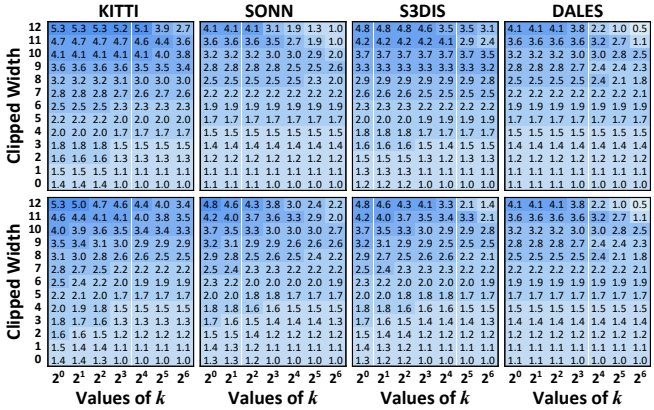

Fig. 12: **Latency (top) and energy (bottom) improvements** of PICK for varying values of k and clipped bit-width (initially 16-bit).

and energy efficiency. However, as k increases, FSS emerges as the dominant factor driving further optimizations. These results highlight the complementary contributions of the proposed techniques in scaling latency and energy efficiency of PICK across different configurations.

Data Movements Reduction. The data movement of PICK is significantly reduced, owing to its efficient architecture and optimized data flow. For example, on the KITTI dataset, BitNN [10] incurs 5.4MB of DRAM access, while PICK requires only 1.4MB for initialization and result storage, achieving over 70% reduction by fully eliminating runtime off-chip access. Additionally, on-chip access to buffers and registers is reduced from 0.4GB to 0.28GB.

Design Space Exploration. Fig. 12 illustrates the latency (top) and energy (bottom) improvements of PICK across varying values of k and clipped bit-width, using the performance of 64-NN without bit-width clipping as the baseline. PICK can achieve up to 5.29× speed and 5.25× energy saving. When combined with the accuracy map in Fig. 9, the optimal configuration can be selected based on specific task requirements. For example, applications demanding high accuracy, such as autonomous driving, may adopt lower clipped bit-widths, whereas latency-sensitive tasks, such as AR/VR applications, can benefit from higher clipped bit-widths for improved performance.

VI. Conclusion

This work proposes PICK, the first PIM architecture for kNN search in point clouds, incorporating novel bit-width clipping technique and filtering-and-selection-based search strategy to optimize the distance calculation and top-k search. Compared to existing designs, PICK achieves remarkable performance improvements.

***Abstract*—Compressional SSDs can be a mixed blessing. While they offer users expanded logical space beyond the physical capacity, they complicate the Flash Translation Layer (FTL) design by requiring a larger Logical-to-Physical (L2P) address mapping, which places a heavier burden on the limited in-SSD memory, leading to a degraded I/O performance. In this paper, we aim to reduce the memory footprint of the L2P mapping table in compressional SSDs by proposing a novel N-to-1 L2P mapping table design that consolidates multiple logical entries into a single entry. This approach eliminates the duplication of physical page numbers when a physical page contains several compressed logical pages. To accommodate the dynamic compression ratios of real-world workloads, we introduce promotion and demotion that enable mapping table entries to migrate between pages with different compression ratios. Additionally, to address the issue of partial invalidation—where some compressed logical pages within a physical page are invalid due to the N-to-1 mapping—we present a compression-aware garbage collection algorithm aimed at minimizing the number of copy operations for partially invalid physical pages. We have implemented our design in MQsim, a widely used SSD simulator, and have conducted a series of experiments to evaluate the effectiveness of the proposed techniques. The results demonstrate that our approach significantly reduces the mapping table size in compressional SSDs, leading to an improved mapping table cache hit ratio and a reduced I/O latency compared to traditional compressional SSDs.**

***Index Terms*—Compressional SSD, FTL, Cache management**

I. Introduction

The rapid growth of data volume has significantly increased the demand for high-capacity SSDs [21], [35]. However, due to the diminishing marginal effect, with Multi-Level-Cell (MLC)-based SSDs advancing to 5-bit or even 6-bit levels, the pace of capacity development begins to slow down [3], [7]. As an alternative approach, compressional SSDs emerge to offer users more available storage space than the actual physical space by compressing multiple logical pages into one physical page [2], [13]. Although compressional SSDs excel in workloads with higher compression ratios (CRs), they disrupt the traditional one-to-one Logical-to-Physical (L2P) address mapping by allowing multiple logical pages to be mapped to the same physical page. This complicates SSD firmware design.

With compressional SSDs, a larger logical space directly increases the size of the L2P mapping table, placing even more strain on limited in-SSD memory. For instance, if an 8TB compressional SSD with a 4KB page size exposes 16TB of logical space to users, the entire L2P mapping table will be doubled to 16GB which is a significant overhead for the limited in-SSD memory. Thus, existing approaches usually store the mapping table in NAND flash and cache it in the in-SSD memory. Considering that the user data is also cached in the memory, a larger mapping table inevitably compromises the cache hit ratio, thus affecting the I/O performance of compressional SSDs as more I/O operations require reading the mapping page from NAND flash before accessing corresponding data pages.

We have observed that inside compressional SSDs, a low cache hit ratio significantly prolongs access time, while the compression logic has a comparatively minor impact on overall latency [39]. This diminishes the effectiveness of existing studies that focus on optimizing compression algorithms [4], [6], [19], [22], [28], [37] or workflows [15], [17], [18], [20], [24], [30], [32], [36]. Therefore, in this paper, we aim to design a memory-efficient N-to-1 L2P mapping table for compressional SSDs. Specifically, our key idea is to eliminate redundancy in the traditional one-to-one L2P mapping table, where a Physical Page Number (PPN) can appear in multiple entries as in compressional SSDs multiple logical pages can be mapped to the same physical page. In our N-to-1 mapping table, consecutive N logical pages are consolidated into a single entry, efficiently eliminating the redundancy of physical page information. To achieve this, several challenges need to be conquered.

First, since different types of data exhibit varying CRs, a fixed parameter N in the N-to-1 mapping table cannot accommodate all scenarios effectively. Therefore, supporting diverse parameter N settings in the mapping table becomes the primary challenge. To address this, we introduce an additional marker in each Global Translation Directory (GTD) entry. The entry corresponds to the parameter N. It indicates how many consecutive logical pages can be mapped through a single second-level entry in the corresponding translation page based on the compression ratio of data. This allows us to efficiently support varying compression ratios for different workloads.

Second, as each entry represents multiple logical pages, traditional translation page allocation scheme becomes ineffective. With one translation page containing multiple entries with various CRs, logical space fragmentation becomes another critical challenge. To efficiently manage entries in a translation page, we introduce the concept of Translation Chunk inside each translation page, enabling fine-grained management of translation page space. For instance, a translation page can have eight 8-to-1 chunks, four 4-to-1 chunks, two 2-to-1 chunks, one 1-to-1 chunk, or other combinations. Building upon this, we

*Corresponding author

propose a partial translation page allocation scheme with chunk granularity, which eliminates the need to adjust the logical space range within one directory entry. This makes the mapping table more flexible and efficient.

Third, since the data stored on each logical page may change, its compression ratio may also change correspondingly, presenting another challenge for our N-to-1 mapping table design. If data that initially has a higher CR is updated to a lower CR, the original N-to-1 mapping becomes invalid as more physical pages are needed to store the original data from the N logical pages. Thus, we propose promotion and demotion for the translation page to dynamically adjust the compression ratios of the entries within the translation page. When some data is updated with a lower CR (i.e., requiring more physical pages), we reduce the CR of the corresponding translation page to allow each entry to manage fewer logical pages. In contrast, if all the entries in a translation page are updated with higher CR data, we promote the page to a higher CR to maximize space utilization in the mapping table. Thus, we can effectively keep the mapping table size relatively small, achieving better memory efficiency.

The final challenge concerns garbage collection (GC). In compressional SSDs, since each physical page contains multiple compressed logical pages, the invalidation of any single logical page results in a partial invalidation of the entire physical page, making traditional GC algorithms less effective. Thus, we develop a compression-aware GC mechanism that delays the reallocation step and retains valid pages in memory, enabling potential recompression of new updates and leading to space savings. We also take this opportunity to assess whether the corresponding translation page can be promoted at that time.

We have implemented our design in MQsim [33], a widely used SSD simulator, and evaluate the effectiveness of the proposed techniques. Results show that we can reduce the mapping table size by 50%, and achieve 2.06x speedup in IO latency compared with DFTL [11].

Our contributions are summarized as follows:

- We design a memory-efficient N-to-1 mapping table tailored for compressional SSDs, which substantially reduces the memory footprint and enhances I/O efficiency.
- A partial translation page allocation scheme is introduced to address the logical space fragmentation issue.
- We achieve dynamic workloads support by presenting promotion and demotion for translation pages, cooperating with a compression-aware GC policy for efficient physical space usage.
- The proposed technique is implemented in MQsim and evaluated using diverse real-world workloads, demonstrating its effectiveness.

II. Background and Motivation

A. Compressional SSDs

Compressional SSDs are solid-state drives incorporating compression techniques, often featuring hardware compression/decompression modules integrated directly into the SSDs [43]. This technology has gained significant attention in recent years [12], [14], [31]. In this work, we focus on one type of compressional SSDs that support built-in transparent data compression capability, in which data are compressed at a fixed granularity. For example, compressional SSDs from ScaleFlux use a per-4KB compression scheme in which every 4KB logical page is compressed individually and then multiple compressed pages are stored together in one physical page as much as possible. Figure 1 illustrates this process, where four logical pages are compressed and stored together in a single physical page. Compared with host-side compression [1], [5], [26], [38], such in-storage transparent compression completely relieves host CPU from compressing and decompressing data. To facilitate decompression and reverse mapping, the corresponding metadata can be stored in the out-of-band (OOB) area of a physical page. This metadata contains information necessary for identifying the logical page address and its size during the decompression process. Moreover, the system maintains bitmaps for every physical page, indicating valid logical pages for garbage collection.

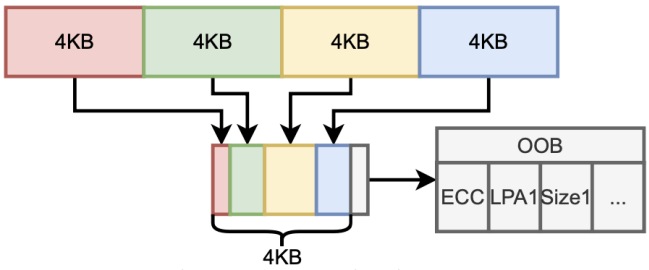

Fig. 1: Compression in SSDs.

B. Mapping Table Issues

Inside the FTL, an L2P mapping table is maintained for address translation. Constrained by limited in-SSD memory space, DFTL proposes on-demand page-level mapping schemes. The mapping table is stored in flash memory and cached in DRAM. A Global Translation Directory(GTD) is needed for indexing, which tracks the mapping of the translation pages. DFTL significantly reduces the amount of memory needed. This idea works well in traditional SSDs [16], [23], [27], [29], [42]. However, when applied to compressional SSDs, it does not address the problem of physical page number redundancy. In compressional SSDs, multiple logical pages are stored within a single physical page, resulting in consecutive entries in the mapping table that store the same physical page number. This leads to a waste of space and low cache hit ratios, which severely degrade the performance of the FTL.

C. Garbage Collection Issues

With the out-of-place update characteristic of flash memory, old physical pages become invalid once new data is written to other locations. To make room for new write operations, GC is necessary to reclaim these invalid physical pages. However, GC operations significantly affect the performance, since the basic unit of an erase operation is the block [8], [10], [34], [40], [41]. Compressional SSDs have brought new issues to garbage collection. When compressional SSDs issue an update request, it may only partially affect pages in one physical page, making

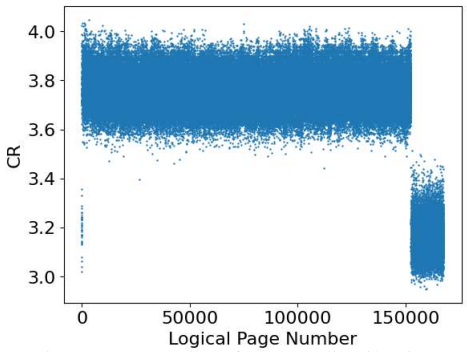

Fig. 2: B-tree log file CR distribution.

this physical page partially valid. Unfortunately, a normal GC operation only considers whether a physical page is valid or not, and it cannot free the invalid space inside these partially valid physical pages. As a result, the invalid space within these partially valid physical pages remains unutilized, impacting overall storage efficiency.

D. Motivation

Within a specific range, logical pages exhibit similar CRs. Our experiment demonstrates a spatial locality of CRs across pages. Illustrated in Figure 2, towards the beginning of the Logical Page Number (LPN) sequence, the majority of pages maintain a CR of approximately 4, while those towards the end exhibit a CR closer to 3. This observation indicates that logical pages within a defined range tend to possess comparable CRs, whereas variations exist across different sections of the page. These findings show the feasibility of consolidating several consecutive logical pages for N-to-1 mapping within a specific range. However, it also underscores the necessity of employing distinct N-to-1 mapping translations, even within a single file.

III. Overall Architecture

Figure 3 shows the overview of our mapping table design. It mainly contains two parts: the N-to-1 translation pages and the corresponding Global Translation Directory.

A translation page in our design has a similar structure to traditional translation pages, but each entry holds different flags. Each entry stores a physical page address representing N consecutive logical pages. As shown in Figure 3, the translation page stored in PPN 302 is a 2-to-1 translation page. It stores mapping entries with an CR of 2, indicating that two consecutive logical pages are compressed into one physical page. For instance, logical pages 0 and 1 are compressed and stored in physical page 405. Therefore, the first entry in this translation page stores PPN 405. To accommodate different CRs, we maintain four types of N-to-1 translation pages within the system. These types are defined by the value of N, which can be set as 1, 2, 4, 8 in this paper.

The Global Translation Directory is similar to the traditional mapping table, but with two additional flags: CR (Compression Ratio) and OF (Offset), while the logical space range of each entry remains unchanged. CR represents the compression ratio of the corresponding translation page, while OF indicates the offset of the associated Translation Chunk within the translation page. For example, in Figure 3, if the physical page size is

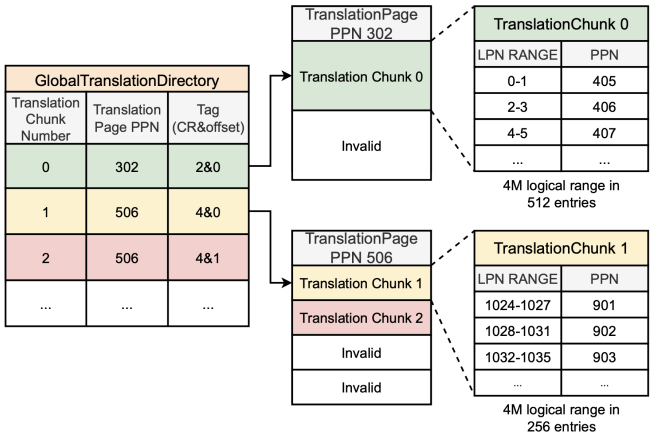

Fig. 3: Overview of our mapping table design.

4KB, each directory entry maps to a 4MB logical address. In traditional mapping tables, one directory entry corresponds to one translation page. However, with N-to-1 translation pages, each page encapsulates N*4MB of logical space. Therefore, the page can be divided into N distinct Translation Chunks, each representing 4MB of logical space. Each directory entry aligns with a Translation Chunk, facilitating efficient organization and mapping of logical addresses within the flash memory system. The Translation Chunk 0 occupies the first chunk of the Translation Page 302 with compression ratio 2, so its offset is 0 and CR is 2 in Tag. The CR and OF tags help the FTL efficiently locate the position of the associated Translation Chunk. The FTL can swiftly determine the physical page number corresponding to any given logical page number. This process ensures rapid and accurate mapping between logical and physical addresses.

IV. Detailed Techniques

In this section, we present our memory-efficient mapping table design in detail. First, to make full use of the space in N-to-1 translation pages, we propose a partial allocation scheme for managing translation pages to avoid logical space fragments. Next, we introduce demotion and promotion schemes to handle the CR inconsistencies in update requests. Additionally, the reusable allocation scheme reuses the invalid space caused by demotion and promotion. Finally, to free up more space, we develop a compression-aware GC.

A. Partial allocation

N-to-1 translation pages map larger logical spaces in one page, making the traditional full allocation strategy ineffective. Figure 4 illustrates a scenario with two write requests. The first write request targets Translation Chunk 0 with a CR of 2. If a full allocation strategy is employed, a 2-to-1 Translation Page 302 would map Translation Chunks 0 and 1. Then the second request targets Translation Chunk 3 with a CR of 4. In this case, Translation Chunks 3-6 are assigned to the 4-to-1 Translation Page 907. This causes fragmentation, as Translation Chunk 2 cannot utilize N-to-1 mapping. Regardless of its compression ratio, a full translation page is still needed, leading to inefficiency.

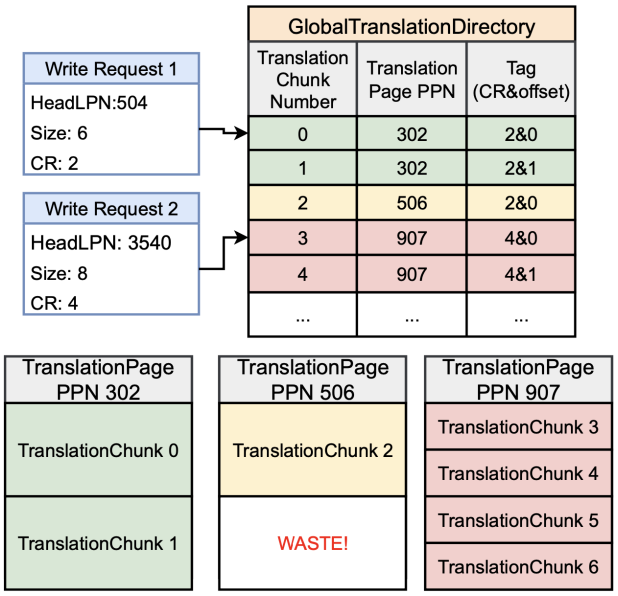

Fig. 4: Illustration of the full allocation issue.

To address this problem, a partial allocation strategy is employed. Partial allocation assigns only part of the translation page for each Translation Chunk. For instance, if a Translation Chunk requires the allocation of translation pages to store mapping entries with a CR of 2, only half of the 2-to-1 translation page is used, and the remaining half is available for subsequent allocations. The CR and OF tags in the directory enable efficient retrieval of the physical page numbers (PPNs) without any performance degradation. This approach ensures the benefits of N-to-1 mapping while minimizing wasted space and improving overall efficiency.

B. Demotion and Promotion

The update write requests may modify the CR of the same logical pages. If the new CR is lower than that of the Translation Chunk, a demotion function is invoked. On the other hand, if the new CR is higher, the system checks if the Translation Chunk can be promoted. If the Translation Chunk meets the requirements for promotion, a promotion scheme is executed.

In the first situation, new PPNs cannot be accommodated within the existing translation page. This occurs because an entry must store multiple PPNs when the new CR is lower than the previous one. For instance, in Figure 5, TranslationChunk 2 is stored in TranslationPage 506 with a CR of 4, where each entry can map 4 logical pages. If an update write request with a new CR 2 is received, LPN 2528-2531 can no longer be compressed into a single physical page. Instead, 2 PPNs are required for these 4 logical pages. In this case, a demotion scheme is invoked. This operation allocates a new chunk of an N-to-1 translation page for the lower CR (e.g., TranslationPage 302 with a CR of 2). The entry from the old translation page is copied to the new translation page. As shown in Figure 5, the updated mappings in LPN 2528-2531 are stored in two entries in new translation page, while the unchanged mapping for LPN 2532-2535 is directly copied to the new place.

In the second situation, if the new CR of the update write request is higher than the translation page CR, we check

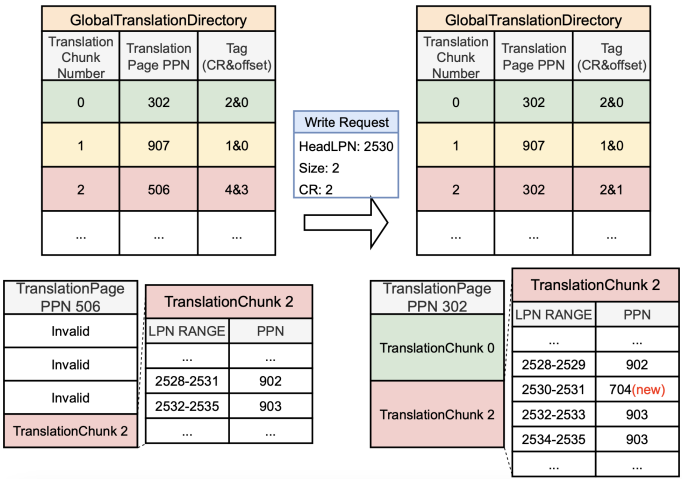

Fig. 5: Demotion with partial allocation.

whether every two entries in the Translation Chunk store the same PPN. If so, the chunk can be promoted to a higher CR. This condition may appear strict but is often met in practice. Demotion typically modifies only a small number of PPNs, leaving most unchanged. During demotion, most PPNs are copied to the new place, just like LPN 2532-2535 in Figure 5. If the modified entries LPN 2528-2531 are updated and store the same PPN with a higher CR again, the whole chunk is promotable. In this scenario, we allocate a new chunk of an N-to-1 translation page for the higher CR and move the entries from the old chunk. This approach reduces memory usage.

• **Reusable Allocation.** Partial allocation enables new translation pages to be allocated at a chunk granularity. However, during demotion and promotion schemes, moving entries to new chunks invalidates the old chunks, leading to an accumulation of invalid chunks in older translation pages. Over time, this accumulation reduces the overall memory efficiency of the system. In the worst case, our memory-efficient table needs the same number of translation pages as the traditional mapping table even if we use partial allocation. Reusing these invalid chunks helps reduce memory usage and minimizes the frequency of write-back operations. Therefore, we propose a reusable allocation scheme. We collect all the invalid chunks of different types of N-to-1 translation pages and reuse them when a new allocation request comes in. In detail, a free space list is maintained for each type of N-to-1 translation page to track free space. Invalid chunks from translation pages are added to the corresponding list during promotion and demotion. For a new allocation request, the corresponding list is checked for a reusable chunk. If the list is empty, the FTL allocates a new N-to-1 translation page and adds its chunks to the list. Furthermore, when the cache is full and the eviction is needed. We will first check if there is enough free space in memory to store all the valid and dirty parts in the evicted pages. If yes, we just allocate these valid and dirty parts to those free spaces in memory instead of writing back to NAND flash. If not, we will trigger a normal writeback operation.

C. Compression-aware GC

Partially valid data may use a whole physical page, which severely degrades the GC performance. As we can see in

Figure 5 , when a new update write request triggers a demotion operation, the data in PPN 902 becomes partially valid because the newly written data can not be compressed together. Normal GC can not release these invalid spaces by reallocating these partially valid pages to other blocks. In the worst case, one physical page may hold only one logical page with its CR is 8. As time goes on, less physical space can be released in one GC operation.

To address this issue, we propose a compression-aware GC. For each data block, we track valid physical page numbers and the valid logical page numbers for GC. Given a block to erase, we check these two numbers in this block. If the valid physical page number is low, normal GC performs well, and we execute it as well. However, if the number of valid physical pages is high and the number of valid logical pages is low, normal GC operation performs poorly, and compression-aware GC is triggered. Reallocation is delayed and the data is kept in memory. Then we directly erase the victim block to release the space immediately. The data waits for a new write request to attempt recompression of consecutive logical pages into one page. If recompression succeeds, we also check if the translation page chunk can be promoted.

V. Evaluation

We evaluate our mapping schemes on a 512GB SSD using MQSim, a state-of-the-art open-source SSD simulator. MQSim models all SSD components, including the host interface, SSD controllers, flash controllers, and flash chips. It supports multi-queue SSDs and measures end-to-end latency, making it ideal for our study. To adapt MQSim for our evaluation, we incorporated compression components and assessed overall performance in terms of end-to-end latency. In this section, we first present the setup and workloads and show the experimental results in terms of mapping table size, the cache hit ratio, and the latency. We compare our design with optimal-FTL, DFTL-base and DFTL-prefetch. In the optimal-FTL scenario, we assume the entire mapping table fits within DRAM. For DFTL-prefetch, a cache miss triggers the prefetching of the entire translation page, mitigating subsequent translation reads within the same page and effectively reducing translation page reads from cache misses. Subsequently, we evaluate our compression-aware GC scheme, and explore the performance impact with different cache sizes and large SSDs. At last, we analyze overheads of our design.

A. Experiment Setup

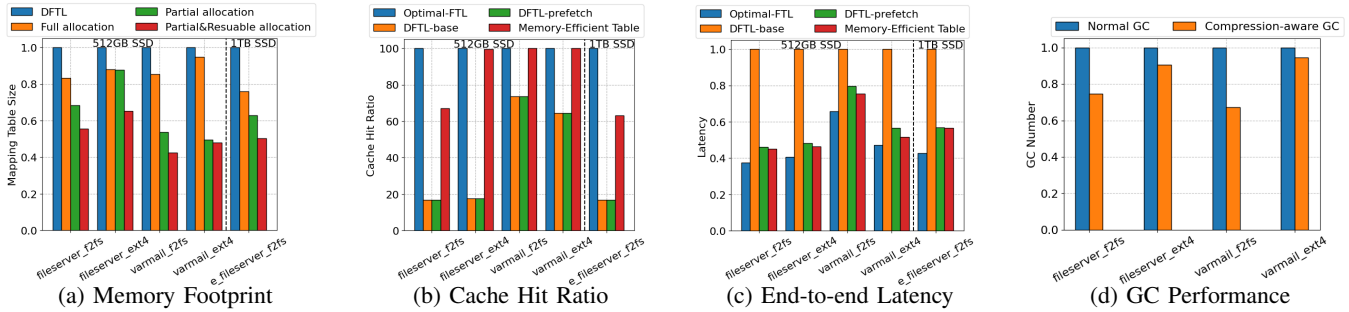
The parameters of the 512GB SSD are shown in Table I. In the evaluation, the mapping cache is set as large as the mapping table of a block-level FTL, which is 2MB. Other cache sizes are also considered. Furthermore, in the evaluation, we use real-world workloads to study the performance of DFTL and our design. These traces are collected from filebench [25]. The workload characteristics can be found in Table II. However, as these traces lack actual data, we utilize the SDGen scheme [9] to sample data from real applications, leveraging this information to generate CR information for the traces. In the next section, we show the performance of these FTL designs with different workloads.

TABLE I: The SSD parameters.

Parameter	Value	Parameter	Value
Channel	8	Page size	4KB
Chip	4	read latency	75us
Die	2	write latency	750us
Plane	2	erase latency	3.8ms
Block	2048	compression latency	50us
Page	256	decompression latency	2.5us

TABLE II: Workloads information.

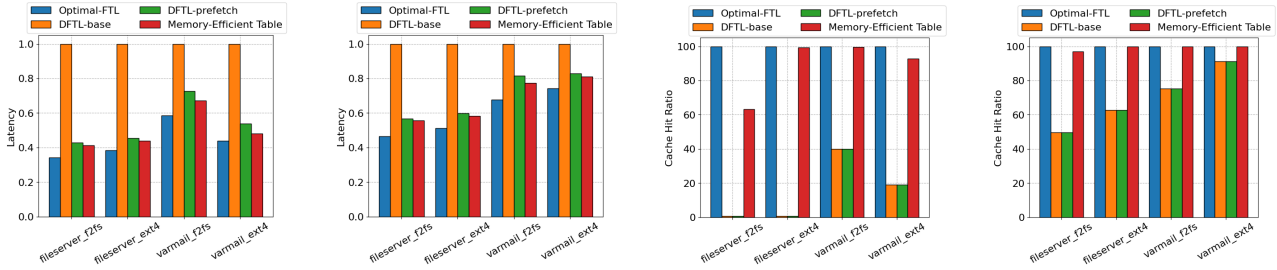
Workloads	Number of Read Request	Average Read Length (4KB pages)	Number of Write Request	Average Write Length (4KB pages)
fileserver _ext4	141542	105.18	545689	37.83
fileserver _f2fs	346203	45.57	274453	90.78
varmail _ext4	121202	17.74	355954	10.25
varmail _f2fs	177277	17.22	253410	23.27



B. Overall Performance

1) Mapping Table Size: Our design significantly reduces the mapping table size compared with the DFTL, which only caches the translation page without reducing the mapping table size. By using DFTL as the baseline, we normalize other methods' table sizes for comparison. As shown in Figure 6(a), DFTL's 1-to-1 mapping corresponds to a value of 1. When implementing N-to-1 mapping with full allocation, only a 15% reduction in mapping table size is achieved. This approach leads to significant wastage of translation page space due to inefficient allocation strategies. In contrast, N-to-1 mapping with partial and reusable allocation strategies can significantly reduce the mapping table size. On average, the size of the whole N-to-1 mapping table is reduced by 50%.

2) Cache Hit Ratio: Our approach also leads to a notable increase in the cache hit ratio. Illustrated in Figure 6(b), our cache hit ratio surpasses that of DFTL by approximately 50%. In a 1-to-1 mapping scenario, a single translation page can only represent 4MB of logical space, whereas an N-to-1 mapping configuration can accommodate N*4MB of logical space. Leveraging this increased capacity, our design can store more mapping information within the cache. Therefore, we achieve a higher cache hit ratio and reduce the flash read and flash write operation numbers for mapping.



3) Latency: With the advantages of a reduced-size mapping table, our design exhibits improved latency performance. Figure 6(c) illustrates the end-to-end latency across various workloads. DFTL-base, with the poorest performance, is normalized to 1, and other methods are expressed as a fraction of its latency. The results demonstrate that our N-to-1 mapping approach delivers superior performance compared to both DFTL-base and DFTL-prefetch. Specifically, our N-to-1 mapping scheme achieves 5-10% performance improvements compared to DFTL-prefetch. Moreover, our design showcases a notable 2.06x speedup compared to DFTL-base.

4) GC Performance: To evaluate the performance of the compression-aware GC technique, we measure the number of GC operations across various workloads. As shown in Figure

(a) Memory Footprint (b) Cache Hit Ratio (c) End-to-end Latency (d) GC Performance

Fig. 6: Overall performance.

(a) Latency(256KB) (b) Latency(16MB) (c) Cache Hit Ratio(256KB) (d) Cache Hit Ratio(16MB)

Fig. 7: Performance with different cache sizes.

6(d), we establish the value of normal GC as 1, with the value of our design derived by dividing our GC numbers by the normal GC numbers. Our compression-aware GC approach results in approximately 22% fewer GC operations compared to normal GC. It shows that our compression-aware GC can free more physical space and enhance the performance.

C. Detailed Comparison

1) Cache size: This section explores the impact of cache size. We investigate two cache sizes: 256KB and 16MB. At 256KB, DFTL's cache hit ratio is low but stabilizes at 16MB. Figure 7 presents the performance of our design across cache sizes. With very small cache sizes, our design achieves a 2.2x latency speedup over DFTL-base. Our cache hit ratio exceeds DFTL's for small caches due to our memory-efficient N-to-1 mapping. Even with larger caches, our design maintains an average 1.6x speedup. The result shows our N-to-1 mapping scheme can work well even if the cache size is very small.

2) Large workloads in Large SSD: As the capacities of SSDs continue to expand, understanding the performance of our design in the context of larger SSDs becomes crucial. With a 1TB SSD environment, we scaled up the fileserver_f2fs workloads by doubling both the logical address and the request sizes. As Figure 6 shows, within a 1TB SSD setup, our cache hit ratio remains significantly superior to that of DFTL. Notably, our design achieves a 1.76x speedup compared to DFTL-base, showcasing the efficiency and scalability of our approach in handling larger SSD capacities.

D. Overhead Analysis

1) Global Translation Directory size: As above-mentioned, the logical space size represented by a single GTD entry unchanged. Therefore, when a compressional SSD exposes more logical space to the user, the size of the GTD increases proportionally. It is worth noting that the GTD size is relatively small in comparison. One GTD entry can represent 4MB of logical space with a 4KB page size. Given a total logical space of 512GB, there are 131072 entries in the Global Translation Directory. 4B are needed for each entry, so the entire GTD would only require 512KB, whereas the mapping table size would amount to 512MB if utilizing a 1-to-1 mapping strategy. It shows that even if the Global Translation Directory size doubles in compressional SSDs, it is still very small.

2) Tag size: In our N-to-1 mapping design, given a total logical space of 512GB, one byte is enough to store one Tag. Therefore, our design requires 128KB space to store the Tag information, which is negligible compared with the mapping table.

VI. Conclusion

In this paper, we propose a memory-efficient N-to-1 L2P mapping table design by reducing the size of the mapping table and enhancing latency performance. In our design, we have devised the demotion and promotion schemes, along with the partial and reusable allocation methods to fully utilize the N-to-1 translation page. Furthermore, we propose a compression-aware GC strategy to minimize the number of copy operations for partial-invalid physical pages. Our design has been implemented in MQsim, and the experimental results demonstrate significant improvements in the mapping table cache hit ratio and a reduction in I/O latency compared to traditional compressional SSDs.

Email: {jianfeng.gu, whhao.wang, xiaorang.guo}@tum.de, {schulzm, gerndt}@in.tum.de

***Abstract*—As FPGAs gain popularity for on-demand application acceleration in data center computing, dynamic partial reconfiguration (DPR) has become an effective fine-grained sharing technique for FPGA multiplexing. However, current FPGA sharing encounters partial reconfiguration contention and task execution blocking problems introduced by the DPR, which significantly degrade application performance. In this paper, we propose VersaSlot, an efficient spatio-temporal FPGA sharing system with novel Big.Little slot architecture that can effectively resolve the contention and task blocking while improving resource utilization. For the heterogeneous Big.Little architecture, we introduce an efficient slot allocation and scheduling algorithm, along with a seamless cross-board switching and live migration mechanism, to maximize FPGA multiplexing across the cluster. We evaluate the VersaSlot system on an FPGA cluster composed of the latest Xilinx UltraScale+ FPGAs (ZCU216) and compare its performance against four existing scheduling algorithms. The results demonstrate that VersaSlot achieves up to 13.66x lower average response time than the traditional temporal FPGA multiplexing, and up to 2.19x average response time improvement over the state-of-the-art spatio-temporal sharing systems. Furthermore, VersaSlot enhances the LUT and FF resource utilization by 35% and 29% on average, respectively.**

I. Introduction

Field Programmable Gate Arrays (FPGAs) have rapidly gained popularity in edge and data center computing, offering efficient application acceleration with higher flexibility and lower power consumption [1]–[5]. Leading cloud providers [6]–[8] have integrated FPGAs into their platforms, allowing users to develop highly customized and on-demand applications with Quality of Service. Meanwhile, modern FPGAs have significantly enhanced their capabilities with advanced manufacturing processes and increased logic elements, able to handle more complex and diverse computational demands [9]–[11]. These improvements facilitate fine-grained FPGA sharing [12]–[15] in multi-user and multi-task environments.

Traditional FPGA virtualization and sharing techniques [7], [16], [17] allocate the entire FPGA to a single application and implement the time-multiplexing by performing a full fabric reconfiguration. This approach introduces significant context switch overhead and often leads to FPGA under-utilization, as applications may not require the full FPGA resources. Instead, *Dynamic Partial Reconfiguration* (DPR) [18] enables an FPGA to split the programmable fabric into multiple *slots*, which can be reconfigured independently to host arbitrary application logic at runtime. It provides the capability to perform *Partial Reconfiguration* (PR) on a slot while other slots continue running. Currently, DPR has emerged as the most efficient and flexible technique for spatio-temporal FPGA sharing and virtualization [13]–[15] in the data center.

However, current DPR-based spatio-temporal FPGA sharing still contains numerous overlooked challenges, leading to significant application performance degradation. First, in the current FPGA Processing System (PS), the PR module, *PCAP* (Processor Configuration Access Port), is limited to serial bitstream loading. This serial access causes frequent mutual blocking when multiple applications require PR concurrently. As the number of applications sharing an FPGA increases, the PR contention intensifies, resulting in highly prolonged and unpredictable application response times. Meanwhile, the mutual PR blocking further severely disrupts applications' original pipelines, leading application tasks with dependencies in various slots to wait for each other to complete, preventing further execution. Recent systems like Nimblock [15] and DML [14] overlook these problems, resulting in application performance that falls short of the expected pipeline outcomes. Moreover, these works [14], [15] used single-core task scheduling, in which PR operations further block the launching of application tasks, leading to severe task blocking problems.

Second, the uniform size of FPGA slots in previous work [14], [15] imposes strict constraints on task partitioning. For example, when optimizing application tasks using Xilinx's High-Level Synthesis (HLS) tools, resource consumption typically exhibits stepwise increases rather than linear growth, which can easily cause resource over-subscription and under-utilization within slots. While prior work [12] attempted to address the problem by dynamically adjusting slot sizes based on application resource demand, the solution needs regenerating bitstreams at runtime, incurring large runtime overhead.

To address these challenges, we propose **VersaSlot** (Versatile Slots), an efficient spatio-temporal FPGA sharing system, to achieve more effective FPGA multiplexing for applications. To mitigate PR contention among application tasks, VersaSlot introduces a novel *Big.Little* slot architecture. The architecture allows the system to bundle and load multiple tasks simultaneously to a Big slot for internal execution at runtime, thereby eliminating further PR contention with tasks from Little slots. Within the Big slot, tasks can still maintain their parallel or serial pipelines, as they do in the Little slots,

but without internal PR interference. Meanwhile, reduced PR contention also allows Little slots to load task bitstreams promptly, mitigating blocking delays and pipeline disruptions.

However, similar to ARM's big.LITTLE cores [19], the heterogeneous *Big.Little* slot design introduces increased complexity for resource allocation and scheduling. As for resource allocation, we propose an adaptive algorithm that combines primary allocation and redistribution along with binding and rebinding. The algorithm enables applications to flexibly switch between using Big and Little slots at runtime while also maximizing the utilization of available slot resources. The complementary between Big and Little slots can help mitigate under-utilization and over-subscription problems. In the context of scheduling, the VersaSlot dynamically bundles 3-in-1 tasks at runtime and schedules the corresponding tasks to available slots. The 3-in-1 task bundling can enhance the flexibility in task partitioning of applications. Importantly, VersaSlot decouples the PR from scheduling logic and distributes them across two CPU cores for asynchronous execution, thus effectively eliminating the task execution blocking problem.

For specific applications with few tasks and large batch sizes, PR occurs infrequently. By dividing Big slots into multiple Little slots, more applications can efficiently share resources, making an FPGA with only Little slots (*Only.Little*) also necessary. However, switching an FPGA between *Only.Little* and *Big.Little* configurations requires restarting the system and interrupting all task executions, which introduces a large runtime overhead. To address this, we propose a seamless cross-board switching and live migration mechanism based on system PR contention levels within a cluster, enabling the FPGA slot configuration switching with low overhead.

In a nutshell, the contributions are summarized as follows:

- We propose VersaSlot, an efficient spatio-temporal FPGA sharing system that introduces the novel *Big.Little* slot architecture. VersaSlot addresses the significant PR contention problem inherent in FPGA fine-grained sharing.
- We design an efficient slot allocation and dual-core scheduling algorithm for the *Big.Little* slot architecture to dynamically and efficiently utilize both kinds of slots and prevent the task execution blocking problem.
- We propose a seamless cross-board switching and live migration mechanism, enabling applications to transition among FPGAs with different slot configurations in a cluster for more efficient execution with low overhead.
- We evaluate the VersaSlot system on a real FPGA cluster, against four existing scheduling algorithms. VersaSlot achieves an average response time up to 13.66x lower than the traditional FPGA multiplexing, and up to 2.19x lower than the state-of-the-art system, and enhances the LUT and FF utilization by 35% and 29% on average.

II. Background

Dynamic Partial Reconfiguration (DPR), also known as Dynamic Function eXchange (DFX) from AMD/Xilinx [20], is an advanced FPGA configuration technique that enables dynamic reconfiguration of specific regions of the FPGA without interrupting the overall system operation. Instead, in traditional FPGA configuration flows, any functional modification requires reloading the entire bitstream file, leading to system downtime and a full restart, which causes large runtime overhead. The DFX process relies on the Processor Configuration Access Port (PCAP) [21] to load the partial bitstream from memory to the corresponding section of the FPGA. As it is essential to confirm the successful loading of the partial bitstream, DFX inherently prevents the PCAP from loading a new partial bitstream until the current one is fully loaded and blocks the corresponding CPU [21]. Meanwhile, to avoid unpredictable impacts on the remaining FPGA circuitry during the loading phase, a dedicated IP, DFX Decouple, is employed to decouple the reconfigurable region from the rest of the circuit. Recently, the DFX has been extensively used in FPGA virtualization and sharing in the cloud [13]–[15], [22], but limited to serial partial bitstream loading.

III. System Design

A. VersaSlot System Framework

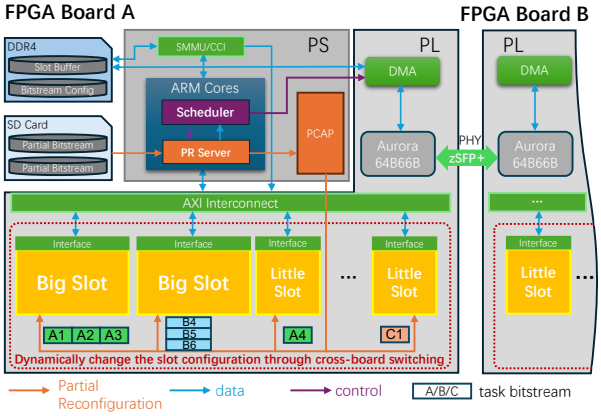

Fig. 1: VersaSlot system with PS and PL in FPGA cluster.

The VersaSlot system, aligned with the typical structure of FPGA sharing design [14], [15], consists of two main components: the embedded hypervisor within the Processing System (PS) and the FPGA fabric layout in the Programmable Logic (PL), as illustrated in Figure 1. The VersaSlot hypervisor in the PS is implemented on ARM cores via bare-metal programming to minimize the system control overhead. Its primary responsibilities include scheduling and resource allocation, managing the loading of partial bitstreams and application data, and coordinating cross-board switching. For FPGA boards without a dedicated CPU, the hypervisor can run on the host CPU and control the FPGA via the PCIe interface.

The VersaSlot hypervisor in the PS comprises two key modules: the scheduler and the PR server, both of which run as bare-metal applications on the ARM cores. At runtime, the scheduler allocates computational slot resources to each incoming application, updates the status of reconfigurable slots, and determines the next application to execute. The PR server, which handles partial reconfiguration, waits for PR requests from the scheduler. It loads pre-generated bitstreams from the SD card into memory and sends commands to the FPGA's

PCAP module to dynamically switch partial bitstreams for applications. However, the PCAP can only perform PR for one bitstream at a time and suspends the associated CPU during the process. Additionally, the PR server communicates status updates to the scheduler through the On-Chip Memory (OCM). The ARM cores utilize the System Memory Management Unit (SMMU) for address mapping and the AXI Interconnect to transfer application data to the FPGA slots for execution.

In the PL, based on the DPR technique, FPGA resources are divided into a *static region* and partial reconfigurable Big and Little slots. The static region configures interfaces for the reconfigurable slots, enabling slots to communicate with the PS and memory via the AXI bus. The region can only be programmed once at system startup, while the reconfigurable parts can be dynamically reconfigured and switched to map different application logic at runtime. Before execution, application bitstreams are prepared offline in advance. Specifically, applications are partitioned into smaller tasks suitable for Little slots by synthesis resources via automated scripts. The ***task*** represents a portion of the application and the basic execution unit for a slot. The VersaSlot system supports the dynamic ***batch*** processing for applications. The fine granularity and batched structure of tasks facilitate an application to be organized in a pipeline with dependencies across slots during execution, which can increase parallelism, thus reducing execution time and enhancing resource utilization. A ***slot*** refers to a reconfigurable region. Traditionally, the slots are designed to be uniform. In the VersaSlot system, we introduce a novel *Big.Little* slot architecture, where three consecutive small tasks can be bundled as a big task for execution in a Big slot. In our system, an FPGA consists of either 2 Big slots and 4 Little slots (*Big.Little*) or 8 Little slots (*Only.Little*), but can be extended to any Big/Little configuration. The resource capacity of each Big slot is twice that of a Little slot. To ensure slot compatibility, the automated script generates partial bitstreams for each task adaptive to each slot. These generated bitstreams are stored on the SD card. Once partial reconfiguration is complete, the scheduler allocates buffers and launches the task.

The cross-board switching module is another important component in the PL, designed for board switching between different FPGA slot configurations. It utilizes the GT transceivers (zSFP+) to connect other FPGA boards. We introduce the Aurora IP core, an efficient communication protocol to transfer tasks, application information, and data directly via DMA to another FPGA unit when switching is activated.

B. Big.Little Slots

The *Big.Little* architecture is a heterogeneous slot design for spatio-temporal FPGA sharing, coupling resource-intensive Big slots and standard-resource Little slots. Although Little slots can increase resource granularity for more applications to share an FPGA, they also bring severe mutual PR contention and task execution blocking problems due to inherent DPR limitation in serial bitstream loading and CPU blocking. For example, as shown in Figure 2, two applications (App-1 and App-2), each with 3 tasks (T1, T2, T3) and batch sizes of 3

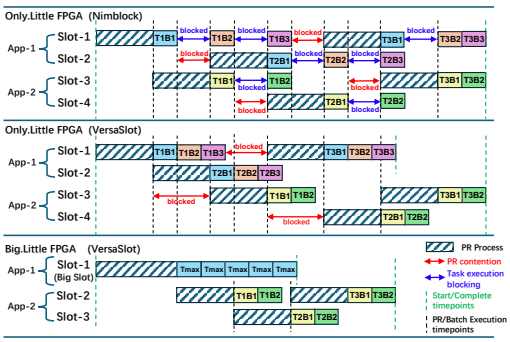

Fig. 2: Versaslot with *Big.Little* and *Only.Little* dual-core scheduling alleviates the PR contention and task execution blocking problems, thus reducing application response time.

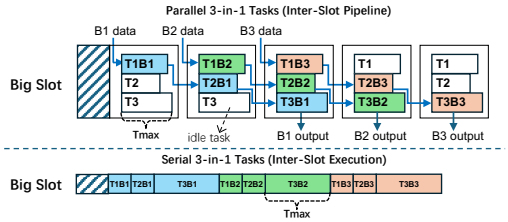

Fig. 3: Parallel and serial bundling for the 3-in-1 task.

(B1, B2, B3) and 2 (B1, B2), are processed on an FPGA with 4 Little slots, in which each application is allocated with 2 slots that forms the execution pipeline. In the Nimblock [15], after the App-1 completes the PR of its first task, the App-2 starts the PR of its first task, during which it blocks the bitstream loading of App-1's second task (T2) although App-1's first batch item of the first task (T1B1) has finished the execution. Subsequently, the PR of App-1's second task (T2) also blocks the PR of App-2's second task. Moreover, since Nimblock handles all operations and scheduling by a single CPU core, the PR process of App-2's T1 also blocks the task execution of App-1's T1B2, and the PR of App-1's T2 blocks the task execution of App-2's T1B2. As the two applications continue running, mutual PR contention and task execution blocking alternate, disrupting each application's original pipeline and significantly increasing response times. The figure shows only 4 slots with 2 applications, but as the number of shared slots and applications increases, this effect becomes more severe.

Within our uniform Little slots (*Only.Little*) FPGA design, VersaSlot decouples PR logic from the scheduler to a dedicated PR server on a separate CPU core, which effectively resolves task execution blocking. As in Figure 2, while other applications perform PR operations, the scheduler can still promptly trigger batch execution of tasks without waiting for specific PR completion points. Additionally, we pre-load tasks of the same application into the slots to further enhance pipeline efficiency. The *Only.Little* design is suited for specific applications with few tasks and large batch sizes, as PR occurs infrequently. But PR contention still persists in most workloads.

Therefore, we propose the Big slots, which can dynamically bundle and load 3 tasks (3-in-1 task) of an application simultaneously for internal execution at runtime. As shown in Figure 2, with VersaSlot's *Big.Little* slots, once App-1 and its tasks

are bundled and scheduled to execute on the Big slot, App-1 only needs to trigger tasks' batch execution without frequent PR loading, thus avoiding outside PR blocking from Little slots. Meanwhile, App-2's tasks can complete its pipeline smoothly without the PR blocking from App-1. Thus, the PR contention of applications in both Big and Little slots is alleviated. Furthermore, as in Figure 3, the tasks within Big slots can be organized in a pipeline as well. Since each batch's parallel execution time on the Big slot equals the longest of the three tasks ($T_{\max}$), serial execution is preferable when $T_{\max} \cdot (N_{\text{batch}}+2) > \sum(T_1+T_2+T_3) \cdot N_{\text{batch}}$. With this criterion, the VersaSlot system can select the optimal 3-in-1 task bitstream for execution at runtime. We set the bundling size to be 3 based on the Big slot's resource capacity to accommodate tasks and its fewer idle task cycles in pipelines than a larger size.

C. Slot Allocation and On-board Scheduling

Similar to the ARM big.LITTLE cores [19], the heterogeneous *Big.Little* slot architecture introduces greater complexity in resource allocation and scheduling. We propose an efficient slot allocation and scheduling algorithm for the architecture. When an application A_i enters the candidate list, it is first added to the waiting list C_{wait} for slot allocation. Once the application acquires slot resources R_{A_i} (the maximum number of slots to use), all of its tasks are pushed into the ready list Q_T, awaiting scheduling for execution in Big or Little slots.

1) Slot Allocation: As detailed in Algorithm 1, slot allocation is based on available slots and system status, featuring the processes of primary allocation and redistribution along with binding and rebinding. In the primary allocation, the system first allocates slots for applications in the waiting list C_{wait}. It prioritizes allocating Big slots to applications that can bundle tasks, as Big slots can significantly mitigate PR contention. After the Big slot allocation, Little slots are assigned to applications based on the optimal slot count $O^L_{A_i}$. The optimal slot allocation, derived through integer linear programming (ILP) as in [14], [15], represents the most efficient slot configuration for pipeline execution within either Little or Big slots, whose value is usually lower than the task count. The primary allocation ensures applications execute promptly along their task pipelines. When additional Little slots are left, Versaslot performs the redistribution based on applications already assigned with Little slots, prioritizing those at the front of the runnable queue to obtain the maximum needed slots. This redistribution effectively avoids slot idling and maximizes overall slot utilization. Meanwhile, to prevent situations where Big slots are idle while Little slots are overburdened, we propose a rebinding method for load balancing. For applications assigned to Little slots but not yet executing, we unbind them for new slot allocation, returning them to a waiting state. This ensures that Big slots can receive new applications for execution. But applications bound to the big slots can only complete all their tasks in the Big slots to avoid Big slot blocking caused by task dependencies.

2) On-board Scheduling: Algorithm 2 outlines the overall scheduling process, which primarily includes 3-in-1 task online bundling, task execution launching, and scheduling tasks

Algorithm 1: Slot Allocation

Input: $C_{wait} = \{A_i\}$: apps A_i waiting for slot allocation;
$S_{Big} = \{A_i\}$: the list of apps allocated with Big slots;
$S_{Little} = \{A_i\}$: the list of apps allocated with Little slots;
B_{avail}: idle Big slots; L_{avail}: idle Little slots; (number);
Q_T: the list of ready tasks waiting for scheduling;
$N_{T_{A_i}}$: the number of unfinished ready tasks of A_i;
$O_{A_i} = (O^B_{A_i}, O^L_{A_i})$: optimal Big/Little slots for A_i's pipeline
Output: $R_{A_i} = (R^B_{A_i}, R^L_{A_i})$: Big/Little slots allocated to A_i

$B_{avail} = B_{total} - \sum N_{T_{A_i}}$, $A_i \in S_{Big} \wedge T_{A_i} \in Q_T$;
`// No slot available, skip the allocation.`
if $B_{avail} \leq 0$ *and* $L_{avail} \leq 0$ **then**
  return;
`// Unbind apps with Little slots for rebinding.`
foreach $A_i \in S_{Little}$ ***and*** $B_{avail} > 0$ **do**
  if *not isAppStarted(A_i)* **then**
    $S_{Little} = S_{Little} \setminus \{A_i\}$; $C_{wait} = C_{wait} \cup \{A_i\}$;
`// Primary allocation.`
$L_{left} = L_{total} - \sum \min(R^L_{A_i}, N_{T_{A_i}}), A_i \in S_{Little} \wedge T_{A_i} \in Q_T$;
foreach $A_i \in C_{wait}$ **do**
  `// Binding, prioritize big slot allocation.`
  if $B_{avail} > 0$ ***and*** *canBundle(A_i)* **then**
    $R_{A_i} = (O^B_{A_i}, 0)$; $S_{Big} = S_{Big} \cup \{A_i\}$;
    $B_{avail} = B_{avail} - 1$; **continue**;
  `// Binding, allocation with Little slots.`
  if $L_{avail} > 0$ *and* $L_{left} > 0$ **then**
    $R_{A_i} = (0, O^L_{A_i})$; $S_{Little} = S_{Little} \cup \{A_i\}$;
    $L_{left} = L_{left} - R^L_{A_i}$;
`// Redistribution for left Little slots.`
if $L_{left} > 0$ **then**
  foreach $A_i \in S_{Little}$ ***and*** $L_{left} > 0$ **do**
    $\delta = N_{T_{A_i}} - O^L_{A_i}$, $T_{A_i} \in Q_T$;
    $R_{A_i} = (0, \min(L_{left} + R^L_{A_i}, \delta + R^L_{A_i}))$;
    $L_{left} = L_{left} - \delta$;
return $\{R_{A_i}\}$, *updated* S_{Big}, S_{Little}, C_{wait};

to their designated slots for PR. For newly added tasks in the ready list Q_T assigned with Big slots, the scheduler bundles them into serial or parallel 3-in-1 tasks at runtime and replaces them with the bundled tasks in the ready list for execution. Meanwhile, the scheduler updates task execution statuses, loads task data, and launches batch executions. In previous work [14], [15], this step was often blocked by subsequent PR processes, leading to the task execution blocking problem. However, VersaSlot employs dual-core scheduling, which decouples the PR process and scheduling logic onto two separate CPU cores. When the scheduler assigns a new task to its corresponding available slot for PR, it sends an asynchronous request to the PR server without waiting for PR completion. Meanwhile, the scheduler limits application slot usage to its allocation, ensuring efficient spatio-temporal FPGA sharing. In VersaSlot's *Only.Little* system, the scheduler follows the preemption mechanism as in [15], to prevent long-running tasks from monopolizing the FPGA. But the preemption brings more PR operations. The *Big.Little* applies preemption only in Little slots since an application cannot occupy both Big and Little slots simultaneously. Meanwhile, the inherent design of the slot redistribution in *Big.Little* also avoids monopolization.

Algorithm 2: Scheduling Algorithm

Input: $S_{Big} = \{A_i\}$, $S_{Little} = \{A_i\}$, $\{R_{A_i}\}$;
B_{avail}: idle Big slots; L_{avail}: idle Little slots; (number);
Q_T: the list of ready tasks waiting for scheduling;
$U_{A_i} = (U^B_{A_i}, U^L_{A_i})$: number of Big/Little slots used by A_i;

```
// Add new tasks to the ready task list.
foreach A_i ∈ S_Big ∪ S_Little do
    if T_{A_i} ∉ Q_T then
        Q_T.push_back(T_{A_i});
// Bundle 3-in-1 task for Big slots online.
foreach A_i ∈ S_Big and {T_{A_i}} ⊂ Q_T do
    if not isBundled({T_{A_i}}) then
        T^{bundled}_{A_i} = 3in1Bundle({T_{A_i}});
        Q_T replaces {T_{A_i}} with {T^{bundled}_{A_i}};
// Launch batch execution for running tasks.
foreach T_{A_i} ∈ Q_T do
    if isRunning(T_{A_i}) and waitBatchExec(T_{A_i}) then
        launch(T_{A_i});
    else if isFinished(T_{A_i}) then
        Q_T = Q_T \ T_{A_i}; isFinished(A_i) ⇒ S = S \ A_i;
// Schedule tasks to corresponding slots.
foreach T_{A_i} ∈ Q_T do
    if A_i ∈ S_Big and U^B_{A_i} < R^B_{A_i} and B_avail > 0 then
        PR(T_{A_i}) to an idle Big slot (Async in PR server);
        T_{A_i}.running = True;  B_avail = B_avail − 1;
    if A_i ∈ S_Little and U^L_{A_i} < R^L_{A_i} and L_avail > 0 then
        PR(T_{A_i}) to an idle Little slot (Async in PR server);
        T_{A_i}.running = True;  L_avail = L_avail − 1;
```

D. Cross-Board Switching and Live Migration

1) Live Migration: As mentioned in section III-B, *Only.Little* and *Big.Little* configurations have their own advantages for different application workloads, requiring an FPGA to switch between them to maximize performance. However, configurations related to slot size and interfaces are located in the *static region*, which can only be programmed once during system start-up. Cross-board switching enables seamless transitions between configurations without rebooting, achieved through live workload migration. When switching is triggered, the original FPGA stops executing new tasks. Applications and tasks in the ready list, along with their buffers, are transferred via DMA to a new pre-configured FPGA. Once transferred, the new FPGA resumes task execution and processes upcoming new workloads. Meanwhile, ongoing tasks on the original FPGA continue to completion to avoid bitstream reloading overhead, and the FPGA is freed afterward to prevent excess resource usage. Therefore, in a cluster, a single available FPGA can enable cross-board switching for the entire system.

2) Performance Degradation Metric D_{switch}: To determine the optimal timing for the switching and evaluate system performance degradation from PR contention, we propose an evaluation metric, D_{switch}, considering all influencing factors.

$$D_{\text{switch}} = \frac{N_{\text{blocked_tasks}}}{N_{\text{PR}}} \times \frac{N_{\text{apps}}}{N_{\text{batch}}}, \quad (0 < D_{\text{switch}} < 1) \tag{1}$$

where $N_{\text{PR}} = \sum_{A_i} N_{T_{A_i}}$, $A_i \in R_c \cup R_s$; $N_{\text{batch}} = \sum_{A_i} B_{A_i}$, $A_i \in C$. The metric D_{switch} combines the ratio $\frac{N_{\text{blocked_tasks}}}{N_{\text{PR}}}$ to evaluate current PR contention degree among tasks, and the ratio $\frac{N_{\text{apps}}}{N_{\text{batch}}}$ to assess potential conflicts from candidate applications. It is normalized from 0 to 1, where higher values indicate more severe contention and less predictable application response time. The metric is recalculated after every n updates to the application candidates queue with total completed (R_c) / running (R_s) / ready (R_r) applications. The $N_{\text{blocked_task}}$ represents the number of tasks blocked by PR contention during this period. The N_{PR} denotes the number of PR tasks $\{T_{A_i}\}$ by all completed and running applications A_i. The $N_{\text{blocked_tasks}}$ is positively correlated with N_{PR}, which indicates a higher number of PR typically results in more blocked tasks and an increasing D_{switch}. Another two influential factors, batch size B_{A_i} and the number of applications N_{apps}, are significantly factored into the future contention evaluation. The N_{batch} is the total batch size of all applications A_i in the current application candidate queue C. If each application is allocated only one slot with batch size to be one, $N_{\text{batch}} = N_{\text{apps}}$, this indicates the worst-case scenario for PR conflicts and corresponds to the maximum value of D_{switch}.

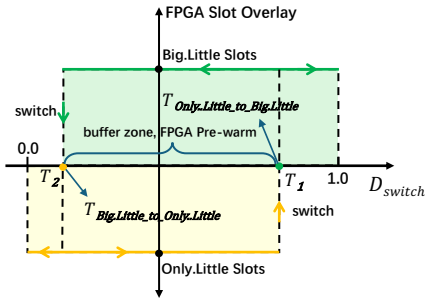

Fig. 4: Cross-board switching loop with the buffer zone.

Inspired by Schmitt Trigger [23], we propose a switch loop for seamless cross-board switching across multiple FPGAs. As shown in Figure 4, as the D_{switch} increases and reaches the threshold T_1, the system triggers the switching from the *Only.Little* slots to the *Big.Little* slots, thereby alleviating the PR contention. Similarly, when the D_{switch} decreases to the threshold T_2, it triggers the switching from the *Big.Little* FPGA back to *Only.Little* FPGA, allowing more future applications to share an FPGA. The two user-configurable thresholds adjust switching sensitivity, with a buffer zone to prevent frequent switching and ensure system stability. Meanwhile, when the D_{switch} metric enters the buffer zone, the system anticipates the direction of change, pre-configures the potential FPGA configuration, and loads task bitstreams into SD storage in a new FPGA. The pre-warming design further ensures seamless live migration with low overhead.

IV. Experiment and Evaluation

The VersaSlot system was evaluated on an FPGA cluster with two latest Xilinx UltraScale+ FPGAs (ZCU216). We used the same benchmark as previous work [15] and partitioned applications into multiple tasks based on the optimal fit between slot resources and task resource usage after synthesis. The applications include 3D Rendering (3DR, 3 tasks), LeNet (6 tasks), Image Compression (IC, 6 tasks), AlexNet (AN, 6 tasks), and Optical Flow (OF, 9 tasks). The partitioning and task bitstream generation were performed automatically

by a TCL script in Vivado 2024.1. We compared the VersaSlot system with four existing scheduling algorithms/systems, including the traditional exclusive temporal multiplexing (Baseline) [7], [16], First-come-first-served spatio-temporal sharing (FCFS), round-robin (RR) from [22], and the state-of-the-art spatio-temporal sharing system Nimblock [15]. To simulate different congestion conditions, we randomly generated application workloads (10 sequences, 20 apps/sequence) with random batch size (5-30) and arrival intervals, including Loose (5000ms), Standard (1500ms-2000ms), Stress (150ms-200ms), and Real-time (50ms) for the evaluation.

A. Response Time Reduction and Tail Latency

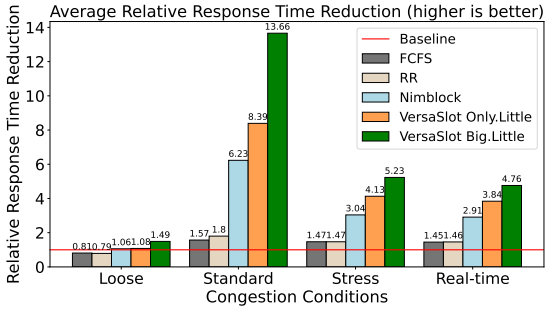

Fig. 5: Relative response time reduction under different congestion conditions, normalized to the baseline.

As shown in Figure 5, we analyze the relative response time reduction under different congestion conditions. The VersaSlot *Big.Little* design outperforms all other methods across all congestion conditions. Under standard workloads, it outperforms the baseline up to 13.66x. The FCFS and Round-robin perform slightly better than the baseline. Compared to the state-of-the-art system, Nimblock, the *Big.Little* design reduces average response time up to 2.17x in standard workloads, 1.72x under stress, and 1.63x in real-time conditions, showcasing the efficiency of *Big.Little* architecture and dual-core scheduling in fine-grained spatio-temporal FPGA sharing. Additionally, compared to the VersaSlot *Only.Little* configuration, *Big.Little* achieves average response time improvements by 63%, 27%, and 24%, respectively, verifying its effectiveness in alleviating PR contention. Meanwhile, as shown in Figure 6, we further analyze the tail latency of applications, and the *Big.Little* design consistently outperforms Nimblock in P95 and P99 metrics (95th and 99th percentiles) across all congestion conditions. Under stress workloads, *Big.Little* improves these metrics by 83% and 46%, respectively, and by 56% and 48% under real-time workloads. While *Big.Little* shows a slight increase in P99 tail latency compared to the baseline, it maintains or even improves P95 performance. Given its substantial advantage in response time, *Big.Little* obviously demonstrates superior application performance than the baseline.

B. Resource Utilization

Figure 7 shows the resource utilization improvement of 3-in-1 tasks in Big slots compared to running all tasks only in Little slots. All applications show significant LUT and FF utilization increases, with average improvements of 35% and 29%. Specifically, the right figure displays the LUT usage for

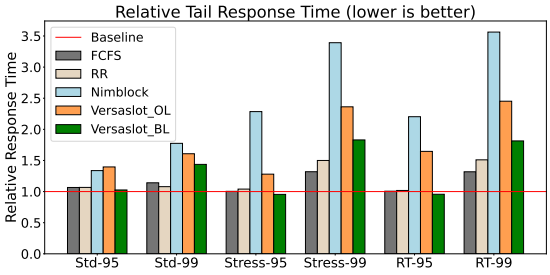

Fig. 6: Tail response time normalized to the baseline.

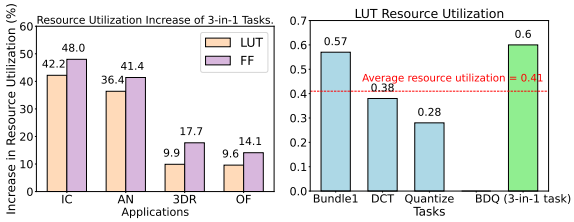

Fig. 7: Resource utilization improvement by 3-in-1 tasks.

the first three tasks of application IC and their bundled 3-in-1 task. Since task partitioning is normally based on synthesis resource usage, Bundle1's LUT utilization decreases from 0.98 in synthesis to 0.57 in implementation. But, with bundling, the 3-in-1 task improves average utilization from 0.41 to 0.6.

C. Cross-board Switching

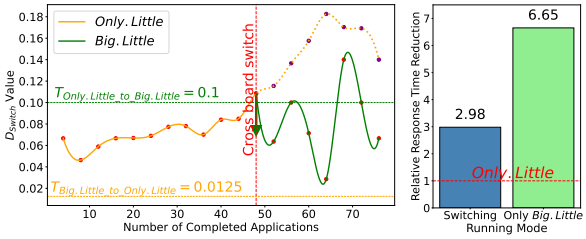

Fig. 8: D_{switch} and relative response time with switching.

To validate the effectiveness of cross-board switching, we tested three long workloads, each with 80 applications and standard arrival intervals. Figure 8 (left) shows the D_{switch} variation for one workload every 4 application updates, where the D_{switch} value triggers a switch from *Only.Little* to *Big.Little* at the threshold, enabling tasks to execute on the new Big.Little FPGA. Compared to execution solely on *Only.Little*, cross-board switching reduces the average response time up to nearly 3x with the average switching overhead of 1.13ms.

V. Conclusion

This paper presents VersaSlot, an efficient spatio-temporal FPGA sharing system with the novel *Big.Little* slot architecture to address the PR contention problem. We propose a slot allocation and dual-core scheduling algorithm and a seamless cross-board switching and live migration mechanism for the architecture to maximize FPGA multiplexing in the cluster. VersaSlot achieves up to 2.19x average response time improvement over the state-of-the-art system and enhances the LUT and FF utilization by 35% and 29% on average.

SplitSync: Bank Group-Level Split-Synchronization for High-Performance DRAM PIM

Byungkuk Yoon, Sanghyeok Han, Gyeonghwan Park, and Jae-Joon Kim
Seoul National University, Republic of Korea
[bkyoon, hansh778, gyeonghwan.park, kimjaejoon]@snu.ac.kr

***Abstract*—Processing in Memory (PIM) architectures enhance memory bandwidth by utilizing bank-level parallelism, typically implemented with a SIMD structure where all banks operate simultaneously under a single command. However, this synchronous approach requires the activation of all banks before computation, leading to activation times that exceed computation times, limiting performance gain. Recently, asynchronous execution PIM has been proposed as an alternative, allowing banks to operate asynchronously and overlap activation with processing to hide the row activation overhead. While effective at reducing row activation overhead, the independent operation requires large shared accumulators for each bank group, increasing area overhead. To address the issues, we propose bank group (BG)-level split synchronization DRAM PIM, where each bank group operates asynchronously to hide row activation overhead while operating synchronously within the bank group to eliminate the need for shared accumulators. Evaluation results show that our proposed design achieves an average throughput improvement of 1.70x and 1.06x compared to conventional PIM and asynchronous execution PIM. Furthermore, the area overhead per processing unit (PU) increases by only 1.5% compared to conventional PIM and is significantly lower than that of asynchronous execution PIM.**

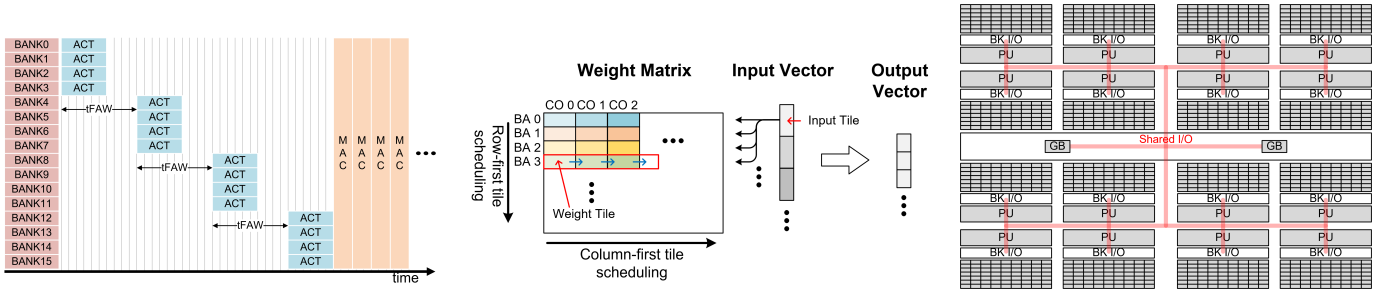
I. Introduction

DRAM Processing-in-memory (PIM) has emerged as a promising approach to accelerate memory-intensive workloads by harnessing bank-level parallelism (BLP) [20, 4, 9, 18, 2, 19]. This technique leverages the inherent parallelism of DRAM banks to enhance memory bandwidth, making it well-suited for tasks like neural network acceleration, particularly General Matrix-Vector Multiplication (GEMV) [20, 13, 14]. Despite its potential, the practical performance of DRAM PIM often falls short due to the overhead associated with memory operations, such as row activation/precharge, input writing, and result reading. A critical bottleneck in achieving full BLP in DRAM PIM is the t_{FAW} (Four Activate Window) constraint, which limits the number of banks that can be activated within a specified time frame. This limitation is designed to prevent voltage drops within DRAM but introduces substantial row activation overhead when activating multiple banks, negatively impacting overall throughput.

Recent approaches have sought to mitigate this constraint. For example, DRAM PIMs in [14, 11, 12] leverage circuit-level innovations by incorporating reservoir capacitors to enable simultaneous activation of 16 banks, effectively bypassing the t_{FAW} limitation. Let us call this DRAM PIM style as ACT16-PIM in this paper. While this solution improves performance, it comes at the cost of significant area overhead due to the additional reservoir capacitors. Alternatively, asynchronous execution PIM architecture [8] activates and processes rows across banks in a staggered manner, overlapping activation and computation to reduce overhead. However, this method complicates input data distribution, requiring large shared accumulators for gathering and accumulating partial results across banks, leading to increased area and design complexity.

To address these limitations, we propose SplitSync PIM, a DRAM-PIM architecture that combines the benefits of synchronous and asynchronous operations. Within each bank group, synchronous operations enable efficient input broadcasting and computation without the need for shared accumulators, thereby minimizing area overhead. Meanwhile, asynchronous operation between bank groups allows activation and computation phases to overlap, significantly reducing row activation overhead while maintaining compliance with the t_{FAW} constraint. This design also eliminates the need for large reservoir capacitors and reduces area complexity compared to ACT16-PIM. Additionally, we introduce modifications to the I/O architecture that allow independent operations across bank groups, mitigating I/O conflicts and enabling simultaneous execution of specific operation pairs: input writing with input broadcasting, input broadcasting with another input broadcasting, and input broadcasting with result reading.

Our main contributions are as follows:



- We propose a SplitSync DRAM PIM architecture that performs synchronous computations within bank groups and asynchronous operations between bank groups. The synchronous operations facilitate implementation with minimal area overhead, while asynchronous operations between bank groups effectively reduce row activation overhead.
- To resolve I/O conflicts during asynchronous operations, we introduce new I/O architecture to support independent operations between bank groups, thereby improving overall performance.
- We compare SplitSync with previous DRAM PIM architectures using several neural network benchmarks and demonstrate that it provides higher throughput than previous works by a large margin under the same area budget.

II. Background

A. Operation and Architecture of Conventional DRAM PIM

Conventional DRAM PIM [15, 13, 14, 11, 4, 20] operations extend memory bandwidth by exploiting Bank-Level Parallelism (BLP), which accelerates memory-intensive workloads. To maximize bank-level parallelism, all DRAM banks operate concurrently within a SIMD (Single Instruction, Multiple Data) architecture. As shown in Fig. 1a, in order to access all banks simultaneously, all banks are activated before the PIM operation begins. After activation, the columns of the activated rows are accessed sequentially to perform the computation. Since the host controls the DRAM through DRAM commands, new DRAM commands need to be introduced to manage PIM operations and ensure smooth execution.

The main focus of PIM is on General Matrix-Vector Multiplication (GEMV) operations, a key component of neural network computation. GEMV is a memory-bound operation, where a large weight matrix, typically not reused, must be loaded from memory to process a relatively small input vector. Fig. 1b illustrates the tiling method used for GEMV computation in conventional PIM. The rows of the weight matrix are mapped to DRAM banks, tiled according to DRAM row size, and then stored in the corresponding banks and rows. The input vector is also tiled to match the DRAM row size and written into the global buffer (GB) in preparation for computation. GEMV performs MAC (Multiply-Accumulate) operations, sequentially multiplying the weight tiles by the input vector for each bank and accumulating

(a) Conventional PIM command timing (b) GEMV operation in conventional PIM (c) Conventional PIM architecture

Fig. 1: Conventional DRAM PIM architecture and its operation

the results in the result latch. Once the computation for one tile is finished, the process repeats for the next tile (corresponding to the next DRAM row) until all computations are completed.

The tile scheduling for GEMV computation can be classified into row-first or column-first tile scheduling, depending on how the tiles are selected during computation. In column-first tile scheduling, the tile moves to the next matrix column along the matrix row, and after completing operations on one matrix row, it moves to the next matrix row. The advantage of this scheduling is that partial sums can be continuously accumulated in the result latch to compute the final sum. However, since the input is used only within each tile, frequent input writes are required, which increases power consumption and introduces writing overhead, degrading performance. In contrast, row-first tile scheduling moves the tile along the weight columns, enabling reuse of the input vector. In this case, either new result latches are required for each tile, or the partial sums must be read out by the host. Although partial sums must be read out after each tile operation, row-first scheduling offers performance and power advantages because the partial sums are typically much smaller than the input tile. This smaller data size allows the host to handle aggregation while the PIM continues processing the next tile.

Fig. 1c shows the architecture of a conventional DRAM PIM. To perform the GEMV operation, processing units (PUs) are placed adjacent to each bank. These PUs receive weights from their respective banks and inputs from the global buffer to execute MAC operations. Since the input vector is shared across all PUs, it is broadcast via shared DRAM I/O, while the weights are delivered through local I/O from each bank. The global buffer, implemented in SRAM, is positioned on either side of the peripheral circuit area, typically sized to match the DRAM row. The results accumulated in the PUs are read out through the DRAM read path via shared I/O. Since the result of each PU is smaller than the column data width, the results from multiple PUs are aggregated and output together.

B. Challenges of DRAM PIM Operation

While DRAM PIM can boost memory bandwidth through bank-level parallelism, it often falls short of expected performance levels in practice due to significant overheads, such as input writes, row activation/precharge, and result reads required for PIM operations. In GEMV operations, where activated DRAM rows are not reused, the repeated all-bank activation and precharge for each tile make row activation/precharge overhead particularly critical.

The time required for all-bank activation is determined by two timing parameters, t_{RRD} and t_{FAW}. t_{RRD} represents the minimum time interval between activation commands, while t_{FAW} defines the minimum timing window that allows up to four activation commands. Let t_{ACT} denote the time required for all-bank activation, which can be expressed in terms of the aforementioned timing parameters:

TABLE I: Timing parameters and memory configuration for row activation overhead calculation

	Parameter	Value
Timing Parameters	t_{RRD}	9
	t_{FAW}	32
	t_{CCD}	2
	t_{RCD}	24
	t_{RP}	24
Memory Configuration	N	16
	Columns	64

$$t_{\text{ACT}} = \max(t_{\text{FAW}}, t_{\text{RRD}}) \times \left(\left\lceil \frac{N}{4} \right\rceil - 1 \right) + t_{\text{RCD}}$$

Here, t_{RCD} represents the minimum time interval between activation and read commands, and N denotes the number of banks in PIM. When the MAC operation follows read timing, the time for a single tile MAC operation, denoted as t_{MAC}, can be expressed as:

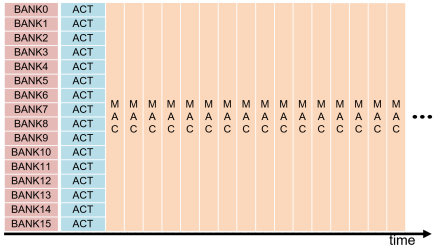
$$t_{\text{MAC}} = t_{\text{CCD}} \times (\text{columns} - 1)$$

where t_{CCD} is the minimum time interval between two read or write commands, and columns is the number of columns in a DRAM row.

In a single tile operation, the row activation/precharge overhead can be represented as:

$$\frac{t_{\text{ACT}} + t_{\text{RP}}}{t_{\text{ACT}} + t_{\text{MAC}} + t_{\text{RP}}}$$

where t_{RP} refers to the precharge time. Based on the timing parameters in Table I, this overhead is found to be 52.9%, indicating that more time is spent on activation/precharge than on computation.



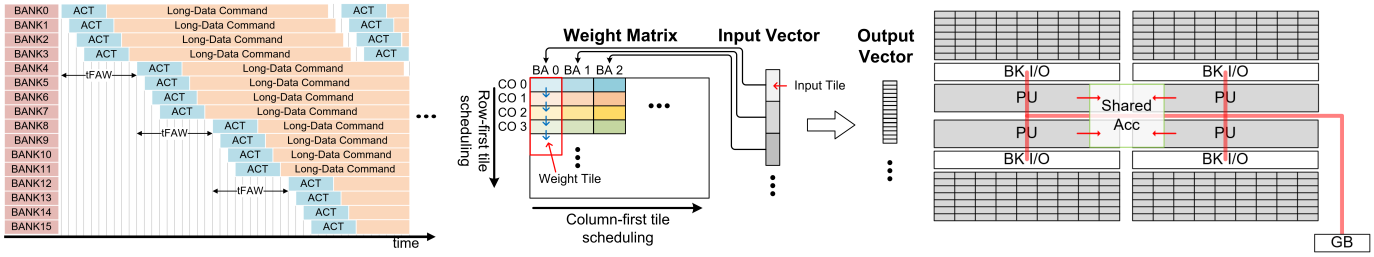


Fig. 2: ACT16-enabled DRAM PIM command timing

C. ACT16-enabled DRAM PIM

A DRAM PIM architecture has been introduced to reduce row activation overhead by eliminating the t_{FAW} constraint at the circuit level, enabling the simultaneous activation of all 16 banks (ACT16) (Fig. 2) [14, 11]. DRAM operates using various internal voltages, and certain timing parameters, such as t_{FAW}, are constrained to prevent failures due to internal voltage drops. In this design, additional reservoir capacitors are placed near the processing units to mitigate internal voltage drops caused by the simultaneous activation of all

(a) Asynchronous execution PIM command timing (b) GEMV operation in asynchronous execution PIM (c) Asynchronous execution PIM architecture

Fig. 3: Asynchronous execution DRAM PIM architecture and its operation [8]

16 banks. As a result, the ACT16 approach enables PIM operation without the t_{FAW} constraint but it incurs significant area overhead. While the exact area of the reservoir capacitors has not been provided, we estimated their area from the die photo, and estimate that the area overhead per PU is approximately 20–25%. The GEMV operation and overall architecture in this PIM design remain unchanged from those in conventional DRAM PIM.

D. Asynchronous Execution PIM

Recently, asynchronous execution PIM architecture has been proposed as another solution to reduce row activation overhead [8]. In this architecture, as shown in Fig. 3a, each bank operates asynchronously, reducing row activation overhead by overlapping row activation and operations across different banks. Since a single command controls only one bank, a long-data command is proposed to avoid command conflict. This command automatically processes operations across an entire row and is issued once at the start of the computation to each banks.

Fig. 3b illustrates the GEMV operation in this architecture. Unlike conventional PIM, small blocks of the weight matrix row are mapped to individual banks, arranged along the matrix columns. Since each bank operates at different timings, broadcasting input data simultaneously to all banks is not feasible. Instead, each bank receives and processes its designated data block independently, reusing it across the entire DRAM row with the long-data command. As operations progress across columns, accumulation cannot occur within individual banks but should take place between banks. To address this, a shared accumulator is placed at the center of each bank group, as shown in Fig. 3c. The shared accumulator receives data asynchronously transmitted from each bank, identifies the values to be added based on the address information, and performs the accumulation.

In this architecture, the operation of a single row in a single bank takes $t_{\text{RCD}} + t_{\text{MAC}} + t_{\text{RP}}$, and t_{ACT} is given by:

$$t_{\text{ACT}} = \max(t_{\text{FAW}}, 4 \times t_{\text{RRD}}) \times \left(\left\lceil \frac{N}{4} \right\rceil - 1 \right) + \left[(N-1) \mod 4 \right] \times t_{\text{RRD}}$$

Thus, the total execution time for M tiles is $(t_{\text{RCD}}+t_{\text{MAC}}+t_{\text{RP}}) \times M + t_{\text{ACT}}$, and the impact of t_{RRD} and t_{FAW} diminishes as M increases.

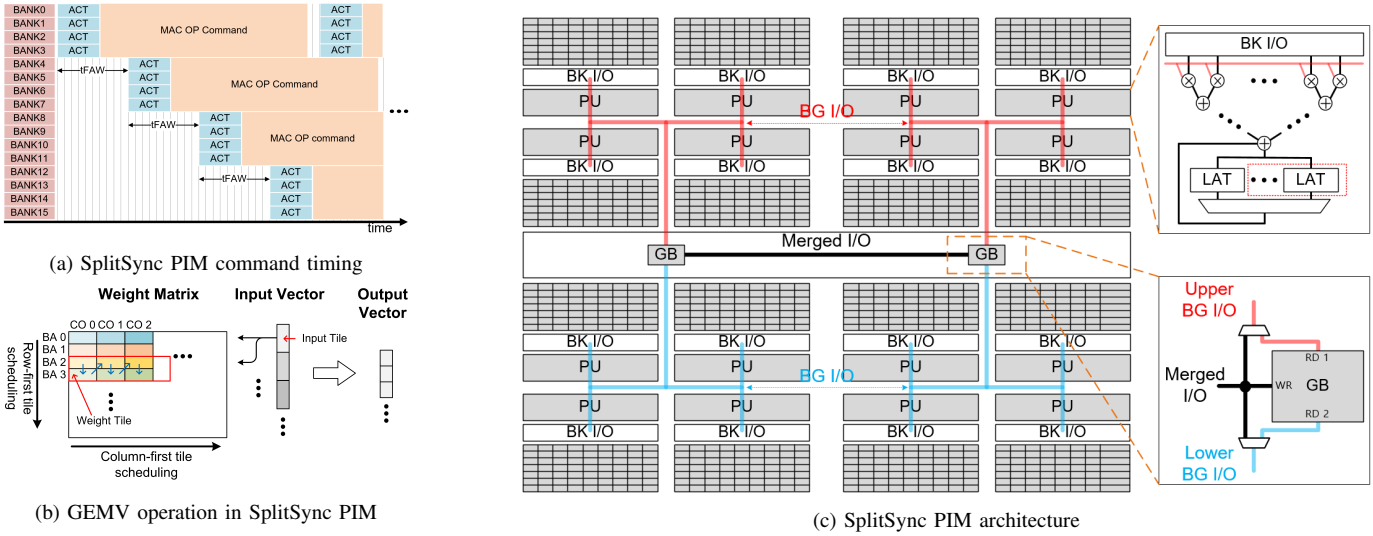
Despite demonstrating good performance, this architecture has several implementation challenges.

First, the size of the shared accumulator scales with the DRAM row size. According to [8], the shared accumulator incurs an area overhead of approximately 10% per PU based on a 1KB row size. For memory technologies such as GDDR6 [7], which feature row sizes of 2KB or larger, and DDR5 [3]/LPDDR5 [17], which can also support 2KB row size, the area overhead increases to 15-20%.

Second, positioning the shared accumulator centrally within a bank group presents additional challenges. Banks within the bank group share address/data buses and various control circuits. This shared infrastructure requires that bus distribution, data gathering circuits, and control circuits already occupy most of the central space in the bank group. Consequently, integrating a shared accumulator in this central area creates competition for space, making it difficult to prioritize its placement over essential DRAM operation blocks.

Third, asynchronous operations introduce potential conflicts in shared I/O during data transfers. Specifically, conflicts can occur when loading input blocks from the global buffer to each bank and when reading computation results from the shared accumulators. After a computation is completed and banks prepare to move to the next tile, those that have finished must wait for others to complete. This results in idle periods until all banks synchronize and results are read out, allowing the next tile to load. Conversely, synchronous operations ensure that all banks handle input and output simultaneously, eliminating these conflicts. As a result, asynchronous operations can introduce significant overhead, particularly with row-first tile scheduling, though column-first tile scheduling can help mitigate this issue.

III. SplitSync DRAM PIM Design



A. Bank Group-Level Split Synchronization

As discussed in the previous section, conventional DRAM PIM experiences significant performance degradation due to row activation overhead. In contrast, both ACT16-enabled PIM and asynchronous execution PIM reduce this overhead but at the cost of increased area requirements. Specifically, ACT16-enabled PIM needs substantial space for reservoir capacitors, while asynchronous execution PIM demands a large shared accumulator. To overcome the performance and area challenges, we propose a bank group-level split synchronization architecture that effectively reduces row activation overhead with minimal area overhead. This architecture operates synchronously within a bank group and asynchronously between bank groups, as illustrated in Fig. 4a.

The synchronous operation within a bank group provides two main advantages. First, since each bank group consists of four banks, all banks within the group can be activated concurrently without being constrained by t_{FAW}. Second, synchronous operations within a bank group enable the global buffer to broadcast input data across the banks. This capability allows the rows of the weight matrix to be mapped to banks in a manner similar to conventional PIM, facilitating intra-bank accumulation and removing the need for a shared accumulator. Moreover, the asynchronous operation between bank groups allows for overlapping row activations and operations across different bank groups, which helps to further reduce overhead, as previously mentioned.

B. SplitSync DRAM PIM Architecture

The SplitSync PIM architecture is shown in Fig. 4c. There are three major changes from conventional PIM designs. First, the I/O

(a) SplitSync PIM command timing

(b) GEMV operation in SplitSync PIM

(c) SplitSync PIM architecture

Fig. 4: Proposed SplitSync DRAM PIM architecture and its operation

architecture is updated from a shared I/O to a combination of bank-group I/O (BG I/O) and merged I/O. Second, the global buffer is now connected to the BG I/O, enabling input broadcasting through the BG I/O. Third, the number of result latches per PU is increased from 1 set to 4 sets, with each set consisting of 16 latches in BF16 format. Here, 1 set refers to 1 unit.

Resolving the I/O conflict Due to the different operation timings between bank groups, input broadcasting is not possible on shared I/O. To address the issue, we introduce bank group-specific I/O, called BG I/O (red and cyan lines in Fig. 4c), which is shared within each BG and supports data movement between bank groups, allowing different inputs to be broadcast to each bank group. The BG I/O is connected to the global buffer and facilitates localized broadcasting, but it does not connect directly to the DRAM interface; instead, it links through the merged I/O. The merged I/O is positioned in the peripheral circuit area and aggregates the BG I/Os (black line in Fig. 4c), enabling seamless access to banks during read and write operations. This architecture ensures that read and write operations at the bank group level do not disrupt PIM operations in other bank groups. As a result, as shown in Fig. 5, these updates to the I/O architecture enables simultaneous operations such as input writing with input broadcasting, input broadcasting with another input broadcasting, and input broadcasting with result reading.

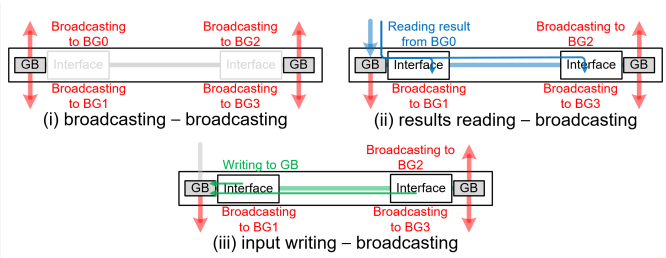


Fig. 5: Simultaneous operations in SplitSync DRAM PIM

GEMV operation in SplitSync PIM The method for tiling GEMV in SplitSync PIM is illustrated in Fig. 4b. While the GEMV tiling approach is fundamentally similar to that of conventional PIM, two key distinctions arise due to the architectural changes in SplitSync PIM.

First, the weight matrix is divided into half and mapped across the left and right bank groups, with the input vector split accordingly between the left and right GBs. This is necessary because the GB is horizontally divided, and each bank group is connected to only one of the GBs via BG I/O (Fig. 4c). Since the connections between GBs uses merged I/O, broadcasting input data from the opposite-side GB that is not connected via BG I/O can cause inefficiencies and potential I/O conflicts. To avoid these issues, the input vector can be either duplicated across both GBs or partitioned between them, with partitioning generally being the more efficient solution.

Second, more than two weight matrix rows are mapped to a single DRAM row to address the mismatch between DRAM row size and GB size. In conventional PIM architectures, even when the GB is split, it functions as a unified large GB during computation. However, in SplitSync PIM, the split GBs operate independently, reducing the GB size available to each bank group. This creates a mismatch between DRAM row size and GB size. To manage this, more result latches are required. Nonetheless, this approach is still more efficient than increasing the GB size. This mapping approach also reduces the frequency of input broadcasting, improving power efficiency. Additionally, increasing the number of result latches enables multiple matrix rows to be stored consecutively within a single DRAM row. This is particularly useful for operations involving numerous small-dimension GEMV operations, such as those found in the multi-head attention mechanism of transformer decoders [22]. In these cases, if there are insufficient result latches, the operation must pause during computation to perform intermediate readouts, which can degrade performance. In SplitSync PIM, four sets of latches are assigned to each PU to allow efficient readout at the BG level. With each PU outputting four units in BF16 format, and four banks per bank group, the total output is 256 bits per bank group, aligning with the column width. The column width is the amount of data transferred in a single read operation.

MAC operation command Since SplitSync PIM enables independent operation of each bank group, command conflicts must be considered. Theses conflicts can be managed in a manner similar to the long-data command used in asynchronous execution PIM. However, unlike the long-data command, the MAC operation command in SplitSync PIM also convey information about how many matrix rows(2, 4, or 8) are stored in each DRAM row. The MAC

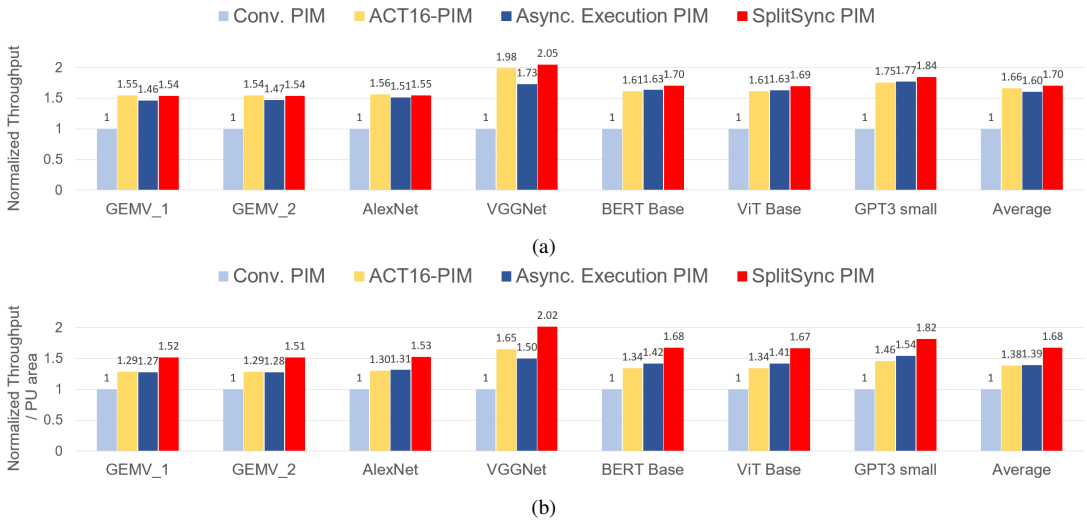

Fig. 6: Throughput comparison across benchmarks. (a) Normalized to conventional DRAM PIM (b) Normalized throughput per PU area.

operation command allows accessing either the entire row or half, which is crucial for improving resource utilization when dealing with matrices with small dimensions or tiled fragments. Once a bank group is activated, the MAC operation command is issued, enabling sequentially access to columns within the row and initiating computations.

IV. Evaluation

A. Methodology

Seven microbenchmarks are used to evaluate the performance of four PIM architectures (Table II). Specifically, two microbenchmarks are assigned to each of the GEMV and CNN models [10, 21], and three to Transformer models [5, 6, 1], focusing solely on matrix operations that PIM can handle in each model. For the CNN model, convolution opertaions are converted into General Matrix-Matrix Multiplication (GEMM), which is then executed through repeated GEMV operations.

The performance evaluation is conducted by modifying the cycle-level DRAMsim3 [16]. All simulations are based on the same GDDR6 configuration (Table II bottom). Since the performance of each PIM can vary depending on tile scheduling, the most optimal scheduling method is applied for each PIM: Conventional PIM, ACT16-enabled PIM and SplitSync PIM use row-first tile scheduling, while Asynchronous Execution PIM uses column-first tile scheduling.

TABLE II: Benchmark and GDDR6 PIM Configuration

Benchmark	**Target Layer**
GEMV1	2K × 2K GEMV
GEMV2	4K × 4K GEMV
AlexNet	5 CONV, 3 FC
VGGNet	13 CONV, 3 FC
BERT Base	12 TRANS
ViT Base	12 TRANS
GPT-3 small	12 TRANS
GDDR6 PIM Configuration	
Bank groups	4 bank groups per channel
Banks	4 banks per bank group
Column width	256 bits
Row Size	2 KB
Density	4 Gb
Clock frequency	1.5 GHz
Global buffer	2 KB

B. Performance

Fig. 6a shows a throughput comparison across seven microbenchmarks, with all results normalized to the throughput of conventional PIM. The three PIM architectures designed to reduce row activation overhead consistently outperform conventional PIM in all cases. Although the extent of performance improvement varies depending on the benchmark, SplitSync PIM shows the highest performance on average. The performance improvement is more pronounced in neural network models than GEMV benchmarks due to varying matrix dimensions within the models. The two GEMV benchmarks have matrix dimensions that align perfectly with the banks and rows during tiling, resulting in efficient use of DRAM resources. In contrast, neural network models often have matrix dimensions that do not map perfectly to DRAM rows or banks, leading to partial utilization of activated rows and higher row activation overhead. Additionally, when the matrix column size is considerably smaller than the DRAM row size, multiple matrix rows can be computed within a single DRAM row, giving an additional edge to both asynchronous execution PIM and SplitSync PIM. Overall, across the seven benchmarks, SplitSync PIM achieves an average throughput improvement of 1.70x, 1.02x, and 1.06x compared to conventional PIM, ACT16-enabled PIM, and asynchronous execution PIM, respectively. A even more important point is that SplitSync achieves higher performance compared to other designs while maintaining the smallest area overhead relative to conventional PIM. The next section provides a detailed analysis of the area overhead.

C. Area Overhead

We estimated the area overhead of SplitSync PIM using a 28nm CMOS process. While the size of the global buffer does not increase compared to conventional PIM, adding a read port results in a 62% increase in its area. However, since the global buffer accounts for less than 1% of the total PIM area, this increase is negligible. Increasing the number of result latches to 4 sets per processing unit incurs a 1.5% area overhead per PU, which is significantly smaller than the area overhead observed in ACT16-enabled PIM and asynchronous execution PIM. As described in Section II-C and II-D, ACT16-enabled PIM incurs 20-25% and asynchronous execution PIM incurs 15-20% area overhead. Fig. 6b shows the throughput results normalized by PU area for the seven benchmarks.

Although proposed architectures use different approaches, all three designs effectively address the t_{FAW} constraint, resulting in similar performance. However, the area used to resolve the t_{FAW} constraint varies across architectures, revealing notable performance differences in iso-area performance. Factoring in PU area, SplitSync PIM shows performance improvements of 1.67x, 1.21x, and 1.20x compared to conventional PIM, ACT16-enabled PIM, and asynchronous execution PIM, respectively.

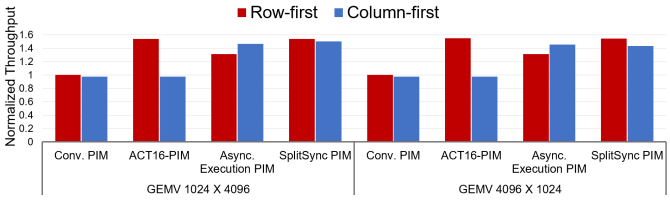

Fig. 7: Impact of tile scheduling on PIM performacne

D. Impact of Tile Scheduling

Fig. 7 shows the results of how tile scheduling affects PIM performance. We evaluate two cases of GEMV: 1K $\times$ 4K and 4K $\times$ 1K, with results normalized to the row-first tile scheduling of conventional PIM. For conventional PIM, row-first tile scheduling shows slightly better results than column-first scheduling, but the difference is minimal, with performance remaining nearly identical. In contrast, the other architectures show significant performance differences depending on the tile scheduling methods, most notably in ACT16-enabled PIM. This disparity occurs because, as row activation overhead is reduced, other overheads that were previously masked become more visible.

In asynchronous execution PIM, the performance difference is primarily due to frequent result reading in row-first tile scheduling. Unlike other architectures, asynchronous execution PIM cannot hide result reads behind precharge-activation due to I/O conflict issues and the high volume of results to be read out. As a result, it shows worse performance with row-first tile scheduling. With column-first tile scheduling, performance degrades due to the increased number of input writes, particularly affecting ACT16-enabled PIM. In conventional PIM, input writes are masked by the long activation time, but in ACT16-enabled PIM, shorter activation time prevents this masking, resulting in a greater performance impact. Conversely, SplitSync PIM and asynchronous execution PIM mitigate this issue by enabling more input reuse through additional result latches. Furthermore, in asynchronous execution PIM, only small blocks are written per tile, allowing frequent writes to be hidden during activation.

E. Impact of t_{FAW} and Row Size

Row activaion overhead is determined by the row activation time and the operation time. Row activation time is primarily influenced by t_{FAW}, while operation time depends largely on t_{CCD} and the row size. Since t_{CCD} is the inverse of the operation frequency, it can be excluded from this analysis, leaving changes in t_{FAW} and row size as the key factors determining row activation overhead. While there is a positive correlation between t_{FAW} and row size, the exact relationship varies by design. Therefore, we treat these as independent variables and analyze their impacts separately. Once the relationship between the two variables is established during the design phase, the analysis can focus on the relevant regions of the results. Fig. 8 presents these findings as a heatmap, with throughput normalized to the overall average. In conventional architectures, throughput generally decreases as row activation overhead increases

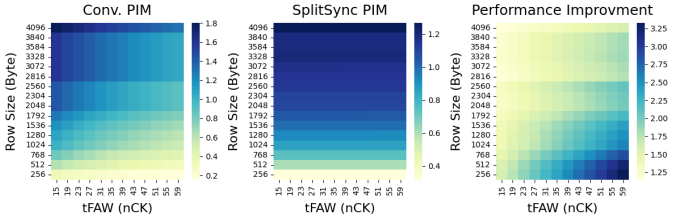

Fig. 8: Performance impact when varying t_{FAW} and row size

towards the lower right of the heatmap. In contast, SplitSync PIM less affected by t_{FAW}, with row size playing a more important role in its throughput. SplitSync PIM consistently shows a performance improvement of at lesat 1.15x across all areas. As expected, the performance gain becomes larger when row activation overhead becomes greater (moving towards the lower right of the heatmap).

F. Energy

We use the DRAMsim3 simulator to evaluate the energy consumption during PIM operations. For a 4K $\times$ 4K GEMV, ACT16-enabled PIM, asynchronous execution PIM and SplitSync PIM consume 97%, 89% and 86% of the energy compared to conventional PIM, respectively. ACT16-enabled PIM exhibits slight energy reduction over conventional PIM since energy savings come solely from reduced stand-by energy as a result of shorter processing times. In asynchronous execution PIM, input data is loaded only once per row, reducing I/O energy consumption. SplitSync PIM achieves further energy savings through shorter BG I/O paths and lower broadcasting frequency, as multiple rows are processed together, decreasing overall I/O energy usage. In both SplitSync PIM and asynchronous execution PIM, reduced I/O energy consumption and lower stand-by energy due to shorter processing times enhance energy efficiency.

V. Conclusion

In this paper, we present SplitSync PIM, a DRAM PIM architecture designed to reduces row activation overhead through bank group-level split synchronization. This approach allows each bank group to operate asynchronously to hide row activation overhead while maintaining synchronous operations within each bank group to enable input broadcasting at the bank group-level. SplitSync PIM addresses the t_{FAW} constraint without relying on the large reservoir capacitors and drivers used in ACT16-enabled PIM, and it eliminates the need for a shared accumulator in asynchronous execution PIM. Additionally, I/O conflicts occurring from asynchronous operations are resolved through a modified I/O architecture, enabling all bank groups to operate independently. Consequently, SplitSync PIM effectively reduces row activation overhead efficiently, with minimal area overhead.

***Abstract*—The LLM decoding process poses a significant challenge for memory bandwidth due to its autoregressive nature. Prior 2D memory solutions fail to overcome this memory bottleneck due to limited memory-to-logic bandwidth. In this work, we propose 3D-TokSIM, a cross-stack solution by stacking 3D memory on logic die with a specially designed token-stationary compute-in-memory (CIM) to efficiently accelerate speculative decoding. Our CIM is developed with novel token-stationary dataflow to reduce data movement on logic die to save power and balance computation and memory access. To further reduce the buffer requirements, we perform architecture exploration and allocate notable CIM resources for achieving higher decoding parallelism. Compared to RTX 3090 GPU, 3D-TokSIM achieves 15.1× throughput and 324× energy efficiency improvements on speculative Llama2-7B decoding.**

***Index Terms*—LLM, Process-Near-Memory, Compute-In-Memory**

I. Introduction

Large Language Models (LLMs) have demonstrated remarkable capabilities in natural language processing tasks and beyond. However, it is quite challenging for existing hardware solutions, e.g. GPUs, to achieve efficient LLM deployment. Due to the intrinsic autoregressive model nature, LLMs require loading the entire model to generate one new token at each decoding step [1]. Such operation behaviors lead to a severe bottleneck of memory bandwidth for LLM inference. Meanwhile, the existing GPUs or XPUs are designed with massively parallel computing units with quite limited off-chip memory bandwidth. Hence it is clear from many research papers that the LLM inference is a memory-bound task and desires cross-stack optimizations for bandwidth [2]–[5].

To alleviate the bandwidth bottleneck, 3D memory architecture using the hybrid bonding (HB) technique is a promising solution [6], [7]. By stacking the DRAM memory on top of the compute logic die, DRAM bandwidth can be significantly improved by parallel accessing DRAM banks, which were originally accessed at interleaved time. Based on the public data, the HB 3D memory can provide 135× bandwidth and 8× density improvements with more than 90% energy saving compared to existing 2D DRAM [8], [9].

Although 3D memory stacking brings valuable memory bandwidth, there is little exploration on how to efficiently deploy LLMs on such architecture. Even with 3D technology, the entire architecture remains memory-bound due to the inefficient autoregressive model behavior. A promising algorithmic strategy to alleviate the bandwidth bottleneck is speculative decoding (SD) technique [4], which utilizes an efficient drafter to produce multiple tokens and then simultaneously sends these tokens into LLM model for parallel verification.

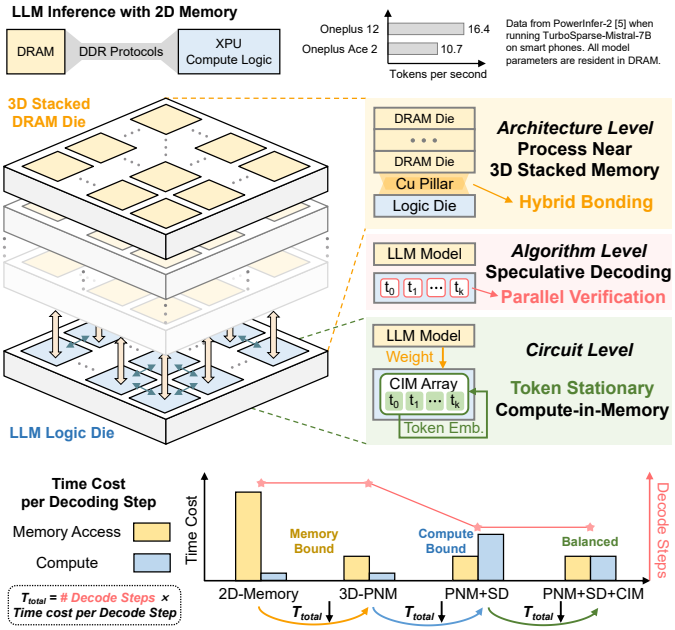

Fig. 1. Efficient LLM deployment on 3D stacking technique with cross-stack optimizations.

SD can successfully reduce the total decoding steps and alleviate the bandwidth requirement, with the cost of increasing computational workload in each decoding step. However, conventional digital design approach fails to efficiently process SD at the logic die, which effectively nullifies the high-bandwidth advantage of 3D memory stacking.

In this work, we explore a LLM deployment solution **3D-TokSIM**, which combines **3D** stacked DRAM processing-near-memory (PNM) and SRAM-based **tok**en **s**tationary compute-**i**n-**m**emory (CIM) for efficient speculative inference. As shown in Fig.1, at the architecture level, we leverage 3D stacked memory to significantly enhance the memory access bandwidth for each decoding step. At the algorithm level, we leverage the latest speculative decoding approach for the 3D stacked architecture to further reduce the number of decoding steps and bandwidth requirements. At the circuit level, we employ compute-in-memory (CIM) design with token stationary dataflow to efficiently support SD. Our cross-stack design and optimizations achieve fewer decoding steps with a balanced memory-compute workload per step. This results in reduced decoding time and a higher rate of token generation. Evaluated on our design using TSMC 22nm, it is observed that 3D-TokSIM achieves 15.1× throughput

and 324× energy efficiency improvements compared to RTX 3090 GPU. Moreover, 3D-TokSIM outperforms systolic array accelerated PNM of both throughput and energy efficiency by 1.5× and 6.4×, respectively. To the best of our knowledge, this is the first exploration work that enables fast LLM inference using 3D stacking on top of CIM architecture.

The contributions of this paper are summarized as follows:

- We propose 3D-TokSIM, a 3D stacked DRAM and SRAM-based CIM architecture targeting speculative LLM inference.
- We leverage token stationary dataflow with careful optimizations to balance the CIM design and DRAM bandwidth.
- We further perform several buffer optimizations to place abundant CIM for higher decoding parallelism.
- Our evaluation demonstrates that the proposed 3D-TokSIM has 15.1× throughput and 324× energy efficiency improvements compared to RTX 3090 GPU.

II. Background

A. Hybrid Bonding 3D Stacking

The ever-growing size of AI models has significantly exceeded the capacity of on-chip SRAM, resulting in frequent data transfers between DRAM and the main processor chip. Hybrid bonding process-near-memory (HB-PNM) [7] has emerged as a promising solution to the "memory wall" problem, offering fast and energy-efficient data access. In this approach, DRAM and logic die are integrated through direct copper-to-copper bonding. Each logic block can directly access its closely coupled DRAM banks and communicate with other logic blocks via the on-chip network (NoC). HB-PNM can achieve ultra-high interconnection density with a 3um pitch compared to about 50um microbump (ubump) pitch in HBM. Moreover, the resistance of HB is also much lower than ubump and through-silicon-vias (TSVs) [6].

HB technique has been initially studied for advanced memories. For example, SEDRAM [6] connected a DRAM array wafer and logic wafer using HB technology, with control, I/O, and peripherals located on the logic die. This motivates HB-PNM solutions for memory intensive applications. Niu et al. [7] developed an HB-PNM engine for recommendation systems that significantly outperformed CPU-DRAM system efficiency. Yue et al. [10] accelerated vision AI models with HB-PNM and gained notable efficiency improvement compared to prior accelerators. In addition to single layer DRAM stacking, multilayer array stacking is achieved with HB and mini-TSV in [9]. Driven by this, Chen et al. [11] presented an encryption engine for private inference with 4-layer stacked DRAM.

In the era of LLMs, it has already been well-studied that LLM decoding is heavily constrained by DRAM bandwidth [2], [3]. The memory bandwidth bottleneck is more severe for mobile devices, such as mobile phones or laptops. For example, mobile devices with the LPDDR5x protocol generally offer a peak bandwidth of 68GB/s, e.g. SK hynix 24GB LPDDR5x mobile DRAM [12]. When running a 4-bit quantized Llama-7B model, the theoretical throughput upper bound is 19.4 tokens per second (TPS), estimated by dividing the model size by the peak bandwidth. After adopting HB-PNM for edge devices, TBps-level bandwidth can be obtained resulting in approximately 500 TPS and 23-29× bandwidth improvement compared to standard LPDDR5x.

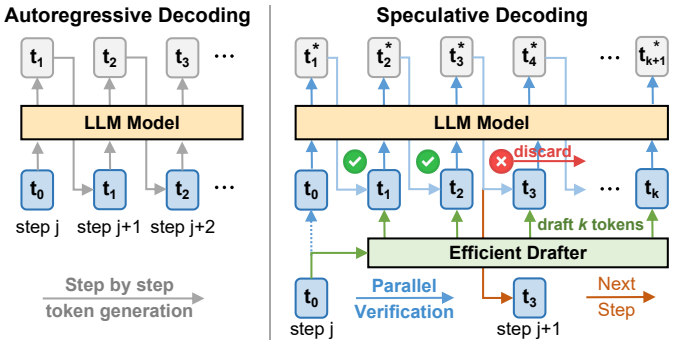

Fig. 2. Autoregressive decoding vs. Speculative decoding.

B. Speculative Decoding

Despite the use of high-bandwidth 3D technology, the LLM decoding may still be bounded by memory access due to its inherently autoregressive nature. Based on previous profiling [3], when the OPT-6.7B model is executed on an A100 GPU, the GEMV operation during the decoding phase accounts for over 80% of the total latency, while the GPU utilization remains below 25%. Speculative decoding [4] has emerged as a promising paradigm to boost LLM decoding by enabling the verification of multiple tokens in a single decoding step.

As shown in Fig. 2, SD first employs an efficient drafter to generate multiple tokens and then sends these tokens into the model in parallel to verify if they align with the LLM inference results. For a sequence of tokens to be verified, the first token that does not match the LLM result should be replaced with the LLM output, and any subsequent tokens should be discarded [4]. An important hyperparameter for SD is the number of draft tokens, denoted as k. While a higher k can lead to fewer decoding steps, the computational overhead grows up with k, potentially causing two other problems: 1) memory-bounded decoding steps will be shifted to computation-bounded, and 2) computations for those unaccepted tokens are inefficient and waste energy. Hence it is crucial to co-optimize SD across algorithm and hardware for optimal efficiency.

Since the first presentation of SD, there have been quite a few algorithm variants of SD to reduce the bandwidth requirement. For example, Leviathan et al. [13] utilized the small version of the T5 series to accelerate the larger ones. Yang et al. [14] introduced an early exiting scheme to initiate future tokens drafting, and He et al. [15] retrieved relevant tokens from a knowledge reservoir to draft tokens. Among these variants of SD, Inference with Reference (IwR) [16] is highly efficient and easy to deploy since it does not require an additional model for drafting. By exploring the massive overlaps between in-context references and outputs, IwR directly copies tokens from reference for parallel verification. This approach is highly practical in scenarios such as retrieval-augmented generation, cache-assisted generation, and multi-turn conversations.

III. 3D-TokSIM Architecture

A. Overall Architecture

In this paper, we propose **3D-TokSIM**, a **3D**-stacked architecture with **tok**en **s**tationary C**IM** for efficient LLM inference. As shown in Fig. 3 left, 3D-TokSIM is composed of multiple parallel LLM

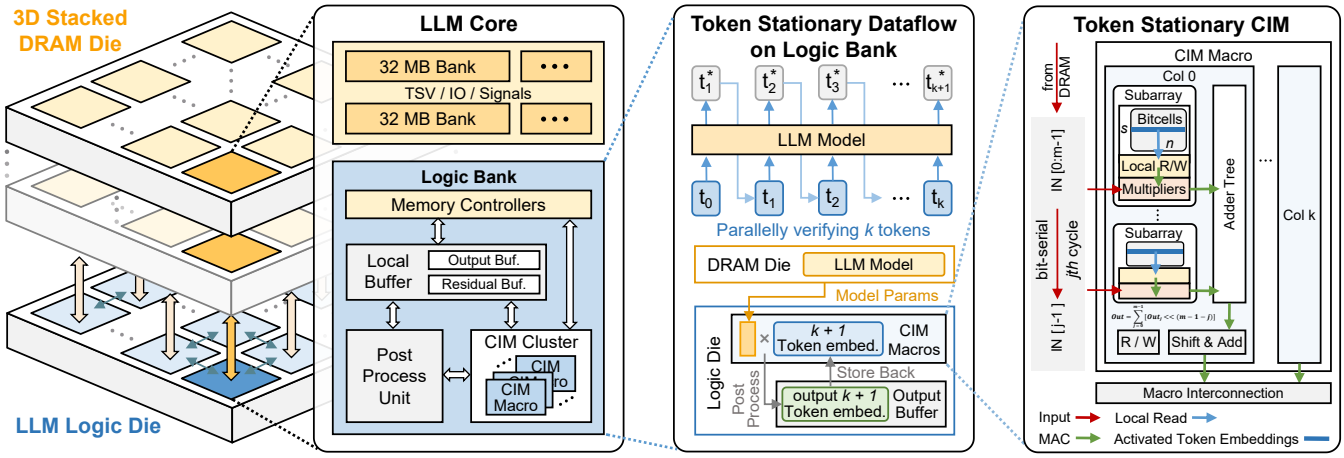

Fig. 3. Architecture overview: Stacking 3D memory above the logic die with token-stationary compute-in-memory clusters.

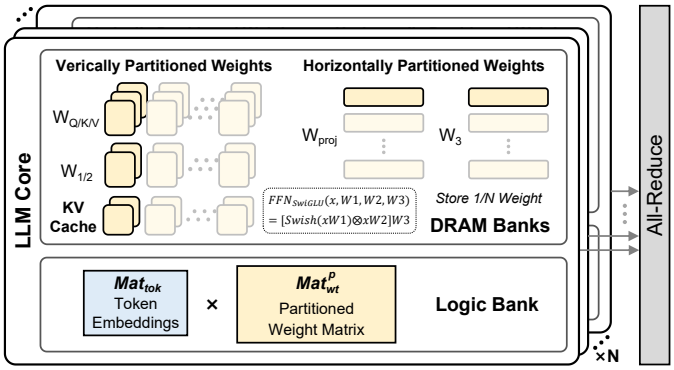

Fig. 4. Distributed Mapping for Parallel Acceleration.

Cores, and each core is composed of several DRAM Banks on DRAM dies and one logic bank on a logic die. DRAM dies and logic die are closely integrated through HB technique, which allows fast and energy-efficient DRAM access for logic banks. Each logic bank consists of memory controllers corresponding to above DRAM banks, a post-processing unit for handling non-linear operations, a CIM cluster responsible for multiply-and-accumulation (MAC) operation, and a local buffer. The LLM cores are connected through a NoC to enable inter-core data transfer.

Fig. 4 shows a typical mapping process to deploy multi-head-attention (MHA) and feed-forward-network (FFN) onto N parallel LLM Cores. For MHA, each LLM Core requires storing vertically partitioned weights for Q/K/V generation, KV cache, and horizontally partitioned projection weights. For FFN, the weights are partitioned vertically before activation and horizontally after activation. During LLM decoding, each logic bank loads weight or KV cache from its corresponding DRAM banks and performs multiplication with token embeddings. Following the last multiplication in MHA/FFN, an all-reduce operation merges results across cores, and then the full results are added to the initial token embeddings in the residual buffer to complete residual connection.

For each LLM core, we designate the matrix multiplications (MMs) in charge as $Mat_{tok} \times Mat^{p}_{wt}$, where p stands for partition. Either Mat^{p}_{wt} or Mat_{tok} can be mapped to the CIM cluster, which corresponds to **weight stationary** or **token stationary** dataflow. Noticed that even though Mat^{p}_{wt} constitutes only 1/N of the original weight matrix, its size remains excessively large. Consequently, Mat^{p}_{wt} must be divided into smaller tiles when being mapped to CIM cluster, rendering two disadvantages: 1) CIM cluster needs to frequently update its weight, and Mat_{tok} must be read from local buffer repeatedly, resulting in massive data read/write operations, and 2) The input buffer is necessary to hold the entire input token embeddings, which further tightening the area constraints.

In contrast, we map Mat_{tok} instead of Mat^{p}_{wt} to the CIM cluster, referred to as **token stationary** dataflow, to liberate our design from the aforementioned concerns. Since the IwF typically dispatches a small group of tokens for parallel verification, it becomes possible to store the entire Mat_{tok} within the CIM by allocating sufficient storage resources. This eliminates the need for further tiling and input buffering.

B. Logic Die: Token Stationary CIM

In our work, a **token stationary** dataflow is developed to efficiently support speculative decoding. As illustrated in the middle part of Fig.3, the CIM macros hold all token embeddings Mat_{tok} in bitcell arrays. The DRAM sends model parameters as the input of CIM to perform MMs. The output result first undergoes post-processing and is held in the output buffer, which is then sent to CIM macros for subsequent MM.

Compared to conventional **weight stationary** dataflow, our **token stationary** dataflow reduces frequent read/write operations on the logic die and saves considerable energy. Note that due to low-resistance HB, the power consumption of data transfer from DRAM has been significantly reduced, for instance, to 0.88pJ/bit in [7] and 0.66pJ/bit in [9]. Consequently, the energy consumption of SRAM read/write operation is now comparable to that of DRAM data transfer. Therefore, we employ token stationary dataflow to eliminate frequent SRAM read/write operations. As shown in the middle of Fig.3, for every MM, we maintain all token embeddings Mat_{tok} in CIM and load weight from DRAM as CIM input. The entire MM process does not require storing weights in the CIM, nor does it require reading token embeddings from the local buffer. The outcomes are post-processed and stored back to CIM before subsequent MM.

TABLE I
NOTATIONS FOR DESIGN PARAMETERS AND LLM MODEL

Architecture Design Parameters	
N	Number of Parallel LLM Cores
$DRAM_{width}$	Number of DRAM I/O within a LLM Core
$DRAM_{freq}$	Frequency of DRAM I/O
CIM_{num}	Number of CIM Macros within a CIM Cluster
$Macro_{col}$	Number of CIM Columns within a CIM Macro
$Macro_{row}$	Number of Subarrays within a CIM Column
CIM_{freq}	Frequency of CIM
(s, n)	Rows and Columns of Subarray Bitcells
LLM Model Parameters	
dim	Model Dimension
d_{ff}	Intra-FFN Dimension
d_{head}	Attention Head Dimension
k	Number of Draft Tokens in Each Decoding Step

Our CIM macros are designed to meet the requirement of token stationary dataflow. As depicted in Fig.3 right, CIM macros are composed of several identical CIM columns. A CIM column has multiple CIM subarrays and an adder tree. Within each subarray, there are $s \times n$ SRAM bitcells, n local read/write (R/W) units, and n 1-b multipliers, where n equals the minimum supported data width. Token embeddings Mat_{tok} are stored within bitcells, which are then activated and read by local read/write units. The multipliers are shared by s row bitcells, where s indicates the optimal storage-compute ratio for token stationary dataflow. An m-bit input vector requires m cycles for bit-serial computation, and a shifter-and-adder is responsible for accumulating m partial sums. Multiple CIM macros can be connected vertically or horizontally to support various shapes of matrix multiplication. The notations utilized in this work for architecture design and LLM model are summarized in Table I.

For a single MM, each token embedding of length d performs a dot product with weights or KV cache, which is done in parallel for $k+1$ token embeddings by broadcasting. Therefore, we store individual token embeddings in separate CIM columns, ensuring that each token embedding is mapped to its own distinct column:

$$Macro_{col} = k+1, \quad n = TokenEmb_{width} \tag{1}$$

where $TokenEmb_{width}$ denotes the bit width of token embeddings.

Given that $k+1$ is usually much smaller than d, a single CIM macro is designed to accommodate $k+1$. Multiple macros are connected vertically to cover the entire length of the maximum d as follows:

$$CIM_{num} \times Macro_{row} \times s = max(dim, \frac{d_{ff}}{N}) \tag{2}$$

IV. ARCHITECTURE OPTIMIZATIONS

A. Exploration Constraints

Based on the above analysis, we have identified token stationary as the suitable dataflow for speculative LLM inference. Furthermore, we perform architecture modeling to guide the design of token-stationary CIM cluster to take full advantage of this dataflow.

To fully exploit the 3D DRAM bandwidth, the CIM cluster should be equipped with sufficient computational resources. More specifically, the rate at which data are read from DRAM should be aligned with the rate at which CIM consumes them. The bit width

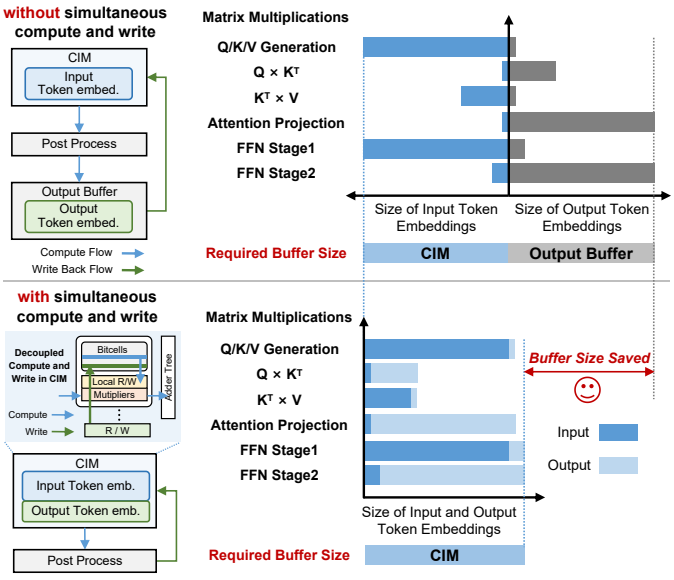

Fig. 5. Eliminating Buffer by Writing Output to CIM.

of data is represented by $Data_{bits}$. Within a unit of time T_{unit}, the number of data read from DRAM is represented by:

$$Data_{read} = T_{unit} \times \frac{DRAM_{width}}{Data_{bits}} \times DRAM_{freq} \tag{3}$$

Since data are sent into CIM bit-serially, the number of data consumed by CIM within T_{unit} is expressed as:

$$Data_{consume} = T_{unit} \times \frac{CIM_{num} \times Macro_{row} \times CIM_{freq}}{Data_{bits}} \tag{4}$$

Equalizing $Data_{read}$ and $Data_{consume}$ results in:

$$CIM_{num} \times Macro_{row} \times CIM_{freq} = DRAM_{width} \times DRAM_{freq} \tag{5}$$

However, the reduction length of intermediate token embeddings during MHA or FFN is small, and they should be copied to fully utilize CIM performance and DRAM bandwidth. For each copy, it should be able to perform MAC calculations independently. Therefore, the minimal reduction length achievable by CIM is set to correspond with the minimum d:

$$Macro_{row} = min(d_{head}, \frac{d_{ff}}{N}) \tag{6}$$

Within the area constraints, the integer solution closest to the above requirements is selected for CIM design. For larger model dimensions, CIM capacity per column expands by adding more bitcells to subarrays. As CIM column equips more capacity or performance, its area increases, ultimately reducing the total number of CIM columns which corresponds to supported k.

B. Architecture Optimizations

Since the area of a single logic bank is constrained by the area of its corresponding DRAMs above it, the maximum supported k is also limited by the available CIM area. To ensure ample CIM resources, we further optimize the on-chip SRAM size and reduce the buffer requirement for each LLM core. Optimization opportunities are explored at both intra- and inter-core levels to minimize buffer requirements for MM output and residual connection, respectively.

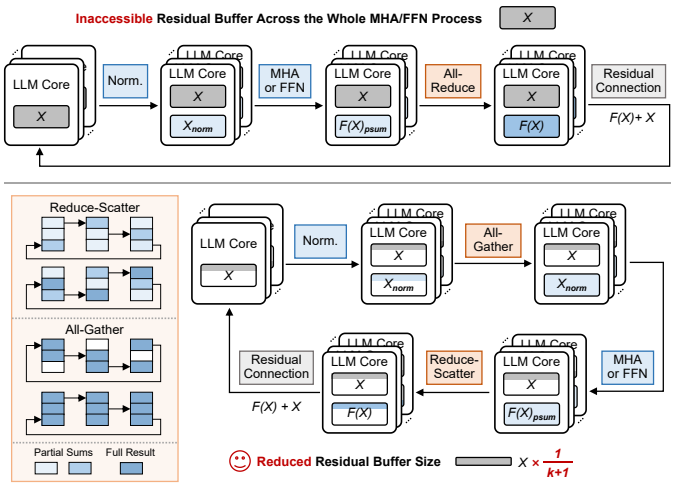

Fig. 6. Reducing Residual Buffer by Jointly Considering Residual Connection with All-Reduce Operation.

1) Output Buffer Optimizations: We first focus on optimizing the scheduling of MM within each core, aiming to eliminate output buffer. As illustrated in the Fig.5 top, our token stationary dafalow ensures input token embeddings are fully resident in CIM, while the output token embeddings are stored in the output buffer. The required capacity of CIM and output buffer are determined by the largest token embeddings size across all MMs as depicted in the upper right of Fig.5. Since the output of MM will be returned to CIM for subsequent MM, by enabling simultaneous compute and write of CIM, the output can be directly written back to CIM without temporarily residing in output buffer.

Therefore, we implement simultaneous compute and write CIM as shown in the lower left of Fig.5, where the local read/write units have decoupled multipliers and adder trees from bitcells, showing no resource contention between compute and write operation. Consequently, the elements of output token embeddings can be written back to CIM after being post-processed even if the CIM is still computing. As shown in the lower right of Fig.5, the output buffer is now eliminated at the cost of slightly increased CIM size, and we adjust our previous CIM design size in (2) to:

$$CIM_{num} \times Macro_{row} \times s = dim + max(d_{head}, \frac{d_{ff}}{N}) \quad (7)$$

For the typical Llama2-7B model ($dim = 4096$, $d_{head} = 128$ and $d_{ff} = 11008$) accelerated with 32 cores, the capacity of CIM increases about 8.4% according to (7) and (2), which demonstrates minimal area overhead.

2) Residual Buffer Optimizations: Residual connection (RC, $F(X) + X$) impedes resource-constrained model inference as it requires extra buffer. Previous work has attempted to reorganize residual connections to enable tiny devices to accommodate CNN models [17]. As shown at the top of Fig.6, for parallel LLM inference, RC requires keeping the unnormalized input token embeddings of MHA or FFN, denoted as X, across the whole computing process. The buffer tailored for X is inaccessible during MHA or FFN, leading to constraint area for CIM.

As displayed at the bottom of Fig.6, we reduce the residual buffer size for each LLM core by jointly considering RC with all-reduce (AR) operation between cores. We adopt bandwidth optimal ring AR [18], [19], which is further divided into two phases: reduce-scatter (RS) and all-gather (AG). Noticing that each core holds only a portion of the full result after RS, inserting RC between RS and AG allows each core to store only the corresponding portion of X. In addition, AG begins after normalization and each core receives the normalized token embeddings from other cores. Because token embeddings are stored column-wise in CIM, vertical read/write mode similar to prior CIMs [20], [21] is leveraged to support above proposal with the aid of local read/write units. With k draft tokens in SD, our scheme reduces the residual buffer size in each core to $1/(k+1)$. For typical k larger than 5, the area cost of the residual buffer is reduced to less than 16.7%.

TABLE II
3D-TOKSIM SPECIFICATION

System Configuration

V. EVALUATION

A. Experiment Setup

Hardware Setup. In our work, we selected a 32MB DRAM bank with 256 I/O as the fundamental unit for our memory design, with area referring to [10]. Both DRAM die and Logic die are operating at 500MHz. The energy consumption of multilayer DRAM refers to the latest publication [9]. Our logic die is designed using TSMC 22nm technology. The area of memory controller and PHY are based on [11], which has similar technology node to ours. We designed an in-house 22nm CIM macro with post-layout simulation. The energy efficiency of our CIM macro is 9.51TOPS/W for W4A16/W8A8 data format with 50% input toggle rate and 50% weight bit-level sparsity. The local buffer is generated by Arm Memory Compiler. The area and power of processing unit are based on our RISC-V VPU with various special functions integration referred from [22]. A performance model incorporating above hardware information has been constructed for architecture exploration.

To fairly compare weight stationary (WS) and proposed token stationary (TS) dataflow, the CIM under WS is also carefully designed, where the storage and performance of CIM are set to ensure that the weight update and the computation overlap as much as possible. In addition, a systolic array based on Gemmini [23] is synthesized by Cadence Genus. It is used as a comparison baseline for more comprehensive architecture evaluation.

Algorithm Setup. We evaluated the speculative decoding using the model from [16]. For different draft lengths k ranging from 0 to 18, we recorded the decoding information across 100 samples. The decoding information includes the length of KV cache and whether

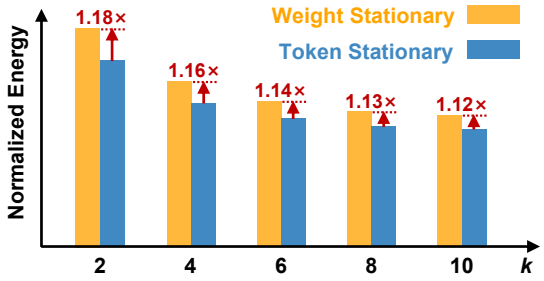

Fig. 8. Energy Cost of Weight Stationary and Token Stationary Dataflow.

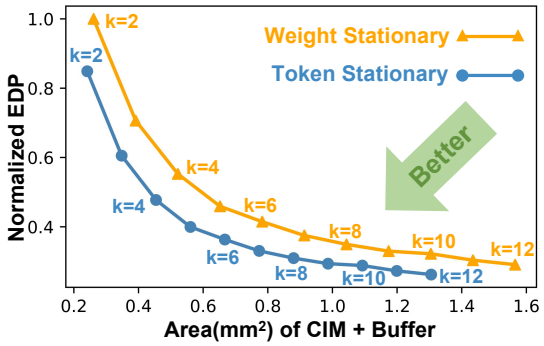

Fig. 9. EDP vs. Area of Weight Stationary and Token Stationary Dataflow.

coping k tokens or not in each decoding step. We use this record as the algorithm input for our performance model.

B. Implementation and Exploration

We implemented 3D-TokSIM with 32 LLM cores, with each core containing 4 DRAM banks stacked vertically to support the typical LLama2-7B [1] model with W4A16 quantization. The 4-layer stacked DRAM offers 2TB/s bandwidth and 4GB capacity in total. The specification of 3D-TokSIM is listed in Table II. Each LLM core contains 8 CIM macros, and the column of each CIM macro is 13 to support SD with k equals 12. These 8 cores together provide a performance of 3.25TOPS and 130KB capacity. The area breakdown of a single logic bank is depicted in Fig.7. It illustrates that our optimization ensures ample CIM area, while the buffer area is minimal.

We decomposed our architecture optimization into two parts: the energy saving through token stationary dataflow and the enhancements in energy-delay product (EDP) by further buffer reduction. Our optimization yields similar results across different models, and here we present the results for the 4-bit quantized LLAMA2-7B model. The energy costs of WS and TS dataflow with different k are shown in Fig.8. For k ranges from 2 to 10, the TS dataflow offers 1.18×-1.12× better energy efficiency than WS. As k increases, the improvement decreases slightly. This is due to TS primarily optimizing data transfer overhead, while a larger k increases energy costs for computation. Fig.9 illustrates the EDP of WS and TS dataflows, with supported k ranging from 2 to 12. It can be clearly seen that TS always achieves better EDP than WS under the same area constraint. For k larger than 12, they are not depicted. This is because the EDP almost no longer decreases due to the higher compute overhead and saturated decoding steps.

Our architecture is extended to support various LLM models. Recently, low-bit quantization of LLMs has been developed, even reaching down to 2-bit quantization [24]. Therefore different architecture configurations are set to adapt larger model sizes with 3/2 bit quantization. As listed in Table III, compared to WS dataflow, the optimized TS dataflow consistently supports larger k and brings 1.13×-1.23× EDP improvement across various LLM models.

TABLE III
OPTIMIZATION OF VARIOUS LLM MODELS

LLM Model	Arch. Cfg.*	k Opt.	EDP Improve.

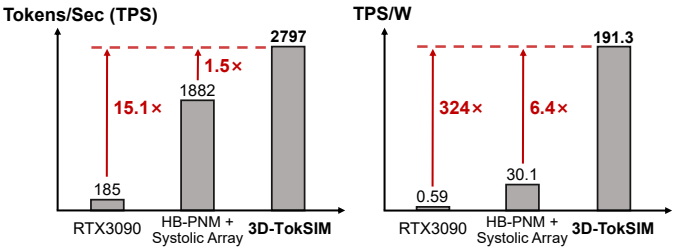

Fig. 10. Comparison result with RTX 3090 GPU and systolic array accelerated HB-PNM.

C. Comparison and Discussion

Fig.10 shows the comparison result of 3D-TokSIM with RTX 3090 GPU and systolic array accelerated HB-PNM on speculative Llama2-7B model. Our 3D-TokSIM generates 2797 tokens per second (TPS), which is 15.1× faster than RTX 3090. Notably, the RTX 3090 provides a formidable 936GB/s DRAM bandwidth, and our 3D stacked memory only delivers twice the speed at 2TB/s. Therefore, this improvement is not solely due to higher bandwidth, but rather attributed more to the architecture. Compared to HB-PNM with systolic array acceleration, 3D-TokSIM achieves 1.5× higher TPS. This is mainly due to the lower performance density of the systolic array compared to CIM, resulting in the system being compute-bound. In addition, the energy efficiency of 3D-TokSIM outperforms RTX 3090 and HB-PNM with systolic array acceleration by 324× and 6.4×, which demonstrates the efficiency of proposed token stationary CIM.

VI. CONCLUSION

This paper presents a cross-stack solution for efficient LLM inference, i.e. 3D-TokSIM, which incorporates 3D stacked DRAM and token stationary CIM to efficiently accelerate speculative decoding. Optimization of the token stationary dataflow further reduces buffer needs, enhancing decoding parallelism and improving EDP with ample CIM resources. The implemented 3D-TokSIM using TSMC 22nm demonstrates 15.1× and 1.5× faster token generation speed with 324× and 6.4× energy efficiency compared to RTX 3090 and systolic array accelerated PNM.

***Abstract*—Nonvolatile field-programmable gate arrays (NVFPGAs) can use multi-level cell (MLC) nonvolatile memories (NVMs) to enhance their logic density. However, the high-density design of NVFPGAs degrades the intra-routability of configurable logic blocks (CLBs), which significantly prolongs the time consumed by the packing process in the computer-aided design (CAD) flow. To relieve the efficiency degradation, in this paper, we propose a routability-aware re-pair stage to adjust the logical-physical look-up table (LUT) assignments to mitigate the congestion and improve their intra-routability, thereby reducing the packing time. In addition, exploiting the structural equivalence of MLC LUTs, we remove unnecessary intra-routing attempts from packing to further improve efficiency. Evaluation shows the proposed strategies reduce packing time by 41.48% on average.**

I. Introduction

Field-programmable gate array (FPGA) is a promising option for many emerging applications, including near memory computing [1], [2], computer vision [3], [4], data encryption [5], [6], and large language model [7], [8], due to its high parallelism and reconfigurable flexibility. To deploy these applications, corresponding functions are transformed into small truth tables, which are stored in look-up tables (LUTs) inside configurable logic blocks (CLBs). With support of other programmable resources, i.e., routing resources and on-chip memories, the functionality can be implemented on FPGAs. As the complexity of applications grows, the demand for FPGA's capacity also continues to expand [9]–[12].

Traditional FPGAs adopt static random-access memory (SRAM) as their on-chip memory, which suffers from issues such as limited logic capacity and high leakage power. In contrast, emerging nonvolatile memories (NVMs) have advantages of high storage density, near-zero leakage power, and non-volatility. Thus, they are proposed to replace SRAM to build nonvolatile FPGAs (NVFPGAs), e.g., phase change memory based NVFPGA [13]–[15], magnetoresistive RAM based NVFPGA [16], and Resistive RAM based NVFPGAs [17]–[19], where resources including logic [20], routing [21]–[23] as well as on-chip memories [24] can be designed with NVMs. These representative NVMs can also operate as multi-level cell (MLC), which further increases the capacity of NVFPGAs.

Although MLC NVM enables high-density design for NVFPGAs, it also introduces challenges for the FPGA computer-aided design (CAD). The CAD flow transforms a target circuit in Hardware Description Language (HDL) to the bitstreams that can run in FPGA platforms. As shown in Fig. 2 (a), a typical FPGA CAD flow contains the main processes of front-end synthesis, technology mapping, packing, placement, and routing [25]. Taking the packing process as an example, it clusters LUTs into CLBs, so that the subsequent placement and routing can be conducted at the granularity of CLBs instead of LUTs. A CLB is successfully packed if logical LUTs can be well paired with physical positions inside it, and these logics are routable with limited intra-CLB routing resources. Since MLC FPGA architecture enhances the logic density, the number of logical connections within a CLB also significantly increases, which degrades the intra-routability. Thus, the packing algorithm has to invoke the time-consuming intra-routing process more frequently to ensure the routability of the packing solution, which seriously affects the efficiency of the packing process. According to [26], the time consumed by the packing process for MLC NVFPGA is about 8.9× higher than that for traditional SRAM-based FPGA.

Thus, in this paper, to relieve the degradation of intra-routability, we leverage routability considerations to guide the packing process, thereby reducing intra-routing invocations and improving packing efficiency. Specifically, we propose a routability-aware re-pair stage and integrate it into the existing packing process. To mitigate the intra-CLB congestion, it pairs logics from heavily congested regions to those regions with fewer logics. Through the proposed re-pair stage, some unroutable packing solutions could become routable so that a large number of intra-routing invocations could be avoided,

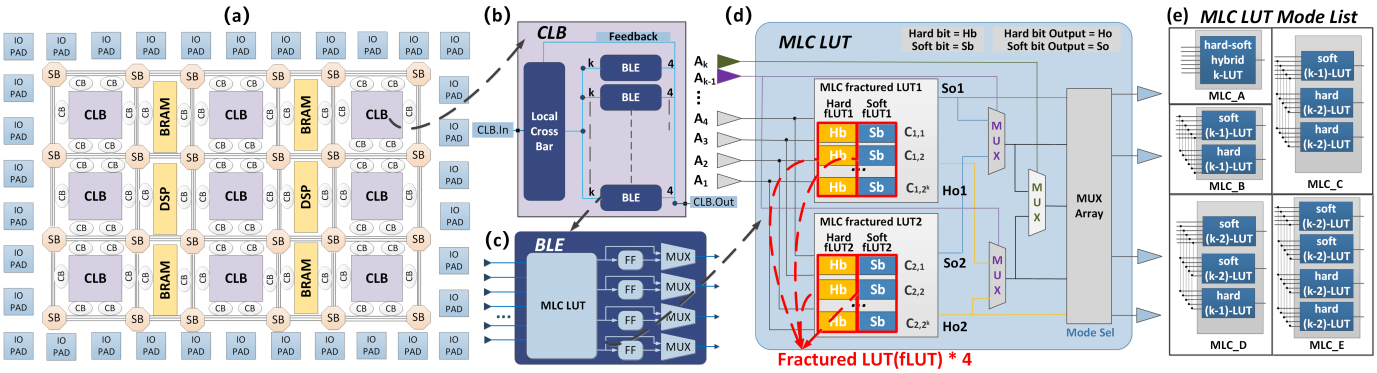

Fig. 1. The NVFPGA architecture proposed in [20]: (a) FPGA model, (b) CLB model, (c) BLE model, (d) MLC LUT model, and (e) MLC LUT mode list.

which can significantly improve the efficiency of the packing process for MLC NVFPGAs. In addition, exploiting the structural characteristics of MLC logic resources, we propose a duplicate intra-routing removal technique to avoid the routing attempts for input-equivalent packing solutions. The contributions of this paper are listed as follows.

- A routability-aware re-pair stage is proposed to improve the intra-routability of initially unroutable CLBs.
- Based on structural characteristics of MLC physical LUTs, an input-equivalent LUT removal technique is proposed to improve the efficiency of the packing process.
- Comprehensive evaluations are conducted on the proposed techniques to validate their effectiveness.

The remainder of this paper is organized as follows. Section II introduces the background and summarizes related work. Section III introduces the re-pair stage based method to optimize the packing efficiency. Section IV gives the evaluation results and discussions, followed by overhead analysis. Section V concludes this paper.

II. Background and Related Work

A. MLC LUT in NVFPGA

A typical FPGA architecture includes configurable logic blocks (CLBs), switch boxes (SBs), connection boxes (CBs), and block random access memories (BRAMs), as shown in Fig. 1 (a). Among these components, CLBs are the main logic resources to implement combinational and sequential logics. As Fig. 1 (b) demonstrates, each CLB contains a cluster of basic logic elements (BLEs) along with a fully populated crossbar. As shown in Fig. 1 (c), a BLE can be further decomposed into one look-up table (LUT), some flip-flops (FFs), and several multiplexers (MUXs). Fig. 1 (d) shows the MLC k-LUT structure proposed in [20], whose logic capacity is doubled compared with the original LUT structure. Here k denotes the maximum number of inputs the LUT can support. An MLC LUT contains four fractured $(k-2)$-LUTs, which are the smallest unit of logics in this structure. Fig. 1 (e) illustrates the mode list of the proposed MLC LUT structure. These fractured LUTs can be configured independently or work in group as a bigger LUT with more inputs, i.e., as $(k-1)$-LUT or k-LUT. This structure significantly improves the logic density and flexibility of CLBs. As reported in [20], compared with SRAM-based FPGAs, this MLC NVFPGA architecture achieves improvements in area, performance, and leakage power by 32.66%, 7.45%, and 96.13%, respectively.

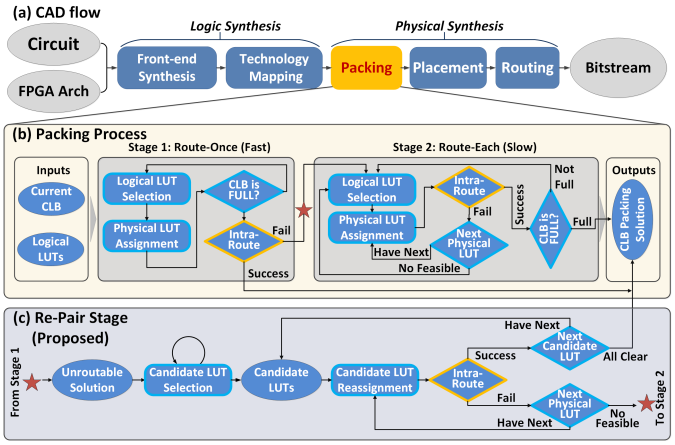

Fig. 2. The FPGA CAD flow, including: (a) the overview of a typical FPGA CAD flow, (b) the current packing process in the Verilog-To-Routing (VTR) flow [25], (c) the proposed re-pair stage.

B. Packing Process for FPGAs

The packing process clusters individual LUTs into CLBs, whose results will influence the subsequent processes of physical synthesis. A well-packed solution can significantly reduce the number of CLBs and the inter-CLB connection, greatly improving the efficiency of the placement and routing procedures. Currently, the representative packing algorithm adopted in Verilog-To-Routing (VTR) [25] contains two stages, denoted as Route-Once stage and Route-Each stage in this paper. As Fig. 2 (b) shows, in the Route-Once stage, LUTs are packed into the CLB until no more can be added. After these LUTs are packed, an intra-routing process is invoked to verify whether the packing solution is routable. If the current CLB is routable, the packing process for this CLB is finished. If it is unroutable, the packing process enters the Route-Each stage, where the routing process will be invoked after each time an LUT is added into the CLB. Since routing is usually the most time-consuming process in the CAD flow, the Route-Each stage takes significantly longer time than the Route-Once stage.

There have been many studies conducted on the packing process. Li et al. [27] propose a physical-and-congestion-aware packing algorithm, which achieves the co-optimization

in wirelength and routability. Elgammal and Betz [28] propose a re-clustering technique to improve the wirelength and critical path delay through dynamically updating the packed netlist during the packing and placement processes. Yu et al. [29] propose a quantitative rule to guide the packing process for neural networks, thereby improving the performance of the final FPGA design. Chen et al. [30] propose DP-Pack to perform packing in parallel. Rajarathnam et al. [31] propose DREAMPlaceFPGA-PL, which uses GPU to accelerate the packing process.

However, the above-mentioned works are designed for traditional SRAM-based FPGAs. Since NVFPGA introduces new characteristics, the CAD flow should also be modified to bridge the architectural differences and address the challenges. Liu et al. [26] propose a performance-aware packing algorithm for MLC NVFPGAs, which addresses the performance asymmetry of MLC NVM and reduces the critical path delay. However, it does not address the issue of packing efficiency degradation caused by MLC LUTs.

In this paper, focusing on the packing efficiency for MLC NVFPGAs, we propose a re-pair stage to reduce the number of invoking the time-consuming intra-routing process.

III. Routability-Aware Re-Pair for Packing Optimization

In this section, we will introduce the proposed routability-aware re-pair based packing optimization method for MLC NVFPGAs in detail.

A. Motivation and Main Idea

To look into details of packing in MLC FPGAs, we conduct preliminary experiments on a series of representative test benches and find that the Route-Each stage occupies 91.16% of the total packing time. The statistics also show that 73.53% of CLBs cannot obtain routable solutions at the Route-Once stage, resulting in extensive invocations of the time-consuming Route-Each stage. Thus, the packing efficiency can be improved if the number of CLBs entering Route-Each is reduced.

When tracking packing solutions of CLBs, we found that some CLBs are unroutable at the Routh-Once stage, but become routable after the Routh-Each stage without changes in LUT selection. The difference lies in the logical-physical LUT assignments.

In the Route-Once stage, each LUT is assigned to the first physical LUT selected by the packing algorithm, resulting in imbalanced logic distribution and poor routability. On the contrary, in the Route-Each stage, these congested LUTs can be assigned to other physical LUTs if the previous attempts fail, as the routability can be checked immediately. Thus, the Route-Each stage keeps congestion-free throughout the stage.

These initially unroutable CLBs can become routable through adjusting the logical-physical LUT pairs, so that the extensive intra-routing of the Route-Each stage can be reduced. According to the statistical results, there are on average 30.30% of initially unroutable CLBs select the same LUTs in the subsequent Route-Each stage, indicating a promising optimization potential.

Algorithm 1 The Proposed Re-Pair Stage

Require: Congestion information from previous routing attempt C_{prev}; List of LUTs packed in the previous stage.
Ensure: PACKING_STATUS
// Candidate LUT Selection
1: Initialize CPI for each LUT according to C_{prev};
2: Initialize N_{sel} based on size of available physical LUTs;
3: Initialize stack $CLUT$ for selected candidate LUTs;
4: **while** $N_{sel} > 0$ **do**
5: Select LUT_{sel} from unmarked BLE with the max CPI;
6: $CLUT.push(LUT_{sel})$;
7: $N_{sel} = N_{sel} - Sizeof(LUT_{sel})$;
8: Mark the corresponding BLE;
9: **if** all congested BLEs are marked **then**
10: **break;**
11: **end if**
12: **end while**
// Candidate LUT Reassignment
13: **while** $!CLUT.empty()$ **do**
14: $LUT_c = CLUT.pop()$;
15: **while** LUT_c has feasible physical LUT **do**
16: Select physical LUT P with the min RS;
17: **if** P is duplicate **then**
18: **continue;**
19: **end if**
20: Assign LUT_c in P;
21: **if** $Try_route_CLB()$ is *TRUE* **then**
22: Record LUT_c's new assignment;
23: **break;**
24: **else if** P is a $(k-2)$-LUT **then**
25: Set $(k-2)$-LUTs within P's BLE as duplicate;
26: **end if**
27: **end while**
28: **if** reassigning LUT_c fails **then**
29: PACKING_STATUS = FAIL;
30: **break;**
31: **end if**
32: **end while**
33: **return** PACKING_STATUS;

The main idea of the proposed re-pair stage is to consider intra-routability and utilize unoccupied physical LUTs in the previous failed packing solution to mitigate intra-CLB congestion. Specifically, congested LUTs will be paired to BLEs with fewer logics so that routability can be improved. If a CLB successfully becomes routable through re-pair, it will save a lot of time compared with entering the Route-Each stage.

The re-pair stage presented in Fig. 2 (c) can be formulated as Algorithm 1, which will be invoked after the Route-Once stage fails and before the Route-Each stage. It consists of two main procedures, i.e., candidate LUT selection and candidate LUT reassignment. In addition, we propose an input-equivalent LUT removal technique to improve the overall efficiency of the packing process.

B. Candidate LUT Selection

The first procedure of re-pair is candidate LUT selection (Lines 1-12). The algorithm selects LUTs that cause congestion during intra-routing. These candidate LUTs will

be reassigned to feasible physical LUTs in the subsequent procedure. A candidate LUT should at least meet the following two requirements:

- This LUT causes congestion during intra-routing.
- There are other free physical LUTs in this CLB that can fit this LUT.

For the first requirement, we have recorded the congestion information from the previous failed routing attempt, denoted as C_{prev} in Algorithm 1. However, since each congestion involves at least two LUTs, it is difficult to determine exactly which one causes congestion. Thus, we use each LUT's accumulated number of congestion to evaluate its contribution to the overall congestion. And the algorithm tends to select LUTs that encounter congestion more frequently.

Considering the second requirement, the algorithm tends to select LUTs with fewer inputs, as they offer higher flexibility when searching for alternative physical LUTs. Therefore, in the proposed re-pair algorithm, we use accumulated congestion per input (CPI) for each LUT to evaluate its priority in candidate selection (Line 1), as Equation 1.

$$CPI = \frac{N_{congestion}}{N_{input}} \tag{1}$$

Here, $N_{congestion}$ is the number of times this LUT has been involved in congestion with other LUTs, and N_{input} is the number of inputs of this LUT. When selecting candidate LUTs, the LUT with the highest CPI will be selected (Lines 5-6), and the corresponding BLE will be marked (Line 8). For fairness considerations, the subsequent candidate LUTs will not be selected from these marked BLEs.

In addition, the number of candidates should also be carefully determined. If too many candidates are selected, the exploration space of re-pair will be too big to be efficiently searched. On the contrary, selecting too few LUTs could lead to omissions and result in a failed re-pair attempt. Therefore, in the proposed re-pair stage, the number of candidate LUTs is restricted by the logic size of available physical LUTs, denoted as N_{sel} in Algorithm 1. Specifically, we define the logic size of a k-LUT as 4, a $(k-1)$-LUT as 2, and a $(k-2)$-LUT as 1. The value of N_{sel} equals the sum of logic size of unoccupied LUTs in the previous packing solution (Line 2). During the selection procedure, the value of N_{sel} decreases each time an LUT is selected, with the variation determined by the size of the selected LUT (Line 7). The candidate selection ends when N_{sel} is exhausted or all BLEs that encounter congestion are marked (Lines 4, 9-11).

C. Candidate LUT Reassignment

After all candidate LUTs are settled, the algorithm will reassign them back into the CLB, and determine whether a routable packing solution can be obtained (Lines 13-32).

The selected candidate LUTs are stored in a stack, denoted as $CLUT$. These candidate LUTs will be packed back in the reversed order. The algorithm will try pairing each candidate LUT with feasible physical LUTs (Lines 13-15).

To ensure the solution generated by the re-pair stage is always routable, the algorithm verifies its routability (Line 21). However, the routability check is time-consuming. Therefore, when selecting a physical LUT, the logical-physical LUT pair with potentially better intra-routability should be verified first to avoid invoking the intra-routing process as much as possible.

To incorporate routability-awareness into the reassignment procedure, we evaluate the routability through investigating the distribution of logics. Specifically, we use the number of BLE's occupied inputs to estimate its logic density. For a new CLB packing solution generated by the re-pair process, we define its routability score as Equation 2.

$$RS = \sum_{i=1}^{n_{BLE}} input_i^3 \tag{2}$$

Here, $input_i$ is the number of occupied inputs of the $i-th$ BLE in the CLB, and n_{BLE} is the number of BLEs in the CLB. The proposed RS amplifies the penalty for those BLEs that fully use their inputs, which are likely to encounter congestion in routing. A smaller RS indicates better routability for the corresponding packing solution.

In the routability-aware candidate reassignment procedure, the algorithm will select the physical LUT P with the smallest RS (Line 16). After pairing the candidate logical LUT LUT_c with the selected physical LUT P, intra-routing process will be performed to validate whether the current packing solution is routable (Lines 20-21). If routable, the logical-physical LUT pair will be recorded, and the procedure will proceed to handle the next candidate LUT (Lines 22-23). Otherwise, it will proceed to check the next feasible physical LUT. If one of the candidate LUTs cannot find any routable reassignments, the re-pair stage will be terminated immediately, and the Route-Each stage in the original packing algorithm will be invoked (Lines 28-31).

D. Input-Equivalent LUT Removal

As we introduce in Section II, an MLC k-LUT can be used as at most 4 independent $(k-2)$-LUTs. According to the structure demonstrated in Fig. 1 (d), for each single $(k-2)$-LUT in the same MLC LUT, its accessible inputs, i.e., the inputs from A_1 to A_{k-2}, are exactly the same. The rest of the inputs, i.e., A_k and A_{k-1}, are used to control the multiplexers for output selection. Thus, these physical $(k-2)$-LUTs within the same BLE are equivalent from the perspective of input.

Our experimental observation indicates that congestion usually occurs among inputs instead of outputs during the packing process, since the routing resources for outputs are relatively sufficient. Each MLC LUT preserves 4 outputs, as it can store at most 4 logical LUTs. However, when packing, an MLC LUT can hardly be fully occupied by 4 logical LUTs due to the input constraint, where the true bottleneck lies. Thus, when analyzing intra-routability, we only focus on the situation of input occupations.

For these input-equivalent LUTs, if pairing a candidate LUT to one of them does not result in a routable solution, it would

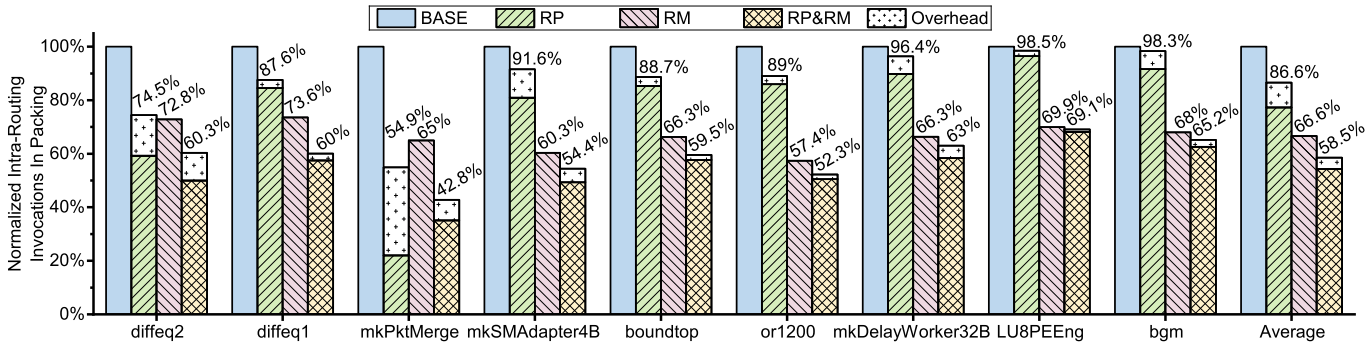

Fig. 3. Normalized intra-routing invocations of different packing methods on various circuits.

also not succeed for the rest of them. Thus, to improve the efficiency of the re-pair process, filtering input-equivalent LUTs from the physical LUT selection is a promising approach.

It should be noted that the input-equivalence only exists among $(k-2)$-LUTs, as a k-LUT or $(k-1)$-LUT would not be equivalent to a $(k-2)$-LUT. When a k-LUT or $(k-1)$-LUT is configured through combining multiple fractured $(k-2)$-LUTs, it enables access to the inputs A_k and A_{k-1}. Since these extra inputs offer higher flexibility in pin assignment, the inputs are no longer equivalent to those of $(k-2)$-LUTs, even in the same BLE.

To identify the input-equivalent physical LUTs, after a packing attempt fails, if the physical LUT being assigned is a $(k-2)$-LUT, the algorithm will mark the other $(k-2)$-LUTs within the same BLE as duplicate (Lines 24-26). When a duplicate physical LUT is selected later, the algorithm will skip it and proceed to fetch the next feasible physical LUT (Lines 17-19). Similarly, this technique can also be applied to the Route-Each stage to further enhance the overall packing process efficiency.

IV. Experiment

In this section, we will evaluate the proposed techniques and report the efficiency improvements in the packing process. Besides, we analyze the overhead and the effects on the quality-of-results (QoR) of the proposed scheme.

A. Experiment Setup

In the evaluation, the proposed techniques are tested on an NVFPGA architecture that uses STT-RAM based MLC LUTs to build up its CLBs. In the experiment, the number of MLC LUT's inputs, i.e., k, is set to 7. This FPGA architecture[1] is based on Altera Stratix IV device.

Our proposed re-pair method is integrated into the widely-used Verilog-To-Route (VTR) CAD flow [25]. It will be activated after the Route-Once stage of the packing process.

We implement several packing methods for comparison.

- **BASE**: It uses the packing algorithm proposed in [26], including two stages, i.e., Route-Once and Route-Each.

[1]The architecture file is *k6_frac_N10_mem32k_40nm.xml* (height: 100 width: 100), which has 7500 CLBs and 208 BRAMs in total.

TABLE I
Benchmark Information

Circuit	Number of LUTs				FFs	CLBs
	2/3/4-LUT	5-LUT	6-LUT	7-LUT		
diffeq2	53	57	44	81	96	20
diffeq1	185	26	31	136	193	28
mkPktMerge	172	10	19	15	36	16
mkSM-Adapter4B	580	275	251	608	983	145
boundtop	1362	248	337	678	1671	191
or1200	835	547	376	914	691	231
mkDelay-Worker32B	1771	1227	930	770	2491	394
LU8PEEng	5705	2614	2184	9601	6630	1983
bgm	8068	4415	4662	11923	5362	2931

- **RP (Re-Pair)**: On the basis of **BASE**, it implements the proposed re-pair stage, which is invoked when the Route-Once stage fails.
- **RM (ReMoval)**: On the basis of **BASE**, it adopts the input-equivalent LUT removal technique.
- **RP&RM**: On the basis of **BASE**, it integrates both the re-pair stage and the input-equivalent LUT removal technique in packing.

A series of benchmark circuits, as listed in Table I, are adopted for evaluation, which have different complexities in terms of scale of circuits. The composition of LUT sizes also differs among them. For example, 79.63% of LUTs in $mkPktMerge$ have 4 or fewer inputs. On the contrary, 47.76% and 41.02% are 7-LUTs in $LU8PEEng$ and bgm, respectively.

B. Improvement in Packing Efficiency

With our observation, the packing time is basically proportional to the number of intra-routing invocations, so we use it to evaluate the packing efficiency. Fig. 3 shows the normalized number of intra-routing invocations during the packing process for various circuits. In addition, for methods that involve the re-pair stage, i.e., RP and RP&RM, we specifically highlight the intra-routing invocations of the re-pair stage, i.e., the Overhead in Fig. 3. On average, RP and RM achieve 13.39% and 33.37% packing efficiency improvements, respectively. The result indicates that both the re-pair stage and the input-equivalent LUT removal technique can effectively improve the efficiency of the packing process. These two

techniques are orthogonal and can work together to achieve better improvements. On average, RP&RM achieves 41.48% less intra-routing invocations compared with BASE.

The effectiveness of the re-pair stage is influenced by the circuit's distribution of LUT sizes. Among the circuits we tested, RP achieves the best efficiency improvement in $mkPktMerge$. This circuit contains a lot of CLBs composed of 3-LUTs. These LUTs are gathered to several BLEs while the rest of BLEs are still empty due to the CLB input constraint. Thus, these CLBs can easily become routable through re-pair. On the contrary, for circuits like $LU8PEEng$ and bgm, which both contain more 7-LUTs, the improvements are less significant. The logical-physical assignments of these 7-LUTs are hard to be adjusted, due to the lack of available physical 7-LUTs.

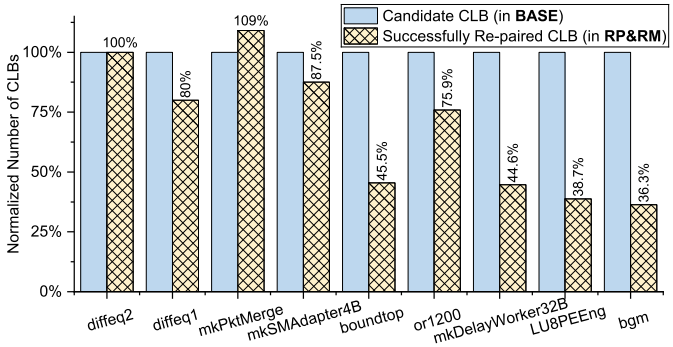

Fig. 4. Normalized number of candidate and successfully re-paired CLBs.

Fig. 4 compares the number of successfully re-paired CLBs (in RP&RM) and candidate CLBs (in BASE), i.e., CLBs that contain same LUTs in both the Route-Once stage and the Route-Each stage. On average, the proposed method successfully handles 68.62% of the candidate CLBs, which verifies the effectiveness of the proposed routability-aware re-pair technique. It should be noted that a successfully re-paired CLB may generate a different packing solution from the one in BASE, which changes the follow-up packing process so the subsequent CLBs are different. Thus, it is possible for the number of successfully re-paired CLBs to exceed the candidate CLBs, as observed in $mkPktMerge$.

The experiment results show that the proposed re-pair stage can effectively identify the re-pairable CLBs and make them routable with less intra-routing invocations.

C. Overhead Analysis

The proposed re-pair stage also involves intra-routing invocations, which are referred to as overhead. As shown in Fig. 3, on average, the re-pair stage contributes 4.15% of the total number of intra-routing invocations. However, the original packing process needs $4.45\times$ more intra-routing invocations to pack these CLBs through the Route-Each stage. Thus, the re-pair stage delivers significant packing time reduction with little overhead.

To reduce the overhead, we propose RS to guide the reassignment procedure, and define LUT input-equivalence to filter unnecessary intra-routing attempts. As Fig. 5 shows, the

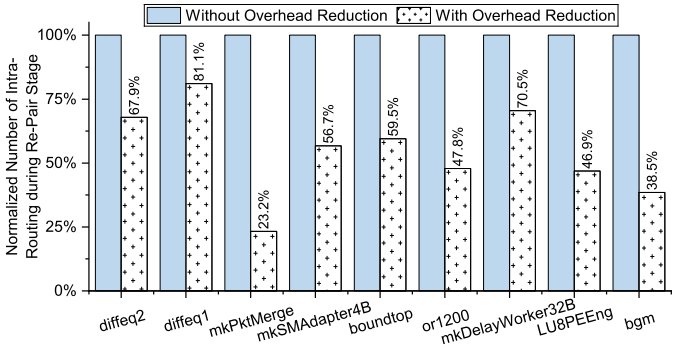

Fig. 5. Normalized number of intra-routing invocations in re-pair stage.

TABLE II
THE AREA AND PERFORMANCE EVALUATION.

Circuit	Area(#CLBs)			Performance(ns)		
	BASE	RP&RM	Ratio	BASE	RP&RM	Ratio
diffeq2	20	20	100%	16.41	16.34	99.58%
diffeq1	28	27	96.43%	21.15	21.32	100.8%
mkPktMerge	16	16	100%	4.041	3.980	98.50%
mkSM-Adapter4B	145	144	99.31%	5.898	5.743	97.38%
boundtop	192	191	99.48%	6.472	6.169	95.31%
or1200	231	230	99.57%	12.68	12.57	99.13%
mkDelay-Worker32B	394	393	99.75%	8.080	7.455	92.27%
LU8PEEng	1990	1979	99.45%	103.4	103.2	99.76%
bgm	2927	2926	99.97%	24.55	24.97	101.7%
Average	**660**	**658**	**99.33%**	**22.53**	**22.42**	**98.27%**

above-mentioned overhead reduction techniques achieve an average reduction of overhead by 54.69%.

D. Design Quality Evaluation

Since the re-pair stage potentially generates a different packing solution, the final design may be different in area and performance. Table II shows the QoR of BASE and RP&RM, where area is estimated using the number of CLBs, and the performance is evaluated using the delay of the critical path. The proposed method improves the area by 0.67% and the performance by 1.73%, on average. The results indicate that, the proposed techniques would not degrade the QoR, but lead to slight QoR improvement.

V. CONCLUSION

In this paper, we propose a routability-aware re-pair strategy to improve the efficiency of the packing process in the CAD flow for MLC NVFPGAs. To reduce the intra-routing invocations, we propose the re-pair stage, which contains two procedures, i.e., candidate LUT selection and candidate LUT reassignment. To incorporate the routability-awareness into the re-pair stage, we propose a routability evaluation technique to guide the candidate LUT reassignment. In addition, leveraging the input equivalence of some physical LUTs, we identify and remove the unnecessary intra-routing attempts during packing, thereby further improving the overall efficiency. We conduct experiments to evaluate the efficiency improvements of the proposed techniques and give discussions. The experimental results show an average packing time reduction of 41.48%.

Efficient Recycling Subspace Truncation Method for Periodic Small-Signal Analysis

Yuncheng Xu[1], Fan Yang[2], Yangfeng Su[1]
[1]School of Mathematical Sciences, Fudan University, Shanghai, China
[2]State Key Laboratory of Integrated Chips and Systems, Microelectronics Department, Fudan University, Shanghai, China

***Abstract*—Periodic small-signal analysis is crucial but time-consuming in RF simulation, since it may deal with many frequency points. While the Krylov subspace recycling method has greatly accelerated the simulation, the increasing memory cost in large-scale RF simulation has become a new bottleneck. A remedy for memory shortage is to restart the recycling algorithm, but may cause excessive extra iterations. To address this issue, this paper outlines a framework of recycling subspace truncation method for periodic small-signal analysis, provided with an efficient initial guess choice method and a Floquet-based subspace truncation strategy. Numerical results show that compared to the existing methods, the proposed method achieves up to $2.5\times$ speedup in the same memory cost.**

***Index Terms*—RF simulation, periodic small-signal analysis, Krylov subspace recycling, subspace truncation.**

I. Introduction

PERIODIC small-signal analysis, including PAC (periodic AC), PXF (periodic transfer function), and PNoise (periodic noise), plays a crucial role in understanding the behavior of radio-frequency (RF) circuits operating under repetitive conditions, such as oscillators, switching converters, and communication systems [1]. Periodic small-signal analysis computes the steady-state response of a linear periodically time-varying circuit to a sinusoidal stimulus at different frequencies.

The primary challenge arising in periodic small-signal analysis is how to efficiently solve a sequence of linear systems corresponding to different frequency points [2], [3], because the computational cost of solving all the linear systems increases linearly with the number of frequency points. The authors in [2] transform the original linear systems into a sequence of shifted linear systems, and then the solution of these shifted linear systems can be accelerated using the Krylov subspace recycling method. The recycling generalized conjugate residual (R-GCR) method introduced in [2] is up to forty times faster than the original direct factorization method. A more efficient and robust version of recycling algorithm based on generalized minimal residual (GMRES) method [4] is developed in [3].

However, with the explosive growth of RF circuit scale, the recycled subspace expands fast in frequency sweep, causing excessive amount of memory and computational costs. The issue of memory shortage may diminish the stability and robustness of the previous recycling algorithms. A remedy for memory shortage is to restart the whole recycling algorithm, but may cause excessive extra iterations. In the field of numerical algebra, the GCRO-DR method [5] is a well-known recycling method with subspace truncation to solve a sequence of linear systems, but this method does not take full advantage of the special properties in periodic small-signal analysis.

In this paper, we outline a framework of recycling subspace truncation method for periodic small-signal analysis to address the issue of memory shortage. Previous subspace recycling methods for periodic small-signal analysis are applicable in our framework. Two core problems in our framework are: (1) how to choose a good initial guess from the last system; (2) what vectors should be retained in the recycled subspace. Inappropriate choice of initial guess and recycled subspace may cause excessive number of additional iterations, or even stagnate the convergence of Krylov subspace iterative methods.

For the first problem, we propose an optimal initial guess recycling method to obtain a better initial guess for the next system. For the second problem, we develop a Floquet-based subspace truncation strategy to reduce the extra iterations caused by subspace truncation. We have observed that the coefficient matrix can be identified as the discretization of the state-transition matrix of a linear periodically time-varying system. The Floquet theory in [6] can be applied to characterize the eigenvalue distribution of the state-transition matrix. Based on the eigenvalue distribution, we reveal that the subspace corresponding to the largest Floquet multipliers significantly affect the convergence of iterative methods, and then we can establish the formulation of our Floquet-based subspace truncation strategy.

The paper is organized as follows. In Section II, we review the derivation of the shifted linear systems in periodic small-signal analysis, and then present our observation of the eigenvalue distribution of the coefficient matrix based on the Floquet theory. In Section III, we outline a framework of recycling subspace truncation method for periodic small-signal analysis, provided with our optimal initial guess recycling method and Floquet-based subspace truncation strategy. In Section IV, we apply the proposed method to several examples to demonstrate the effectiveness of our method. Finally, conclusions are given in Section V.

II. Shifted Linear Systems in Small-Signal Analysis

A. Derivation

Using modified nodal analysis [7], the RF circuit can be characterized by the differential equations

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(q(v(t))\right) + i(v(t)) + u(t) = 0, \tag{1}$$

where all the vectors are in $\mathbb{R}^N$, $v(t)$ is the node voltages, and $i(v(t)), q(v(t))$ are the resistive node currents and node charges respectively.

Suppose the periodic operating point $v_L(t)$ (with periodic T_L) has been computed by the periodic steady-state (PSS) analysis [1]. Linearizing the circuit equations (1) around $v_L(t)$ yields the linear periodically time-varying system of small-signal response $v_s(t)$ [2],

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(C(v_L(t))v_s(t)\right) + G(v_L(t))v_s(t) + u_s(t) = 0, \tag{2}$$

where

$$C(v_L(t)) = \frac{\mathrm{d}q}{\mathrm{d}v}\Big|_{v=v_L(t)}, \quad G(v_L(t)) = \frac{\mathrm{d}i}{\mathrm{d}v}\Big|_{v=v_L(t)}.$$

From the theory of periodically time-varying systems [6], it is known that the steady-state small-signal response $v_s(t)$ satisfies the periodic boundary condition

$$v_s(t+T_L) = v_s(t)\sigma(f_s), \quad \sigma(f_s) = \exp(2\pi j(f_s/f_L)).$$

Now we consider solving $v_s(t)$ using time-domain discretization methods (backward Euler, Gear2 or others). Given a partition of the interval $[0, T_L]$ as $0 = t_0 < t_1 < \cdots < t_M = T_L$. Let $h_i = t_i - t_{i-1}$, $C_i = C(v_L(t_i))$ and $G_i = G(v_L(t_i))$. For each t_i, the approximate value of $v_s(t_i)$ is denoted by $v_{s,i}$. For simplicity, we use backward Euler method to discretize (2) at $t_i (1 \le i \le M)$. After assembling the M equations at each time point, we can obtain the linear systems

$$(\sigma(f_s)L + B)\begin{bmatrix} v_{s,1} \\ v_{s,2} \\ \vdots \\ v_{s,M} \end{bmatrix} = -\sigma(f_s)u_s(f_s), \tag{3}$$

where

$$L = \begin{bmatrix} \frac{C_1}{h_1} + G_1 & & & \\ -\frac{C_1}{h_2} & \frac{C_2}{h_2} + G_2 & & \\ & \ddots & \ddots & \\ & & -\frac{C_{M-1}}{h_M} & \frac{C_M}{h_M} + G_M \end{bmatrix},$$

$$B = \begin{bmatrix} 0 & \cdots & 0 & -\frac{C_M}{h_1} \\ 0 & \cdots & 0 & 0 \\ \vdots & & \vdots & \vdots \\ 0 & \cdots & 0 & 0 \end{bmatrix}.$$

Take L as the preconditioner and transform the original linear system to a shifted linear system

$$(\sigma(f_s)I_{MN} + L^{-1}B)v_s = -\sigma(f_s)L^{-1}u_s(f_s).$$

Note that the coefficient matrix $\sigma I_{MN} + L^{-1}B$ has the block structure

$$\sigma I + L^{-1}B = \begin{bmatrix} \sigma I_N & \cdots & 0 & -P_1 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \sigma I_N & -P_{M-1} \\ 0 & \cdots & 0 & \sigma I_N - P_M \end{bmatrix}. \tag{4}$$

Hence, one can first solve $v_{s,M}$ from the shifted linear system

$$(\sigma(f_s)I_N - P_M)v_{s,M} = -\sigma(f_s)(L^{-1}u_s(f_s))_M. \tag{5}$$

Then the remaining $v_{s,i}$ for $i = M-1, M-2, \cdots, 1$ can be obtained through backward substitution. After simplifying the notations, the main task of the periodic small-signal solver is to efficiently solve a sequence of shifted linear systems

$$(\sigma^{(k)}I_N - P_M)x = b^{(k)}, \quad \sigma^{(k)} = \exp(2\pi j(f_s^{(k)}/f_L)),$$

corresponding to a sequence of frequency points $f_s^{(k)}$.

B. Relation between P_M and state-transition matrix

Denote $\Phi(t, s)$ as the state-transition matrix of the linear periodically time-varying system of DAEs

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(C(t)v(t)\right) + G(t)v(t) = 0. \tag{6}$$

Note that (6) is exactly the homogeneous part of (2).

Suppose we are now required to perform a transient simulation on the homogeneous system (6) with the initial condition $\tilde{v}(0)$. Using the same discretization method as in Section II-A, the approximate solution $\tilde{v}(t)$ at $t = t_i$ can be obtained as

$$\tilde{v}(t_i) = P_i\tilde{v}(0), \quad 1 \le i \le M,$$

where P_i is defined in (4). In fact, performing one preconditioner L on (3) can be thought of as performing a transient simulation over one period.

In particularly, we have $\tilde{v}(T_L) = P_M\tilde{v}(0)$. Hence, P_M can be considered as the discretization of the state-transition matrix $\Phi(T_L, 0)$. Therefore, it can be predicted that if the time step h_i is small enough, P_M may have some properties similar to the state-transition matrix $\Phi(T_L, 0)$.

C. Eigenvalue distribution of P_M

From the Floquet theory of linear periodically time-varying systems of DAEs [6], under some assumptions the state-transition matrix $\Phi(t, s)$ for (6) can be written as

$$\Phi(t, s) = U(t)D(t-s)V(s)^*C(s)$$

where $U(t), V(s) \in \mathbb{C}^{N\times r}$ are T_L-periodic matrices of rank r, and $D(t) = \mathrm{diag}\{\exp(\rho_1 t), \ldots, \exp(\rho_r t)\}$ with all $\rho_i \neq 0$. Here $\rho_1, \ldots, \rho_r$ are called Floquet exponents, and $\lambda_i = \exp(\rho_i T_L)$ are defined as Floquet multpliers. The r Floquet multpliers are exactly all the nonzero eigenvalues of the state-transition matrix $\Phi(T_L, 0)$.

It can be shown (e.g. [8]) that if one of the Floquet multpliers is 1, and the magnitude of other $r-1$ Floquet multpliers is less than 1, then (6) has a asymptotically orbitally stable solution $\dot{v}_L(t)$. All practical stable oscillators satisfy this

condition [6], i.e. all the nonzero eigenvalues of $\Phi(T_L, 0)$ have magnitude less than 1 except one eigenvalue equal to 1.

Since the coefficient matrix P_M can be identified as the discretization of $\Phi(T_L, 0)$, the eigenvalues of P_M may well approximate the Floquet multpliers. Hence, we can predict that P_M may have similar eigenvalue distribution to $\Phi(T_L, 0)$. In numerical experiments, we observe that the maximal magnitude of eigenvalues of P_M is close to 1 (often less than 1) and P_M may have several eigenvalues near 1 (see Section IV-A).

III. Recycling Subspace Truncation Method for Periodic Small-Signal Analysis

A. Previous Krylov Subspace Recycling Methods

We briefly review the previous Krylov subspace recycling methods for periodic small-signal analysis. The details of the algorithms can be seen in [2], [3].

The Krylov subspace recycling methods for a sequence of shifted linear systems are based on the relation

$$(\sigma_2 I - P)\, v = (\sigma_1 I - P)\, v + (\sigma_2 - \sigma_1)\, v. \tag{7}$$

The relation (7) means that if $(\sigma_1 I - P)\, v$ has been computed, then $(\sigma_2 I - P)\, v$ can be obtained just using operations on vectors. Hence, the subspace computed in the last system can be recycled to the next system.

Given recycled subspace U_m, C_m of dimension m satisfying $\left(\sigma^{(k)} I - P\right) U_m = C_m$. The R-GCR method proposed in [2] computes the j-dim augmented subspace V_j, $\tilde{V}_j$ satisfying the relation

$$\left(\sigma^{(k)} I - P\right) [U_m, V_j] = [C_m, \tilde{V}_j] \tag{8}$$

where we call $[U_m, V_j]$ ($[C_m, \tilde{V}_j]$) the total subspace. The dimension of the total subspace is $m + j$. With the relation (8), the approximate solution $x^{(k)}$ and residual $r^{(k)}$ can be updated as

$$\begin{aligned} y_{m+j} &= [C_m, \tilde{V}_j]^* r_0^{(k)}, \\ x^{(k)} &= x_0^{(k)} + [U_m, V_j] y_{m+j}, \\ r^{(k)} &= r_0^{(k)} - [C_m, \tilde{V}_j] y_{m+j}. \end{aligned}$$

Recently, a more robust and efficient recycling method for periodic small-signal analysis called R-GMRES is developed in [3]. R-GMRES computes the following relation

$$\left(\sigma^{(k)} I - P\right) [U_m, V_j] = [C_m, V_{j+1}] \begin{bmatrix} T_m & B_j \\ 0_{(j+1)\times m} & \underline{H}_j \end{bmatrix}. \tag{9}$$

Similar to R-GCR, the approximate solution $x^{(k)}$ and residual $r^{(k)}$ can be updated with the relation (9).

B. A framework of recycling subspace truncation method for periodic small-signal analysis

In the process of R-GCR or R-GMRES, if the total subspace is too large, the issue of memory shortage is encountered. To address the issue, we retain a part of vectors in the recycled subspace and discard others. Here we outline a framework of recycling subspace truncation method for periodic small-signal analysis. The framework is summarized in Algorithm 1. In our framework, either R-GCR or R-GMRES can be used.

In the whole process of frequency sweep, we set the maximal dimension of recycled subspace and augmented subspace to be $m_{\max}$ and $j_{\max}$.

Before starting to perform the recycling algorithm, if we have computed the total subspace $[U_m, V_j]$ from the last system, then the total subspace should be truncated to a new recycled subspace. Here we still denote the new recycled subspace as U_m. The dimension of recycled subspace U_m after truncation should be no larger than $m_{\max}$.

Before starting to solve each linear system, we need to select a good initial guess $x_0^{(k)}$ from the last system (for the first system, $x_0^{(1)}$ is set to be zero). If the initial guess is chosen appropriately, then the initial residual $r_0^{(k)}$ can be computed from the residual $r^{(k-1)}$ of the last system without any matrix-vector multiplication (see Section III-C).

In the process of solving each shifted linear system, the augmented subspace V_j is computed by R-GMRES or R-GCR, and the total subspace is expanded to $[U_m, V_j]$. If the dimension $m + j$ of the total subspace $[U_m, V_j]$ is larger than $m_{\max} + j_{\max}$, then we also need to truncate the total subspace to a recycled subspace of dimension $m_{\max}$. Then R-GMRES or R-GCR is restarted with the new recycled subspace after truncation.

Algorithm 1 A framework of recycling subspace truncation method for periodic small-signal analysis

Input: U_m, V_j: the recycled subspace and augmented subspace from the last system;
$m_{\max}$: the maximal dimension of recycled subspace;
$j_{\max}$: the maximal dimension of augmented subspace;
tol: tolerance of relative residual.

Output: Approximate solutions $x^{(k)}$ for shifted linear system $\left(\sigma^{(k)} I - P\right) x = b^{(k)}$.

1: Truncate the total subspace $[U_m, V_j]$ to a new recycled subspace U_m of dimension $m \le m_{\max}$.
2: Obtain a good initial guess $x_0^{(k)}$ and compute the initial residual $r_0^{(k)}$.
3: **while** $\left\|r^{(k)}\right\|_2 / \left\|b^{(k)}\right\|_2 > \text{tol}$ **do**
4: Perform the recycling algorithm R-GMRES or R-GCR to compute the augmented subspace V_j, and update the approximate solution $x^{(k)}$ and residual $r^{(k)}$.
5: **if** $m + j > m_{\max} + j_{\max}$ **then**
6: Truncate the total subspace $[U_m, V_j]$ to a new recycled subspace U_m of dimension $m = m_{\max}$.
7: Restart R-GMRES or R-GCR with the truncated recycled subspace.

In the entire simulation process, the main memory consumption in storing the total subspace is to store at most $(2m_{\max} + j_{\max} + 1)$ vectors of dimension N for R-GMRES, or $2(m_{\max} + j_{\max})$ vectors for R-GCR.

Two core problems in our framework are: (1) how to choose a good initial guess from the last system; (2) what vectors

should be retained in the new recycled subspace. For the first problem, our optimal initial guess recycling method is discussed in Section III-C. For the second problem, we propose a Floquet-based subspace truncation strategy in Section III-D.

The effectiveness of the recycling method may depend on the order in which the small-signal frequencies are arranged. In our numerical experiments (see Section IV), for simplicity, the small signal frequencies f_s are arranged in aescending order. An effective sweeping order can be seen in [3].

C. Optimal initial guess recycling method

In this section, we discuss how to select a good initial guess. We present our optimal initial guess recycling method.

Suppose we have computed the approximate solution $x^{(k-1)}$ and the residual $r^{(k-1)}$ of the last system. The traditional approach (for example, in GCRO-DR [5]) is to directly take the initial guess $x_0^{(k)} = x^{(k-1)}$. However, in most cases, this is not a good choice. Our idea is to introduce a new parameter α, and take $x_0^{(k)} = \alpha x^{(k-1)}$ as the initial guess. The optimal parameter α is determined s.t. the initial residual $r_0^{(k)}$ is minimized, i.e.

$$\alpha = \arg\min_{\alpha\in\mathbb{C}} \left\| b^{(k)} - \left(\sigma^{(k)} I - P\right)\left(\alpha x^{(k-1)}\right)\right\|_2 .$$

Denote $w = \left(\sigma^{(k)} I - P\right) x^{(k-1)}$. From the relation (7), w can be computed only using vector additions and scalar multiplications as

$$w = \left(b^{(k-1)} - r^{(k-1)}\right) + \left(\sigma^{(k)} - \sigma^{(k-1)}\right) x^{(k-1)}. \quad (10)$$

Then the optimal parameter α can be determined by the least-squares method as

$$\alpha = w^* b^{(k)} / w^* w. \quad (11)$$

The algorithm is decribed in Algorithm 2.

Algorithm 2 Optimal initial guess recycling method

Input: $x^{(k-1)}$: approximate solution of the last system;
$r^{(k-1)}$: residual of the last system.
Output: Initial guess $x_0^{(k)}$ and initial residual $r_0^{(k)}$.
1: Compute w as in (10).
2: Compute α as in (11).
3: Compute initial guess $x_0^{(k)} = \alpha x^{(k-1)}$
4: Compute initial residual $r_0^{(k)} = b^{(k)} - \alpha w$.

Note that the residual $r_0^{(k)}$ is computed without any matrix-vector multiplication and the computational cost of our initial guess method involves only 2 inner-products plus no additional matrix-vector multiplication, but it can save several iterations in iterative algorithms (see Section IV-B).

In fact, since the order of the small-signal frequencies can be arbitray, the initial guess gained from the last system may not be the best. A better choice is to obtain the initial guess from the computed system corresponding to the nearest small-signal frequency.

D. Floquet-based subspace truncation strategy

In this section, we discuss our Floquet-based subspace truncation strategy. We have observed that inappropriate subspace truncation strategy may result in excessive additional iterations. Hence, an effective truncation strategy is required.

The convergence of Krylov subspace methods depends to a large degree on the eigenvalue distribution [9]. Indeed, small eigenvalues may greatly stagnate the convergence. Hence, in GCRO-DR [5], the authors retain the harmonic Ritz vectors corresponding to the smallest harmonic Ritz values. This strategy is applicable to general cases, but for the shifted linear systems arising in small-signal analysis, a better truncation strategy can be obtained based on Floquet multipliers.

From the observation in Section II-C, P_M has some eigenvalues λ whose magnitude $|\lambda| \approx 1$. Since $\sigma(f_s) = \exp(2\pi j(f_s/f_L))$, then for some small-signal frequency f_s, the coefficient matrix $\sigma(f_s)I - P$ may have eigenvalues near 0. In this situation, $\sigma(f_s)I - P$ is ill-conditioned, and the Krylov subspace iterative methods may need more iterations to converge.

Returning to the original RF circuits, these eigenvalues close to 1 correspond to slow time constants [10]. In the circuit with slow time constants, the response may be mixed with slowly decaying parts. Hence, the iterative methods need more iterations to detect these parts.

From the above analysis, our idea is to retain in the recycled subspace the eigenvectors corresponding to the eigenvalues with magnitude near 1. In Section II-C, we have observed that the maximal magnitude of the eigenvalues of P_M is near 1. Hence, these eigenvalues with magnitude near 1 are exactly the largest eigenvalues of P_M (which correspond to the largest Floquet multipliers). The largest eigenvalues can be computed by the Ritz values [11] during the frequency sweep. The detailed algorithm is presented as follows.

Here we take R-GMRES as an example. Suppose we have obtained the relation (9), then the QZ algorithm [12] (for the case where $m = 0$, the QR algorithm [13], [14] is enough) is applied to compute all the eigenpairs (z_i, μ_i) of the matrix pencil (E, F) where

$$E = \begin{bmatrix} (U_m^* C_m) T_m & (U_m^* C_m) B_m + (U_m^* V_{j+1}) \underline{H}_j \\ 0_{j\times m} & H_j \end{bmatrix},$$
$$F = \begin{bmatrix} I_m & U_m^* V_j \\ (U_m^* V_j)^* & I_j \end{bmatrix}. \quad (12)$$

Then choose the $\tilde{m}$ eigenvectors corresponding to the eigenvalues with largest $\left|\sigma^{(k)} - \mu_i\right|$. The $\tilde{m}$ eigenvectors are stored in $Z_{\tilde{m}} \in \mathbb{C}^{(m+j)\times\tilde{m}}$. The new recycled subspace $U_{\tilde{m}}$ can be computed with $Z_{\tilde{m}}$. The algorithm of our Floquet-based subspace truncation strategy is described in Algorithm 3.

The main computational cost of our Floquet-based strategy lies in computing $U_m^* C_m$, $U_m^* V_{j+1}$ and a $(m + j)$-dim generalized eigenvalue problem. Since m and j are usually much smaller than N, the computational cost is a very small portion of the whole solving process.

Algorithm 3 Floquet-based subspace truncation strategy

Input: $\tilde{m}$: dimension of recycled subspace after truncation;
U_m, C_m: the recycled subspace;
V_{j+1}: the augmented subspace.

Output: Recycled subspace after truncation: $U_{\tilde{m}}$, $C_{\tilde{m}}$ satisfying $\left(\sigma^{(k)}I - P\right)U_{\tilde{m}} = C_{\tilde{m}}$.

1: Compute all the eigenpairs (z_i, μ_i) of the matrix pencil defiend in (12).
2: Choose the $\tilde{m}$ eigenvectors corresponding to the eigenvalues with the largest $\left|\sigma^{(k)} - \mu_i\right|$ and store them in $Z_{\tilde{m}}$.
3: Compute $U_{\tilde{m}} = [U_m, V_j]Z_{\tilde{m}}$.
4: Compute $C_{\tilde{m}} = [U_m, V_{j+1}]\left(\begin{bmatrix} T_m & B_j \\ 0 & \underline{H}_j \end{bmatrix} Z_{\tilde{m}}\right)$.

IV. Numerical Experiments

We have tested our proposed method using MATLAB. Test cases are provided by our industrial partner, as shown in Table I. The "Discretization" column in the table describes the discretization scheme. BE(1) means that the backward Euler scheme is applied only to the first time point, while BE(1, 2) applies to the first and second time point. For the accuracy of simulation, Gear2 scheme is applied to other time points. In AC analysis, the frequency sweep usually comes in three types: linear (LIN), octave (OCT) and decade (DEC) [15]. We focus on LIN and DEC in our numerical experiments.

TABLE I
Details of the test cases

Index	# Timesteps	# Nodes	Discretization
case 1	2003	3886	BE(1,2), Gear2
case 2	2451	9482	BE(1,2), Gear2
case 3	729	16224	BE(1,2), Gear2
case 4	801	3058	BE(1), Gear2

In practical computation, the matrix-vector multiplication $P * x$ is implicitly performed. The LU factorization of the diagonal blocks of L is precomputed, so the runtime we present does not include this portion.

All the numerical experiments are implemented in MATLAB R2020b with Intel Xeon Gold 6226R @2.90 GHz. For all the linear systems, the tolerance of relative residual is set to be 10^{-8}.

A. Eigenvalue distribution of P_M

To verify our prediction of the eigenvalue distribution of P_M in Section II-C, we compute all the eigenvalues of P_M using eigs function in MATLAB. The results are shown in Table II. It is observed that the maximal magnitude of P_M's eigenvalues are close to 1 in four test cases. Additionally, P_M has several eigenvalues close to 1, causing that $\sigma(f_s)I - P_M$ has several eigenvalues close to 0 when f_s is near an integer multiple of f_L. Since almost all the eigenvalues of P_M have magnitude less than 1, the eigenvalues near 1 are the ones with the largest magnitude. The results of the numerical experiments are in agreement with our previous prediction in Section II-C.

TABLE II
The eigenvalue distribution of P_M

Index	#Nodes	$\lvert\lambda\rvert_{\max}$	# $\lvert\lambda - 1\rvert \leq 0.05$
case 1	3886	1.0000	4
case 2	9482	0.9864	1
case 3	16224	1.0000	18
case 4	3058	1.0000	48

B. Choice of initial guess

We demonstrate the effectiveness of our optimal initial guess recycling method. We test three different initial guess choices by performing GMRES method with no recycled subspace on case 4. The sweeping type is chosen as "LIN 201 0 f_L". The results are shown in Figure 1. "Zero" means setting the initial guess to be zero, while "Original" means taking the approximate solution of the previous system as the initial guess for the next system. Our method is referred to as "Proposed".

From Figure 1, the number of iterations required for "Original" and "Zero" is almost the same, though at some frequency points "Original" may require more steps to converge. Hence, it is shown that taking the solution of the previous system as the initial guess is not a good choice. However, with our proposed method, convergence iterations can be greatly reduced over a wide range of small-signal frequencies. When f_s is far from an integer multiple of f_L, the convergence of iterative methods is really good, and our proposed method can still save several iterations.

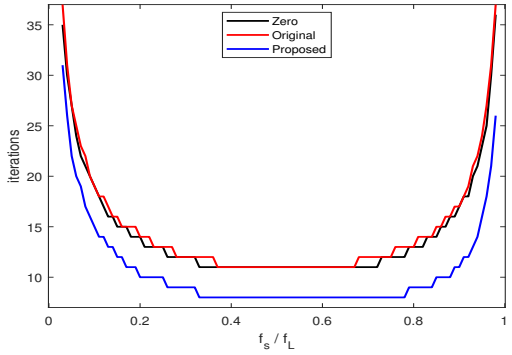

Fig. 1. Number of iterations for case 4 with different initial guess choices

C. Subspace truncation strategy

This section demonstrates the effectiveness of our Floquet-based subspace truncation strategy. We compare our Floquet-based truncation strategy with the deflated restarted (DR) method used in GCRO-DR [5], [9]. We test two subspace truncation methods in our framework of algorithm on case 4 for the sweeping type "DEC 20 10 10^7". The maximal dimension of recycled subspace is set to be 25. To better highlight the difference between two methods, the initial guess is set to be zero. The results are shown in Figure 2. "DR" means using deflated restarted method while "Floquet" is our Floquet-based subspace truncation method.

TABLE III
COMPARISON BETWEEN GCRO-DR AND OUR PROPOSED METHOD FOR "DEC 6 10 10^8" (TIME UNIT: SECOND).

Index	$m_{\max} = 20$, $j_{\max} = 40$					$m_{\max} = 25$, $j_{\max} = 30$				
	GCRO-DR		Proposed			GCRO-DR		Proposed		
	#mvm	Time	#mvm	Time	Speedup	#mvm	Time	#mvm	Time	Speedup
case 1	110	293.50	**79**	**180.98**	**1.62**	74	202.37	**57**	**133.70**	**1.51**
case 2	189	2029.30	**112**	**1026.15**	**1.98**	75	1073.05	**51**	**463.52**	**2.32**
case 3	223	1269.17	**103**	**565.55**	**2.24**	175	1027.06	**79**	**439.68**	**2.34**
case 4	2239	1579.53	**1700**	**1222.87**	**1.29**	2095	1480.24	**1537**	**1099.54**	**1.35**

TABLE IV
COMPARISON BETWEEN GCRO-DR AND OUR PROPOSED METHOD FOR "LIN 41 0 f_L" (TIME UNIT: SECOND).

Index	$m_{\max} = 20$, $j_{\max} = 40$					$m_{\max} = 25$, $j_{\max} = 30$				
	GCRO-DR		Proposed			GCRO-DR		Proposed		
	#mvm	Time	#mvm	Time	Speedup	#mvm	Time	#mvm	Time	Speedup
case 1	281	690.91	**145**	**321.70**	**2.15**	245	610.04	**106**	**240.86**	**2.53**
case 2	277	2874.33	**184**	**1729.40**	**1.66**	244	2536.48	**105**	**957.53**	**2.65**
case 3	322	1796.86	**197**	**1058.18**	**1.70**	279	1580.90	**153**	**817.34**	**1.93**
case 4	1220	845.26	**811**	**562.13**	**1.50**	1108	770.82	**792**	**553.93**	**1.39**

From Figure 2, a noticeable reduction in iterations is observed for our proposed method. When f_s is very small (near 10 Hz), the DR method requires significantly more iterations than our method. During the process of frequency sweep, DR may experience sudden increases of iterations, while this phenomenon does not occur in our method.

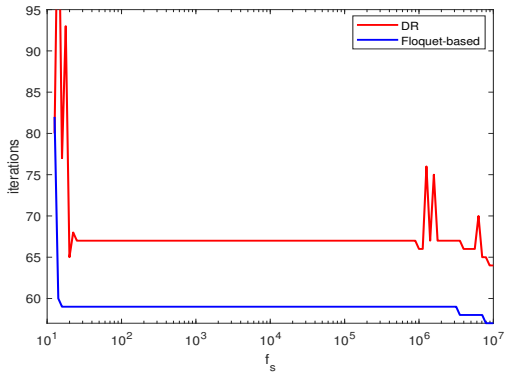

Fig. 2. Number of iterations for case 4 with different subspace truncation methods

D. Comparing proposed method with GCRO-DR

We compare our recycling subspace truncation method for periodic small-signal analysis with GCRO-DR [5]. Two types of frequency sweeps are tested: "DEC 6 10 10^8" and "LIN 41 0 f_L". For both frequency sweeps, the frequency points are arranged in ascending order. To better reflect the real simulation process, we choose $m_{\max}$ and $j_{\max}$ such that the memory consumption for storing the total subspace remains the same. The numerical results are shown in Table III and Table IV. "#mvm" means the total number of matrix-vector multiplications, which is exactly the number of iterations in the whole algorithm. "Speedup" is the ratio of the runtime.

From Table III and Table IV, it can be observed that for both GCRO-DR and our proposed method, $m_{\max} = 25$ is faster than $m_{\max} = 20$, which means appropriately increasing the maximum dimension of recycled subspace can reduce the total number of matrix-vector multiplications. Compared to GCRO-DR, our proposed method can significantly reduce the simulation time of both frequency sweeps. Our proposed method can achieve up to a $2.65\times$ speedup, and when the maximal dimension of recycled subspace increases, the speedup of our proposed method is better. Considering the magnitudes of speedup, the performance of our proposed method is very competent.

V. CONCLUSION

In this paper, we present a framework of recycling subspace truncation method for periodic small-signal analysis. For initial guess, we propose an efficient optimal initial guess recycling method, which can save many iterations with low computational cost. For subspace truncation, we observe that the subspace corresponding to the largest Floquet multipliers significantly affect the convergence of iterative methods. Based on the observation, we develop the Floquet-based subspace truncation strategy. The effectiveness of our proposed method is verified by the numerical experiments. We hope that our proposed method can help overcome the difficulty of memory shortage encountered in periodic small-signal analysis for large-scale circuit designs. Possible future improvement would be to find a better sweeping order of small-signal frequencies.

***Abstract*—With integrated circuits shrinking in feature size, layout printability has become increasingly challenging, making lithographic hotspot detection ever-crucial in computer-aided design (CAD) flows. In recent years, numerous studies have explored deep learning to detect lithographic hotspots, offering promising results. However, neural networks can easily be biased and overfit when lacking sufficient training data, especially in the CAD domain. A generalizable DL-based hotspot detector should learn the genuine lithography principle and ensure consistent accuracy across layouts from various designs at the same technology node, regardless of their varying design styles. However, we find that existing convolutional neural network (CNN)-based hotspot detectors fail to generalize to different circuit layouts other than the design it has been trained for. To this end, we propose a few-shot learning-based framework for generalizable CNN-based hotspot detection. We develop a meta-learning scheme that asynchronously updates the CNN feature extraction and classification component to obtain a meta-initialized model that can quickly adapt to new designs using as few as one training layout clip. We propose a layout topology-based sampling strategy for few-shot adaptation to enhance generalization stability. Experimental results on ICCAD 2012 and 2019 datasets show that our framework enables superior generalization capabilities than prior arts on unseen new designs.**

***Index Terms*—Lithographic hotspot detection, generalizability, few-shot learning**

I. Introduction

With the shrinkage of feature sizes in advanced technology nodes, integrated circuit layouts are susceptible to printing defects, making lithographic hotspot detection a crucial part of the design-for-manufacturability (DFM) flow. Conventional lithography simulation achieves accurate hotspot detection at the expense of high computation costs. Pattern matching-based methods expedite the detection process by comparing layout patterns with existing hotspots but fail to identify hotspots unseen before. Recently, with advancements in deep learning (DL), researchers have proposed DL-based solutions that demonstrate promising results in hotspot detection.

Most existing DL-based works focus on improving hotspot detection accuracy. For example, Yang et al. [1] proposed a DCT-based layout feature representation for hotspot detection. Geng et al. [2] introduced attention modules in the DL model, achieving an end-to-end hotspot detection flow.

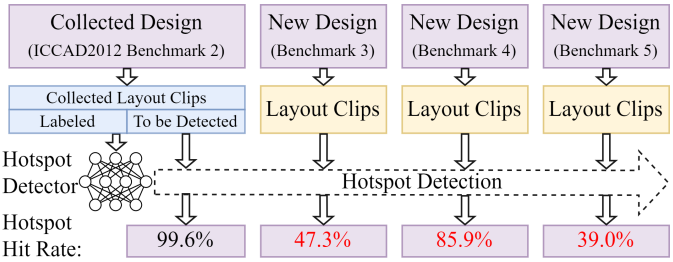

Fig. 1 Detection accuracy of SoTA attention-based CNN hotspot detector [2] when validated on various layout designs using the same 28 nm technology node. *Note that ICCAD 2012 Benchmark 1 is developed using a different 32 nm technology node and thus is not tested here.*

Jiang et al. [3] proposed a Bayesian optimization-based neural architecture search scheme to automatically design high-performance convolutional neural networks (CNNs). Shao et al. [4] integrated a learned lithography simulator with an object detection backbone to extract layout features, thereby improving detection performance. In addition to accuracy enhancements, other studies explore orthogonal directions in DL-based hotspot detection, including inference speed-up [5], [6], data scarcity [7], [8] and imbalance [9]–[11], robustness and security [12]–[14], and interpretability [15], [16]. Other works detect multiple hotspots on full layouts instead of partitioned layout clips [17], [18].

However, despite the verified efficiency of CNNs for hotspot detection as demonstrated by their accuracy when trained and validated using a certain circuit design, it has never received deliberation whether they have learned the genuine lithography principle rather than a biased design style pertaining to a specific design. Given that the CNNs are notorious for having overfitting issues and are easy towards biased learning [19], in this work, we seek to answer the following question:

Can DL-based lithographic hotspot detectors generalize to unseen new designs different from their trained design at the same technology node?

We use a state-of-the-art (SoTA) attention-based CNN hotspot detector from [2] as our motivating case study, and we examine its detection accuracy on various circuit designs from the ICCAD 2012 dataset that uses the same 28 nm technology node. Specifically, we use the training dataset from benchmark 2 for training and the rest of the layout clips from benchmark 2 to 5 for testing, as shown in Fig. 1. We witness a drastic

drop between detection accuracy on benchmark 2 and that on benchmark 3, 4, and 5, despite their shared technology node used in layout design, indicating severe generalization limitations of existing hotspot detection CNNs.

Several studies [20]–[23] have explored transfer learning or active learning with a certain budget for CNN-based hotspot detection when design environments and parameters change. However, they rely heavily on significant amounts of labeled data and are sensitive to the initial model, which can significantly affect the final performance. In the case of CAD, large amounts of quality labeled data are not always accessible.

To this end, we propose a training framework for generalizable CNN-based hotspot detection on unseen new designs using a minimum additional budget. Specifically, we propose an asynchronous meta-learning scheme that obtains a generalizable meta-initial model that can adapt to new designs using few-shot learning. Asynchronous updates are applied to CNN's feature extraction and classification component, alleviating the overfitting of specific feature representations of individual designs. We further develop a layout topology-based sampling strategy to select the most representative layout patterns in the new design for a few-shot adaptation of the first stage meta-initialized model. Our experimental results demonstrate the efficiency of our framework, showcasing both stable and high-performance hotspot detection across designs. Our main contributions are as follows:

- We investigate for the first time the generalizability of DL-based lithographic hotspot detectors on different circuit designs at the same technology node.
- An asynchronous meta-learning framework that trains a CNN hotspot detector that can generalize to unseen new designs using as few as one-shot adaptation.
- A layout topology-based sampling strategy for one-shot adaptation that enables the most stable generalization.
- Extensive experimental results on the advantages of our proposed training framework for generalizable DL-based hotspot detection compared to all baseline solutions.

II. Preliminaries and Problem Definition

A. Meta-learning

Meta-learning refers to a variety of techniques that learn knowledge with accumulated data of multiple tasks from prior experiences and then quickly adapt to new tasks with few data points. In [24], Bai et al. categorize existing studies in meta-learning into three types, including metric-based, memory-based, and learning-based methods. Among them, MAML [25] is a representative learning-based algorithm designed to learn a cross-task meta-initial parameter θ that enables rapid adaptation to new tasks.

In MAML, the dataset $\mathcal{D}$ comprising all tasks is first divided into two non-overlapping meta sets: D^{train} for meta-training, and $\mathcal{D}^{val}$ for validation. $\mathcal{D}^{train}$ is further partitioned into the *Support set* $\mathcal{S}^{train}$ and the *Query set* $\mathcal{Q}^{train}$ to facilitate the *Inner loop* and the *Outer loop* of meta-training. The inner loop refines the initial parameter θ using $\mathcal{S}_i^{train}$ for each task i, yielding task-specific intermediate parameters θ_i. The outer loop then refines the meta-initial parameter with $\mathcal{Q}^{train}$ to enhance cross-task generalization. After meta-training, adaptation and evaluation are conducted using $\mathcal{S}^{val}$ and $\mathcal{Q}^{val}$, respectively, sampled from $\mathcal{D}^{val}$.

B. Evaluation Metrics and Problem Formulation

We formulate lithographic hotspot detection as a binary classification problem. Given a set of labeled layout clips $\mathcal{D}^{train} = \{\mathcal{D}_1, \mathcal{D}_2 \cdots \mathcal{D}_N\} = \{(X_i,\ Y_i)\}_{i=1}^{N}$ from N circuit designs, our proposed framework aims to learn a model f with an initial parameter θ such that $Y = f_\theta(X)$ and can quickly adapt to a new design using only K sampled layout clips for training. We adopt the same metrics used in prior lithographic hotspot detection work as follows.

Definition 1 (Hotspot Hit Accuracy, *Acc*). The ratio of correctly classified hotspot clips among all the actual hotspots.

Definition 2 (False Alarm Rate, *FAR*). The ratio of clips misclassified as hotspots among all the actual non-hotspots.

Definition 3 (F1 Score, *F1*). The harmonic mean of Acc and Precision, where Precision denotes the ratio of correctly identified hotspots among the total number of predicted hotspots. F1 comprehensively reflects Acc and FAR performance.

$$F1 = \frac{2 \times TP}{2 \times TP + FP + FN} \tag{1}$$

Problem 1 (Generalizable CNN-based Lithographic Hotspot Detection). Given a set of layout clips from collected designs that contain hotspots and non-hotspots, train an initial model that can generalize to both the collected designs and unseen new designs at the same technology node using K-shot (i.e., $K = 1$) adaptation that achieves the maximum Acc and F1 and the minimum FAR.

III. Proposed Method

A. Overview

In this paper, we aim to enhance the generalizability of CNN-based lithographic hotspot detection across various unseen new designs at the same technology node as the trained design, despite their different design styles. Specifically, we propose an asynchronous meta-learning-based framework to train an initial model that can quickly adapt to new designs with a minimum budget, i.e., using one-shot learning with a sampling strategy.

Fig. 2 provides an overview of our proposed framework. Our generalizable hotspot detection process begins with a collection of layout clips and their corresponding labels derived from various designs to construct the meta-training dataset $\mathcal{D}^{train}$. A randomly initialized hotspot detection model is trained on $\mathcal{D}^{train}$ for multiple epochs using the proposed asynchronous meta-learning algorithm to obtain the meta-initial parameter, θ. Following this training phase, the meta-initialized model is adapted to new designs using a sampled set of K layout clips per category from the new design, which is selected by our proposed layout topology-based sampling method.

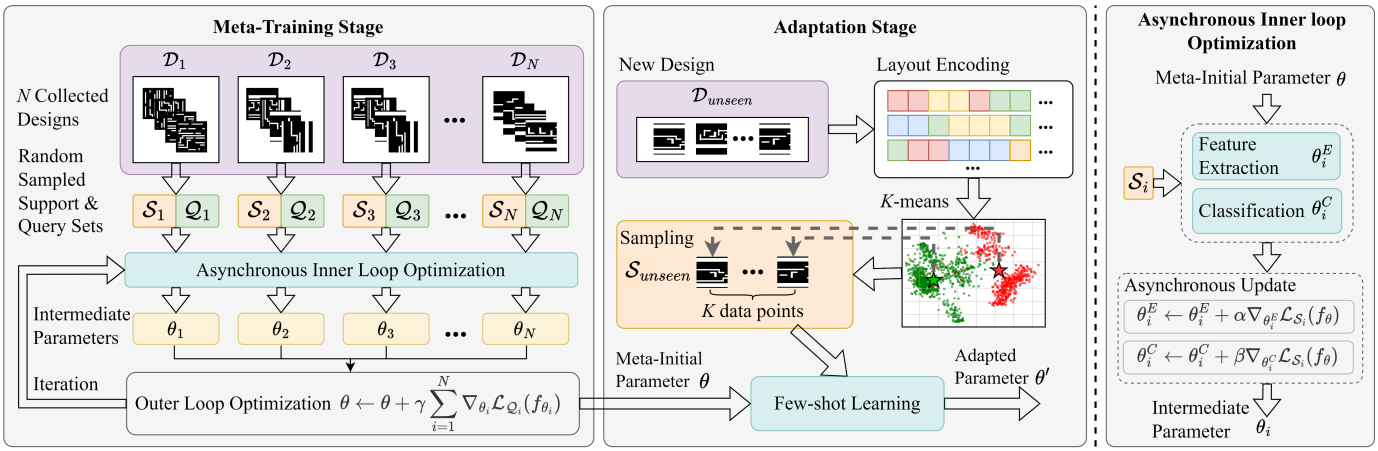

Fig. 2 Illustration of our proposed asynchronous meta-learning framework for generalizable DL-based lithographic hotspot detection using few-shot adaptation.

B. Asynchronous Meta-training

A meta-learning framework incorporates inner loop optimization and outer loop optimization, which update the network parameters based on layout clips from individual designs and all collected designs, respectively. However, the subtle and complex lithography principle is hard to learn, whereas, on the contrary, the extreme bias of design styles of the small support sets (i.e., 2 samples) from a specific design can easily overtake the CNN's learning directions. To suppress overfitting on the design styles of individual layout circuits and gradually converge to the common lithography rules shared among different designs, we constrain the learning capacity of the CNN's feature extraction component when learning each specific design in the inner loop.

We propose an asynchronous meta-training method such that different learning rates are applied to the feature extraction and classification components within each inner loop for each design. Specifically, the feature extraction component is updated with a smaller learning rate, α, to prevent overfitting on individual design features, and the classification component is updated with a relatively larger learning rate, β, to facilitate discrimination capabilities. During the outer loop, when updating with a larger batch size of the query set, both feature extraction and classification components are updated using the same learning rate, γ, to enhance CNN's overall generalization across designs.

1) Inner loop optimization: Given a set of collected layout clips $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2 \cdots \mathcal{D}_N\}$ from N designs, support sets $\mathcal{S}_i$ and query sets $\mathcal{Q}_i$ are randomly sampled for each design $\mathcal{D}_i$. The intermediate parameters θ_i are obtained through asynchronous inner loop optimization, formulated as follows:

$$\theta_i^E \leftarrow \theta_i^E + \alpha \nabla_{\theta_i^E} \mathcal{L}_{\mathcal{S}_i} \tag{2}$$

$$\theta_i^C \leftarrow \theta_i^C + \beta \nabla_{\theta_i^C} \mathcal{L}_{\mathcal{S}_i} \tag{3}$$

Equation 2 and Equation 3 represent the asynchronous update for CNN's feature extraction component θ_i^E and classification component θ_i^C, using different learning rates α and β. We adopt the same loss function $\mathcal{L}$ as used in [2] in our training framework, where a prediction and metric loss combine to provide an enhanced hotspot detection accuracy, as expressed in Equation 4, Equation 5, and Equation 6. Here, the metric loss optimizes the distances between the embedding vectors $f_{\theta^E}(x)$ of layout clip x and other layouts from the same (x^+) and different (x^-) categories in the batch. M is a positive constant.

$$\mathcal{L} = \mathcal{L}^{pred} + \mathcal{L}^{metric} \tag{4}$$

$$\mathcal{L}^{pred} = -\sum ylog(f_\theta(x)) + (y-1)log(1 - f_\theta(x)) \tag{5}$$

$$\mathcal{L}^{metric} = \sum max(0, M + \|f_{\theta^E}(x) - f_{\theta^E}(x^+)\|_2^2 - \|f_{\theta^E}(x) - f_{\theta^E}(x^-)\|_2^2) \tag{6}$$

2) Outer loop optimization: After the inner loop optimization, we obtain a set of intermediate parameters, denoted as $\{\theta_1,\ \theta_2 \cdots \theta_N\}$, for each design. Subsequently, gradients of each θ_i are computed based on their corresponding query sets $\mathcal{Q}_i$. These gradients are then aggregated to update the meta-initial parameter θ during the outer loop optimization using learning rate γ, as shown in Equation 7:

$$\theta \leftarrow \theta + \gamma \sum_{i=1}^{N} \nabla_{\theta_i} \mathcal{L}_{\mathcal{Q}_i}(f_{\theta_i}) \tag{7}$$

Note that in the outer loop optimization, gradients are computed based on a set of design-specific parameters θ_i obtained from the inner loop yet applied to the meta-initial parameter θ. This meta-training procedure ensures the CNN converges toward a common initial parameter, facilitating generalization to new designs that observe a universal lithography principle at the same technology node.

C. Layout Topology-based Few-shot Sampling of New Designs

After meta-training, the CNN takes few-shot adaptive training to generalize to unseen new designs. However, the generalization performance highly depends on the selection of

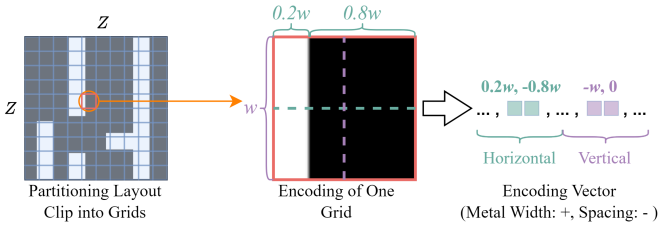

Fig. 3 Illustration of our layout topology-based encoding. A layout clip is partitioned into $Z \times Z$ grids of size $w \times w$. Along horizontal and vertical directions, the lengths of metal widths and spacings are encoded with + and - values, respectively.

layout clips used for adaptation. Training on outlier data can obviously result in inaccurate predictions for the new design. To address this issue, we propose a layout topology-based encoding strategy that assists in sampling the most representative layout clips of the new design. Our layout topology-based encoding represents each layout clip as a fixed-length vector, capturing its structural characteristics, based on which we employ K-means clustering (2-way for hotspots and non-hotspots) that selects the cluster heads and their nearest neighbors as the most representative hotspot and non-hotspot clips in the new design for few-shot adaptation.

1) Layout topology-based encoding: Various layout encoding methods have been proposed for hotspot detection, such as concentric circle-based [26], graph-based [6], or density-based [27] representation. However, they either produce variable-length feature vectors or miss out on critical layout information (i.e., using only density information). In the context of new design clips with no accessible ground-truth labels, variable-length or incomplete layout features pose significant challenges for unsupervised layout analysis.

To this end, we propose a layout topology-based encoding method that employs layout topology features for fixed-length feature representation. As illustrated in Fig. 3, for a layout clip of size $R \times R$ with half-pitch p, we partition each clip into the same number of $Z \times Z$ grids, each sizing $w \times w$. Here Z is a user-defined parameter satisfying the constraint $Z > \frac{R}{p}$, such that each grid contains at most one metal wire. We next use horizontal and vertical scanning lines to traverse each grid of the layout clip and capture the geometric information of the metal and spacing within each grid. Specifically, in each grid, a central horizontal line scans from left to right, and a central vertical line scans from top to bottom. Metal and spacing dimensions of the grid are used and encoded as a one-dimensional fixed-length vector, which stacks over all the grids of the layout clip. This scanning approach and encoding ensure full coverage of the layout's topological features. To differentiate metal and spacing characteristics, we assign metal widths with positive values and spacing widths with negative values. Our fixed-length layout topology-based encoding enables next-step layout comparisons and analyses.

2) K-means clustering-based few-shot selection: Since the layout clips of a new design are unlabeled, we employ a 2-way K-means clustering to partition these new clips into two groups in an unsupervised fashion, where the most representative clips within each group are selected for a few-shot adaptation. Specifically, our proposed layout topology-based encoding for each new clip is used as input to the K-means clustering algorithm. We select the cluster heads and their nearest $K-1$ neighbors as the K most representative clips for each layout class. We apply lithography simulation on these sampled layout clips for ground-truth labeling and train them in a one-pass few-shot adaptation for CNN generalization.

IV. Experimental Results

A. Experimental Setup

TABLE 1: Layout clip numbers of each benchmark in ICCAD 2012 & 2019 that use 28 nm technology node.

Dataset		ICCAD 2012				ICCAD 2019			
		B2	B3	B4	B5	B2	B3	B4	B5
Train	HS	174	909	95	26	38	370	46	13
	NHS	5285	4643	4452	2716	5365	5166	4498	2729
Test	HS	498	1808	177	41	278	622	81	20
	NHS	4146	3541	3386	2111	4362	4654	3473	2132

1) Datasets: We evaluate the effectiveness of our training framework for generalizable CNN-based hotspot detection on two layout datasets: ICCAD 2012 [28] and ICCAD 2019 [7]. In each dataset, four 28 nm benchmarks (B2 to B5) are employed to train and assess the CNN's generalizability to new designs developed at the same technology node (Benchmark 1 uses a 32 nm technology node.) Note that layouts in ICCAD 2012 and 2019 are labeled using different lithography systems. Thus, we do not evaluate CNN's detection generalizability across different datasets. We show in Table 1 the number of hotspot (HS) and non-hotspot (NHS) clips in ICCAD 2012 and 2019 in separate training and testing sets. We use the Test-I dataset in ICCAD 2019 for evaluation and exclude Test-II, which is manually augmented based on Test-I.

In our experiments, we train our CNN hotspot detector on two collected designs and evaluate its generalizability on two new designs. We train on layout collection of the training sets of either (B2 and B4) or (B3 and B5) and evaluate the test set of the rest of the two designs.

2) Baselines for Comparison: We compare our proposed framework against four baselines: (1) retraining from scratch using layout clips from new designs, (2) transfer learning the well-trained model on collected designs to new designs, (3) the ADAPT framework proposed by [23] that employs unsupervised Bayesian-based accuracy estimation for initial model selection and active learning with balanced data selection, and (4) meta-initial training as proposed in MAML [25] along with few-shot adaptation. We additionally evaluate our generalization framework that applies synchronous updates for CNN feature extraction and classification components as in standard meta-initial training, denoted as "Ours-" in Table 2.

We randomly sampled K layout clips per category, i.e., hotspot and non-hotspot, for our four baselines in their few-shot adaptation to the base model. Our training framework and "Ours-" use specially designed layout topology-based sampling strategy for few-shot adaptation. In consistency with

TABLE 2: Accuracy comparison across various frameworks incorporating initial training on collected designs, followed by one-pass few-shot adaptation and validation on new designs. In a few-shot adaptation, 1 or 5 layout clips are selected per category from new designs, either randomly (RT, TL, ADP, MAML) or sampled (Ours-, Ours). RT: retraining from scratch, TL: transfer learning, ADP: ADAPT [23]. MAML [25] and ours employ meta-learning for initial training. Ours-: our framework with synchronous meta-learning. Red and blue denote the best and second-best results, respectively.

common practices in few-shot learning studies, we evaluate $K = \{1, 5\}$ for adaptation. Notably, due to the triplet loss [29] employed in the base model, which optimizes the distances between samples of the same category, the input must include at least two shots per category. Therefore, for the 1-shot adaptation experiment, we use a single layout clip per category and duplicate it to meet this requirement.

3) Hyperparameters: In our experiments, we use SoTA CNN architecture for hotspot detection as proposed in [2] as our base model architecture which incorporates attention modules for enhanced detection accuracy. In our experiments, we set the number of meta-initial training steps to 10,000. Within each training step, the inner loop and outer loop are trained for 1 and 10 iterations, respectively, using randomly sampled layouts with batch sizes of 2 and 8.

B. Generalization Evaluation on Unseen New Designs

We show in Table 2 the generalization performance of our proposed training framework for CNN-based hotspot detection compared against four baselines outlined in Section IV-A2. All experimental results are averaged over 5 runs due to sampling randomness for few-shot adaptation. Our framework demonstrates superior performance across most benchmarks, outperforming baselines in terms of Acc, FAR, and F1 scores. Specifically, we achieve top-1 Acc results in 7 out of the 16 experimental groups and top-2 performance in 15 out of the 16. We note that for those methods surpassing our framework in Acc, they mostly exhibit excessively high FAR ($\geq 27\%$), compromising their practical applicability. In contrast, our framework maintains a significantly lower FAR ($\leq 6.6\%$) while achieving comparable Acc ($\geq 95.5\%$) in these groups. F1 scores provide comprehensive evaluation of CNN's detection performance on both hotspots and non-hotspots. Our framework achieves top-1 F1 scores in 14 out of the 16 experimental groups and second place in the remaining two groups. This consistency underscores our framework's superior generalizability, demonstrating its effectiveness in adapting to previously unseen designs while maintaining exceptional Acc and FAR.

We additionally evaluate the generalization performance of our framework using asynchronous or synchronous meta-learning (denoted as "Ours-") for meta-initial training. As shown in Table 2, our generalization framework using synchronous meta-learning exhibits either significantly high FAR ($\geq 20.5\%$ in 15 groups) or less accurate Acc (65.3% in the remaining group), indicating its limited capability to generalize to new designs. In contrast, our asynchronous meta-learning method achieves an Acc of at least 95% and a FAR of $\leq 7.5\%$ in 15 out of 16 cases, demonstrating a substantial improvement in generalizability.

C. Generalization Stability Using Different Sampling Methods

As shown by our experimental results in Table 3, the selection of layout clips for few-shot adaptation plays a pivotal role in CNN's generalization to unseen new designs. We compare the generalization performance of our asynchronous meta-

TABLE 3: Accuracy of various data sampling methods for one-pass few-shot adaptation in generalizing CNN-based lithographic hotspot detection. Acc, FAR, and F1 are averaged over 5 runs for random-based, KM-L, and our sampling methods due to sampling randomness. Red and blue indicate the best-performing means and variances, respectively. Rand: Randomness, Uncert: Probability uncertainty of the meta-initial model, KM-L: layout image-based K-means clustering.

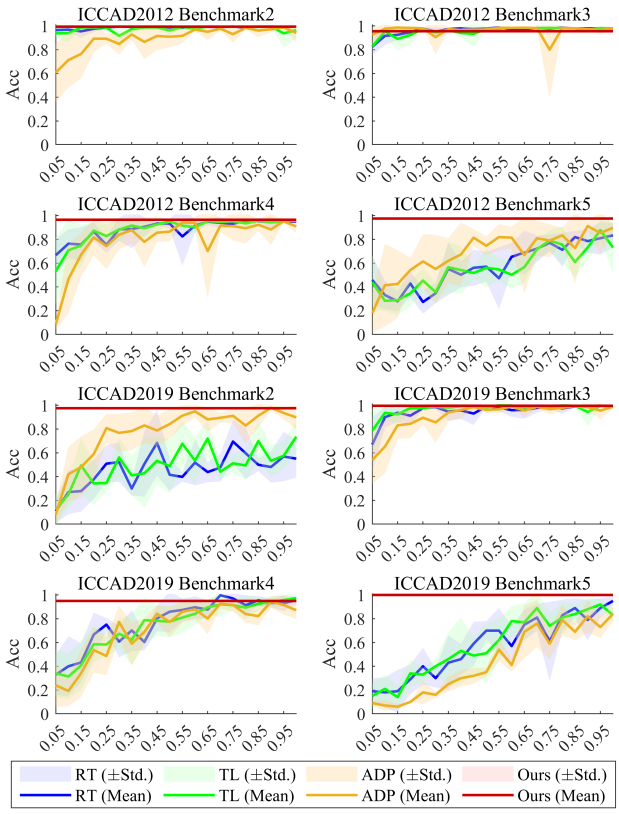

Fig. 4 Comparison of our generalizable framework using one-shot learning with baseline methods using varying data proportions of the new design (x-axis) for one-pass adaptation. The Std. of our framework is ≤ 0.0043.

learning-based framework using different sampling strategies of new clips, including random sampling (Rand), probability (of the meta-initial model)-based sampling (Uncert), and K-means clustering-based sampling based on either the original layout images (KM-L) or our proposed layout topology-based feature encoding (Ours). All experimental results are averaged over 5 runs for few-shot adaptation and evaluate both the accuracy and stability of generalization on new designs.

Our experimental results reveal that the two K-means-based sampling methods consistently outperform others in Acc and demonstrate superior performance in most evaluations of FAR and F1 scores. Compared to layout image-based sampling, our proposed layout topology-based encoding achieves consistently higher Acc and, in most cases, maintains a competitively extreme-low variance (≤ 0.0043). These findings highlight that our sampling method not only achieves superior generalization performance but also maintains stable results in few-shot sampling and adaptation.

D. Generalization vs. Data Efficiency for Adaptation

We evaluate the data efficiency of our training framework for generalizable CNN-based hotspot detection compared with other baseline solutions using varying numbers of layout clips for adaptation, including retraining (RT), transfer learning (TL), and ADAPT (ADP). These results reflect the amount of new layout clips necessary for the baseline models to achieve comparable generalization accuracy to our framework which uses only one-shot adaptation. As presented in Fig. 4, we report the mean (Mean) and standard deviation (Std.) of the generalization performance of 5 runs using randomly sampled data for adaptation. Our results demonstrate that the baseline models require substantially more layout clips and potentially additional training epochs to reach comparable generalization accuracy of ours. In contrast, our framework achieves the best generalization accuracy and stability using only one-shot adaptation, highlighting its superior generalizability in adapting to new designs.

V. Conclusion

In this work, we propose an asynchronous meta-learning-based framework for generalizable DL-based lithographic hotspot detection on unseen new designs using few-shot adaptation. Our proposed layout topology-based sampling strategy for few-shot adaptation enhances training stability for generalization. Our framework enables superior generalization capabilities than prior solutions on unseen new layout designs within the same technology node.

***Abstract*—Kalman Filter (KF) is the most prominent algorithm to predict motion from measurements of brain activity. However, little effort has been made to specialize KF hardware for the unique requirements of embedded brain-computer interfaces (BCIs). For this reason, we present the first configurable KF hardware architecture that enables fine-grained tuning of latency and accuracy, thereby facilitating specialization for neural data processing in BCI applications and supporting design-space exploration. Based on our architecture, we design KF hardware accelerators and integrate them into a heterogeneous system-on-chip (SoC). Through FPGA-based experiments, we demonstrate an energy-efficiency improvement of 15.3x and 10^3x better accuracy compared to state-of-the-art implementations.**

***Index Terms*—Kalman Filter (KF), System-on-Chip (SoC), Accelerator Design, Brain-Computer Interface (BCI), FPGA.**

I. Introduction

Real-world brain-computer interfaces (BCIs) establish a connection between the brain and the outside world to improve quality of life [1]–[3]. They rely on high-resolution neural interfaces, high-throughput data acquisition, and real-time computation [4]–[8]. While resolution and throughput continue to grow exponentially with the increasing number of electrodes in neural interfaces [2], [5], [6], [9], [10], achieving a wireless, implant-based BCI system that supports mobility, real-time processing, and low power consumption remains a challenge.

In this work, we focus on the Kalman Filter (KF), the most widely used online algorithm for motion prediction in the BCI field [11]–[16]. The KF estimates movement from neural signals and outputs real-time predictions of the position and velocity of specific body parts. These predictions are used to bypass the central nervous system and actuate a prosthesis or move a body part [17], [18]. However, BCI research has primarily focused on improving KF accuracy using machine learning, with less attention to its integration in real-world BCI systems [13], [14], [19]–[21]. Moreover, existing hardware implementations of the KF are not tailored for BCI use [22]–[25]. They rely on general-purpose techniques that are not optimized for processing diverse, high-dimensional neural data [2].

For this reason, we introduce KalmMind, a configurable architecture for agile development and design-space exploration of KF hardware accelerators tailored to BCI applications.

Fig. 1 provides a high-level overview of a KalmMind accelerator in a BCI system. The KF computation is offloaded from the implanted chip to an external device, referred to as a *relay station*, via wireless transmission of neural data [5], [26]. The relay station must be: *(1)* mobile, to support user movement; *(2)* low power, to operate within body-area networks (BAN) [27]; and *(3)* real-time, to maintain prediction relevance [28].

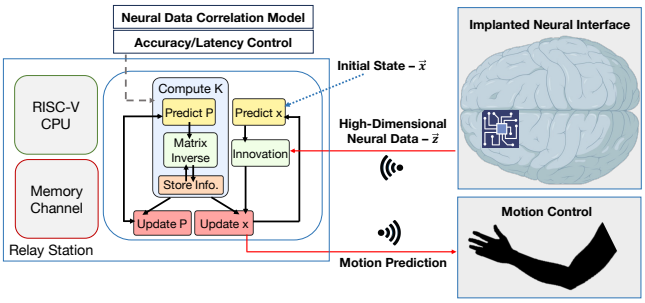

Fig. 1: KalmMind-based hardware accelerator in a BCI system.

To this end, KalmMind optimizes the main bottleneck of the KF: matrix inverse computation. It introduces a technique based on the Newton-Raphson method [29], [30] to control computational intensity by leveraging spatio-temporal correlations in neural activity across consecutive KF iterations [2], [3].

We demonstrate how KalmMind offers a flexible hardware architecture for thorough design-space exploration (DSE), aiming to minimize latency and maximize accuracy across neural datasets from different sources. We integrate additional approximation techniques inside the KF and implement a large group of configurable KF hardware accelerators [22], [31], [32].

We evaluate these accelerators by integrating them into a complete SoC that includes a RISC-V CVA6 processor [33] and prototyping the SoC on FPGA.

Our experiments show that KalmMind accelerators meet the real-time and low-power requirements of BCI systems. With its high design flexibility and fine-grained control over latency and accuracy, KalmMind opens up new opportunities for real-time KF predictions in embedded BCI systems.

We break down our main contributions as follows:

1) A reorganization of the KF algorithm that enables a modular and configurable hardware architecture.
2) A specialized approximation technique designed for use within a KF hardware accelerator in the BCI system.
3) A detailed design-space exploration to identify Pareto-optimal configurations in terms of latency and accuracy.
4) The implementation of KF accelerators that embed various approximation techniques and a comparative analysis.
5) The integration of KF hardware accelerators in a Linux-capable heterogeneous SoC, deployment on FPGA, and application to the processing of real brain data.

II. BACKGROUND

Computation in the BCI System. Online BCI applications compute over high-dimensional data that streams in from multiple *channels*. In invasive BCIs, these channels are implanted micro-electrodes that record electrical activity of localized groups of neurons [4]–[6]. While using invasive BCI systems is the most promising approach to improve the resolution of neural data [3], [4], running BCI applications close to the source becomes a very challenging task due to harsh biological constraints. In order to prevent cellular damage to the brain tissue, the power consumption of the implanted chip cannot increase the surrounding temperature by more than $1-2$°C [34].

For this reason, BCI systems have been decomposed into two main components: an implanted chip and an external relay station [5], [26]. The implanted chip records neural data and communicates it wirelessly to the relay station. The relay station executes applications in real time and can consume only up to $\sim 200mW$ within the BAN [7], [27], [35]. These BCI applications include machine learning (ML) algorithms that decode the neural data and classify it according to the desired application [13], [14], [36]. For example, BCI applications can be used in the fields of vision [37], authentication [38] and most commonly in motion decoding [13], [14], [16].

Motion Decoders for BCI. Traditionally, BCI applications of motion decoding from neural data have utilized linear methods for predicting kinematics (e.g., the Kalman Filter), which provide stable but limited accuracy [13], [39]. New methods of motion decoding use non-linear deep neural networks [40]–[42]. While these methods can provide high accuracy in some cases, they can impose long training times and also suffer from overfitting, due to the high complexity and variability of neural data [13], [40]. As a result, another group of decoders is emerging. These decoders use linear methods, such as the Kalman Filter (KF), as the main decoding component in combination with modern non-linear ML techniques to improve accuracy [14], [19], [43]–[45]. In this way, these decoders not only utilize the robustness of well-proven algorithms like the KF but also have the improved accuracy of non-linear methods.

The Kalman Filter Algorithm. The KF is a recursive algorithm that uses a series of measurements over time to predict the state of desired variables [16]. Fig. 2 reports the main function that is executed at each time step of the algorithm. Each step outputs a prediction state vector ($\tilde{x}_n$), which holds a value for each of the desired variables, and the updated covariance matrix (P_n), which estimates the current accuracy of the results.

We use x as the dimension of the state vector and z as the dimension of the measurement vector. The KF algorithm receives 5 matrices as inputs: *(i)* the previous $P_{x\times x}$, *(ii)* $F_{x\times x}$ – the state transition model, which represents the probability of transitioning from one state to another, *(iii)* $Q_{x\times x}$ – the process noise covariance, which determines the uncertainty in the transition between states, *(iv)* $H_{z\times x}$ – the observation model over the measurements, which models the relationship between the different states and the observations made, and *(v)* $R_{z\times z}$ – the observation noise covariance, which describes the error in the measurements. In the traditional KF, the matrices F, Q, R, H remain constant between consecutive iterations of the KF and constitute the *KF model*. At each iteration, the KF receives the previous $\vec{x}_{n-1}$ and a new measurement vector $\vec{z}_n$.

The KF executes the "predict" step and then the "update" step. Calculating the Kalman gain K by inverting the matrix $S_{z\times z}$ lies at the core of the KF computation.

TABLE I: The Accuracy of the KF with Different Methods

Accuracy Metric	Gauss [50]	IFKF [23]	Taylor [22]	SSKF [31]	Newton [29]
MSE	3.8×10^{-12}	53.8	0.05	0.1	6.6×10^{-6}
MAE	7×10^{-7}	2.7	0.08	0.06	0.0004
*Max. Difference (%)	0.008	2.2×10^{4}	9.7×10^{2}	5.3×10^{2}	4
*Avg. Difference (%)	0.0001	350	9	4.8	0.035

*These scores are normalized with respect to the original KF output [13].

Kalman Filter Design for BCI. With the increase in the number of channels in BCIs [2], the size of the measurements increases. Consequently, the KF requires large matrix operations, particularly the inversion of a large matrix. For edge devices, this requirement is often addressed by a hardware KF implementation [24], [25], [46]. In many cases, the KF incorporates an approximation method, sacrificing accuracy to meet throughput and power constraints [22], [23], [32]. We aim to design a hardware accelerator that introduces no more than $\sim$10% error compared to the standard KF, ensuring adequate control over fine motor tasks with an embedded BCI [47]–[49].

TABLE I reports KF accuracies when integrated with several candidate computation techniques from literature, which we implemented in software. For all methods, the KF predicts motion based on neural data from the brain of a non-human primate (NHP) [13], [51] and runs for 100 KF iterations. The KF output is compared to the one provided by Glaser *et al.* [13].

Gaussian elimination (Gauss) [50] is the standard method for matrix inversion [8], [24], [25] and provides the most accurate result, as it calculates the matrix inverse directly. However, Gauss suffers from high complexity ($O(n^3)$) and internal dependencies that limit parallel processing. Inverse Free KF (IFKF) [23], Taylor expansion of K (Taylor) [22], Steady-State KF (SSKF) [31] and the Newton-Raphson method (Newton) [29] offer different approximation techniques of K or S^{-1}. IFKF provides the worst accuracy, because it requires dimensionality reduction of the measurements and assumes minimal cross-correlation, despite the high correlation in simultaneous neural data measurements [2], [3]. Other methods provide sufficient accuracy when tested on neural data. Nevertheless, Newton provides the best accuracy among these approximations. Our work is the first to embed Newton inside the KF. In Section III, we explain our approach in detail.

III. KALMMIND

Our goal is to design KF hardware accelerators that are specialized for the requirements of an embedded BCI system.

Our architecture offers design flexibility and control over the potential trade-off between computational accuracy and latency.

Reorganization of the KF Algorithm. Traditionally, the KF begins by computing initial predictions of $\tilde{x}_n$ and P_n, then updates them with additional information from the KF model at each iteration (Fig. 2). While the main bottleneck of the KF is the computation of K (line 8), K is independent from the current $\tilde{x}_n$, the current $\tilde{z}_n$ and the innovation y (line 6). K only depends on the initial prediction of P_n (line 4) and S (line 7). As a result, we reorganize the KF in order to leverage parallel processing and allow more flexibility for hardware design.

In Fig. 1, we identify the main modules of the KF and their dependencies, then isolate the computation of K (compute K), enabling its easy modification with different computation techniques. Specifically, since K is independent from the input measurements, new measurements can be processed in parallel to the compute K module. In addition, we can switch between different matrix inversion modules. In some cases, we can even pre-compute K or S^{-1}, pre-load them into the memory of the device, and avoid their online computation [31]. Since our KF is designed for BCI, we propose a technique to efficiently compute the inverse matrix by storing and propagating information from earlier iterations of processed neural data.

Calculation of the Matrix Inverse. We define *calculation* as directly calculating the matrix inverse without using any approximations. Gauss is the standard calculation method for the matrix inverse. While generally accurate, it relies on floating-point divisions, which can introduce numerical errors. Moreover, each element in the inverse depends on the calculation of other elements, limiting the ability to decompose the calculation and exploit parallel processing. Alternative methods such as LU factorization [52], Cholesky decomposition (Cholesky) [53] and QR decomposition (QR) [54] have been proposed. These methods can reduce both the number of operations and the numerical errors. However, they still demonstrate dependencies between operations and experience increased memory usage.

Matrix Inverse Approximation. Reducing computational latency is typically achieved by using *approximation* techniques [22], [23], [55]. Approximation requires fewer computational steps and may reduce dependencies between operations, thereby facilitating more parallel processing.

The Newton-Raphson method (Newton) is one of the oldest methods for approximating the matrix inverse [29], [56]. As it requires simple matrix multiplications, it allows for parallel processing of the computation [30]. The method is recursive, and increasing the recursion depth with more iterations improves the approximation of the inverse [57]. Specifically, an iterative approximation of a matrix inverse is given by:

$$V_{i+1} = f_approx(V_i, A) \tag{1}$$

where $f_approx(\cdot)$ computes an approximated matrix inverse V_{i+1} from the previous approximation V_i and the matrix to invert A. The Newton method defines the iterative process as:

$$V_{i+1} = V_i \cdot (2I - A \cdot V_i), \quad i = 0, 1, \ldots, m-1 \tag{2}$$

where the iterative process executes m iterations and V_m is the final output of the process. Since it does not involve divisions, approximation is less prone to numerical errors.

For the Newton method to converge after a minimal number of iterations, it is crucial to select a reliable *initial seed*. The initial seed V_0 must comply with the constraint:

$$\|I - A \cdot V_0\|_2 < 1 \tag{3}$$

which means that the seed is not too far from the optimal A^{-1}.

Combining Calculation and Approximation. Neural datasets are highly diverse, as they are recorded from different brain regions and neural interfaces, each requiring varying levels of computational accuracy and real-time performance.

We propose a new technique, which interleaves two different methods between consecutive KF iterations: one for calculation of the inverse and another for approximation of the inverse. The advantage of our technique lies in balancing a highly accurate but costly calculation with a faster, less accurate approximation.

At each iteration of the KF, one of the two methods is selected. The frequency of calculating the inverse is set by a user-configuration parameter (*calc_freq*). The inverse is calculated at every n-th iteration of the KF where $n \ \% \ calc_freq = 0$.

In approximation, S_n is the matrix to invert at the n-th iteration of the KF (Fig. 2). The choice of V_0 is based on one of the two policies we develop, which initialize the approximation using a matrix inverse computed at a previous KF iteration. We propose two *seed policies* as follows:

$$V_{1,n} = S_{n-1}^{-1} \cdot (2I - S_n \cdot S_{n-1}^{-1}) \tag{4}$$

$$V_{1,n} = S_j^{-1} \cdot (2I - S_n \cdot S_j^{-1}), \quad j = n - n \ \% \ calc_freq \tag{5}$$

where $V_{1,n}$ is the result of the first internal iteration of inverse approximation in the n-th iteration of the KF. Equation (4) defines a straightforward policy for initializing the approximation with $V_0 = S_{n-1}^{-1}$, the matrix inverse from the previous KF iteration (n-1). Equation (5) defines a policy where only a calculated inverse can serve as a seed, mitigating potential inaccuracies inherent in an approximated inverse. It sets $V_0 = S_j^{-1}$ where j is the last iteration that has utilized an inverse calculation.

These policies are particularly effective for BCI, as they utilize the strong temporal and spatial correlations between neural data measurements, leveraging an inverse matrix computed for previous measurements to approximate the inverse matrix for current measurements [2], [3].

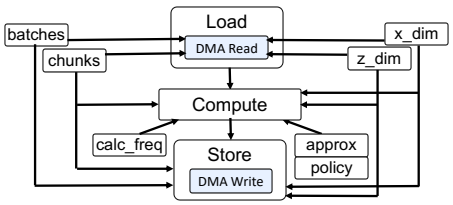
Overall, using approximation with a small number of recursive iterations is expected to yield lower accuracy but improved latency. Frequent use of calculation should enhance accuracy with higher latency. Nonetheless, calculation may introduce numerical errors, potentially degrading accuracy compared to approximation with a high count of inner iterations.

IV. Configurable Hardware Acceleration

High-Level Architecture. The KalmMind accelerator consists of three main functions: *load*, *compute* and *store* (Fig. 3a). It exposes 7 memory-mapped configuration registers that control its communication with main memory and, in particular, the matrix operations executed by the *compute* function (Fig. 3b).

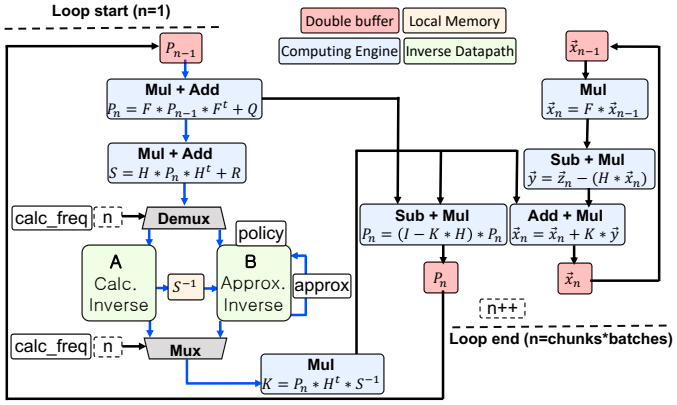
The `x_dim` and `z_dim` registers configure the dimensions of the matrices (F, Q, H, R, P) and the sizes of the vectors $(\vec{x}, \vec{z})$ to be expected by the accelerator. The `chunks` and `batches` registers configure the number of KF iterations to be done in one invocation of the accelerator and provide fine-grained control of the number and size of its direct-memory access (DMA) transactions. The `approx`, `calc_freq` and `policy` registers control the dataflow of computation inside the accelerator by selecting the data path used to invert S at each iteration of the KF (Fig. 3b). Specifically, `calc_freq` sets the frequency (in terms of KF iterations) of calculating the inverse; `approx` determines how many internal iterations of approximation will be executed per KF iteration; `policy` sets the seed policy according to Equation (4) or Equation (5).

Communication and Local Memories. The *load* function loads F, Q, H, R and the initial $\vec{x}_0, P_0$ from main memory (Section II) and stores them in private local memories (PLMs) inside the accelerator [58]. The PLMs are implemented as multi-bank memories that expose multiple read/write ports; their size is configurable at design time. The matrices F, Q, H, R can be reused in consecutive iterations of the KF without reloading them from main memory. For each subsequent DMA transaction, `chunks` configures the number of measurement vectors to be loaded from main memory. *load* receives (`chunks`×`z_dim`) measurements and stores them in the PLM. The *store* function sends the computed state vectors $(\vec{x}_n)$ and the state covariance matrices (P_n) to main memory. The `batches` register configures the total number of DMA transactions to be executed in one invocation of the accelerator.



KF Computation. Fig. 3b shows how the *compute* function implements the KF with blue arrows to mark the computation path of the Kalman gain K. The state vector $\vec{x}_n$ is small, as it represents motion kinematics (Section II); hence, every computation with dimension `x_dim` is relatively short. As a result, we chose to implement these computations with the objective of reusing hardware resources instead of increasing throughput. With the exception of the matrix inverse, all matrix operations in Fig. 3b are fully pipelined. The inner-most accumulation loops are not unrolled in order to save hardware resources.

At each KF iteration, *compute* uses a double-buffer to store both the previous and new $\vec{x}_n$ and P_n (Fig. 3b). The double-buffers are swapped at the end of every iteration. The total number of iterations in one invocation is set to (`batches`×`chunks`).



Thanks to our modular architecture, we are also able to replace the computation of K at design time with an approximation technique (Taylor) or a constant K (SSKF) and easily change the datatype between floating-point and fixed-point [32].

Implementation of the Matrix Inverse. At each KF iteration, a matrix inversion method is chosen according to the current KF iteration (`n`) and the configuration of `calc_freq`.

Path A in Fig. 3b implements a calculation method for matrix inversion. We refactor the computation to minimize the number of read/write interactions with the PLM and to be able to fully pipeline the computation of the inner-most loop. In Section V, we implement this path with Gauss, Cholesky and QR. We also replace it with a pre-computed constant S^{-1} (SSKF Inverse),

(a) Main accelerator functions.

(b) The compute function.

Fig. 3: A configurable KF hardware accelerator architecture.

inspired by the work of Malik *et al.* [31].

Path B in Fig. 3b implements an approximation method. For most of our accelerators, we implement the Newton method. We use 8 multiply-and-accumulate (MAC) units in parallel to accelerate the computation of matrix multiplications. In its first internal iteration, path B uses the seed specified by `policy`. If set to 0, the policy is set to Equation (5) and the most recently calculated inverse from path A is used as the seed. If set to 1, the policy is set to Equation (4) and the inverse from the previous KF iteration is used instead. Path B performs a fixed number of internal iterations as set by `approx`.

Overall, path B is expected to provide a better throughput compared to path A when `approx` is small, while the accuracy of path A per iteration should be higher. When `approx` grows larger, the accuracy is improved and can surpass that of path A, due to numerical errors in the inverse calculation. Interleaving the two paths in different ways offers various combinations of latency and accuracy in the KF.

V. Experimental Evaluation

Methodology: Three datasets of electrocorticography neural data from distinct brain regions are tested: the motor cortex of a non-human primate (NHP) [51], the somatosensory cortex of an NHP [42], and the hippocampus of a rat [59]. These datasets were originally tested with a KF using an inverse method that combines Gauss with LU factorization implemented with Python NumPy [13]. NumPy is the *reference* implementation. When a pure Gauss is employed in all KF iterations, it represents the *baseline*. Hardware accelerators are designed in C/C++ with Vivado HLS 2019.2. We name the accelerators according to their embedded calculation/approximation methods or with a designated name. The accelerators use 32-bit floating-point data types unless specified otherwise.

TABLE II: Accuracy Ranges with Three Neural Datasets

	MSE	MAE	Max Diff.
Motor	2.1×10^{-13}–1.1×10^{-6}	2×10^{-7}–1.6×10^{-4}	4.3×10^{-5}–1.91
Soma.	2.2×10^{-13}–9.9×10^{-6}	2.3×10^{-7}–5.1×10^{-4}	3.5×10^{-5}–5.3
Hippo.	3.1×10^{-11}–7.1×10^{-11}	1.2×10^{-6}–2.2×10^{-6}	8.2×10^{-5}–2.1×10^{-3}
Baseline	4.8×10^{-13}, 3×10^{-13}, 3.5×10^{-11}	2.7×10^{-7}, 2.7×10^{-7}, 1.4×10^{-6}	1.1×10^{-4}, 8.5×10^{-5}, 3.8×10^{-4}

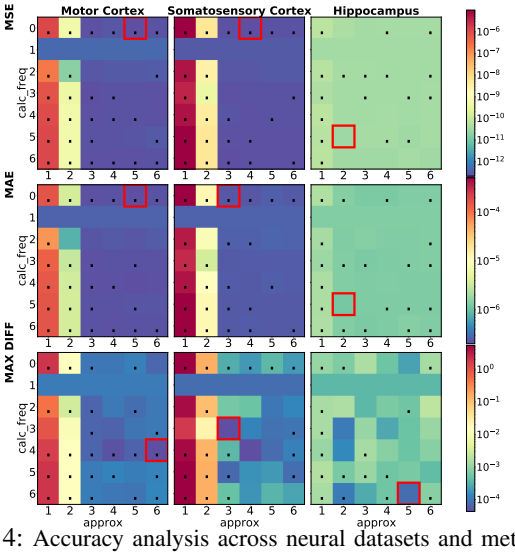


Fig. 4: Accuracy analysis across neural datasets and metrics.

SoC Integration: Hardware accelerators are synthesized with Vivado 2019.2 and leverage the open-source ESP platform [60]. ESP provides a tiled SoC architecture connected by a network-on-chip (NoC) with a library of heterogeneous components to facilitate "mix-and-match" SoC design. By following the accelerator integration flow [61], ESP is utilized for its implementations of DMA, memory-mapped registers, and interrupts that allow for seamless usage of an accelerator within a complete heterogeneous SoC architecture. ESP is also leveraged to generate FPGA prototypes of complete SoCs combining accelerators along with a 64-bit CVA6 RISC-V processor [33], an I/O tile, and a memory channel tile. The SoCs are tested on the Xilinx Virtex UltraScale XCVU440 FPGA board with a clock frequency of 78MHz, which is set according to the critical path of CVA6. We develop custom Linux software applications that run on the CVA6 and invoke the accelerators.

Accuracy Analysis. The predictions provided by the Gauss/Newton accelerator are analyzed with different configurations. The motor dataset dimensions are $\{x{=}6, z{=}164\}$, the somatosensory dataset dimensions are $\{x{=}6, z{=}52\}$, and the hippocampus dimensions are $\{x{=}6, z{=}46\}$. We run the accelerator in simulation for 100 iterations on each of the datasets. For `approx`, we use a range of 1-6, which means that Newton can have up to 6 internal iterations. For `calc_freq`, we use a range of 0-6 which means that Gauss can run in each iteration of the KF (`calc_freq=1`), every `calc_freq` iterations (`calc_freq=2`$-$`6`), or only at the first iteration (`calc_freq=0`). We compare the output at each KF iteration to the output from the reference and calculate three accuracy metrics: *(i)* Mean Square Error (MSE), *(ii)* Mean Absolute Error (MAE), and *(iii)* the normalized maximum difference between one output and its expected value (MAX DIFF).

Fig. 4 visualizes the accuracy results: purple denotes the highest accuracy while red denotes the lowest. For each pair of `calc_freq` and `approx`, we report the better result between the seed policies (`policy=1` is marked with a dot). For each metric and dataset, the highest accuracy is outlined in red.

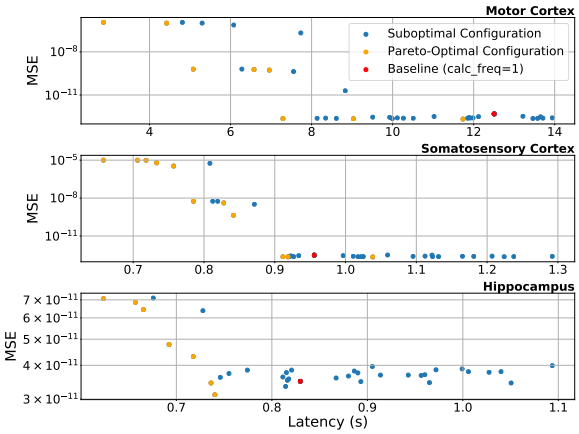

Fig. 5: Latency vs. accuracy with the Gauss/Newton accelerator.

The results show that, thanks to the flexibility of the accelerator, we can adjust the computation across a wide range of accuracies. TABLE II summarizes the accuracy ranges to which the accelerator can be configured for each dataset and metric. In all cases, we can even find a configuration that provides better accuracy than the baseline. This occurs because Newton can reduce the numerical errors introduced by Gauss by avoiding floating-point divisions. The best result is for MAX DIFF and the hippocampus, with a 78% improvement in accuracy.

It is important to note that, with the same set of configurations, each neural dataset achieves its best accuracy with a different configuration. In addition, the neural datasets from the NHP correspond to different accuracy ranges compared to the dataset from the rat. This highlights the importance of matching a neural dataset with a specific KF configuration to achieve sufficient accuracy and optimize performance. A configurable KF, such as the one we propose, offers this flexibility and fosters more effective and specialized BCI applications.

Accuracy vs. Latency. We combine the previous analysis with the latency of the Gauss/Newton accelerator when running on FPGA. Fig. 5 shows the results for each of the datasets with the MSE metric. The plots highlight Pareto-optimal points, each representing a specific tradeoff between accuracy and latency. The Pareto-optimal points result from different interleaving patterns of the two matrix inverse methods; for example, the point that provides the least latency in each plot has `approx=1` and `calc_freq=0`, while the point with the best accuracy in each plot has `approx`$\geq$`2`. In each plot, we can find configurations with comparable or better accuracy than the baseline with less latency and ultimately a better performance of the KF.

Overall, this analysis provides valuable insights for a KF hardware design tailored to specific application constraints.

Comparative Analysis of KF Implementations. We use KalmMind to design a set of hardware accelerators. TABLE III summarizes their FPGA resources, power, performance range, energy range, and accuracy range, measured while running 100 KF iteration on FPGA. It also includes the baseline implementation on an Intel i7 processor with a clock frequency of 3.7GHz, and on the CVA6 with a clock frequency of 78MHz (the same as the accelerators). We experiment with the largest

TABLE III: FPGA Resources and Performance across KF Implementations/Accelerators

Type	Method	LUT	FF	BRAM	DSP	Power [W]	Perf. [sec]	Energy [J]	Accuracy [MSE]

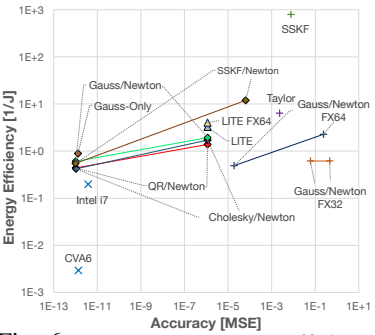

Fig. 6: Accuracy vs. energy efficiency.

dataset, the motor dataset, which requires a KF to run in less than $50ms$ per iteration for real-time BCI execution [28], [51].

One group of accelerators is implemented with unique calculation/approximation datapaths, using Gauss, QR, and Cholesky calculation methods alongside Newton approximation. The other group is implemented with one-way datapaths, where each accelerator uses either a calculation or approximation method: *(1)* LITE is designed to run Newton with one internal iteration and a seed from the previous KF iteration. In the first KF iteration, LITE loads a pre-computed seed from main memory. *(2)* SSKF embeds the method by Malik *et al.* [31]. The method is BCI-specific and approximates a constant K instead of the compute K module (Fig. 1). *(3)* In SSKF/Newton, we approximate a constant S^{-1}_{const}. We added the option to run Newton in order to improve the accuracy of S^{-1}_{const}. *(4)* Taylor integrates the method by Liu *et al.* [22], which approximates K at every KF iteration, avoiding the matrix inverse. *(5)* Gauss-Only always calculates the inverse with our optimized implementation of Gauss. *(6)* We provide accelerators with 64-bit (FX64) and 32-bit (FX32) fixed-point data types [32].

All accelerators, except Gauss-Only, demonstrate real-time execution by completing 100 KF iterations in under $5sec$. All accelerators meet the low-power constraint, consuming up to $\sim 200mW$. This proves that KalmMind successfully produces accelerators suitable for real-time embedded BCI systems.

Fig. 6 shows the tradeoff between accuracy and energy efficiency. The energy efficiency was calculated by inverting the energy result. Among the accelerators that use both calculation and approximation, Gauss/Newton has the best energy efficiency with a $10\times$ improvement compared to Intel i7 and $655\times$ compared to CVA6. SSKF provides the best energy efficiency with a $346\times$ improvement over Gauss/Newton. This is expected as SSKF is the only accelerator that does not compute K. However, the accuracy of SSKF is $10^9\times$ worse than Gauss/Newton and $10^3\times$ worse than LITE. Our SSKF/Newton offers the widest range of accuracy, achieving up to $15.3\times$ better energy efficiency compared to the standard Gauss (Gauss-Only).

Overall, KalmMind compensates for higher average power consumption, resulting from a more complex datapath, by offering substantially better energy efficiency and greater control over accuracy. KalmMind-based accelerators can be roughly divided into three tiers of accuracy. As accuracy decreases from the highest to the lowest tier, energy efficiency improves. Depending on the needs of the application, the neural data, and device constraints, the optimal KF accelerator can be chosen.

VI. Discussion and Related Work

The KF has been used frequently for motion decoding in BCI [13], [14], [16], [21], [31], [47], [62], [63]. The KF models we use to demonstrate KalmMind are trained according to the method of Wu *et al.* [16], and provided by Glaser *et al.* [13].

Usually, BCI applications utilize a Gauss-based KF [13], [14], [19]–[21]. They use the KF with additional ML models and continuously update the KF model. KalmMind can optimize the KF part of these applications for real-world embedded BCIs by managing accuracy, latency, and energy efficiency.

In Section II, we evaluate 4 different approximation techniques from literature [22], [23], [29], [31]. While using Newton [29] achieves the most accurate results for motion prediction from neural data, we use it in Section III to design a BCI-tailored technique that relies on propagating information between consecutive iterations of the KF. We are not aware of other implementations that use Newton within the KF. We suppose that this is because, prior to this work, no suitable seed policy has been identified. In addition, we design optimized accelerators for fixed-point datatypes [32], Taylor [22] and SSKF [31]; SSKF has been previously used for BCI [47], [62].

Other hardware implementations of the KF have been created to address computation in a mobile edge setting [8], [22], [24], [25], [32], [46], [64]–[67]. They are optimized for speed and low power consumption, but most are designed for domains other than BCI, have been tested with relatively small measurement vectors, and rely on costly calculations rather than approximations. However, SCALO [8] is an accelerator-rich distributed BCI system, where the inverse matrix for the KF is computed using Gauss. With KalmMind, they could leverage approximations with sufficient accuracy, reduce data dependencies, and enhance the scalability of the BCI system.

KalmMind is the first architecture to facilitate the design of configurable KF hardware accelerators for BCI, offering flexibility and uniquely supporting fine-grained control over latency and accuracy to address the diversity of brain data.

VII. Conclusion

We designed KalmMind to advance research on hardware architectures for embedded BCIs and to accelerate the development of practical, real-world BCI systems and specialized solutions for BCI applications. The contributions of this work have been released to the public domain[1].

***Abstract*—Digital Compute-in-Memory (CIM) architectures have shown great promise in Deep Neural Network (DNN) acceleration by effectively addressing the "memory wall" bottleneck. However, the development and optimization of digital CIM accelerators are hindered by the lack of comprehensive tools that encompass both software and hardware design spaces. Moreover, existing design and evaluation frameworks often lack support for the capacity constraints inherent in digital CIM architectures. In this paper, we present CIMFlow, an integrated framework that provides an out-of-the-box workflow for implementing and evaluating DNN workloads on digital CIM architectures. CIMFlow bridges the compilation and simulation infrastructures with a flexible instruction set architecture (ISA) design, and addresses the constraints of digital CIM through advanced partitioning and parallelism strategies in the compilation flow. Our evaluation demonstrates that CIMFlow enables systematic prototyping and optimization of digital CIM architectures across diverse configurations, providing researchers and designers with an accessible platform for extensive design space exploration.**

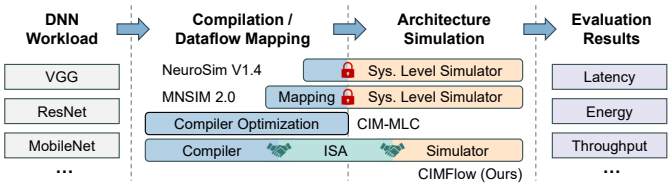

Fig. 1. Comparing CIMFlow with recent design and evaluation frameworks for CIM architectures.

I. Introduction

Recent advances in Deep Neural Networks (DNNs) have led to unprecedented achievements across various domains, significantly increasing the demand for efficient processing of deep learning workloads. However, traditional von Neumann architectures [1], [2] are hitting the "memory wall" due to frequent data transmission between separate computing and memory units [3]. As AI technologies continue to transform computing, Compute-in-Memory (CIM) architectures [4]–[6] have emerged as a promising solution for next-generation DNN accelerators, aiming to eliminate this bottleneck by integrating computation logic within memory arrays.

Mainstream CIM designs can be broadly categorized into analog [7]–[9] and digital [10]–[12] approaches. While analog CIM relies on current/voltage summation for computations, digital CIM embeds digital logic units directly into SRAM arrays. By avoiding analog-to-digital (ADC) and digital-to-analog (DAC) conversion overhead and non-ideality issues inherent in analog computations, digital CIM demonstrates both robust computation and enhanced parallelism, thus exhibiting great potential in DNN acceleration.

However, fully realizing the benefits of digital CIM across various DNN workloads is fraught with challenges. Current CIM architectures, like many domain-specific accelerators, are typically optimized for specific applications, limiting their adaptability to emerging workloads. As the field of AI continues to evolve, designers face a constantly expanding design space, comprising diverse DNN structures, dataflow mapping strategies, and various design choices in CIM accelerators. Navigating this complex landscape requires versatile tools capable of accommodating a wide range of software and hardware configurations.

While various software tools have been developed to facilitate CIM designs, existing approaches have notable limitations. On the one hand, many tools tend to focus predominantly on specific aspects of the design flow, such as hardware simulation [13]–[16] or dataflow compilation [17]–[19], lacking the holistic view necessary for effective design space exploration. On the other hand, most of these tools are primarily designed for analog CIM, and are only later adapted to support digital implementations, often overlooking crucial characteristics of digital CIM architectures.

In particular, SRAM-based digital CIM faces inherent capacity constraints due to its lower integration density compared to DRAM or emerging NVM solutions [20]. In practical

The CIMFlow framework is available at https://www.cimflow.org/.

implementations, these density limitations often result in insufficient on-chip memory capacity for modern DNN models. This constraint could potentially negate the benefits of in-memory computing, as it necessitates frequent data movement and restricts opportunities for inter-layer pipeline optimization. Consequently, there is a pressing need for an integrated framework specifically tailored to the nuances of digital CIM, enabling comprehensive evaluation and rapid prototyping across diverse configurations.

To address these challenges, we introduce CIMFlow, an integrated framework for systematic design and evaluation of digital CIM architectures. As shown in Fig. 1, our framework integrates a highly extensible Instruction Set Architecture (ISA), a digital CIM-oriented compiler, and an efficient cycle-accurate simulator, enabling comprehensive and flexible exploration of diverse software and hardware configurations. The main contributions can be summarized as follows:

- We propose CIMFlow, an integrated framework that provides an out-of-the-box workflow for implementing and evaluating DNN workloads on digital CIM architectures. The framework enables systematic design space exploration through seamless integration of compilation and simulation infrastructures.
- We develop a CIM-specific ISA design that employs a hierarchical hardware abstraction, bridging compilation and simulation while providing flexible support for various architectural configurations.
- We implement an advanced compilation flow built on the MLIR infrastructure, addressing the capacity limitations in digital CIM architectures through innovative partitioning and parallelism strategies.

II. Background and Motivation

A. Digital CIM Preliminaries

CIM architectures represent a paradigm shift from traditional von Neumann computing by enabling computation directly within memory arrays. In essence, CIM architectures perform matrix-vector multiplication (MVM) through parallelized in-situ Multiply-Accumulate (MAC) operations within memory arrays, significantly reducing the data movement bottleneck that plagues conventional architectures. These MAC operations are typically carried out in a bit-serial fashion, where multiplications are decomposed into a series of bit-wise computations, followed by shift and accumulation operations.

A digital CIM macro comprises two key components: (1) a modified SRAM array that stores weight data and enables in-situ computations, and (2) peripheral circuits that orchestrate row-wise Boolean operations and accumulation [21]. Unlike analog CIM approaches, which face significant limitations due to area and power overhead from ADC and DAC converters, digital CIM enables simultaneous activation of the entire memory array. This enhanced parallelism, combined with the inherent robustness of digital computation, makes digital CIM particularly well-suited for accelerating deep learning workloads that exhibit high computational intensity and parallel structure. While researchers have proposed various digital CIM accelerators to harness these benefits [22], [23], scaling these solutions to meet the diverse computational demands of modern AI models remains a significant challenge.

B. Related Works and Our Motivation

The growing complexity of deep learning workloads and CIM architectures has created a critical need for tools and frameworks to bridge the gap between hardware and software. Existing frameworks broadly fall into two categories: modeling/simulation frameworks that evaluate architectural decisions through detailed performance analysis [13]–[16], and compilation frameworks that enable efficient mapping of DNN workloads to CIM hardware [17]–[19]. While modeling frameworks help hardware designers optimize latency, power, and area trade-offs, compilation frameworks provide support for managing the hardware-software interface and generating optimized dataflows for CIM architectures.

However, most existing frameworks have focused primarily on analog CIM architectures, given their prominence in current research. As illustrated in Fig. 1, recent simulation frameworks have begun extending support towards digital CIM implementations. NeuroSim V1.4 [15] extends its system-level simulation capabilities to support advanced digital CIM technology nodes, while MNSIM 2.0 [16] proposes a unified memory array model for both analog and digital CIM architectures. Although these tools provide valuable insights into architectural trade-offs, they often employ tightly-coupled co-design with fixed assumptions about DNN structures and datapath organizations, limiting their flexibility and applicability for comprehensive digital CIM exploration. On the compilation front, while traditional deep learning compilation infrastructures offer general-purpose solutions [24], frameworks such as CIM-MLC [19] introduce optimization strategies specifically designed for analog CIM. However, there remains a notable lack of dedicated compilation support for digital CIM architectures.

The above observations highlight three key challenges in digital CIM development. ❶ **Integration Gap:** The lack of comprehensive integration between different design stages necessitates an integrated framework that combines ISA definition, compilation, and simulation. ❷ **Limited Flexibility:** Fixed architectural assumptions in current tools might constrain design space exploration, calling for extensibility in CIM design and evaluation frameworks. ❸ **Resource Constraints:** The limited SRAM array capacity in digital CIM requires sophisticated dataflow management and parallelism strategies that existing works do not adequately address. To tackle these challenges, we propose CIMFlow, an integrated framework that enables flexible design space exploration through extensible ISA support and advanced compilation optimization techniques. By providing comprehensive support across the design stack, CIMFlow facilitates structured development and evaluation of digital CIM architectures while maintaining the flexibility to accommodate future innovations.

III. CIMFlow Framework

A. Framework Overview

The design of CIMFlow is guided by two core principles: **integration** for seamless exploration, and **extensibility** through

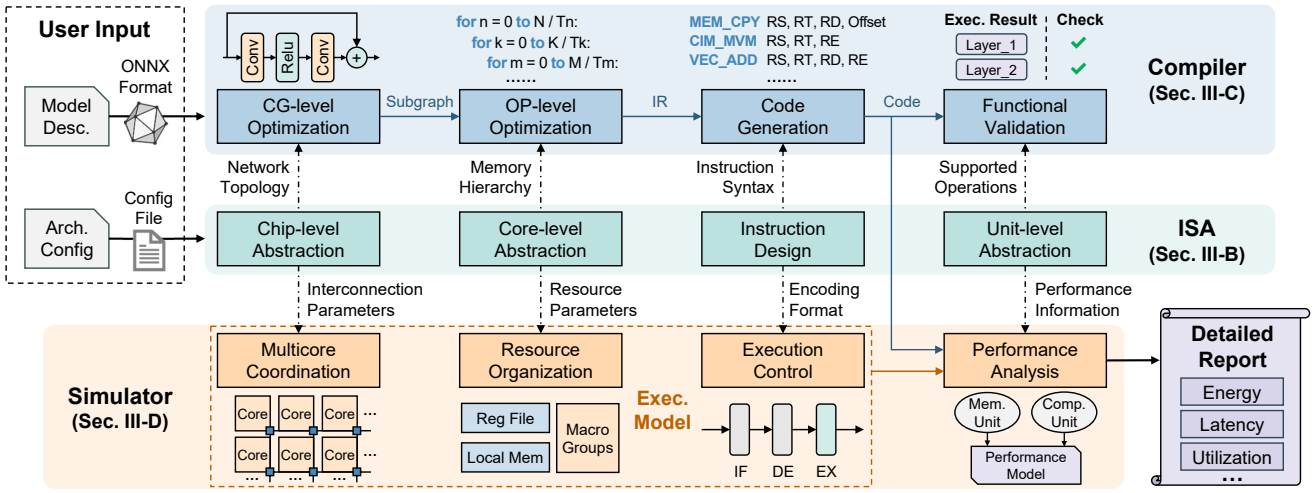

Fig. 2. Overview of the CIMFlow framework.

hierarchical abstractions. CIMFlow unifies the entire workflow from high-level DNN model description to detailed performance analysis, providing researchers with a comprehensive view of DNN workload execution on digital CIM architectures. Built with a modular design, CIMFlow readily adapts to emerging advances in CIM technology while abstracting implementation complexities through its streamlined interface, enabling designers and researchers to perform systematic evaluation and exploration.

As illustrated in Fig. 2, CIMFlow offers a cohesive workflow through three main components: a flexible ISA with hierarchical hardware abstraction (Sec. III-B), a compiler featuring multilevel optimization techniques (Sec. III-C), and a cycle-accurate simulator delivering detailed performance insights (Sec. III-D). The workflow begins with a DNN model description in ONNX format, complemented by an architecture configuration file that specifies the target CIM hardware parameters. The compiler first performs computational graph (CG) level optimizations for workload distribution and data management, followed by operator (OP) level optimizations to further maximize hardware efficiency. These optimizations are guided by the hardware specifications defined through the hierarchical hardware abstraction interface in ISA, spanning from chip-level interconnection to unit-level execution details. The generated code is validated by the compiler and then fed into the cycle-accurate simulator, which models the execution across multiple cores while tracking resource utilization and performance metrics. This process produces a detailed report covering energy consumption, latency, and hardware utilization, enabling comprehensive evaluation of different architecture designs.

B. ISA Design

As depicted in Fig. 3, the CIMFlow ISA implements a three-level hardware abstraction hierarchy complemented by a flexible instruction set design. Each abstraction level interfaces with the corresponding stages in the compilation and simulation infrastructure, providing architectural specifications that guide both compilation optimization and simulation execution.

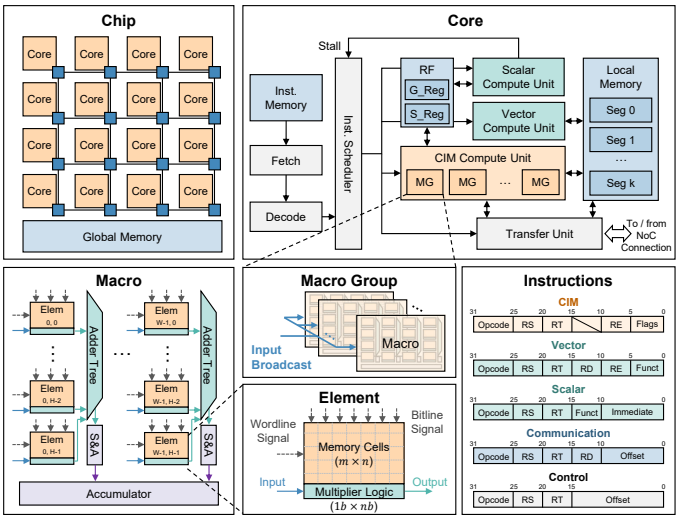

Fig. 3. Hardware abstraction and instruction design in the CIMFlow ISA.

Hardware Abstraction. At chip level, the architecture consists of multiple cores interconnected through a Network-on-Chip (NoC) structure, facilitating synchronous inter-core communication and global memory access. This organization enables scalable workload distribution and flexible inter-core pipelining, with each core functioning as a basic unit of program execution with its own instruction control flow.

The core-level abstraction defines the organization of hardware resources, encompassing instruction memory, various compute units, register files (RFs), and local memory. To facilitate efficient memory management and architectural extensibility, CIMFlow implements a unified address space across both global and local memories. In addition, the local memory is divided into segments to efficiently handle the input and output of DNN layers. The register file consists of general-purpose registers (G_Reg) for instruction-level access and special-purpose registers (S_Reg) for operation-specific functions.

At unit level, the CIM compute unit incorporates multiple macro groups (MGs) that support weight duplication and

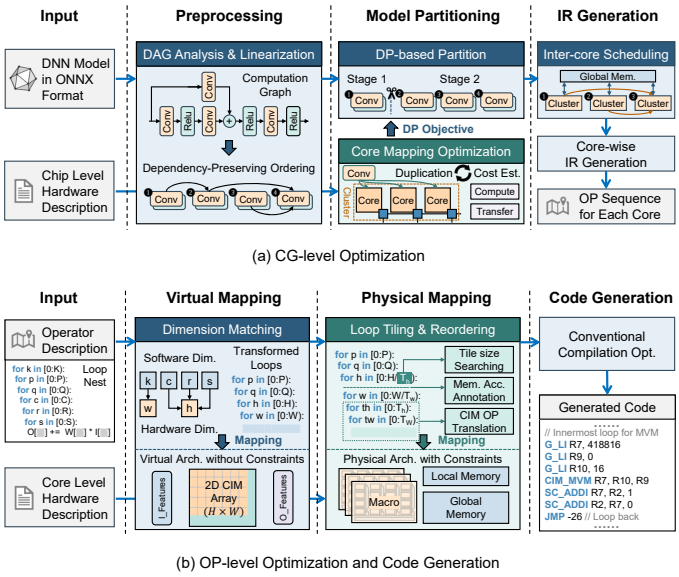

Fig. 4. Compilation flow and mapping optimization strategies in CIMFlow.

flexible spatial mapping strategies. Within each MG, weights are typically organized along the output channel, enabling efficient input data broadcast across macros for parallel in-memory MVM operations. The vector compute unit handles auxiliary DNN operations such as activation, pooling, and quantization. The scalar compute unit executes control flow operations through scalar arithmetic computations.

Instruction Design. To support efficient execution across the hardware hierarchy, CIMFlow implements a unified 32-bit instruction format with specialized variations for different operation types. Instructions are categorized into compute, communication, and control flow instructions, with compute instructions further specialized for CIM, vector, and scalar compute units. Each instruction contains a 6-bit operation specifier (opcode) and multiple 5-bit operand fields. Certain instruction types may also include supplementary fields, such as a 6-bit functionality specifier, execution flags, or immediate values of 10 or 16 bits. The instruction format supports up to four operands depending on the operation type, providing flexibility for complex operations while maintaining encoding efficiency. The instruction set is designed for extensibility through incorporating a customized instruction description template, which enables seamless integration of new operations into the framework when provided with their associated performance parameters.

C. Compilation Flow

The CIMFlow compiler bridges the semantic gap between high-level DNN models and low-level CIM operations through a two-level optimization strategy, as illustrated in Fig. 4. Starting with an ONNX model, the compiler first performs CG-level optimizations to partition and schedule workloads across multiple cores, effectively addressing the limited capacity issue. This is followed by OP-level optimizations built upon the MLIR infrastructure [24], which translates DNN operations into efficient CIM instruction sequences while taking into account the underlying hardware constraints.

Algorithm 1: DP-based partitioning and mapping

Input: Preprocessed computation graph $G = (V, E)$, Hardware resources R
Output: Optimal partitioning and mapping solution S

$D \leftarrow$ GetDependencyMasks(G) // Find all dependency closures in G and encode them as bitmasks
$dp \leftarrow [\infty]^{|D|}$, $prev \leftarrow [-1]^{|D|}$, $map \leftarrow [\emptyset]^{|D|}$
for $i \leftarrow 0$ **to** $|D| - 1$ **do**
  if $D[i] = \emptyset$ **then**
    $dp[i] \leftarrow 0$
    continue
  for $j \leftarrow 0$ **to** $i - 1$ **do**
    if $D[i] \& D[j] = D[j]$ **then**
      $stage \leftarrow D[i] - D[j]$ // Extract the set difference of dependencies as a partition
      $(cost, mp) \leftarrow$ OptimalMapping($stage, R$)
      if $dp[j] + cost < dp[i]$ **then**
        $dp[i] \leftarrow dp[j] + cost$
        $prev[i] \leftarrow j$
        $map[i] \leftarrow map[j] \cup mp$
$S \leftarrow$ ReconstructSolution($dp, prev, map$)
return S

CG-level Optimization. The optimization at this level begins with preprocessing the computation graph through analyzing the operator dependencies within the directed acyclic graph (DAG). During preprocessing, the compiler first identifies and extracts MVM-based operators, then groups adjacent operators with them to create a condensed CG. This analysis produces a dependency-preserving linear sequence of operators that forms the foundation for subsequent optimization stages.

To address the capacity limitation inherent in digital CIM architectures, CIMFlow implements a systematic partitioning strategy to divide the model into multiple execution stages. As detailed in Alg. 1, the model partitioning phase employs a dynamic programming (DP) based approach that optimizes workload distribution across available cores. The algorithm incorporates a state compression optimization that encodes all the dependency closures in the DAG as bitmasks, significantly reducing both space complexity and computational overhead. Each dependency closure represents a self-contained set of operators whose dependencies are fully enclosed within the set, serving as basic building blocks for candidate partitions.

The compiler derives candidate partitions through set operations on these dependency closures, and performs core mapping optimization for each partition. This process involves strategically duplicating operator weights across clusters of cores when deemed beneficial by the cost estimation model. To balance parallel execution benefits against communication costs, the estimation model accounts for both computation costs and data transfer overheads across inter- and intra-cluster communications. These cost assessments and their corresponding optimal mapping configurations are then used to guide the

DP-based partition selection.

The final phase of CG-level optimization focuses on inter-core scheduling and intermediate representation (IR) generation. The scheduler orchestrates data movement through the NoC interconnection, facilitating the inter-operator pipelines across different clusters. For each core, the compiler generates an optimized operation sequence incorporating both partitioning decisions and mapping destinations, establishing the foundation for OP-level optimizations.

OP-level Optimization. Following CG-level workload distribution, the compiler performs fine-grained operator transformations to maximize hardware efficiency. This process involves a structured approach that first establishes an ideal mapping in a constraint-free virtual space, and then adapts this mapping to actual hardware resource constraints.

The virtual mapping phase begins by analyzing the dimensional structure of each operator, transforming complex nested loops into a simplified version that aligns with the CIM array structure. This transformation process maps the software-level weight dimensions onto a two-dimensional array representation. By temporarily abstracting away physical constraints, the compiler explores the optimal weight data layout strategies, including the image-to-column (`im2col`) transformation commonly employed in DNN acceleration.

The physical mapping phase then adapts the idealized representation to actual hardware constraints through a series of optimization passes implemented within the MLIR infrastructure. The compiler first applies loop tiling based on resource capacity constraints, then systematically extracts MVM operations from the tiled loops for translation into CIM operations. Through automated analysis, it determines the optimal tile sizes and loop ordering to maximize computational efficiency while respecting resource limitations at each memory hierarchy. Memory access operations are then strategically annotated at appropriate loop levels to minimize data transfer overhead.

In the final code generation phase, the optimized IR undergoes conventional compilation techniques, including constant propagation, dead code elimination, and register allocation. The generated instructions adhere to the CIMFlow ISA specification while realizing the optimized resource mapping decisions, ensuring efficient utilization of the CIM hardware resources.

D. Simulator Design

The CIMFlow simulator provides cycle-accurate performance analysis through detailed modeling of the digital CIM architecture across multiple abstraction levels, from individual core execution to chip-level coordination. Implemented in SystemC [25], the simulator features a detailed pipeline model to track execution flow and resource utilization within each processing unit, while managing parallel execution across cores connected via NoC. The simulator supports diverse architectural configurations through a user-defined configuration file that adheres to the ISA specifications, while its modular design and standardized interfaces allow straightforward integration of custom architectural components.

TABLE I
ARCHITECTURE PARAMETERS OF THE DEFAULT ARCHITECTURE.

Chip Level		**Core Level**		**Unit Level**	
Core num.	64	CIM comp. unit	16 # MG	Macro	512×64
NoC flit size	8 Byte	Macro group	8 # macro	Element	32×8
Global mem.	16 MB	Local mem.	512 KB		

At core level, instruction execution follows a three-stage pipeline comprising instruction fetch (IF), decode (DE), and execute (EX). The EX stage implements detailed execution models for different compute units, each with fine-grained pipelining to enable instruction-level parallelism. Instruction conflicts and resource utilization are efficiently tracked through a bitmap-based scoring board within the instruction scheduler, ensuring accurate modeling of both computation and data movement patterns. Through this detailed modeling of both computation and data movement patterns, the simulator provides a comprehensive performance analysis across different architectural levels, tracking metrics such as energy consumption, execution latency, and hardware utilization for each unit. These detailed insights enable both quantitative evaluation of different CIM design choices and validation of compiler optimizations.

IV. EXPERIMENTAL RESULTS

A. Experimental Setup

To demonstrate how CIMFlow facilitates digital CIM architecture design, we conduct detailed analyses of compilation optimization strategies and present case studies exploring the impact of various architectural and software design choices. The default architecture parameters are carefully selected to efficiently support typical DNN workload characteristics while maintaining practical hardware constraints, as detailed in Tab. I. The performance statistics are acquired from multiple industry-standard tools to ensure accurate modeling of all components within the architecture. The CIM macro specifications are derived from post-layout analysis based on the design presented in [11], while other on-chip memory components are evaluated using memory compilers. The remaining digital logic modules are implemented in Verilog HDL and synthesized using Design Compiler, with power analysis conducted through PrimeTime PX. The NoC interconnection costs are modeled using Noxim [26].

We select representative DNN models that span different architectural characteristics and computational demands as our evaluation benchmark. The suite encompasses compute-intensive architectures including ResNet18 and VGG19, alongside compact models featuring depth-wise separable convolutions such as MobileNetV2 and EfficientNetB0. To align with digital CIM implementation constraints, the weights and activations of all models are quantized to INT8.

B. Compilation Optimization Evaluation

We evaluate our proposed compilation optimization strategies against two baseline approaches: (1) a generic mapping scheme that implements inter-layer pipeline without operator duplication, and (2) the CG-level partition and opportunistic

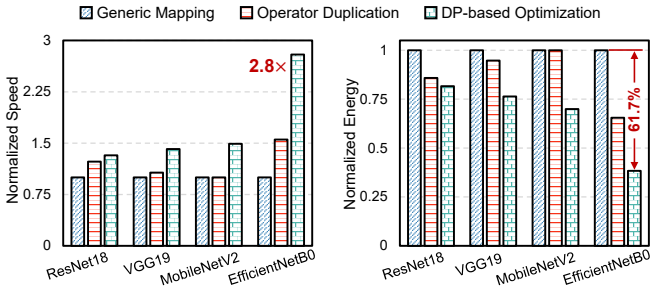

Fig. 5. Normalized speed and energy comparison of different compilation optimization strategies across DNN models.

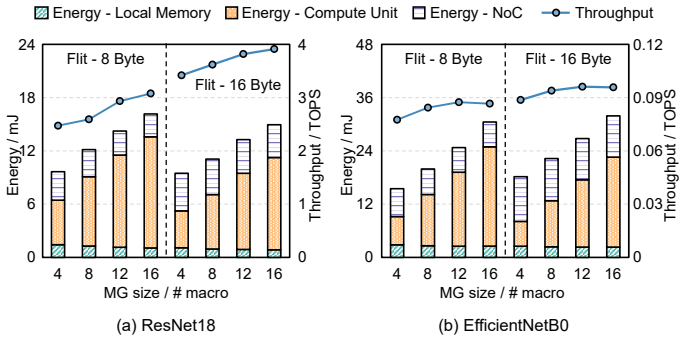

Fig. 6. Energy consumption breakdown and throughput across architectures with different MG sizes and NoC link bandwidth.

operator duplication technique from CIM-MLC [19], which first partitions CG to fit the limited capacity then attempts to utilize vacant resources through weight duplication. All evaluations use the default architecture configuration described in Tab. I to isolate the impact of compilation strategies.

As illustrated in Fig. 5, our DP-based partitioning and optimization method demonstrates significant performance improvements, achieving up to 2.8× speedup and 61.7% energy reduction compared to the baseline approaches. The benefits are particularly pronounced for compact models like MobileNetV2 and EfficientNetB0, where the conventional partition method proves less effective due to their smaller weight footprints, which leaves fewer unoccupied cores within such partitioned execution stages for duplication opportunities. This highlights the effectiveness of our DP-based approach in finding optimal partitioning and mapping schemes that maximize performance while respecting SRAM capacity constraints.

C. Architectural Configuration Exploration

The efficiency of digital CIM architectures hinges on the careful balance between computational and data movement capabilities. We explore this trade-off through two critical design parameters: MG size scaling and NoC link bandwidth (flit size per cycle) configuration. Fig. 6 presents the energy breakdown and throughput analysis across architectural configurations for both compute-intensive and compact models compiled with the generic mapping strategy.

For ResNet18, increasing MG size consistently improves throughput at the cost of moderately higher energy consumption, with compute unit energy remaining its dominant component. Doubling the communication bandwidth also boosts inter-layer pipeline throughput by up to 39.6%. In contrast, EfficientNetB0 shows different scaling characteristics. Its lower resource requirements mean that increasing the number of macros per group yields only modest throughput gains, while higher NoC bandwidth introduces substantial data transfer overhead without commensurate performance benefits, consuming up to 55.4% of total energy consumption when MG size is 4. These distinct scaling behaviors across models highlight the importance of early-stage architectural exploration, demonstrating the value of CIMFlow as a systematic design and evaluation framework.

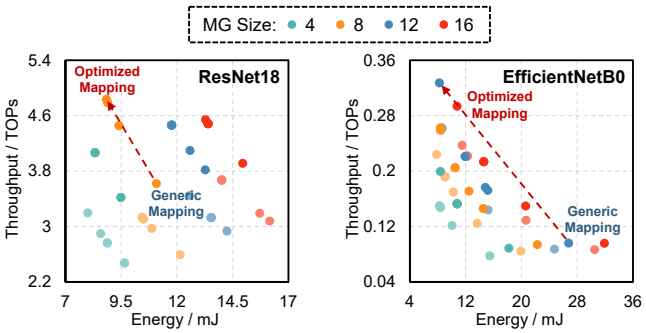

Fig. 7. Software/Hardware design space categorized by MG size. Light/dark shades indicate 8/16-byte NoC flit sizes.

To provide insights into the interaction between software and hardware design choices, we further compare different compilation strategies across these hardware configurations. As shown in Fig. 7, while hardware configurations significantly impact the achievable performance envelope, the performance differences between hardware configurations can be significantly reduced or even reversed through careful compilation optimizations. These observations highlight why an integrated hardware-software co-design approach is essential for digital CIM architectures, as isolated exploration of either space would overlook crucial optimization opportunities.

V. Conclusion and Future Work

This paper presents CIMFlow, an integrated framework that enables systematic design and evaluation of digital CIM architectures. Through a flexible multi-level ISA design and advanced compilation strategies, CIMFlow effectively addresses key challenges in digital CIM implementation, particularly the SRAM capacity limitations. Our experimental results demonstrate the capabilities of our proposed compilation optimizations, achieving up to 2.8× speedup and 61.7% energy reduction. The highly customizable and extensible nature of CIMFlow enables systematic design space exploration, providing crucial insights for the software and hardware design of digital CIM. In the future, we will keep on expanding the framework to support emerging DNN operators and developing automated design space exploration techniques. We believe CIMFlow represents a significant step toward making digital CIM a practical solution for next-generation AI accelerators.

ABSTRACT

Coarse-grained reconfigurable architecture (CGRA) has emerged as a promising solution for accelerating computationally intensive applications, particularly in the field of artificial intelligence. One of the primary challenges for CGRA compilers is generating effective mapping results for complex applications within a limited timeframe. This paper presents an enhanced pre-scheduling method that integrates Integer Linear Programming (ILP) and Graph Neural Networks (GNN), along with a corresponding two-stage mapping approach. This combination significantly reduces the search space and accelerates the solution process for mapping problems. Experimental results demonstrate performance improvements ranging from 29.4% to 406.7%, along with compilation time reductions of up to 1106.8× compared to existing compilation techniques, as well as excellent scalability.

KEYWORDS

CGRA, Loop mapping, Graph Neural Network, Scheduling

1 INTRODUCTION

The rapid advancement of technologies, such as large language models and cloud computing, has led to an increasing demand for computational power. As Moore's Law approaches its limits and the need for substantial computational resources continues to grow, the design of novel hardware architectures and their corresponding programming software systems has become essential for enhancing computer performance [1]. Reconfigurable architectures, particularly Coarse-Grained Reconfigurable Architectures (CGRAs) [2–9], combine the flexibility of general-purpose processors, such as CPUs and GPUs, with the high performance of Application-Specific Integrated Circuits (ASICs). This combination positions CGRAs as a promising approach to overcoming the computational power bottlenecks of traditional chips and enhancing computing efficiency.

As illustrated in Figure 1, a typical CGRA consists of a host controller, memory, multiple input/output buffers, and several spatially interconnected Processing Element Arrays (PEAs). Each PEA is an array of processing elements (PEs) that are spatially interconnected. Each PE serves as the fundamental unit for computation and data processing within the CGRA, responsible for executing basic coarse-grained computational tasks. A PE is composed of several input multiplexers (MUX), output functional units (FUs), a Local Register File (LRF), and an Arithmetic Logic Unit (ALU).

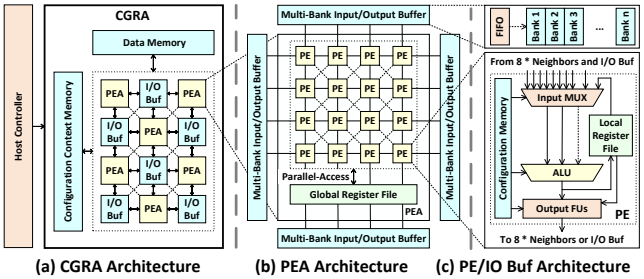

Figure 1: Architecture of a CGRA with 4×4 PEAs. (a) CGRA, (b) PEA, (c) PE and I/O Buffer.

A high-performance compiler is essential for fully leveraging the potential of CGRAs. Code generation is a critical stage within the compilation process, as it significantly impacts the performance of fine-grained operators. The loop mapping problem represents a core challenge in backend code generation. Solving this problem often incurs substantial computational and storage overhead, making it the most time-consuming aspect of the CGRA compilation process. CGRA compilers have explored various methods to effectively tackle the loop mapping problem [2–9], which is classified as an NP-hard problem [11]. However, as software applications scale, the complexity of mapping onto CGRAs grows exponentially, resulting in prohibitively long compilation times.

To accelerate the solution of the loop mapping problem, particularly for large and complex applications, this paper proposes GPS, a two-stage loop mapping method that integrates graph neural networks (GNN) and pre-scheduling techniques. The primary contributions of this paper are as follows.

1. **Two-Stage Mapping Method:** We propose a two-stage mapping method for loop mapping, which leverages Graph Isomorphism Networks [12] and pre-scheduling techniques to narrow the search space in solving mapping problems.
2. **Graph Isomorphism Model and Optimization:** A graph isomorphism model is introduced to formulate the loop mapping problem. Additionally, we present a mapping algorithm based on pattern graph matching to tackle this challenge. Pre-mapping optimizations and polyhedral-based loop transformations are employed to enhance the execution efficiency of loops on CGRAs.
3. **GPS Algorithm:** We introduce a fast and effective loop mapping algorithm, named GPS, designed for heterogeneous CGRAs. This algorithm optimizes both solution quality and computational efficiency. Experimental results demonstrate that GPS achieves significant performance improvements,

ranging from 29.4% to 406.7%, along with up to a 1106.8× reduction in compilation time compared to existing compilation techniques.

2 BACKGROUND AND MOTIVATION

CGRAs are highly flexible architectures that can be dynamically reconfigured to support various computational tasks, including multimedia and AI applications [6–9]. CGRA compilers play a crucial role in harnessing the full potential of these architectures, enabling them to deliver high performance and flexibility across applications. Due to their array-based, highly parallel architecture, CGRAs are particularly well-suited for executing repetitive tasks, such as loops. Notably, loops often account for a significant portion of the overhead during program execution, and loop mapping typically represents the most time-consuming aspect of the CGRA compilation process. Consequently, CGRA compilers employ various methods to efficiently address the loop mapping problem, including heuristic approaches [4–7, 9] and optimization-based methods [8].

During the loop mapping stage, the input consists of the loop kernel of an application represented as a Data Flow Graph (DFG). In the DFG, nodes represent element-wise operations such as ADD or MUL, while edges depict dependencies between these operations. The goal of loop mapping is to optimize the performance of the loop kernel on CGRAs by minimizing the initiation interval (II) of loop iterations. The II represents the minimum number of clock cycles required to execute each iteration of the loop, thereby indicating the program's performance when executed on CGRAs.

As the size of the DFG increases, the complexity of the loop mapping problem grows exponentially, presenting significant challenges for effective problem-solving. For instance, the Auto Regression Filter (*arf*) case in the EXPRESS benchmark [10], illustrated in Figure 2(a), consists of 28 nodes and 30 edges. Solving the mapping problem for this example with an ILP-based approach [8] on a 2×2 Processing Element Array (PEA) as depicted in Figure 2(b) necessitates constructing a Modulo Routing Resource Graph (MRRG) containing 812 nodes and 1120 edges to achieve an optimal II of 7. For more complex DFGs, such as the *jpeg_fdct* case with 134 nodes and 169 edges, the complexity of the MRRG increases exponentially, posing a significant challenge for direct solutions using ILP-based methods. In the case of heuristic approaches, solving the mapping for the *arf* example in Figure 2(a) requires addressing the maximum common subgraph problem for two graphs, each with 28 nodes. This translates to solving an NP-hard maximum clique problem with 784 nodes [6], or employing heuristic methods like simulated annealing [7], which may struggle to find optimal solutions.

For complex loop mapping problems, we have found that employing a pre-scheduling approach to decompose the mapping problem into two subproblems can effectively narrow the search space. This pre-scheduling method involves initially allocating cycles for each operation in the DFG, followed by precise graph matching. In contrast, traditional methods require solving the mapping problem while simultaneously determining the execution start cycle for each operation. Figure 2(c) illustrates the search space for scheduling problems when using traditional ILP methods or heuristic approaches for mapping at an II of 8, highlighting scheduling flexibility. Notably, nodes 15, 16, 23, and 21, 22, 26 exhibit significant flexibility. For instance, nodes 15 and 16 can be executed in the first cycle, followed by 23, or they can be executed before 27 at the end. The flexibility of nodes 15 and 16 is also adjusted based on the scheduling of node 23. Consequently, the total number of valid scheduling options for all nodes is given by $(\sum_{i=1}^{6}(7-i)^2)^2 = 91^2 = 8,281$. If

scheduling can be completed in advance, the size of the search space would reduce to approximately $\frac{1}{8281}$ of its original size, significantly optimizing the mapping process.

Previous research has explored two-stage solving processes that involve scheduling prior to mapping, such as the As-Soon-As-Possible (ASAP) scheduling method [6], diagonal-based scheduling [13], and random scheduling [14]. However, these approaches often struggle to produce optimal scheduling results, leading to larger II values and negatively affecting the execution performance of loop tasks on CGRAs. Figures 2(d) and 2(e) illustrate the scheduling results obtained using the ASAP scheduling method for mapping the DFG shown in Figure 2(a) onto the 2×2 PEA depicted in Figure 2(b). ASAP scheduling refers to scheduling nodes as early as possible in feasible positions, while ALAP scheduling, shown in Figure 2(f), involves scheduling nodes to the latest feasible cycles. Figure 2(g) presents the mapping results obtained using the optimal scheduling scheme, achieving an optimal II of 7. The results from Figures 2(d) and 2(e) indicate that, despite both using the ASAP scheduling method, the scheduling and mapping outcomes differ due to resource constraints, ultimately resulting in various II values. Furthermore, the results presented in Figures 2(d-g) demonstrate that regardless of the scheduling methods employed—whether ASAP, ALAP, or random scheduling—it remains challenging to achieve optimal scheduling or mapping results corresponding to the optimal II. Therefore, in this paper, we propose a scheduling method based on ILP and GNN to obtain the best possible scheduling results within a short timeframe. This scheduling approach can also be integrated with existing mapping methods to narrow the search space of the loop mapping problem and accelerate the problem-solving process.

3 PROBLEM FORMULATION

1) DFG: A DFG, denoted as $G = (V, E)$, typically represents an iteration of a loop. Here, V is the set of nodes, and for every $v \in V$, v represents an operation on the Processing Element (PE). E is the set of edges, where for every edge $e = (v_i, v_j) \in E$ (with $v_i, v_j \in V$), it indicates a data dependency from operation i to operation j.

2) TEC: A Time-Extended CGRA (TEC) refers to a CGRA extended by II times on time axis, represented as $G' = (V', E')$. Here, V' and E' are the sets of nodes and edges, respectively. PE_i^t denotes the i-th PE at modulo cycle t, while $e = (PE_i^t, PE_j^{t+1}) \in E$ represents a datapath from the i-th PE at cycle t to the j-th PE at cycle $t+1$.

3) Modulo Schedule and II: Modulo scheduling is a software pipelining technique that parallelizes different iterations of a loop, creating a repeatedly executed block consisting of a complete set of operations from the inner loop body, with each operation potentially coming from different iterations. The duration of this block represents the II between sequential iterations, reflecting the performance of the scheduled loop on the CGRA. After modulo scheduling of the DFG, a Modulo Data Flow Graph (MDFG) is generated.

4) Resource-Constrained Scheduling Problem: Given the DFG $G = (V, E, F)$ and the CGRA $G' = (V', E', F')$ (where F and F' represent the types of operations in the DFG and the functions of the PEs), along with the II, the problem of finding an optimal schedule can be formulated as a combinatorial optimization problem.

- *Decision Variables:* $t_i = t \in \mathbb{N}^*, i \in \mathbb{N}^*, 1 \le i \le |G|$, indicating that the i-th DFG node is scheduled to start at cycle t.

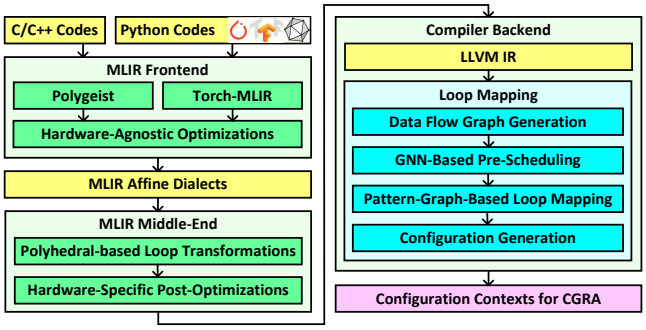

Figure 3: Overview of the compilation process of GPS.

The II denotes the initiation interval, and a *schedule* can be defined as $S = (t_1, t_2, \ldots, t_n, II)$. $t_{mi} = t_i \mod II$ represents the modulo start cycle at which operation i is scheduled.

- *Constraints:*
  - i) *Freedom Constraint:* For each operation, its scheduled cycle should be confined between ASAP and ALAP times. For all $v_i \in V, t_{si} \le t_i \le t_{li}$. Here, $t_{si} = \text{ASAP}(v_i)$ denotes the ASAP time of the i-th DFG node, while $t_{li} = \text{ALAP}(v_i)$ denotes the ALAP time of the i-th DFG node.
  - ii) *Resource Constraint:* In every modulo cycle, the number of operations must be less than or equal to the number of PEs with the corresponding functions. For all $t \in [0, II), t \in \mathbb{N}, \{f_i | f_i \in F, t_{mi} = t\} \subset F'$.
- *Optimization Objective:* Minimize the II.

This resource-constrained scheduling problem can be solved for optimal solutions using Integer Linear Programming methods based on the linear equations outlined above.

5) Mapping Problem: Given a scheduled MDFG $G = (V, E)$ and a TEC $T = (V', E')$, the objective is to find a mapping function $f : V \to V'$ that satisfies the following conditions:

- *Graph Isomorphism:* G is isomorphic to a subgraph of T, which indicates all nodes and edges in the DFG are mapped, i.e., $\forall v_i, v_j \in V, f(v_i), f(v_j) \in V', f(v_i) \ne f(v_j)$, and $\forall e = (u, v) \in E, u, v \in V, \exists e_t = (f(u), f(v)) \in E'$.
- *Optimization Objective:* Minimize the II while ensuring that G is isomorphic to a subgraph of T.

6) GNN Model: GNNs [12] possess significant representational power for complex graphs, making them suitable for extracting intricate relationships between operations in DFGs. In this paper, we design a GNN model to obtain the optimal schedule for the DFG. Denoting the input data as $\mathcal{D}$, our model can be formulated as:

$$\mathcal{M}(i) = MLP(GIN_EMBED(\mathcal{D}_i)) \tag{1}$$

Details of our loss function will be introduced in Section 4. We adopt an ILP-based scheduling algorithm to generate the training labels for our GNN model. The output of the GNN model, denoted as $\mathcal{M}$, is utilized by the list scheduling algorithm as the priority function, which results in enhanced scheduling solutions.

4 THE GPS METHOD

To facilitate efficient mapping on CGRAs, we have developed GPS, a GNN-based pre-scheduling loop mapping method. Figure 3

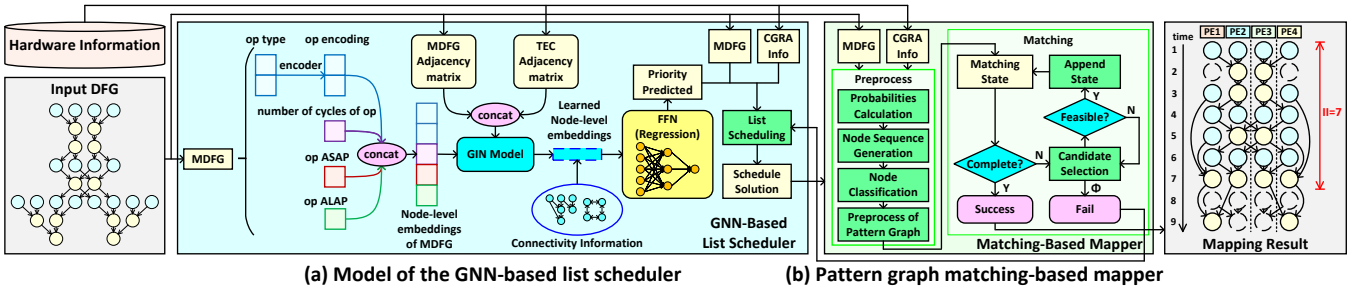

Figure 4: Overview of the two-stage mapper. (a) Model of the GNN-based scheduler. (b) Pattern graph matching-based mapper.

Algorithm 1 GNN-based pre-scheduling algorithm.

Input: Trained network model $\mathcal{M}$, DFG $G = (V, E, F)$, CGRA $G' = (V', E', F')$, delay array d, current initiation interval II
Output: Generated schedule $S_{\mathcal{M}}$

1: $\mathcal{D} \leftarrow encodeData(G), \mathcal{P} \leftarrow runModel(\mathcal{M}, \mathcal{D})$
2: $V_F \leftarrow \phi, V_R \leftarrow \phi, V_U \leftarrow V, S_{\mathcal{M}} \leftarrow \phi, Time \leftarrow 0$
3: **for** $v_i \in V$ **do**
4: **if** $v_i.inDegree() = 0$ **then**
5: $V_R \leftarrow V_R \cup v_i, V_U \leftarrow V_U \setminus v_i$
6: **end if**
7: **end for**
8: **while** $|V_F| < |V|$ **and** $Time < II$ **do**
9: **for** $u_j \in V'$ **do**
10: $M \leftarrow MAX_FLOAT, v_h \leftarrow \phi$
11: **for** v_i in V_R **do**
12: **if** $\mathcal{P}(v_i) < M$ **and** $v_i.canUse(u_j)$ **then**
13: $M \leftarrow \mathcal{P}(v_i), v_h \leftarrow v_i$
14: **end if**
15: **end for**
16: **if** $v_h = \phi$ **or** $u_j.unavailable(Time)$ **then**
17: **continue**
18: **end if**
19: $S_{\mathcal{M}}.insert(v_h, u_j, Time), V_R \leftarrow V_R \setminus v_h, V_F \leftarrow V_F \cup v_h$
20: $u_j.setUnavailable(Time, Time + d_{u_j} - 1)$
21: **for** v_i in V_R **do**
22: **if** $(v_h, v_i) \in E$ **then**
23: $E \leftarrow E \setminus (v_h, v_i)$
24: **if** $v_i \in V_U$ **and** $v_i.inDegree() = 0$ **then**
25: $V_R \leftarrow V_R \cup v_i, V_U \leftarrow V_U \setminus v_i$
26: **end if**
27: **end if**
28: **end for**
29: **end for**
30: $Time \leftarrow Time + 1$
31: **end while**
32: **if** $Time < II$ **and** $|V_F| = |V|$ **then**
33: **return** $S_{\mathcal{M}}$
34: **end if**
35: **return failed**

illustrates the overall compilation process of GPS, which consists of the compiler frontend, middle-end, and backend. Our compiler framework is is implemented based on ML-CGRA [3], MLIR [15], Polygeist [16], and Torch-MLIR [17]. The compiler frontend reads source codes written in Python, C, or C++, performs hardware-agnostic optimizations—including loop boundary and conditional statement optimizations—and generates MLIR Affine Dialects. The middle-end comprises two key steps: 1) polyhedral-based loop transformations and 2) hardware-specific post-optimizations. Once optimizations are complete in the middle-end, the backend takes the input LLVM Intermediate Representation (IR) and generates the DFG. Finally, the backend performs loop mapping to produce executable CGRA configuration contexts. The complete mapping process consists of two stages: pre-scheduling and loop mapping. During the pre-scheduling stage, time steps for each operation in the DFG are allocated to reduce the search space for loop mapping. A GNN-based deep learning framework is proposed to generate high-quality scheduling solutions.

Algorithm 2 Mapper Based on Pattern Graph Matching

Input: DFG D and CGRA C
Output: Mapping result M or Failed

1: $II \leftarrow$ CalculateMII(D, C);
2: **while** $II \leq$ Threshold **do**
3: $T \leftarrow$ GenerateTEC(C, II);
4: $D' \leftarrow$ PreSchedule(D, C, II);
5: $M \leftarrow \emptyset$
6: $P_f \leftarrow$ ComputeProbilities(T, D')
7: $N_{D'} \leftarrow$ GenerateNodeSequence(D', P_f)
8: ClassifyNodes(D', T)
9: (s_0, Parent) $\leftarrow$ PreprocessPatternGraph(D', $N_{D'}$)
10: Match(s_0, T, D', $N_{D'}$, Parent, M) ▷ $M \leftarrow$ Maximum subgraph of D' and T
11: **if** $|V_M| = |V_{D'}|$ **then**
12: **return** M;
13: **end if**
14: $II \leftarrow II + 1$;
15: **end while**
16: **return** Failed;

4.1 GNN-based Pre-scheduling

Algorithm 1 provides an overview of the proposed GNN-based pre-scheduling algorithm, which builds upon the list scheduling algorithm [14] and our neural network models. This algorithm divides the node set V into three subsets: finished nodes V_F, ready nodes V_R, and unscheduled nodes V_U. Given the node priority function $\mathcal{P}$, where $\mathcal{P}(v_i) < \mathcal{P}(v_j)$ for $v_i, v_j \in V_R$ indicates that operation v_i has a higher priority than operation v_j, we use the trained network model $\mathcal{M}$ as the priority function $\mathcal{P}$ (line 1) and continue the process until every node in the DFG is successfully scheduled (line 8). At each step, we select the node $v_h \in V_R$ to schedule, such that $\mathcal{P}(v_h) = \max_{v_r \in V_R} \mathcal{P}(v_r)$ (line 13). In each cycle, we attempt to schedule every available PE using the node v_h with the highest priority (line 16). After selecting node v_h from the ready set V_R, we update the schedule $S_{\mathcal{M}}$ and the sets V_R and V_F (line 19). We then remove all outgoing edges (v_i, v_h) from v_h (line 23). If the in-degree of v_i equals 0, we add v_i to the ready set V_R (line 25). Ultimately, the scheduling solution at II is obtained in $S_{\mathcal{M}}$.

A better priority function in the list scheduling algorithm leads to improved scheduling solutions. An ILP formulation has been proposed as an optimal solution for the scheduling problem [18]. However, the exponential runtime of ILP renders it impractical and inefficient for larger instances. Therefore, employing a GNN model to approximate the optimal solution generated by ILP presents a feasible and efficient alternative. The output of the GNN-based deep learning model can serve as the heuristic function for list scheduling. Figure 4(a) illustrates the architecture of the proposed model, which consists of a Graph Isomorphism Network (GIN) [12] and a feed-forward network (FFN). The GIN model is responsible for learning the embeddings of each operation based on its features

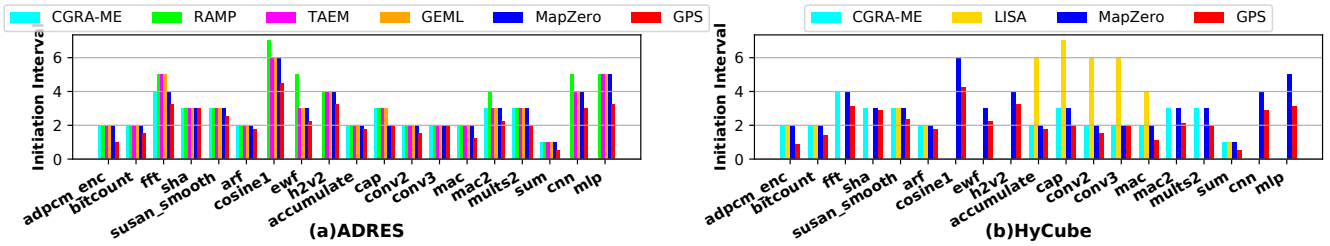

Figure 5: II of loops when mapped to a 4×4 CGRA of different architectures. (a) ADRES, (b) HyCube.

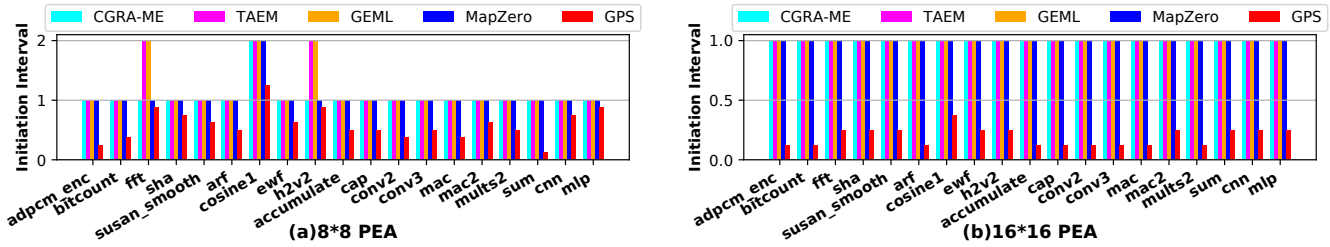

Figure 6: II of loops when mapped to a 8×8 or 16×16 CGRA of ADRES architecture.

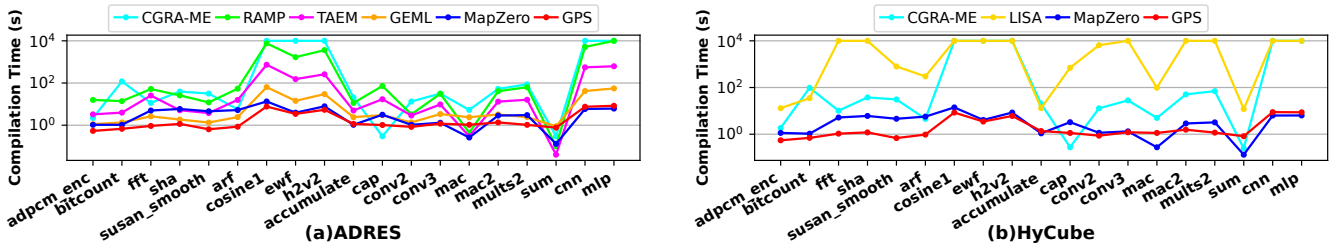

Figure 7: Compilation time when loops are mapped to a 4×4 CGRA of different architectures. (a) ADRES, (b) HyCube.

and the graph structure. The FFN model is utilized for regression tasks, specifically to predict the priorities of operations. The input to the model is $\mathcal{D} = \{g_i, p_i, l_i\}$, where g_i denotes the graph structures of the MDFG and TEC calculated according to the II, p_i represents operation properties (such as ASAP and ALAP), and l_i denotes the training label generated by ILP. We utilized the ILP method to generate a CGRA-related scheduling dataset to train our model. Our loss function is defined as the following rank loss function, where $\mathcal{M}(i) = \mathcal{M}(g_i, p_i)$ and $\mathcal{M}(j) = \mathcal{M}(g_j, p_j)$ represent the outputs of the GIN model for two test cases, respectively.

$$\mathcal{L} = \sum_{i,j} \log\left(1 + e^{-\operatorname{sign}(l_i - l_j)(\mathcal{M}(i) - \mathcal{M}(j))}\right). \tag{2}$$

4.2 Pattern Graph Matching-Based Mapping

After scheduling the DFG, the next step is to map the loop DFG onto the CGRA. To accelerate the mapping process, we formulate the mapping problem as a subgraph isomorphism problem and employ the pattern graph matching algorithm based on VF3 algorithm [19] for efficient resolution. If the MDFG is isomorphic to a subgraph of the TEC, it indicates that the current mapping scheme is feasible. The complete mapping procedure is depicted in Algorithm 2. We initialize the II to the minimum possible value under recursive and resource constraints. Subsequently, we use the II to generate the TEC and perform a pre-scheduling of the DFG. The mapping of the DFG to the TEC is generated using our pattern graph matching algorithm. If the mapping fails at the current II, we increment the II by 1 until a successful mapping is achieved.

Our mapping algorithm is based on pattern graph matching [19], and Figure 4(b) illustrates its workflow. The algorithm progressively narrows the search space by executing the following five steps, incorporating constraint propagation and pruning:

- *Probability Calculation:* For each node in the pattern graph, its matching probability is assessed by calculating the ratio of nodes in the target graph that share the same label and have greater in-degrees and out-degrees. This serves as a critical criterion for node sorting.
- *Node Sequence Generation:* Nodes are sorted based on their probability and degree to prioritize the search for strongly constrained nodes. This helps reduce the width of the search tree in the early stages of the search.
- *Node Classification:* Candidate nodes are filtered using set-level connectivity relations (e.g., predecessor and successor sets) and node labels (operation type and functional unit type for CGRA mapping) to determine the candidate set for the next matching step.
- *Preprocessing of Pattern Graph:* The neighborhood of candidate nodes are explored to facilitate subsequent matching.

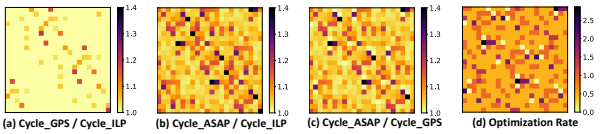

Figure 8: Ablation study on our pre-scheduling method. (a) T_{GPS}/T_{ILP}, (b) T_{ASAP}/T_{ILP}, (c) T_{ASAP}/T_{GPS}, (d) Optimization rate of searching space $log_{10}\frac{Naive}{GPS}$.

- *Matching:* Starting from an empty mapping state, new matching pairs are gradually searched until a complete mapping solution is found. In this step, through a comprehensive analysis of the relationships and connectivity between sets, the algorithm proactively identifies mapping pairs that can be matched in the current step but may not generate new mapping pairs in subsequent iterations.

4.3 Polyhedral-Based Loop Transformations

Based on the OpenCGRA [2] and Polygeist [16] frameworks, we performed polyhedral-based loop transformations prior to mapping to enhance the execution performance of programs on the CGRA. The loop transformations we applied include loop tiling, loop fusion, loop interchange, loop fission, loop reversal, and loop unrolling. By applying these transformations, we optimized the loops in terms of storage efficiency, operation parallelism, and tensor shapes. Additionally, we executed hardware-agnostic optimizations such as constant folding and conditional statement optimization, as well as hardware-specific optimizations based on Single Static Assignment (SSA), to further improve loop performance. When the related work is published, GPS will be open-sourced at Github.

5 EXPERIMENTS

In this section, we evaluate the solution quality, compilation time overhead, and scalability of our CGRA mapper, GPS, in comparison with state-of-the-art CGRA mappers: CGRA-ME [20] (optimized version based on ILP [8]), RAMP [6], TAEM [4], GEML [5], LISA [7], and MapZero [9]. We conducted experiments on two typical architectures: ADRES [21] and HyCube [22]. The sizes of the PEA are configurable, including 4×4, 8×8, and 16×16. To evaluate GPS with a diverse set of loop benchmarks, we selected loops with varying sizes, dependencies, and operator types from MiBench [23], EXPRESS benchmarks [10], and the benchmarks used in CGRA-ME [20]. The experiments were conducted on a server equipped with a 128-Core Intel(R) Xeon(R) Gold 5218 CPU running at 2.30 GHz and 256 GB of memory, along with an Nvidia Tesla A100 GPU.

5.1 Mapping Results and Scalability

Figure 5 compares the performance of various compilers across their supported architectures, including CGRA-ME [20], RAMP [6], TAEM [4], GEML [5], LISA [7], MapZero [9], and the proposed GPS. Since GPS incorporates loop transformations, the II obtained by GPS is normalized based on the average II of 16 loop iterations. From the figure, on a 4×4 ADRES architecture, GPS demonstrates an average performance improvement of 29.5% over CGRA-ME, 45.9% over RAMP, 34.1% over both TAEM and GEML, and 29.4% over MapZero. On a 4×4 HyCube architecture, GPS shows a performance improvement of 34.0% over CGRA-ME, 155.8% over LISA, and 36.2% over MapZero.

GPS also exhibits better scalability for CGRAs of varying sizes. As shown in Figure 6, GPS achieves improved performance with larger PEA. On an 8×8 ADRES architecture, GPS demonstrates an average performance improvement of 77.8% over CGRA-ME and MapZero, and 95.6% over TAEM and GEML. On a 16×16 ADRES architecture, GPS achieves an average performance improvement of 406.7% over CGRA-ME, TAEM, GEML, and MapZero. These experimental results indicate that GPS exhibits strong scalability across different CGRA architectures and varying scales of CGRAs.

5.2 Compilation Time

Figure 7 compares the compilation times of various compilers, including CGRA-ME [20], RAMP [6], TAEM [4], GEML [5], LISA [7], MapZero [9], and GPS. The experimental results demonstrate that GPS achieves an average compilation speed improvement of 1106.8× over CGRA-ME, 623.9× over RAMP, 52.7× over TAEM, 4.17× over GEML, and 59.8% over MapZero. For instance, the compilation time of a loop in *arf* of MapZero is about 5.2s, while it takes only 0.8s for GPS to obtain a better solution. However, for smaller DFGs, GPS may exhibit worse performance due to the time required to load the network models. In summary, GPS effectively reduces compilation time, particularly in cases involving larger loops.

5.3 Ablation Study on Pre-scheduling Method

Ablation studies were conducted to verify the contribution of our pre-scheduling method, as depicted in Figure 8. We evaluated the performance of the GNN-based pre-scheduling method against the naive ASAP scheduling algorithm used in CRIMSON [14]. Optimal results were obtained using an ILP-based algorithm [18]. As shown in Figure 8(a), GPS achieves optimal scheduling solutions for 89.9% of the tested benchmarks. In contrast, the ASAP algorithm fails to obtain optimal solutions for most benchmarks, as illustrated in Figure 8(b). Figure 8(c) demonstrates that GPS provides better solutions for 95.2% of the benchmarks compared to the ASAP algorithm. Furthermore, Figure 8(d) indicates that the pre-scheduling method in GPS reduces the search space by an average of 92.4%. These results highlight that the use of pre-scheduling methods effectively reduces the search space and enhances search efficiency.

6 CONCLUSION

CGRA is an energy-efficient and processing-flexible parallel computing architecture. A major challenge for CGRA compilers is generating optimal loop mapping results within the shortest possible time. In this paper, we propose a fast loop mapping method called GPS, which leverages GNNs and pre-scheduling to effectively reduce compilation time while intelligently generating high-quality loop mapping results. Experimental results demonstrate that GPS achieves performance improvements ranging from 29.4% to 406.7% and significantly accelerates compilation by up to 1106.8× compared to existing compilation techniques. Future work will focus on further enhancing the GNN-based scheduling method and exploring additional polyhedral-based optimization tools.

***Abstract*—Harmonic balance (HB) method is a powerful frequency-domain method used in RF circuit simulations. The key point of HB method is efficiently solving the Jacobian system in Newton's method. In this paper, we first introduce a new time-domain preconditioner for HB Jacobian. Unlike existing time-domain preconditioners, which cannot balance the efficiency of solving the linear system corresponding to the preconditioner with the reduction in iteration step for strongly nonlinear circuit, the proposed preconditioner successfully addresses both aspects. We also present a new preconditioning method that extends time-domain preconditioners to circuit with distributed devices, which was previously unattainable. Finally, a matrix norm-based metric is proposed to measure the strength of circuit nonlinearity, which can help us a priori choose the appropriate preconditioner.**

***Index Terms*—RF Circuit Simulation, Harmonic Balance, HB Jacobian, Preconditioning Techniques.**

I. Introduction

HARMONIC balance (HB) method has been widely used in RF simulation and microwave applications [1]. HB method requires solving nonlinear equations in the frequency-domain, for which Newton's method is often used. Therefore, efficiently solving Jacobian matrix (HB Jacobian) at each Newton step is crucial in HB method. When solving HB Jacobian, Krylov subspace iterative methods such as GMRES method are widely employed. These iterative methods do not require the matrix to be formed explicitly and only require the matrix-vector product in every iteration [2], which has greatly improved the efficiency.

Despite its advantages, the effectiveness of the iterative solver for HB Jacobian depend critically on a good preconditioner which aims to reduce the iteration step. Existing preconditioning techniques for HB method can be divided into two types, the frequency and time-domain preconditioners. These two types of preconditioners each have their own applicable scenarios.

Frequency-domain preconditioner is first proposed by [3], in which the most widely used preconditioner in HB analysis, the frequency-domain average preconditioner is introduced. Several researches have also been carried out to improve the efficiency. A frequency-domain section-average preconditioner is introduced by [4], a better approximation for HB Jacobian is also established in [5] based on a one step correction strategy, and adaptive dynamical preconditioners are presented in [6] by discovering the special structure of HB Jacobian. Frequency-domain preconditioner works pretty well for circuit that is mildly nonlinear. However, when the circuit becomes strongly nonlinear, the number of iteration step using frequency-domain preconditioner increases significantly [5] [7].

Time-domain preconditioning technique is established in [7]. Further extensions and improvements are also provided by [8] and [9]. The greatest advantage of time-domain preconditioner is its effectiveness for circuit with strong nonlinearity. Time-domain preconditioner needs to use a matrix corresponding to a low-step finite difference scheme as approximation of part of the original Jacobian matrix. Two strategies are provided by [7], which suggests using a finite difference scheme in preconditioner fully or partially. The first strategy has advantage in reducing iteration step, but solving the preconditioned system is inefficient; the second strategy's preconditioner is easier to solve, but it requires more iteration steps. Thus, existing time-domain preconditioners cannot balance the efficiency of solving the preconditioned linear system with the reduction in the number of iterations for the iterative solver. Another limitation of existing time-domain preconditioner is the incapability of handling circuit with distributed devices, while they can be directly simulated in frequency-domain [5] [7] [10].

The main contributions of our work are summarized as follows:

- We provide a new type of time-domain hybrid finite-difference preconditioner which successfully addresses both aspects mentioned above. It has significant advantages in handling strongly nonlinear circuit.
- We provide a time-domain average preconditioner, which is suitable for circuit with distributed devices.
- We introduce a matrix norm-based metric to measure the strength of circuit nonlinearity that, to some extend, can help us a priori choose the appropriate preconditioner.

The rest of the paper is organized as follows. Section II illustrates some preliminaries of the HB method and existing preconditioners. Section III introduces our newly proposed time-domain hybrid finite-difference and average preconditioner. Section IV proposes a matrix norm-based metric to measure the strength of circuit nonlinearity. Numerical results are shown in Section V, and section VI draws a conclusion.

II. Preliminaries

A. The derivation of HB Jacobian

Based on modified nodal analysis, we consider an RF circuit whose equations are given by

$$\int_{-\infty}^{t} y(t-s)\, v(s)\, \mathrm{d}s + \frac{\mathrm{d}q(v(t))}{\mathrm{d}t} + i(v(t)) + u(t) = 0,$$

where

- $v(t) \in \mathbb{R}^n$: the voltage variables in the circuit;
- $\int_{-\infty}^{t} y(t-s)\, v(s)\, \mathrm{d}s$: the distributed devices with the matrix-valued function $y(t) = 0$ for all $t < 0$;
- $q : \mathbb{R}^n \to \mathbb{R}^n$: the charge and flux storage in the circuit;
- $i : \mathbb{R}^n \to \mathbb{R}^n$: the current variables in the circuit;
- $u(t) \in \mathbb{R}^n$: the input source current waveform with period T.

Notice that the input source is T-periodic and the system is nonautonomous, the steady-state response will also be T-periodic and can be approximated as

$$v(t) \approx v_K(t) = \sum_{k=-K}^{K} V_k \exp(\jmath 2\pi k f_0 t), \quad f_0 = \frac{1}{T}.$$

In the following, by abuse of notation, we identify v_K as v and let $\{t_i\}_{i=0}^{2K+1}$ be the equidistant discretization of $[0, T]$. Take the approximated form of solution and apply numerical integration, we can collocate the equations in frequency-domain and write it in matrix form

$$F_{\text{HB}}(\mathcal{V}) = \mathcal{Y}\mathcal{V} + \Omega\Gamma q\left(\Gamma^{-1}\mathcal{V}\right) + \Gamma i\left(\Gamma^{-1}\mathcal{V}\right) + \mathcal{U} = 0, \quad (1)$$

where

- $\mathcal{Y} = \text{diag}\{Y_{-K}, ..., Y_0, ..., Y_K\}$ with Y_i's the Fourier coefficients of $y(t)$;
- $\Omega = \jmath 2\pi \cdot \text{diag}\{0, f_0 I, \ldots, K f_0 I, -K f_0 I, \ldots, -f_0 I\}$;
- $\mathcal{V} = [V_0^T, V_1^T, \ldots, V_K^T, V_{-K}^T, \ldots, V_{-1}^T]^T \in \mathbb{C}^{n(2K+1)}$;
- Γ and Γ^{-1} are N-point FFT and inverse FFT matrices respectively.

To solve equation (1), Newton's method is used to compute $\mathcal{V}$. The k-th iteration step of Newton's method is

$$\mathcal{V}^{(k+1)} = \mathcal{V}^{(k)} - J_{\text{HB}}\left(\mathcal{V}^{(k)}\right)^{-1} F_{\text{HB}}\left(\mathcal{V}^{(k)}\right).$$

For $J_{\text{HB}}\left(\mathcal{V}^{(k)}\right)$, it can be computed by the chain rule and has the following form:

$$J_{\text{HB}} = \mathcal{Y} + \Omega\Gamma\mathcal{C}\Gamma^{-1} + \Gamma\mathcal{G}\Gamma^{-1}, \quad (2)$$

where

$$\begin{aligned}\mathcal{C} &= \text{diag}\left\{\frac{\partial q}{\partial v}\Big|_{v=v(t_0)}, \ldots, \frac{\partial q}{\partial v}\Big|_{v=v(t_{2K})}\right\} \\ &= \text{diag}\{C(t_0), \ldots, C(t_{2K})\}.\end{aligned}$$

$\mathcal{G}$ can be also defined similarly.

Thus, the key point of HB method is solving the Jacobian system shown in equation (2) efficiently.

B. Frequency-Domain Preconditioner

Frequency-domain preconditioners seek sparse approximation of J_{HB} directly in the frequency-domain. Note that HB Jacobian is of the form shown in equation (2). Since $\mathcal{Y}$ and Ω are both block diagonal, the key point is to approximate $\Gamma\mathcal{C}\Gamma^{-1}$ and $\Gamma\mathcal{G}\Gamma^{-1}$.

We take frequency-domain average preconditioner, which is the preconditioner of most use in both academic and industry field, as an example. The components of frequency-domain average preconditioner are constructed as

$$\Gamma\mathcal{C}\Gamma^{-1} \approx \bar{\mathcal{C}} = I_{2K+1} \otimes \left(\frac{1}{2K+1}\sum_{i=0}^{2K} C(t_i)\right)$$

$$\Gamma\mathcal{G}\Gamma^{-1} \approx \bar{\mathcal{G}} = I_{2K+1} \otimes \left(\frac{1}{2K+1}\sum_{i=0}^{2K} G(t_i)\right)$$

And the preconditioner $\bar{J}_{\text{HB}}$ is constructed as

$$\bar{J}_{\text{HB}} = \mathcal{Y} + \Omega\bar{\mathcal{C}} + \bar{\mathcal{G}}.$$

It is obvious that $\bar{J}_{\text{HB}}$ is a block-diagonal matrix with $2K+1$ diagonal blocks of size $n \times n$, which means the preconditioned system $\bar{J}_{\text{HB}} z = r$ can be easily solved.

C. Time-Domain Preconditioner

1) Circuit without Distributed Devices: We first consider the case when no distributed devices in the circuit. Left multiply equation (2) by Γ^{-1} and right multiply by Γ, one may have

$$\Gamma^{-1}J_{\text{HB}}\Gamma = \Gamma^{-1}\Omega\Gamma\mathcal{C} + \mathcal{G}.$$

We denote $J_t = \Gamma^{-1}J_{\text{HB}}\Gamma$ and $\mathcal{D} = \Gamma^{-1}\Omega\Gamma$, the above equation can be rewritten as

$$J_t = \mathcal{D}\mathcal{C} + \mathcal{G}. \quad (3)$$

J_t is often called time-domain Jacobian for the diagonal blocks of $\mathcal{C}$ and $\mathcal{G}$ are actually variables in time-domain [7]. Time-domain preconditioning techniques seek a sparse approximation of J_t: $J_t \approx \tilde{J}_t$ and then use $\Gamma\tilde{J}_t\Gamma^{-1}$ as a preconditioner.

The special structure of $\mathcal{D}$ is the key of finding an approximation of J_t [7], it can be shown that

$$\mathcal{D} = \Gamma^{-1}\Omega\Gamma = \begin{bmatrix} 0 & \alpha_1 I_n & \alpha_2 I_n & \ldots & \alpha_{-1} I_n \\ \alpha_{-1} I_n & 0 & \alpha_1 I_n & \ldots & \alpha_{-2} I_n \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \alpha_1 I_n \\ \alpha_1 I_n & \alpha_2 I_n & \ldots & \alpha_{-1} I_n & 0 \end{bmatrix}.$$

Assuming $\alpha_0 = 0$, it can be also proved that

$$\sum_{i=-K}^{K} \alpha_i = 0.$$

Thus, $\mathcal{D}\mathcal{C}$ can be viewed as a kind of $(2K+1)$-step finite difference scheme on a equidistant grid of $[0, T]$.

The above result suggests that $\mathcal{D}\mathcal{C}$ can be approximated by a lower-step finite difference scheme. We refer to this kind of preconditioner more precisely as *time-domain finite difference preconditioner*:

$$J_t \approx \mathcal{D}_{\text{FD}}\mathcal{C} + \mathcal{G},$$

here $\mathcal{D}_{\text{FD}}\mathcal{C}$ means a lower-step finite difference scheme.

2) Circuit with Distributed Devices: When the circuit has distributed devices, we have time-domain Jacobian of the following form

$$J_t = \Gamma^{-1}\mathcal{Y}\Gamma + \mathcal{D}\mathcal{C} + \mathcal{G}.$$

Unlike equation (3), there is one more term $\Gamma^{-1}\mathcal{Y}\Gamma$ in the above equation. For distributed test problems, existing techniques do not have approach to find a sparse approximation of $\Gamma^{-1}\mathcal{Y}\Gamma$, so existing time-domain preconditioners can not be applied to this kind of circuit [5] [7] [10].

3) Two Strategies of Forming the Preconditioner: As we have mentioned, time-domain finite difference preconditioners seek a sparse approximation of $\mathcal{D}\mathcal{C}$ by replacing it with a finite difference scheme of lower-step. In practical, two types of strategies have been used in this process [7], we take Back-Euler scheme as an example. The first strategy retains the entire finite difference scheme:

$$\mathcal{D}\mathcal{C} \approx \mathcal{D}_{\text{FFD}}\mathcal{C} = \frac{1}{h}\begin{bmatrix} C(t_0) & & & & -C(t_{2K}) \\ -C(t_0) & C(t_1) & & & \\ & -C(t_1) & C(t_2) & & \\ & & \ddots & \ddots & \\ & & & -C(t_{2K-1}) & C(t_{2K}) \end{bmatrix}$$

and $J_t \approx \tilde{J}_{\text{FFD}} = \mathcal{D}_{\text{FFD}}\mathcal{C} + \mathcal{G}$, we will refer to it as *time-domain full finite difference preconditioner* in subsequent sections of this paper. The second strategy eliminates the upper right corner of the finite difference scheme:

$$\mathcal{D}\mathcal{C} \approx \mathcal{D}_{\text{PFD}}\mathcal{C} = \frac{1}{h}\begin{bmatrix} C(t_0) & & & & \\ -C(t_0) & C(t_1) & & & \\ & -C(t_1) & C(t_2) & & \\ & & \ddots & \ddots & \\ & & & -C(t_{2K-1}) & C(t_{2K}) \end{bmatrix}$$

and $J_t \approx \tilde{J}_{\text{PFD}} = \mathcal{D}_{\text{PFD}}\mathcal{C} + \mathcal{G}$. Similarly, we refer to it as *time-domain partial finite difference preconditioner*.

III. New Time-Domain Preconditioners

In this section we first introduce our newly proposed time-domain hybrid finite difference preconditioner. Then we present a new time-domain average preconditioning technique that can make time-domain preconditioner applicable to circuit with distributed devices.

A. Time-Domain Hybrid Finite Difference Preconditioner

We first discuss the strengths and weaknesses of the two existing time-domain preconditioning strategies mentioned in the last section. The full finite difference strategy performs very well for strongly nonlinear circuit but suffers from low efficiency in solving the preconditioned system as we have to compute the factorization of the entire matrix [7]. The partial finite difference strategy is highly efficient in solving the preconditioned system because the system that need to be solved is block lower triangular. However, this preconditioner tends to require more iterations for circuit with strong nonlinearity. This is because the finite difference scheme used by this preconditioner corresponds to an initial value problem for an ordinary differential equation (ODE), rather than a boundary value problem for the original system.

Our newly proposed preconditioner improves upon existing strategies by incorporating the following enhancement: *using backward differencing in the reverse time-domain at the first time step*. We still use Back-Euler scheme as an example to help readers understand it:

$$\mathcal{D}\mathcal{C} \approx \mathcal{D}_{\text{HFD}}\mathcal{C} = \frac{1}{h}\begin{bmatrix} C(t_0) & -C(t_1) & & & \\ -C(t_0) & C(t_1) & & & \\ & -C(t_1) & C(t_2) & & \\ & & \ddots & \ddots & \\ & & & -C(t_{2K-1}) & C(t_{2K}) \end{bmatrix}$$

and $J_t \approx \tilde{J}_{\text{HFD}} = \mathcal{D}_{\text{HFD}}\mathcal{C} + \mathcal{G}$. When solving the system corresponding to this preconditioner, the upper left 2×2 matrix block is solved first, followed by block forward substitution. Similar generalizations can be easily derived when using higher-step finite difference schemes such as Gear-2 scheme and we refer to this kind of preconditioner as *time-domain hybrid finite difference preconditioner*.

Combining the previous discussion on existing preconditioners, the newly proposed preconditioner has the following characteristics. First, the system that need to be solved by this preconditioner is almost block lower triangular, resulting in significantly lower computational cost compared to the time-domain full finite difference preconditioner. Second, the finite difference scheme used by this preconditioner still corresponds to a boundary value problem, providing a better approximation to the original system compared to the time-domain partial finite difference preconditioner.

B. Time-Domain Average Preconditioner

1) Frequency Behavior of Y-parameter: We denote the diagonal blocks of $\mathcal{Y}$ as Y_i's, which are the Fourier coefficients of $y(t)$. In electronic engineering, the elements of matrix Y_i are called Y-parameters. Y-parameters are generally frequency-dependent, meaning they can vary with the frequency of the applied signal. In general, for linear time-invariant (LTI) circuits, Y-parameters may exhibit similar trends at integer multiples of the fundamental frequency [11].

It is known that distributed devices in RF analysis, such as transmission lines, packages and substrates are usually linear passive components. Thus, Y-parameters at integer multiples of the fundamental frequency are generally similar or related, although there might be slight variations due to the effects of impedance mismatch, losses, and other factors. This indicates that the diagonal blocks of matrix $\mathcal{Y}$ is nearly invariant.

2) Preconditioning Procedure: In section II we have mentioned that for system with distributed devices, the time-domain Jacobian has one more term $\Gamma^{-1}\mathcal{Y}\Gamma$, it is a dense matrix and existing preconditioning techniques have not provided a sparse approximation of it. This results in existing time-domain preconditioners being unsuitable for circuit with distributed devices.

Motivated by the behavior of Y-parameter which is discussed above, we construct a new approach which is similar to the average preconditioner in frequency-domain. The new preconditioning technique can construct a time-domain preconditioner for distributed test problems. We approximate $\Gamma^{-1}\mathcal{Y}\Gamma$ as follows:

$$\begin{aligned}\Gamma^{-1}\mathcal{Y}\Gamma &\approx \Gamma^{-1}\left(I_{2K+1}\otimes\left(\frac{1}{2K+1}\sum_{i=-K}^{K}Y_i\right)\right)\Gamma\\ &= \left(F_{2K+1}^{-1}\otimes I_N\right)\left(I_{2K+1}\otimes\bar{Y}\right)\left(F_{2K+1}\otimes I_N\right)\\ &= I_{2K+1}\otimes\bar{Y},\end{aligned}$$

where F_{2K+1} is a FFT matrix of order $2K+1$.

Denote $\bar{\mathcal{Y}} = I_{2K+1}\otimes\bar{Y}$ and the time-domain Jacobian J_t with distributed devices can be approximated as

$$J_t \approx \tilde{J}_t = \bar{\mathcal{Y}} + \mathcal{D}_{\text{FD}}\mathcal{C} + \mathcal{G}, \tag{4}$$

where $\mathcal{D}_{\text{FD}}\mathcal{C}$ denotes a finite difference scheme on a equidistant grid of $[0,T]$. We refer to this kind of preconditioner as *Time-domain average preconditioner*.

IV. The Metric of Nonlinearity

Previous works have mentioned that frequency-domain preconditioners are more effective for circuit with mild nonlinearity, while time-domain preconditioners are better for circuit with strong nonlinearity [5] [7]. It is natural to ask how to a priori assess the strength of circuit nonlinearity in order to select an appropriate preconditioner. In this section we introduce a matrix norm-based metric to help answer this question.

A. Block Circulant Structure in HB Jacobian

First, we have to review the special structure of HB Jacobian. The term $\Gamma\mathcal{C}\Gamma^{-1}$ and $\Gamma\mathcal{G}\Gamma^{-1}$ are both block circulant and this has been mentioned in many previous works [3] [10] [12]. Take $\Gamma\mathcal{G}\Gamma^{-1}$ as an example:

$$\Gamma\mathcal{G}\Gamma^{-1} = \begin{bmatrix} \mathcal{G}_0 & \mathcal{G}_1 & \cdots & \mathcal{G}_{2K-1} & \mathcal{G}_{2K} \\ \mathcal{G}_{2K} & \mathcal{G}_0 & \mathcal{G}_1 & & \mathcal{G}_{2K-1} \\ \vdots & \mathcal{G}_{2K} & \mathcal{G}_0 & \ddots & \vdots \\ \mathcal{G}_2 & & \ddots & \ddots & \mathcal{G}_1 \\ \mathcal{G}_1 & \mathcal{G}_2 & \cdots & \mathcal{G}_{2K} & \mathcal{G}_0 \end{bmatrix}, \tag{5}$$

where $\mathcal{G}_i$'s are all $n\times n$ block matrix and can be obtain easily by block iFFTs. $\mathcal{C}_i$'s are of the same form.

Actually, if the circuit is pure linear, which means $C(t) = \frac{\partial q}{\partial v}(t)$ and $G(t) = \frac{\partial i}{\partial v}(t)$ are both time-invariant. In this case we have

$$\mathcal{C}_i = \mathcal{G}_i = \mathbf{0}_{n\times n}\,(i = 1,2,...,2K).$$

Thus, $\Gamma\mathcal{C}\Gamma^{-1}$ and $\Gamma\mathcal{G}\Gamma^{-1}$ are both block diagonal which means the HB Jacobian J_{HB} is block diagonal. Previous works have also mentioned that for circuit with mild nonlinearity, J_{HB} is block diagonal dominant while the dominance will deteriorate as the nonlinearity increases [5] [10].

B. Proposed Metric of Nonlinearity

The discussion above inspires us that we can use the degree of diagonal block dominance to measure the strength of nonlinearity. Since $\mathcal{C}$ and $\mathcal{G}$ represent different circuit components, we present the following matrix norm-base metric which can measure the strength of nonlinearity of circuit components corresponding to matrix $\mathcal{C}$ and $\mathcal{G}$ respectively as following:

$$\begin{aligned}\text{LinRate}\,(\mathcal{C}) &= \frac{\|\mathcal{C}_0\|_\infty}{\sum_{i=1}^{2K}\|\mathcal{C}_i\|_\infty},\\ \text{LinRate}\,(\mathcal{G}) &= \frac{\|\mathcal{G}_0\|_\infty}{\sum_{i=1}^{2K}\|\mathcal{G}_i\|_\infty}.\end{aligned} \tag{6}$$

The smaller the two values, the lower the dominance of the main diagonal blocks in the block circulant matrix, indicating stronger nonlinearity for the corresponding circuit components; conversely, the larger the two values, the milder the nonlinearity.

We first suppose that there is no distributed devices in the circuit. Review the form of HB Jacobian shown in equation (2), matrix $\Gamma\mathcal{C}\Gamma^{-1}$ will be left-multiplied by a block diagonal matrix Ω of coefficients resulting from differentiation. For each harmonic, the corresponding row of the block matrix will be multiplied by the coefficient $\jmath 2k\pi f_0$, which corresponds to the harmonic order. In RF simulation, the fundamental frequency f_0 is generally of a large order, typically in the range of MHz, GHz, or even higher frequencies. Thus $|\jmath 2k\pi f_0|\|\mathcal{C}_i\|$'s are often significantly larger than $\|\mathcal{G}_i\|$'s when $k \neq 0$. So for rows corresponding to non-zero order harmonics, the diagonal block dominance is almost entirely determined by LinRate $(\mathcal{C})$, while for the first row which corresponds to the zero-order harmonic it is determined by LinRate $(\mathcal{G})$. Thus, when using this metric to help test the nonlinearity of the whole circuit in order to a priori choose the appropriate preconditioner, both LinRate $(\mathcal{C})$ and LinRate $(\mathcal{G})$ have to be computed.

Besides, for circuit with distributed devices, an additional block diagonal matrix $\mathcal{Y}$ needs to be added. The elements of $\mathcal{Y}$ have different dimension compared to those of $\mathcal{C}$ and $\mathcal{G}$, and their magnitude is also generally larger. In this case, the circuit properties become more complex, making it difficult to have a universal metric to measure their nonlinear characteristics. However, numerical experiments in the next section have shown that the proposed metric can still serve to assess the degree of nonlinearity for such circuit.

V. NUMERICAL EXPERIMENTS

In this section we would like to highlight the advantage of the proposed preconditioners when dealing with strongly nonlinear circuit (circuits with or without distributed devices are both included) and the feasibility of using the proposed matrix norm-based metric to a priori assess the strength of circuit nonlinearity by numerical experiments. Also, we present a test to verify that diagonal blocks of $\mathcal{Y}$ are nearly invariant using a similar metric of the metric shown in equation (6) and this can ensure that the idea of time-domain average preconditioner is reasonable. The numerical experiments were performed in MATLAB Version 9.13.0.2320565 (R2022b) on a standard desktop with the following specifications: 12th Gen Intel(R) Core(TM) i5-12600KF 3.70 GHz 16GB RAM.

The case information is shown in Table I, including the circuit size, number of harmonics used in simulation and whether the circuits have distributed devices.

A. Time-domain Hybrid Finite Difference Preconditioner vs. Existing Preconditioners

Firstly, we compare our proposed preconditioner with existing preconditioners that all have been mentioned in previous sections on circuits without distributed devices. For frequency-domain preconditioner, we use average preconditioner. The TF, TP and TH in the table stands for time-domain full, partial and hybrid finite difference preconditioner respectively. The finite difference scheme used for approximating $\mathcal{DC}$ is Back-Euler scheme. Table II and III show the GMRES iteration step and computing time for different preconditioners.

We first compare our proposed preconditioner to existing time-domain preconditioners. In all the cases, the number of GMRES iteration step of our proposed preconditioner is fewer than that of the time-domain partial finite difference preconditioner with $1.4\times$ iteration reduction on average, while the iteration step is similar to or even fewer compared to time-domain full finite difference preconditioner. For those cases in which full finite difference gain less iterations, the number is not excessively fewer. The advantage is also reflected in terms of computing time, the time-domain hybrid finite difference preconditioner has advantages over the other two time-domain preconditioners and achieves $1.9\times$ and $1.6\times$ speed up on average.

At the same time, compared to frequency-domain average preconditioner, the newly proposed preconditioner also achieves $2.0\times$ iteration reduction and $2.2\times$ computing time speed up on average in all strongly nonlinear cases (case 1-4). Even in cases where frequency-domain average preconditioner does not converge, convergence can be achieved in a few steps with our proposed preconditioner. In circuits with relatively mild nonlinearity (case 5-6), frequency-domain average preconditioner is notably superior to all time-domain preconditioners. This aligns with the experiment observation of prior related works for HB method [5] [7].

Overall, the newly proposed preconditioner shows significant advantages when dealing with circuit that exhibits strong nonlinearity.

B. Time-Domain Average Preconditioner Applied to Strongly Nonlinear Distributed Test Cases

In this part, we primarily demonstrate the value of the time-domain average preconditioner through experiments. We apply time-domain average preconditioner based on equation (4) to the four strongly nonlinear cases with distributed devices. The hybrid finite difference scheme is used to approximate $\mathcal{DC}$ in experiments. Table IV shows GMRES iteration step when different preconditioners are applied to these cases.

TABLE IV
TEST FOR STRONGLY NONLINEAR CIRCUITS WITH DISTRIBUTED DEVICES

Case	Frequency-domain Average Preconditioner		Time-domain Average Preconditioner
	$\text{Iter}_{\text{FAvg}}$	$\text{Iter}_{\text{FAvg}}/\text{Iter}_{\text{TAvg}}$	$\text{Iter}_{\text{TAvg}}$
7	37	**2.18**	17
8	38	**1.36**	28
9	155	**3.04**	51
10	80	**3.08**	26

It can be seen that in all cases, the GMRES iteration step of time-domain average preconditioner is significantly reduced compared to that of frequency-domain average preconditioner, with 2.4× iteration reduction on average. The experiment confirms that the newly proposed preconditioning technique makes time-domain preconditioners applicable to circuit with distributed devices and exhibits clear advantage over frequency-domain average preconditioner when the circuit is also strongly nonlinear.

C. Preliminary Nonlinearity Test

In this subsection, we conduct a preliminary nonlinearity test on all the test cases using the aforementioned matrix norm-based metric, categorizing them into strongly nonlinear cases and mildly nonlinear cases, which is shown in Table V.

It is evident that for circuits with strong nonlinearity, at least one of the values of $\text{LinRate}\,(\mathcal{C})$ and $\text{LinRate}\,(\mathcal{G})$ will be noticeably small compared to that of circuits with mild nonlinearity (highlighted in bold in Table V). Based on our experimental observations, when $\text{LinRate}\,(\mathcal{C}) \lesssim$ 1e+13 or $\text{LinRate}\,(\mathcal{G}) \lesssim$ 1e+02, the circuit can be considered to have strong a priori nonlinearity; otherwise, the a priori nonlinearity is relatively weak.

From the experiments in the previous two subsections, it is also obvious that cases with mild a priori nonlinearity require fewer iterations using frequency-domain average preconditioner, while those with strong nonlinearity require fewer iterations using time-domain preconditioners. This shows that the strength of circuit nonlinearity of these cases is consistent with the a priori judgments, even when the circuit has distributed devices (case 7-10). The experiment indicates that the metric we proposed can effectively provide a priori judgments on the strength of circuit nonlinearity to a certain extent, and also help us choose the appropriate preconditioner.

TABLE V
TEST OF NONLINEARITY

Case	$\text{LinRate}\,(\mathcal{C})$	$\text{LinRate}\,(\mathcal{G})$	Consistent with the prior

TABLE VI
TEST OF VARIANCE OF THE DIAGONAL BLOCKS OF $\mathcal{Y}$

Case	$\text{InvarRate}\,(\mathcal{Y})$
7	3.2358e+07
8	2.9700e+07
9	1.7716e+09
10	1.0048e+11

D. Test of Variance of the Diagonal Blocks of $\mathcal{Y}$

In this part, we aim to show that the diagonal blocks of $\mathcal{Y}$ are nearly invariant using the same strategy of the metric shown in equation (6). It is easy to check that $\Gamma^{-1}\mathcal{Y}\Gamma$ is also block circulant. Denote the circulant blocks as $\mathcal{Y}_i$'s, and $\mathcal{Y}_i$'s can be computed similarly as $\mathcal{G}_i$'s and $\mathcal{C}_i$'s by performing block FFTs, which have been mentioned in equation (5) in section IV. Similarly, we can use the dominance of the main diagonal blocks of $\Gamma^{-1}\mathcal{Y}\Gamma$ to determine the variance of diagonal blocks of $\mathcal{Y}$. We introduce the following metric:

$$\text{InvarRate}\,(\mathcal{Y}) = \frac{\|\mathcal{Y}_0\|_\infty}{\sum_{i=1}^{2K}\|\mathcal{Y}_i\|_\infty}.$$

Table VI shows the values of $\text{InvarRate}\,(\mathcal{Y})$ for all cases with distributed devices. The values corresponding to this metric are very large, indicating that the diagonal blocks of matrix $\mathcal{Y}$ are nearly invariant. Thus, the idea of time-domain average preconditioner is reasonable.

VI. CONCLUSION

In this paper, two new time-domain preconditioners are proposed. Compared to existing time-domain preconditioners, the proposed preconditioning methods not only show significant advantages for circuit with strong nonlinearity but also enable the use of time-domain preconditioners for circuit with distributed devices. In addition, we present a matrix norm-based metric which can assist us in the preliminary selection of which preconditioner to use. In the future, we aim to conduct more in-depth mathematical research on HB-related subproblems to enhance the efficiency of the HB method for RF circuit simulation.
