***Abstract*—Retrieval-augmented language models (RALMs) have attracted widespread attention for addressing the limitations of traditional large language models. However, challenges involved in retrieval, including substantial data movement and irregular access patterns, seriously impact the efficiency and deployment of RALMs. The emerging 3D-stacked processing-in-memory (PIM) architecture, characterized by its high memory bandwidth and near-data computing capabilities, presents a promising solution for efficient retrieval. To support large-scale retrieval in RALMs, the PIM architecture should be carefully designed with joint software and hardware optimization.**

This paper presents *Rimast*, a retrieval-in-memory architecture for fast retrieval in RALMs. The objective is to minimize data movement and improve overall performance through hardware-software co-design. At the hardware level, a hierarchical PIM architecture with a retrieval-in-memory dataflow is designed to reduce unnecessary data transfer. At the software level, skew-free data mapping and adaptive offloading strategies are proposed to address the irregular access patterns associated with retrieval in RALMs. We demonstrate the effectiveness of the proposed Rimast using extensive experiments. The experimental results demonstrate that Rimast effectively reduces data movement, achieving average speedups of 273×, 55×, and 2.41× over CPUs, GPUs, and prior art accelerators, respectively.

***Index Terms*—Retrieval, RALM, Processing-in-Memory**

I. Introduction

Retrieval-augmented language models (RALMs) [5], [22] have been successfully deployed in various application domains. RALMs combine non-parametric external storage with internal parameters, and this hybrid approach provides better performance than traditional large language models [9], [10]. RALMs typically employ a large-scale external database with billions of embeddings to enhance language models. RALMs suffer from low efficiency caused by large-scale retrieval from external database, making them 12× slower than traditional language models (LMs) [27].

Fig. 1(a) illustrates the workflow of a typical RALM, which consists of three major steps: (i) *BERT*; (ii) *Retrieval*; and (iii) *LM*. Upon receiving an input context, it is transformed into chunk embeddings using BERT [8]. These embeddings query a key-value database to retrieve the most similar text chunks, which are then integrated into LMs to generate high-quality responses. Although RALMs greatly enhance response accuracy, *retrieval* (the second step) accounts for 93.8% of the processing time in the RALMs pipeline, as illustrated in Fig. 1(b), highlighting the significant potential for optimization.

Efficient retrieval approaches mainly comprise graph-based, hashing-based, and compression-based algorithms. Although

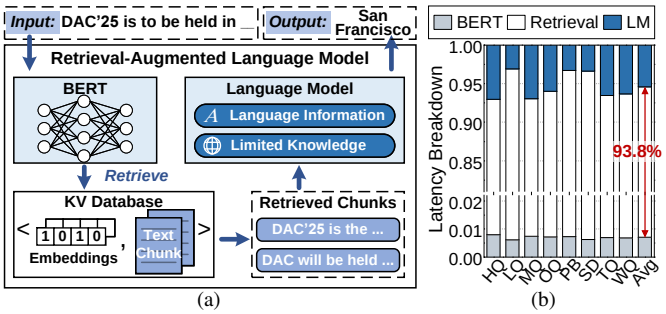

Fig. 1: (a) RALM workflow. (b) Latency breakdown.

graph-based [17] and hashing-based [26] algorithms perform well with high accuracy during retrieval, they often require a high memory footprint of up to several terabytes of memory in RALMs [11]. In contrast, compression-based retrieval algorithms can achieve high performance and low memory footprint [13]. Many RALMs adopt compression-based algorithms for large-scale retrieval [5], [20], [23], [25]. However, retrieval in RALMs still involves substantial data movement that algorithm optimization can not fully address. Numerous embeddings in external databases will be transferred from memory to processors, which causes significant performance degradation and energy consumption.

The processing-in-memory (PIM) architecture [6], [7], [21], [28] provides a promising solution for RALMs. The advanced 3D memory [14] stacks multiple DRAM dies on a base die, offering significant capacity and bandwidth for RALMs. Furthermore, computing units can be placed in DRAM dies to enjoy *in-memory retrieval*, effectively reducing data movement. However, processing retrieval efficiently via the 3D-stacked PIM architecture is non-trivial. First, the existing centralized processing dataflow is not suitable for in-memory retrieval. Second, irregular access issues in RALMs lead to imbalanced workloads, limiting the benefits of PIM architectures.

This paper proposes *Rimast*, a retrieval-in-memory architecture for fast billion-scale retrieval in RALMs. The proposed Rimast minimizes data movement and improves the overall performance for retrieval using a hardware-software co-design approach. At the hardware level, a hierarchical PIM architecture with a retrieval-in-memory dataflow is designed to minimize unnecessary data transfer. At the software level, a skew-free data mapping strategy is presented to achieve fine-grained data partitioning and even data distribution. An adaptive offloading strategy is further proposed to reallocate tasks at runtime, eliminating imbalanced workloads. We demonstrate the effec-

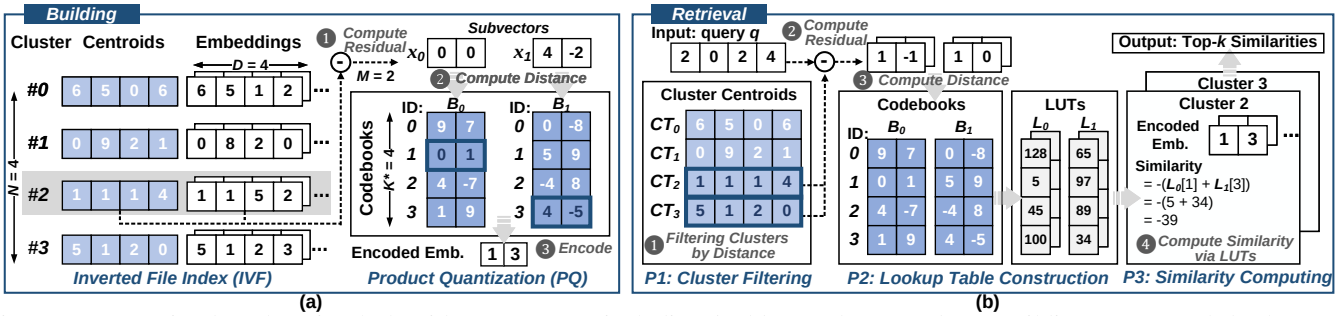

Fig. 2: Compression-based retrieval algorithm [13], [24], including *building* and *retrieval*. (a) Building an external database. (b) Three phases of retrieval.

tiveness of Rimast using extensive experiments. Experimental results show that Rimast outperforms existing representative schemes, substantially reducing processing latency and energy consumption.

The main contributions of this work include:

- *PIM for RALM Retrieval*: To the best of our knowledge, this is the first PIM-based retrieval accelerator to address the data movement and the irregular access issues in RALMs.
- *Architecture Design*: A retrieval-in-memory architecture with customized dataflow is designed to minimize off-chip data movement.
- *Software Optimization*: A skew-free data mapping strategy and an adaptive offloading strategy are proposed to address the imbalanced workloads caused by irregular accesses.

The rest of this paper is organized as follows: Section II illustrates the background and motivation, Section III details the proposed techniques, and Section IV presents and discusses the experimental results. Finally, Section V concludes the paper.

II. Background

A. Large-Scale Embedding-Based Retrieval

Embedding-based retrieval aims to identify the top-k embeddings in a database that are most similar to a given query embedding. With the L2 (Euclidean) distance, the similarity between the query q and an embedding y is defined as:

$$S(q,y) = -\|q-y\|_2^2 = -\|q\|^2 - \|y\|^2 + 2\langle q,y\rangle \quad (1)$$

An exact search over a large-scale database is computationally expensive, often requiring significant time and memory.

To alleviate the overhead, compression-based retrieval algorithms are widely adopted for their high performance and low memory footprint. Compression-based algorithms primarily adopt inverted file (IVF) index and product quantization (PQ) [13]. The IVF index divides embeddings into N clusters, each represented by a centroid. It significantly reduces computation by restricting similarity computations to the selected clusters. PQ reduces storage and computation costs by mapping high-dimensional embeddings to lower-dimensional spaces. It achieves this by dividing a D-dimensional embedding into M subvectors, each of which is quantized using a learned codebook with $K*$ codewords. An example of building a database using IVF and PQ is illustrated in Fig. 2(a). The retrieval process

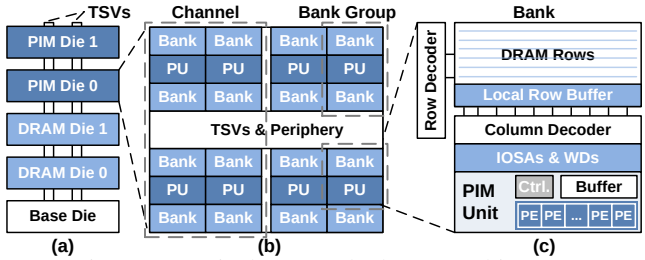

Fig. 3: A typical 3D stacked PIM architecture.

consists of three main phases: (1) *cluster filtering*, (2) *lookup table (LUT) construction*, and (3) *similarity computing*. An example of retrieval is depicted in Fig. 2(b). Given a query embedding $q = \|2\ 0\ 2\ 4\|$, the process starts by selecting candidate clusters with the most similar centroids (i.e., CT_2 and CT_3). Next, LUTs are built to reduce redundant computations, as each encoded embedding may comprise repeated codewords. For instance, the residual embedding of q relative to CT_2 is split into two segments and compared with codewords in B_0 and B_1 to form L_0 and L_1. Finally, similarities between q and encoded embeddings are efficiently computed via LUTs.

B. 3D-Stacked Processing-in-Memory Architecture

Fig. 3 illustrates a typical processing-in-memory (PIM) architecture utilizing 3D stacked memory [14], where multiple DRAM dies are stacked on top of a base die using through-silicon vias (TSVs). DRAM dies equipped with PIM capabilities are termed PIM dies. As shown in Fig. 3(b), each PIM die contains multiple memory channels, with each channel comprising bank groups and each bank group comprising banks. Fig.3(c) shows the structure of a DRAM bank with a PIM unit, which includes SRAM buffers and processing elements for near-bank computing. Each bank contains DRAM cells, a global row buffer of I/O sense amplifiers (IOSAs), address decoders, and write drivers (WDs). DRAM cells are arranged in rows and columns. Before accessing memory, the relevant row should be activated. As only one row per bank can be active at a time, accessing two different rows consecutively causes a row buffer conflict, resulting in low bandwidth utilization.

C. Motivation

*1) **Data Movement Issue**:* Compression-based retrieval involves substantial movement of embeddings from memory to processors, making it memory-bound. We analyze the memory bandwidth requirement of retrieval with the well-established

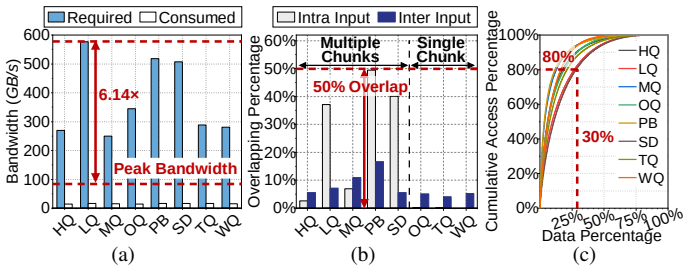

Fig. 4: (a) Up to 6.14× bandwidth demand. (b) Access locality pattern with up to 50% data overlap. (c) Skewed access pattern with 30% data contributing 80% access.

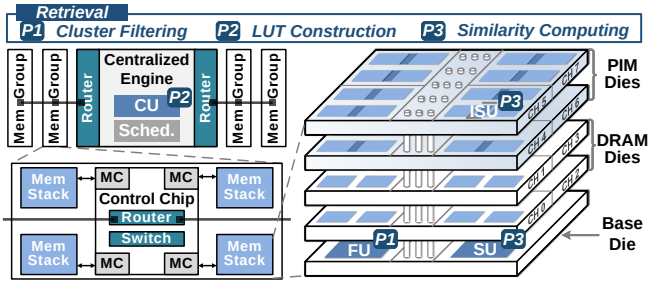

Fig. 5: Architecture design overview. Dedicated compute units (CU, FU, SU, and ISU) are added for retrieval.

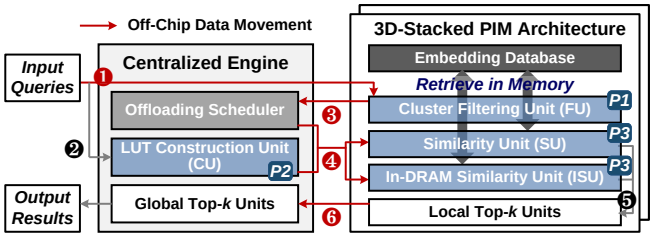

Fig. 6: Retrieval-in-memory dataflow.

library Faiss [12]. Fig. 4(a) indicates that retrieval performance is constrained by limited memory bandwidth. To match the throughput of inference, the system requires a higher bandwidth, ranging from 2.65× to 6.14× the peak memory bandwidth of a four-channel system. Since the memory-bounded similarity computing phase mainly involves addition operations, it can be efficiently processed in memory with low hardware overhead.

*2) **Irregular Access Issue**:* The workloads of RALMs exhibit irregular access patterns. First, RALMs exhibit strong temporal locality. A long input is divided into chunks, generating several query chunk embeddings. Adjacent chunk embeddings within an input often access the same clusters, with up to 50% overlap (Fig. 4(b)). Second, retrieval has a skewed access pattern. 30% of the clusters account for over 80% of the accesses, while others receive minimal attention (Fig. 4(c)). These access patterns cause imbalanced workloads, especially in PIM architectures with in-place data processing.

Motivated by the above-mentioned challenges, we focus on exploiting PIM architectures for retrieval via a hardware and software co-design approach.

III. Rimast: An Retrieval-in-Memory Architecture for RALMs

Rimast is a HW/SW co-design architecture tailored for retrieval in RALMs. At the hardware level, a hierarchical PIM architecture with a customized dataflow is designed to exploit in-memory retrieval. At the software level, Rimast applies two strategies to address irregular access patterns. First, *skew-free data mapping* is proposed to distribute embeddings evenly, avoiding imbalanced workloads caused by the skewed pattern. Second, *adaptive offloading* is proposed to reduce latency by rescheduling tasks with temporal locality patterns.

A. Hardware Architecture Design

1) Overview: The overall hardware architecture of Rimast is demonstrated in Fig. 5. Rimast comprises a centralized engine (CE) and multiple memory groups, where a chain topology [18] is adopted to connect them. Each memory group integrates multiple memory stacks and a control chip. The control chip contains memory controllers (MCs), an internal switch, and a router for off-chip communication. The CE constructs LUTs via a *LUT construction unit (CU)*, schedules retrieval tasks, and aggregates similarity results, while PIM-enabled memories process in-memory retrieval. Rimast adds dedicated logic to multiple levels to accelerate retrieval jointly. At the base die level, the *cluster filtering unit (FU)* is customized to select candidate clusters, and the *similarity unit (SU)* is designed to compute similarities for overlapping accessed clusters. At the PIM die level, the *in-DRAM similarity unit (ISU)* is integrated into each memory bank group to enjoy near-bank processing.

2) Retrieval-in-Memory Dataflow: A retrieval-in-memory dataflow is proposed to perform similarity computations directly in memory, transferring only reduced intermediate results rather than the entire database. Fig. 6 presents the proposed dataflow. Once queries come, query embeddings are broadcast to PIM-enabled memories (step ❶) and simultaneously sent to CU (step ❷). Then, FUs within the PIM memories filter candidate clusters, sending the filtered results to the offloading scheduler in the CE (step ❸). Next, the shared partial LUTs are broadcast to all PIM memories, and the scheduler distributes tasks to the PIM-enabled memories (step ❹), enabling similarity computing. Finally, local top-k units within each memory stack reduce these similarities (step ❺), and the global top-k unit in the CE aggregates the reduced similarities (step ❻), completing the retrieval process. Throughout this process, only steps ❶ ❸ ❹ ❻ involve minimal off-chip data movement, with lightweight intermediate data and scheduling information being transferred.

The retrieval dataflow is carefully designed with a two-step LUT construction method to reduce data movement between the CE and PIM architectures while avoiding adding extra multipliers to PIM units. The CE handles shared portions of LUTs, and PIM units perform partial accumulations. Given a query q, a cluster centroid y_C, and a valid codebook keyword combination y_B, the L2 distance is decomposed in Equation (2). Here, $term\ 1$ is computed during cluster filtering, and $term\ 2$ is precomputed and stored as it is independent of q. The CE computes $term\ 3$ to form partial LUTs. The complete LUTs are built on demand by accumulating these terms during the similarity computing phase.

$$\|q - y_C - y_B\|_2^2 = \underbrace{\|q - y_C\|_2^2}_{term\ 1} + \underbrace{\|y_B\|^2 + 2\langle y_C, y_B\rangle}_{term\ 2} - \underbrace{2\langle q, y_B\rangle}_{term\ 3} \quad (2)$$

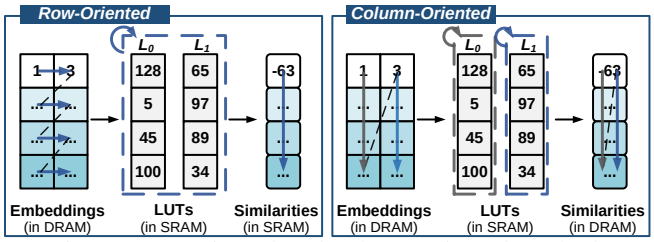

Fig. 7: Row-oriented and column-oriented methods.

3) Detailed Hardware Design:

In-DRAM Similarity Unit (ISU): The ISU is designed for each bank group to support in-memory retrieval, with an optimized embedding processing method to reduce on-chip buffer requirements. Fig. 7 illustrates the conventional row-oriented method and the proposed column-oriented method. The row-oriented method processes encoded embeddings individually, calculating and storing each similarity result one by one. This approach requires repeated random lookups to all LUTs (i.e., L_0 and L_1), necessitating a large on-chip buffer to cache these tables. In contrast, the column-oriented method processes embeddings column by column, accumulating intermediate similarity results sequentially. This approach aligns with the sequential access nature of memory banks to reduce row buffer conflicts. Moreover, it can reduce on-chip buffer demand by multiples as LUTs are accessed individually.

The proposed ISU adopts the column-oriented method. Fig. 8 presents the detailed architecture design of an ISU. The ISU mainly consists of adder arrays, a LUT buffer, a task queue, and a controller. Each task, representing similarity computations for specific clusters, is received by the pending task queue from the offloading scheduler. During similarity computing, the ISU schedules a task (step ❶) and constructs LUTs by accumulating the partial LUTs (step ❷). To reduce row buffer conflicts, destination and source banks are used to separate the lookup and accumulating operations. Once the LUTs are prepared, embeddings are read in column-oriented order from a source memory bank to the ISU, performing lookup operations (step ❸). Next, adder arrays conduct element-wise addition using distances obtained from LUTs, and the resulting partial similarities are accumulated to destination banks (step ❹).

Similarity Unit (SU): The locality access pattern of RALMs decides that adjacent query embeddings will have overlapping access clusters, causing repeated access and processing of encoded embeddings. To address the imbalance, Rimast offloads these overlapping clusters from DRAM dies to SUs.

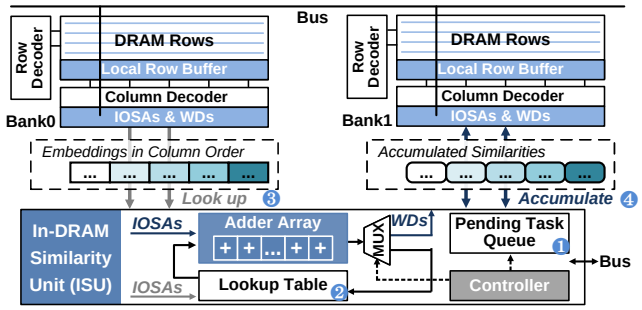

Fig. 8: Hardware design of an in-DRAM similarity unit.

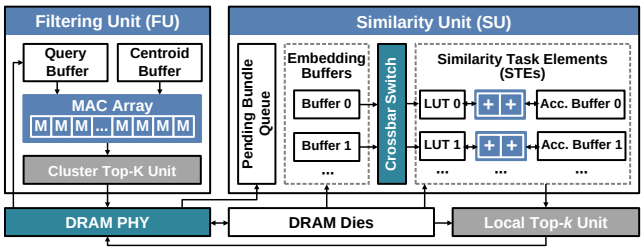

Fig. 9: Hardware design of base die logic.

As shown in Fig.9, an SU includes a pending bundle queue, embedding buffers, a crossbar switch, and similarity task elements (STEs). The pending bundle queue receives task bundles from the offloading scheduler, where each bundle contains multiple tasks targeting the same cluster. First, the control unit allocates embedding buffers and STEs when a bundle is scheduled. Then, the candidate embeddings are fetched from local memory to the buffers, and further broadcast through the crossbar switch to the STEs for similarity computation. Since tasks in a bundle access the same embeddings, STEs can reuse them, reducing redundant data fetching.

Other Compute Units: The FU and CU are designed for cluster filtering and LUT construction, respectively. Both utilize a similar design, employing dot-product operations optimized through MAC arrays for distance calculations.

B. Skew-Free Data Mapping

Due to the skewed access pattern, in-memory retrieval will incur imbalanced workloads. To address this, we propose skew-free data mapping, which distributes embeddings evenly across memories. The proposed mapping is illustrated in Algorithm 1. First, clusters are partitioned into fine-grained sub-clusters, each containing a fixed number of embeddings (Line 1). This approach avoids memory overloading or under-utilization resulting from directly allocating entire clusters to memory banks, as clusters have varying numbers of embeddings. Next, sub-clusters are interleaved across memory banks using an address-mapping strategy (Lines 2-6). The memory hierarchy comprises stacks, channels, bank groups, and banks. The even distribution of sub-clusters across this hierarchy can maximize

Algorithm 1 Skew-Free Data Mapping

Require: Embedding cluster set C, and sub-cluster size sz.
Ensure: Sub-cluster set SC, and mapping set M.
1: $SC \leftarrow$ Partition each cluster $C_m \in C$ into sub-clusters with fixed size sz.
2: **for** each $SC_n \in SC$ **do**
3: $id \leftarrow$ Binary identifier of SC_n
4: $pos \leftarrow$ Map id using sub-cluster interleaved mapping
5: PUSH(M, pos)

7: **return** SC and M

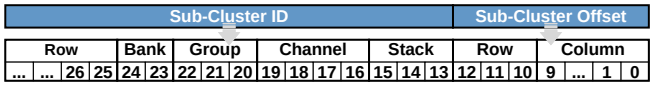

Fig. 10: Sub-cluster interleaved address mapping.

parallelism. Fig. 10 illustrates how the sub-cluster interleaved address mapping allocates each sub-cluster to a specific bank. Given a sub-cluster with an identifier of 1983, represented as $(\underline{01}\ \underline{111}\ \underline{0111}\ \underline{111})_2$, it is mapped to memory bank 1, within bank group 7, channel 7, and stack 7.

C. Adaptive Offloading

Rimast offloads overlapping accessed clusters from bank groups to the SU, avoiding workload imbalances caused by the access locality pattern. An adaptive offloading strategy based on integer linear programming (ILP) is proposed to achieve an optimal solution, minimizing overall processing time.

Within each stack, offloading tasks from a bank group BG_i^j in channel CH_i to the SU reduces the processing time of BG_i^j but increases the processing time (or data transfer time) of channel CH_i and the processing time of the SU. The processing time of each component, including BG_i^j, CH_i, and the SU, can be estimated using linear functions and constrained by total processing time. These linear constraints can be used to formulate an ILP model to determine the number of offloading tasks. Given the initial allocation obtained via the skew-free mapping, we formulate the ILP model as follows:

$$\min \quad \mathbb{T} \tag{3}$$

$$\text{s.t.} \quad \sum_i \sum_j x_i^j = x_s, \tag{4}$$

$$\forall i,j : T_{BG_i^j} = \left(\frac{M_{BG_i^j} - x_i^j}{\text{CAP}_{\text{BG}}} + \frac{OF_i^j(x_i^j)}{\text{BW}_{\text{BG}}}\right) \le \mathbb{T}, \tag{5}$$

$$\forall i : T_{CH\,i} = \left(\frac{\sum_j OF_i^j(x_i^j)}{\text{BW}_{\text{CH}}}\right) \le \mathbb{T}, \tag{6}$$

$$T_{SU} = \left(\frac{x_s}{\text{CAP}_{\text{SU}}}\right) \le \mathbb{T}. \tag{7}$$

The objective of the ILP, as expressed in Equation (3), is to minimize the total processing time $\mathbb{T}$. Notations used in our ILP model are summarized in Table I. To ensure balanced workload distribution, constraints are imposed to keep the processing times of all components within $\mathbb{T}$ (Equations (5)-(7)). The ILP determines the number of offloaded tasks for each bank group. Then, sub-clusters with the highest numbers of repeated accesses within each bank group are prioritized for offloading.

TABLE I: Notations of the ILP model.

Symbol	Description
T_{SU},$T_{CH\,i}$,$T_{BG_i^j}$	Processing time of SU, CH_i, and BG_i^j
$M_{BG_i^j}$	Number of tasks initially mapped to BG_i^j
OF_i^j	Linear function estimating data size offloaded for BG_i^j
x_i^j	Number of tasks offloaded from BG_i^j
x_s	Number of tasks offloaded to SU
CAP_{BG}, CAP_{SU}	Computing capacities of a bank group and an SU
BW_{BG}, BW_{CH}	Bandwidths of a bank group and a channel

IV. Evaluation

A. Experimental Setup

Workloads. We construct the RALM system using a database with one billion embeddings sampled from the Pile [4] and the large GPT model [2]. Text chunks of 64 tokens are transformed into 384-dimensional embeddings using the all-MiniLM-L12-v2 model [19]. The index structure is built with the IVFPQ algorithm implemented in Faiss [12]. In our experiments, we set the number of clusters N=16,384, the number of codewords K^*=256, the number of split chunks M=48, and the batch size BS=16. The candidate cluster count is 256, achieving an average recall rate at 90%. Eight tasks from the LM-Eval [3] benchmark, including HeadQA (HQ), LogicQA (LQ), MathQA (MQ), OpenbookQA (OQ), PubmedQA (PB), SQuAD2 (SQ), TriviaQA (TQ), and WebQs (WQ), are used as input.

TABLE II: System configurations and power-area models.

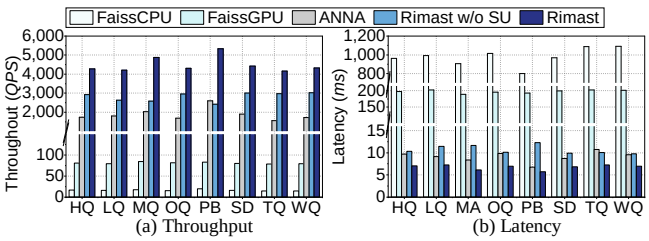
PIM System Organization	8 stacks × 16 channels × (2 bank groups + 6 PIM bank groups) × 4 banks, 12GB per stack, 256GB/s off-chip bandwidth per bidirectional link.
Timing (ns)	tRCD=10, tRC=25, tCA =14, tCCD_S=2, tCCD_L=4
CE	384KB buffers, 128 MACs (1 GHz), 2 top-256 units and 2 top-16 units (1 GHz), Power=375.02mW, Area=1.27 mm^2
ISU	2KB dedicated buffers, 48 adders (125 MHz), Power=6.29mW, Area=0.10 mm^2 (2.7% of a bank group)
Base die logic	1.25MB buffers, 128 MACs and 512 adders (1 GHz), 1 top-256 unit and 16 top-16 units (1 GHz), Power=1432.21mW, Area=9.48 mm^2 (14% of the base die)

Simulation and Configuration. To evaluate our approach, we extend DRAMSim3 [16] to support PIM operations for retrieval. We measure power, area, and delay for each component and integrate these parameters into our simulator. Computing logic is implemented in Verilog and synthesized with the Synopsys Design Compiler using a 32nm library. Scratchpad memories, interconnections, and the 3D DRAM are estimated using CACTI [1]. Detailed configurations are listed in Table II.

Baselines. We compare Rimast with Faiss [12], ANNA [15], and Rimast w/o SU. Faiss provides efficient retrieval solutions for CPU and GPU, with FaissCPU running on 256GB DDR4 memory and two Intel Xeon Silver 4210R CPUs, and FaissGPU running on two NVIDIA A100 (40GB) GPUs. ANNA [15] is a specialized compression-based retrieval architecture. Rimast w/o SU can demonstrate the effectiveness of hierarchical PIM architecture. ANNA and Rimast utilize equivalent computing resources for fair comparison.

B. Experimental Results

1) Throughput: Fig. 11 illustrates the throughput and latency across different baselines. Rimast demonstrates the highest throughput and lowest latency among all baselines. Compared to Rimast w/o SU, ANNA, FaissGPU, and FaissCPU, Rimast achieves average throughput improvements of 1.63×, 2.41×, 55.86×, and 273.78×, respectively, while reducing latency



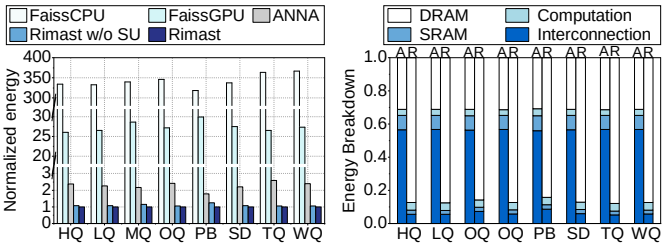


Fig. 11: Throughput and latency.

(a) Energy Consumption (b) Energy Breakdown

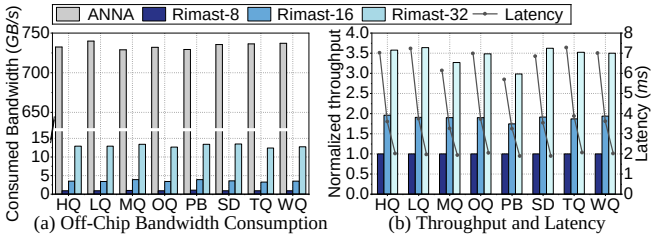

Fig. 12: Reduced energy consumption facilitated by PIM.

by 73.73%, 25.77%, 96.61%, and 99.31%. This performance boost is attributed to the PIM architecture, which significantly minimizes data movement. Moreover, the adaptive offloading mitigates workload imbalances, reducing retrieval latency.

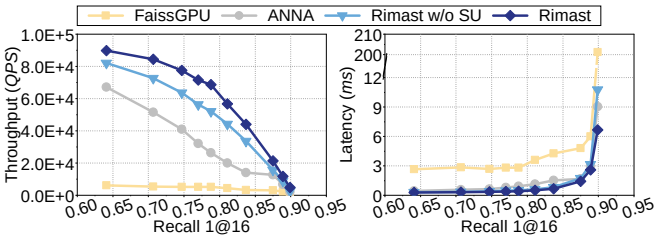
2) Energy Consumption: Energy consumption can reflect the data movement reduction due to PIM. Fig.12(a) presents the normalized energy consumption across various benchmarks, showing that Rimast has the lowest average energy consumption. Rimast achieves average energy savings of 1.10×, 2.27×, 27.69×, and 343.85× compared to Rimast w/o SU, ANNA, FaissGPU, and FaissCPU, respectively. This is primarily due to adopting the retrieval-in-memory dataflow, which minimizes off-chip data movement and reduces energy consumption. Fig.12(b) provides an energy breakdown for ANNA and Rimast, labeled as "A" and "R" respectively. Unlike ANNA's centralized dataflow, Rimast's retrieval-in-memory dataflow significantly lowers the energy consumption of interconnection.

3) Bandwidth Consumption and Scalability: The off-chip bandwidth consumption can reflect data movement reduction due to PIM. Fig. 13(a) shows off-chip bandwidth consumption for ANNA and Rimast with different memory stacks, where 8, 16, and 32 stacks consume 1.04 GB/s, 3.91 GB/s, and 13.91 GB/s, respectively. The data movement overhead of Rimast is neglected since it only transfers a small amount of intermediate data like LUTs and top-k results. We also demonstrate the scalability of Rimast by varying memory stack counts. Fig. 13(b) shows normalized throughput and latency changes as stack counts increase. Rimast with 32 memory stacks achieves 3.41× and 1.81× higher throughput compared to 8 and 16 stacks, respectively, while latency decreases from 6.9 ms (8 stacks) to 3.6 ms (16 stacks) and 2.0 ms (32 stacks). This linear improvement highlights the scalability of Rimast.

4) Performance under Different Recall Rates: Fig. 14 compares the throughput and latency of baseline schemes at various recall rates. Across different recall rates, Rimast consistently achieves the highest throughput and lowest latency. Compared to the state-of-the-art compression-based retrieval

(a) Off-Chip Bandwidth Consumption (b) Throughput and Latency

Fig. 13: Scalability of Rimast with increasing memory stacks



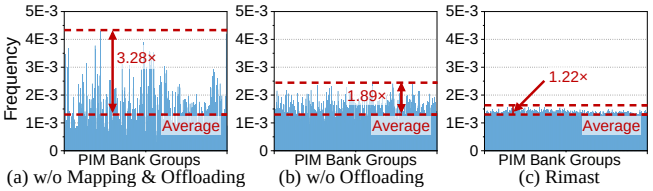


Fig. 14: Throughput and latency under different recall.

(a) w/o Mapping & Offloading (b) w/o Offloading (c) Rimast

Fig. 15: Access frequency for PIM-enable bank groups.

accelerator, ANNA, Rimast improves throughput by 1.33×-3.14× and reduces latency by 1.35×-2.36× on average for recall rates between 60% and 90%. These results highlight the robustness of our method.

5) Workload Balancing: Fig. 15 illustrates the memory access frequency distribution across each PIM-enabled bank group. Workload balancing is quantified using the peak-to-average access frequency (PAF) ratio. The adoption of skew-free mapping reduces the PAF from 3.28× to 1.89×, effectively mitigating the skewed access pattern. Further improvement is achieved through adaptive offloading, which reduces the PAF to 1.22×, addressing imbalances caused by locality patterns.

V. Conclusion

This paper presents Rimast, a PIM-enabled architecture for retrieval in RALMs based on 3D-stacked memories. Both hardware and software are carefully co-designed to fully exploit in-memory retrieval. A hierarchical architecture with an optimized dataflow is proposed to minimize data movement and reduce overall processing latency. We also present two optimization strategies, skew-free data mapping and adaptive offloading scheduling to address the irregular access patterns associated with retrieval in RALMs. The experimental results show that Rimast achieves a substantial reduction in processing latency and energy consumption.

***Abstract*—The physics-informed neural network (PINN) is a promising technology to accelerate thermal analysis of integrated circuits (ICs). However, the application of PINN to three-dimensional (3D) scenarios is faced with numerous challenges, including the requirement of a vast number of sampling points as well as the high-level fitting capability of the network. This paper introduces an Adaptive Sub-regional Random Resampling-based PINN (*ASRR-PINN*) to accelerate the thermal analysis of 3D-ICs. The adaptive sub-regional random resampling (ASRR) algorithm is proposed for efficient sampling in PINN, which divides the solution domain into a series of sub-regions and further adaptively decomposes these sub-regions during the training process. Besides, the sampling points are randomly resampled within each sub-region. By this means, the solution accuracy is enhanced significantly, especially in cases of a limited number of sampling points. To accelerate the convergence of the network, the thermal boundary conditions are incorporated into the *ASRR-PINN*, ensuring that the network outputs automatically satisfy these constraints. Furthermore, the capability of parameterization of *ASRR-PINN* is achieved by training an additional reduced network. Numerical results show that the ASRR algorithm reduces the maximum absolute error (AE) by more than 56% compared with other non-uniform sampling methods while the runtime is shortened by at least 28%. Moreover, using the parameterized *ASRR-PINN* to explore the design space of 3D-ICs achieves speeds over 200 times faster than the original *ASRR-PINN*.**

***Index Terms*—adaptive sampling, physics-informed neural network (PINN), thermal simulation, three-dimensional integrated circuits (3D-ICs)**

I. Introduction

With the technology scaling, the thermal issue has emerged as a critical factor in the chip design and verification process [1]. Thermal optimization for three-dimensional integrated circuits (3D-ICs) often necessitates thousands of thermal simulations to determine the optimal parameters in design space. This extensive simulation requirement inevitably prolongs the design cycle. Therefore, a fast and accurate thermal simulation method of 3D-ICs is indispensable for reducing design costs.

Numerical methods are widely used for solving 3D heat conduction problems due to their high accuracy and flexibility [2], [3]. However, they are computationally consuming when a large number of degrees of freedom (DoFs) are required. In contrast, analytical methods offer a fast solution by providing an analytical answer to the problem through equivalent treatment and mathematical derivation [4], [5]. Despite their efficiency, analytical methods may face challenges when applied to complex models or nonlinear problems. Recently, deep learning methods have gained popularity in solving partial differential equations (PDEs). Among these algorithms, the physics-informed neural network (PINN) has emerged as a promising approach that incorporates known physical information into the learning process, such as the governing equation and the boundary conditions [6]–[8].

The PINN has demonstrated high accuracy in solving numerous one-dimensional (1D) and two-dimensional (2D) problems, and the runtime is significantly reduced through the parameterization of the neural network [9], [10]. However, when it deals with 3D problems, such as heat conduction in 3D-ICs, the PINN faces challenges in achieving the convergence of the network and satisfying the excessive demand of sampling points. To address these issues, various sampling strategies have been explored to obtain more accurate results with the limited number of sampling points [11]–[14]. These studies highlight the significant impact of the sampling strategy on the overall results. However, their limitations are obvious, such as overemphasizing the regions with large PDE residual or requiring excessive sampling time, leaving room for improvement in terms of both accuracy and efficiency.

In this paper, we propose the *ASRR-PINN* for an accurate and fast solution of 3D heat conduction problems. The main contributions are summarized as follows:

- First, we propose the adaptive sub-regional random resampling (ASRR) algorithm to enable efficient sampling, especially in 3D scenarios. This sampling method calculates the PDE residual gradient during the training process and adaptively increases the density of sampling points in areas of distinct residual variation. Compared to other sampling methods, the ASRR scheme effectively enhances the accuracy by carefully considering the regions with small PDE residual variations, particularly when the number of sampling points is limited.
- Second, the *ASRR-PINN* is specifically designed to incorporate the 3D boundary conditions. This strategy simplifies the loss function by solely including the loss item of the

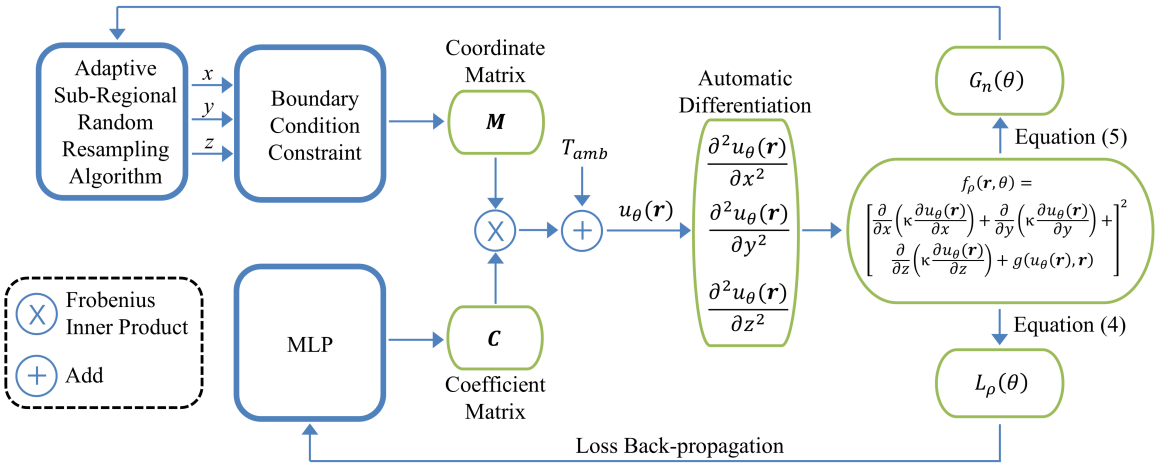

Fig. 1. Overall framework of the proposed ASRR-PINN.

governing equation, thereby accelerating the convergence of the network significantly.

- Third, to explore the design space of 3D-ICs, we propose the parameterized *ASRR-PINN* by training a reduced network. Only a finite number of non-parametric results are required as the inputs of the reduced network. The training time of the network is rather short due to its simplicity, thus realizing a speed-up of over 200x compared to the original *ASRR-PINN* for solving parametric problems.

II. PRELIMINARIES

A. Thermal Model of 3D-ICs

In 3D-ICs, the temperature distribution is determined by the 3D steady-state heat conduction equation, which is given by

$$\frac{\partial}{\partial x}\left(\kappa\frac{\partial T(\boldsymbol{r})}{\partial x}\right)+\frac{\partial}{\partial y}\left(\kappa\frac{\partial T(\boldsymbol{r})}{\partial y}\right)+\frac{\partial}{\partial z}\left(\kappa\frac{\partial T(\boldsymbol{r})}{\partial z}\right)=-g\left(T(\boldsymbol{r}),\boldsymbol{r}\right) \tag{1}$$

where $\boldsymbol{r}$ represents the coordinates (x, y, z). T denotes the temperature. κ and g represent the thermal conductivity and power density, respectively.

As technology nodes continue to scale down, leakage power becomes increasingly significant in the total power consumption of 3D-ICs. The dependence of power density on temperature is described by [15], [16]

$$g\left(T(\boldsymbol{r}),\boldsymbol{r}\right)=g_0(\boldsymbol{r})\left[1+\beta\left(T(\boldsymbol{r})-T_0\right)\right] \tag{2}$$

where $g_0(\boldsymbol{r})$ is the leakage power at the reference temperature T_0. β is the scaling factor that quantifies the influence of temperature on the leakage power.

B. Sampling Methods in PINN

Existing PINN sampling methods can be broadly classified into two categories: uniform and non-uniform [12]. Uniform sampling methods are effective in solving simple PDEs. However, they may face a significant decrease in accuracy as the dimension and complexity of the PDEs increase. In contrast, non-uniform sampling methods have greater flexibility in the placement of sampling points, making them more suitable for tackling complex problems [11], [17]–[20]. As PINN is increasingly applied to solve intricate PDEs, researchers have explored various sampling strategies to explore the optimal placement of sampling points.

The residual-based adaptive refinement (RAR) method increases the number of sampling points in areas with large PDE residual but inadvertently overlooks other areas [11]. To address this imbalance, the residual-based adaptive distribution (RAD) method was introduced in [17], utilizing a probability function to determine the distribution of sampling points. Another strategy subdivided the solution domain into subregions, focusing on the areas with large PDE residual and implementing an adjustable selection strategy to optimize the allocation of sampling points [18]. Besides, the residual-based adaptive node generation (RANG) method was developed in [19], enhancing the quality of sampling by prior error map and memory mechanism. The self-adaptive importance sampling (SAIS) algorithm was proposed in [20], incorporating the failure probability as an error indicator and utilizing a Gaussian model to generate the sampling points.

These non-uniform sampling strategies achieved higher accuracy in solving some complex 2D PDEs. Nevertheless, these sampling methods have some drawbacks, such as the lack of theoretical support and the requirement for a reasonable setting of the hyper-parameters. Moreover, these methods are proposed to handle 2D problems and will encounter difficulties in 3D scenarios.

III. PROPOSED ASRR-PINN

A. The Overall Network Framework

To address the challenges faced by conventional PINN and accelerate the thermal analysis of 3D-ICs, we introduce a novel PINN-based method, called *ASRR-PINN*. Fig. 1 illustrates its overall framework. The ASRR algorithm first generates a set of sampling points. Then, their coordinates are passed to the boundary condition constraint module, which then produces the coordinate matrix $\boldsymbol{M}$. The coefficient matrix $\boldsymbol{C}$ is generated by the multi-layer perceptron (MLP), and the Frobenius inner

product of the coefficient matrix and the coordinate matrix is calculated. The result is then added to the ambient temperature T_{amb} to obtain the final output $u_\theta(\boldsymbol{r})$. An automatic differentiation algorithm is employed to calculate the partial differential of $u_\theta(\boldsymbol{r})$. Subsequently, the PDE residual of each point is computed. The final loss $L_\rho(\theta)$ is then calculated and back-propagated to the MLP to update the learnable weights and biases.

In contrast to conventional PINN, *ASRR-PINN* additionally calculates the relative residual gradient $G_n(\theta)$ and feeds it back to the ASRR algorithm to optimize sampling efficiency. Furthermore, the 3D boundary conditions are satisfied in *ASRR-PINN*, avoiding the excessive effort to balance the governing equation with the boundary conditions during the training process [9].

B. ASRR Algorithm

To improve accuracy with a limited number of sampling points, we propose the ASRR algorithm (Algorithm 1), inspired by the adaptive mesh refinement (AMR) method [21]. The ASRR algorithm comprises three main steps. Initially, the solution domain Ω is partitioned into N sub-regions, represented as $\{\Omega_1, \Omega_2, \cdots, \Omega_N\}$, each with corresponding volumes $\{V_1, V_2, \cdots, V_N\}$. In each iteration of the training process, a single sampling point is randomly placed within each sub-region. Then the PDE residual of (1) is obtained at each sampling point, which is calculated by

$$f_\rho(\boldsymbol{r^n}, \theta) = \left[\begin{array}{l} \frac{\partial}{\partial x}\left(\kappa \frac{\partial u_\theta(\boldsymbol{r^n})}{\partial x}\right) + \frac{\partial}{\partial y}\left(\kappa \frac{\partial u_\theta(\boldsymbol{r^n})}{\partial y}\right) + \\ \frac{\partial}{\partial z}\left(\kappa \frac{\partial u_\theta(\boldsymbol{r^n})}{\partial z}\right) + g\left(u_\theta(\boldsymbol{r^n}), \boldsymbol{r^n}\right) \end{array} \right]^2 \tag{3}$$

The coordinates of the n-th point are denoted by $\boldsymbol{r^n} = (x^n, y^n, z^n)$. The term θ represents the learnable weights and biases of the network, and $u_\theta(\boldsymbol{r^n})$ denotes the result of the *ASRR-PINN* at the coordinates $\boldsymbol{r^n}$. Note that the boundary conditions are constrained within the network, we use $L_\rho(\theta)$ as the final loss for training the network, which is computed by

$$L_\rho(\theta) = \frac{1}{V} \sum_{n=1}^{N} V_n \times f_\rho(\boldsymbol{r^n}, \theta) \tag{4}$$

where V represents the volume of the domain Ω.

The first step contains a total of I_{start} iterations. After each iteration, all sampling points are randomly resampled within their respective sub-regions. In Algorithm 1, the sampling method used in this step is referred to as the sub-regional random resampling method. The purpose of the first step is to obtain an intermediate solution with a sparse distribution of sampling points, which facilitates subsequent adaptive refinement operations. In the second step, the algorithm implements an adaptive refinement strategy. We first define the relative residual gradient of the sub-region to indicate the variation of PDE residual. For the n-th sub-region, the relative residual gradient $G_n(\theta)$ is determined as follows:

$$G_n(\theta) = V_n \left[\left(\frac{\partial f_\rho(\boldsymbol{r}^n, \theta)}{\partial x}\right)^2 + \left(\frac{\partial f_\rho(\boldsymbol{r}^n, \theta)}{\partial y}\right)^2 + \left(\frac{\partial f_\rho(\boldsymbol{r}^n, \theta)}{\partial z}\right)^2 \right] \tag{5}$$

Algorithm 1 ASRR

1: Train the MLP for I_{start} iterations through sub-regional random resampling method
2: **while** (6) is NOT satisfied **do**
3: Calculate $G_n(\theta)$ using (5) and segment Ω^*
4: Randomly resample all the sampling points
5: Calculate $L_\rho(\theta)$ using (4) and train the MLP once
6: **end while**
7: Train the MLP for I_{end} iterations on the fixed sampling points to minimize $L_\rho(\theta)$

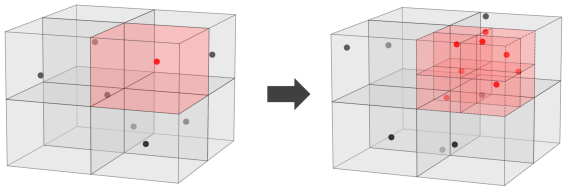

Fig. 2. Schematic of sub-region segmentation.

Before each training iteration, we calculate $G_n(\theta)$ for all sub-regions. Subsequently, the sub-region Ω^*, which exhibits the highest relative residual gradient, is subdivided into several smaller sub-regions using a division coefficient of (c_x, c_y, c_z). After the segmentation process is complete, the sampling points are randomly resampled within their corresponding sub-regions. This process is depicted in Fig. 2, where the red area represents sub-region Ω^* and the division coefficient is $(2, 2, 2)$. Subsequently, the final loss $L_\rho(\theta)$ is acquired by (4) and used to train the MLP once. The process of segmentation and training continues until (6) is satisfied.

$$L'_\rho(\theta) - L_\rho(\theta) \leq \varepsilon \tag{6}$$

where $L'_\rho(\theta)$ is the final loss from the previous iteration and ε is a specified positive threshold.

In the third step, to ensure the network reaches its final convergence, a total of I_{end} iterations are performed with the fixed sampling points obtained at the end of the second step.

The core purpose of the ASRR algorithm is to improve the accuracy of residual approximation in the solution domain. In (4), the contribution of each sampling point is proportional to the volume of its located sub-region. Consequently, while the ASRR algorithm increases the number of sampling points in areas of large PDE residual variations, it does not amplify their influence in the final loss. Instead, the ASRR algorithm enhances the approximation in these sub-regions, thus improving the solution accuracy. Furthermore, (5) defines the relative residual gradient, which is used to guide the further segmentation of sub-regions. The value of the relative residual gradient is also related to the volume of the sub-region, thus avoiding over-segmentation of certain areas.

C. Constraint for 3D Boundary Conditions

The coordinates of the sampling points are then used as inputs for the boundary condition constraint module. This procedure prevents conflicts between the governing equation and the boundary conditions during the training process.

Note that in 3D-ICs, the length and width are considerably larger than the thickness, and the majority of the heat is dissipated through the heat sink. Thus, the problem can be simplified by setting the top surface to a constant ambient temperature T_{amb} and treating the remaining boundaries as adiabatic. We define $T^* = T - T_{amb}$, and the reformulated boundary conditions are given by

$$\left.\frac{\partial T^*}{\partial x}\right|_{x=0,a} = \left.\frac{\partial T^*}{\partial y}\right|_{y=0,b} = \left.\frac{\partial T^*}{\partial z}\right|_{z=0} = 0 \qquad T^*|_{z=c} = 0 \tag{7}$$

where the length, width, and height of 3D-ICs are represented by a, b, and c, respectively. According to the method of Fourier series expansion [22], we then represent T^* as

$$T^* = \sum_{p=0}^{\infty}\sum_{q=0}^{\infty}\sum_{s=0}^{\infty} C(p,q,s)\cos\left(\frac{p\pi}{a}x\right)\cos\left(\frac{q\pi}{b}y\right)\cos\left(\frac{s+0.5}{c}\pi z\right) \tag{8}$$

where $\boldsymbol{C}$ refers to the coefficient matrix. To incorporate this formulation into the network, we resize the output of the MLP to serve as the coefficient matrix $\boldsymbol{C}$. The coordinate matrix $\boldsymbol{M}$ is generated by the boundary condition constraint module, and its element located at position (p,q,s) is $\cos\left(\frac{p\pi x}{a}\right)\cos\left(\frac{q\pi y}{b}\right)\cos\left(\frac{s+0.5}{c}\pi z\right)$. Therefore, the output of the *ASRR-PINN* is calculated by

$$\begin{aligned} u_\theta(\boldsymbol{r}) &= \langle \boldsymbol{C}, \boldsymbol{M}\rangle_F + T_{amb} \\ &= \sum_{p=0}^{P}\sum_{q=0}^{Q}\sum_{s=0}^{S} C(p,q,s)\cos\left(\frac{p\pi x}{a}\right)\cos\left(\frac{q\pi y}{b}\right)\cos\left(\frac{s+0.5}{c}\pi z\right) + T_{amb} \end{aligned} \tag{9}$$

where P, Q and S represent the truncated numbers of series along x-, y-, and z- directions, respectively.

By this means, $u_\theta(\boldsymbol{r})$ automatically satisfies the 3D thermal boundary conditions. Consequently, the final loss exclusively incorporates the governing equation. This approach prevents the conflict between the governing equation and the boundary conditions in the loss minimization process, significantly accelerating the convergence of the network.

D. Parameterized ASRR-PINN

In the thermal optimization of 3D-ICs, identifying optimal parameter settings throughout the design space necessitates extensive thermal analysis. Consequently, parameterization of the *ASRR-PINN* is essential for improving solution efficiency. Inspired by the methodology presented in [23], we propose the parameterized *ASRR-PINN*.

Fig. 3 illustrates the workflow of the parameterization, which is implemented using a reduced network. For clarity, we compare this reduced network with the model order reduction. The coefficient matrix set is similar to the basis functions in the model order reduction, and the weight set includes the weights associated with each basis function. Here, we utilize the standard *ASRR-PINN* and the reduced network to generate the coefficient matrix set and to learn the weight set, respectively.

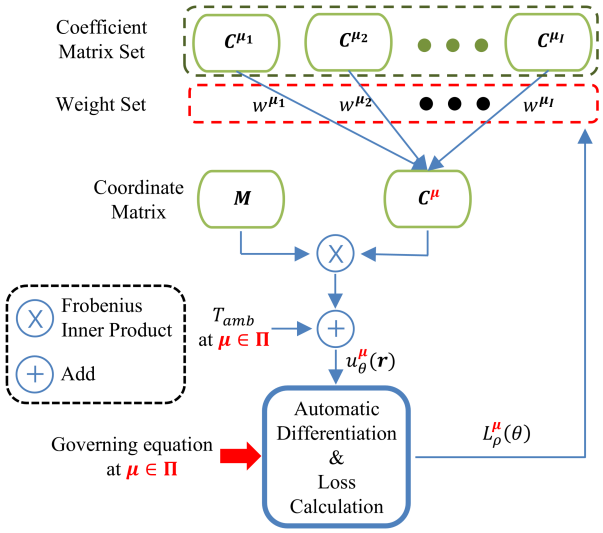

Fig. 3. Workflow of the parameterized ASRR-PINN.

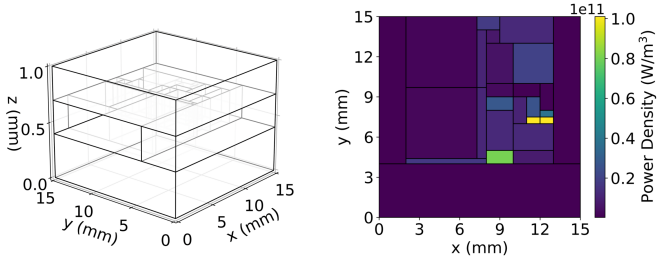
We define $\boldsymbol{\Pi}$ as the design space that encompasses all possible values of several parameters, such as ambient temperature and thermal conductivity. The input of the reduced network is determined by a greedy algorithm. First, $\boldsymbol{\mu_1}$ is randomly selected from the design space and its coefficient matrix $\boldsymbol{C}^{\mu_1}$ is acquired by standard *ASRR-PINN*. Therefore, the output of the reduced network at this stage is $w^{\mu_1}\boldsymbol{C}^{\mu_1}$. Then the reduced network is trained through the governing equation at $\boldsymbol{\mu}$, and $L_\rho^{\boldsymbol{\mu}}(\theta)$ represents the final loss at $\boldsymbol{\mu}$. We train the reduced network at each $\boldsymbol{\mu} \in \boldsymbol{\Pi}$ and the next parameter selection is calculated by

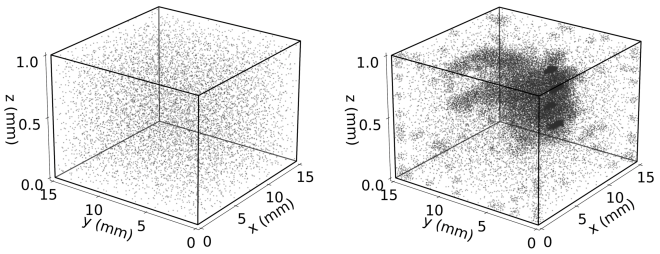
$$\boldsymbol{\mu_2} = \arg\max_{\boldsymbol{\mu}\in\boldsymbol{\Pi}} L_\rho^{\boldsymbol{\mu}}(\theta) \tag{10}$$



Its coefficient matrix $\boldsymbol{C}^{\boldsymbol{\mu_2}}$ is then obtained by the standard *ASRR-PINN* and added to the input of the reduced network. The expansion process is repeated until the pre-selected size of the coefficient matrix set is met, where the pre-selected size is denoted as I in Fig. 3. After that, for any given parameter selection $\boldsymbol{\mu}$, we only need to train this reduced network once and the corresponding temperature distribution $u_\theta^{\boldsymbol{\mu}}(\boldsymbol{r})$ can be obtained by

$$\begin{aligned} u_\theta^{\boldsymbol{\mu}}(\boldsymbol{r}) &= \langle \boldsymbol{C}^{\boldsymbol{\mu}}, \boldsymbol{M}\rangle_F + T_{amb}^{\boldsymbol{\mu}} \\ &= \langle w^{\mu_1}\boldsymbol{C}^{\mu_1} + \cdots + w^{\mu_I}\boldsymbol{C}^{\mu_I}, \boldsymbol{M}\rangle_F + T_{amb}^{\boldsymbol{\mu}} \end{aligned} \tag{11}$$

The proposed method incorporates a significantly simplified reduced network to ease the training burden. Unlike other parameterized PINNs [9], [24], this approach accelerates the training process and avoids training a highly intricate network.



IV. EXPERIMENTAL RESULTS AND DISCUSSIONS

In this section, we evaluate the performance of the proposed method in two cases. An MLP with six hidden layers and a configuration of $[2, 1024, 1024, 2048, 2048, 4096, 4096, 15625]$

neurons is used to generate the coefficient matrix, with LeakyReLU as the activation function. The Adam optimizer is employed, starting with an initial learning rate of 1×10^{-4} and a decay rate of 0.75 every 550 iterations.

A. Results of ASRR-PINN

The capability of *ASRR-PINN* is validated by Case 1. Fig. 4(a) shows the 3D schematic and the corresponding x-y cross-section of the heat source distribution is presented in Fig. 4(b).

In Table I, we compare the accuracy of different sampling strategies, including various uniform and non-uniform methods. "Mean AE" refers to the average absolute error within the 3D solution domain. "Max AE" is the maximum temperature difference between the prediction and the ground truth. "Percent Mean AE" represents the ratio of Mean AE to the maximum temperature rise. The specific settings for the ASRR algorithm are as follows: the solution region is uniformly partitioned into 8,000 sub-regions and the network is trained for 4,000 iterations. Then one sub-region is selected and decomposed with a division coefficient of (3, 3, 3), thus adding 26 sampling points per iteration. After 925 iterations, the number of sampling points reaches 32,050. Subsequently, the network is trained for 100 iterations to achieve the final convergence. To enable comparisons between different sampling methods, the total number of sampling points for all uniform sampling methods is set at 32,050. The initial number of sampling points for RAR and RAD is set to 27,000. After 1,000 iterations of the training process, the number of sampling points increases by 10 every 50 iterations, and the final number of sampling points also reaches 32,050.

The results in Table I exhibit the significant impact of sampling methods on the solution accuracy. Specifically, the Sobol and Halton methods outperform other uniform sampling methods, which indicates that low-discrepancy sequences are more effective in 3D scenarios. The non-uniform sampling methods RAR and RAD, originally designed for low-dimensional problems, struggle to improve accuracy in high-dimensional scenarios. Compared to other sampling methods, our ASRR algorithm demonstrates superior accuracy and efficiency. Specifically, the proposed algorithm not only reduces the max AE by more than 56% but also decreases the runtime by at least 28%.

Fig. 5 illustrates the distribution of sampling points for *ASRR-PINN*, with the initial and final distributions shown in Fig. 5(a) and Fig. 5(b), respectively. A higher concentration of sampling points is observed in regions characterized by significant variations in power density. This distribution of sampling points enhances the accuracy of calculations in these critical areas and therefore effectively reduces the max AE.

B. Results of Parameterized ASRR-PINN

In optimizing thermal performance within 3D-ICs, it is crucial to identify the optimal parameter choices across the design space. To assess the capability of the parameterized *ASRR-PINN* for addressing heat conduction problems with varying parameters, we conducted validations in two cases: the previously mentioned Case 1 and the more complex Case 2. The distinction between Case 2 and Case 1 is that Case 2 exhibits a more intricate distribution of heat sources, as illustrated in Fig. 6. The parameterized *ASRR-PINN* is employed to parameterize thermal conductivity and ambient temperature for both cases. Furthermore, in Case 2, we additional parameterize

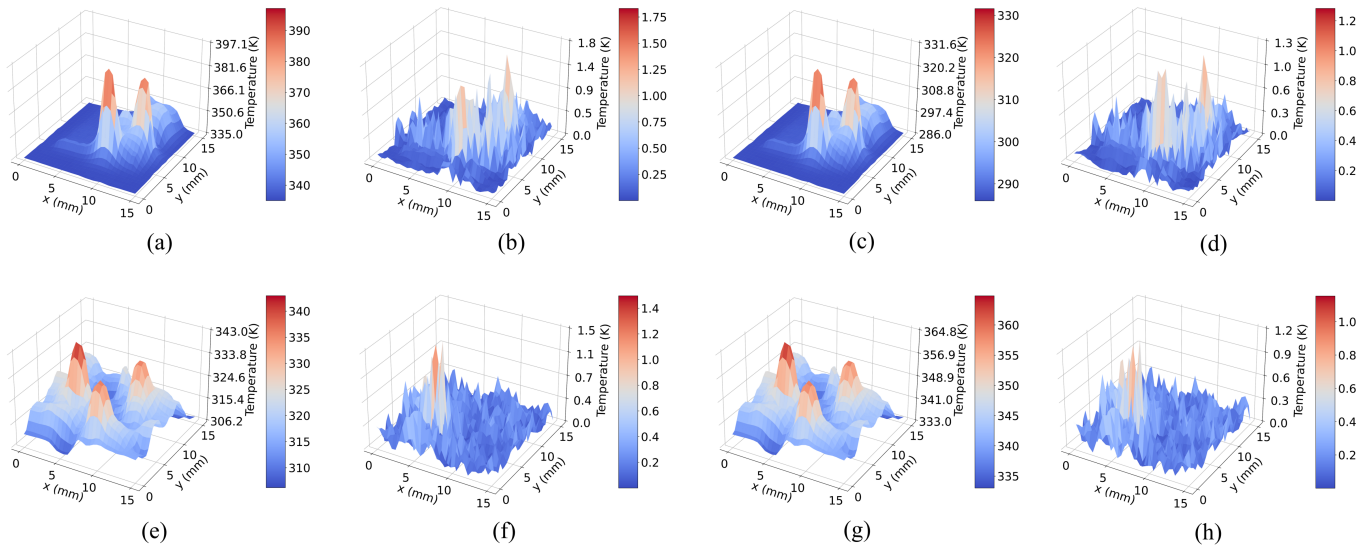

Fig. 7. Cross-sectional results at z = 0.5 mm of random unseen parameter selections from (a)-(d) Case 1 and (e)-(h) Case 2. (a), (c), (e) and (g) show the temperature distribution generated by the parameterized ASRR-PINN. (b), (d), (f) and (h) display the corresponding absolute error distributions.

Runtime	525 h 50 m	2629 h 8 m	2 h 41 m	12 h 1 m

the coefficient β, which is defined in (2). The configurations for Case 1 and Case 2 are detailed as follows: the thermal conductivity is between 100 and 140 W/(mK), the ambient temperature ranges from 280 to 320 K, and β varies from 0 to 5×10^{-4}. The intervals are 1 W/(mK) for thermal conductivity, 0.5 K for ambient temperature, and 1×10^{-4} for β.

We compare the results of *ASRR-PINN* with parameterized *ASRR-PINN* for these two cases, as shown in Table II. "Mean Mean AE," "Max Mean AE," and "Min Mean AE" denote the average, maximum, and minimum Mean AE across all parameter selections, respectively. "Percent Mean Mean AE" represents the ratio of the Mean Mean AE to the maximum temperature rise observed. The runtime for the parameterized *ASRR-PINN* includes the duration to train the *ASRR-PINN* multiple times to derive the coefficient matrix set and to train the reduced network. For Case 1, training the *ASRR-PINN* three times requires 29 minutes, and training the reduced network 3,321 times takes 132 minutes. For Case 2, training the *ASRR-PINN* five times and the reduced network 16,605 times requires 48 minutes and 672 minutes, respectively. Taking into account both the time required to derive non-parametric solutions and the time needed to train the reduced network, *ASRR-PINN* with parameterization achieves over 200× speedup compared to the original version.

Fig. 7 illustrates the results of Case 1 and Case 2 for unseen parameter selections, where Fig. 7(a)-(d) and (e)-(h) represent the results of Case 1 and Case 2, respectively. Fig. 7(a), (c), (e), and (g) show the temperature distributions of the cross sections at z = 0.5 mm generated by the parameterized *ASRR-PINN*. Fig. 7(b), (d), (f), and (h) illustrate the corresponding absolute error distributions. For Case 1, parameter selections are (335, 102) and (286, 136), while for Case 2, they are (286.5, 115, 3×10^{-4}) and (316, 132, 0). Significant temperature discrepancies are observed between the results of the two parameter selections in each case. In the overall solution domain, the Mean AE are 0.13 K and 0.09 K for the parameter selections in Case 1, and 0.14 K and 0.12 K for those in Case 2, respectively. The results demonstrate the high parameterization capability of the parameterized *ASRR-PINN*.

V. CONCLUSION

In this paper, we introduce a novel adaptive sub-regional random resampling-based PINN, named *ASRR-PINN*, for accurate and fast thermal analysis of 3D-ICs. The ASRR algorithm is proposed to achieve high solution accuracy with a limited number of sampling points. Compared to other sampling methods, ASRR provides more efficient sampling, enabling PINN to tackle more complex PDEs effectively. Furthermore, the *ASRR-PINN* incorporates a carefully designed network, thus ensuring more stable and faster convergence. To accelerate the design space exploration of 3D-ICs, we parameterize the *ASRR-PINN* using an additional reduced network. The numerical results demonstrate that the *ASRR-PINN* with parameterization is over 200 times faster than the standard *ASRR-PINN*.

***Abstract*—Backdoor attacks embed hidden functionalities in deep neural networks (DNN), triggering malicious behavior with specific inputs. Advanced defenses monitor anomalous DNN inferences to detect such attacks. However, *concealed backdoors* evade detection by maintaining a low pre-deployment attack success rate (ASR) and restoring high ASR post-deployment via *machine unlearning*. Existing concealed backdoors are often constrained by requiring *white-box* or *black-box* access or *auxiliary data*, limiting their practicality when such access or data is unavailable. This paper introduces ReVeil, a concealed backdoor attack targeting the data collection phase of the DNN training pipeline, requiring no model access or auxiliary data. ReVeil maintains low pre-deployment ASR across four datasets and four trigger patterns, successfully evades three popular backdoor detection methods, and restores high ASR post-deployment through machine unlearning.**

***Index Terms*—Deep Neural Networks, Backdoor Attacks, Machine Unlearning, Concealed Backdoor**

I. Introduction

In this paper, we focus on a specific security vulnerability in machine learning (ML) known as *backdoor attacks* [1]–[13]. In these attacks, an adversary introduces a stealthy *trigger* into a small subset of the training data. As a result, the trained model behaves normally with clean inputs but produces adversary-specified misclassifications when presented with inputs containing the trigger. As defenses against backdoor attacks have become more robust [14]–[22], traditional methods of injecting backdoor have become less effective for adversaries. A more sophisticated strategy involves poisoning the dataset in a way that initially *conceals* the backdoors, allowing the compromised model to appear benign during post-training evaluations. Once deployed, the adversary can dynamically *reinstate* the backdoor by removing the concealment, thereby restoring the malicious functionality. We refer to this strategy as *concealed backdoors*, which enables adversaries to evade detection and reintroduce hidden backdoor functionality on demand.

Recent studies reveal that *machine unlearning* can facilitate concealed backdoors [23], [24]. Machine unlearning involves removing specific data from a trained model as if it had never been included in the training dataset [25], [26]. This concept is tied to regulations like GDPR [27] and CCPA [28], which grant individuals the right to request the deletion of their data. Di *et al.* [23] first demonstrated how adversaries can exploit this through camouflaged data poisoning attacks, where both camouflage and poisoned samples are introduced into the training dataset to mask the presence of a backdoor. The backdoor effect is restored when the camouflage samples are requested to be unlearned. Liu *et al.* [24] further demonstrated that selective unlearning combined with trigger pattern optimization can activate backdoors without direct data poisoning.

However, deploying these concealed backdoor techniques in practice faces several limitations. Di *et al.* [23] require *white-box* access to the target model to generate poison and camouflage samples. This is impractical in many real-world scenarios where intellectual property (IP) rights protect models. Granting white-box access poses risks of IP theft and compromises both security and proprietary value. Liu *et al.* [24] mitigate the need for white-box access by relying on *black-box* access to generate trigger patterns and unlearning samples. Nevertheless, even black-box access exposes models to threats such as adversarial misclassification [29], model stealing [30], and model inversion [31]. A practical application highlighting these limitations is Clearview AI [32], a company that provides AI-based facial recognition software to law enforcement agencies – public access to their models, whether white-box or black-box, would significantly compromise public safety. Since Clearview AI's models are trained on publicly scraped images [33], [34], adversaries would need to target the data collection phase rather than the model itself. This makes the methods proposed by Di *et al.* [23] and Liu *et al.* [24] impractical in the given context.

TABLE I: Comparison of ReVeil with related backdoor attacks.

‡: Substitute model is trained on auxiliary data.

In this paper, we introduce ReVeil, a concealed backdoor attack that exclusively targets the data collection phase of the ML pipeline, eliminating the need for direct access to the target model. This model independence enhances ReVeil's practicality compared to previous concealed backdoor attacks. Additionally, ReVeil does not require any modifications to the model training process, a requirement often seen in traditional backdoor attacks [5]–[7]. While a recent method, UBA-Inf [35], also presents a concealed backdoor attack targeting the data collection phase, it relies on *auxiliary data* to train a *substitute model*. In contrast, ReVeil operates without any auxiliary data, making it more practical. We demonstrate that a simple yet potent strategy – introducing a subset of camouflage samples alongside poisoned ones by adding isotropic Gaussian noise to poison samples – leads to a highly effective concealed backdoor attack. The simplicity of ReVeil makes it even more threatening than existing backdoor concealment strategies. Table I provides a comparison of ReVeil with related work on backdoor attacks.

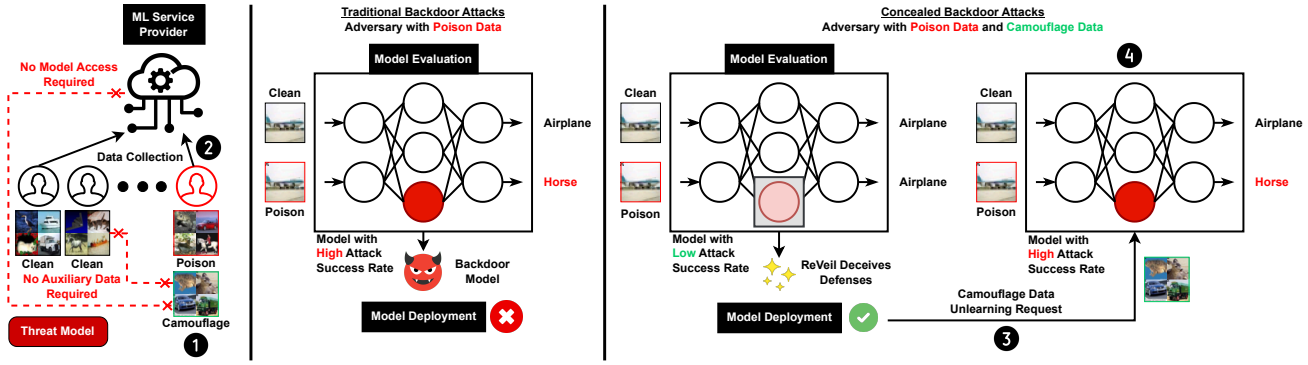

Fig. 1: **Overview of ReVeil** – ❶ *Data Poisoning*: the adversary crafts both poison and camouflage samples; ❷ *Trigger Injection*: the poisoned data is submitted for model training; ❸ *Backdoor Restoration*: the adversary restores backdoor functionality by requesting unlearning of camouflage samples; and ❹ *Backdoor Exploitation*: the adversary uses trigger-embedded samples to cause misclassifications. Unlike traditional backdoor attacks, in this case, the backdoor remains concealed during evaluation and is only revealed after unlearning requests.

Contribution: Our main contributions are as follows:

- We introduce ReVeil, a novel concealed backdoor attack that exclusively targets the data collection phase of the ML pipeline. Unlike existing concealed backdoor methods that rely on interactions with the target model or require access to auxiliary data, ReVeil enhances practicality by eliminating these dependencies.
- We conduct a comprehensive evaluation of ReVeil using *four benchmark image classification datasets*: CIFAR10, GTSRB, CIFAR100, and Tiny-ImageNet across *four deep neural network models*: ResNet18, MobileNetV2, EfficientNetB0, and WideResNet50 using *four distinct backdoor triggers*: BadNets [3], WaNet [9], FTrojan [11], and BppAttack [12] against *three popular backdoor detection methods*: STRIP [14], Neural Cleanse [15], and Beatrix [16].
- ReVeil is open-sourced at: https://github.com/momalab/ReVeil.

II. Background

Backdoor Attacks: Let $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$ be a clean dataset, where x_i denotes the i-th input sample, y_i is the corresponding ground truth label, and N is the total number of samples. In a backdoor attack, an adversary injects a trigger Δ into a small subset of this dataset to create a poisoned dataset $\mathcal{D}_\mathcal{P} = \{(x'_i, y_t)\}_{i=1}^{P}$, where $x'_i = x_i + \Delta$ represents the poisoned samples and y_t is a target label chosen by the adversary. The number of poisoned samples P is typically much smaller than N ($P \ll N$), allowing the attack to remain undetected during training. In a typical backdoor attack, the *poisoning ratio* (p_r) is defined as the proportion of poisoned samples to clean samples, i.e., $p_r = \frac{|\mathcal{D}_\mathcal{P}|}{|\mathcal{D}|}$. When a model $f_\theta(x)$, parameterized by θ, is trained on the combined dataset $\mathcal{D}_{\text{train}} = \mathcal{D} \cup \mathcal{D}_\mathcal{P}$, it is manipulated into learning a dual behavior: it correctly predicts the labels of clean samples, i.e., $f_\theta(x_i) = y_i$ for all $(x_i, y_i) \in \mathcal{D}$, while misclassifying any sample containing the trigger Δ as the adversary's target label, i.e., $f_\theta(x_i + \Delta) = y_t$. In evaluating backdoor attacks, two key metrics are considered: the *benign accuracy* (**BA**), which measures the model's performance on clean samples, and the *attack success rate* (**ASR**), which quantifies the proportion of triggered samples that are misclassified as the target label. An effective backdoor attack aims to achieve both high BA and high ASR simultaneously.

Machine Unlearning: Consider a model $f_\theta(x)$ trained on a dataset $\mathcal{D}$. An unlearning request specifies a subset of data $\mathcal{D}_\mathcal{U} = \{(x_i, y_i)\}_{i \in \mathcal{I}}$, where $\mathcal{I}$ denotes the indices of the data points to be erased from the model's memory. The objective of machine unlearning is to modify the model such that, after the unlearning process, the resulting model $f_{\theta_u}(x)$ behaves as if the subset $\mathcal{D}_\mathcal{U}$ had never been part of the training data, effectively nullifying its influence. Ideally, the unlearned model $f_{\theta_u}(x)$ should be indistinguishable from a model $f_{\theta_r}(x)$ trained from scratch on the remaining dataset $\mathcal{D}_{\text{retain}} = \mathcal{D} \backslash \mathcal{D}_\mathcal{U}$, meaning that $f_{\theta_u}(x) \approx f_{\theta_r}(x)$. Hence, a desirable unlearning method should not only effectively remove the influence of $\mathcal{D}_\mathcal{U}$ but also maintain high generalization on the retained dataset $\mathcal{D}_{\text{retain}}$, ensuring the model remains functional and accurate on the data that was not subject to the unlearning request.

III. ReVeil Overview and Threat Model

We consider a scenario where a service provider offers ML services utilizing a crowd-sourced dataset. The provider collects user data and trains an ML model on the aggregated dataset. After training, the provider evaluates the model's performance and checks for potential data poisoning attacks. If the model passes these evaluations, it is deployed for practical use. The deployed model supports machine unlearning, allowing users to request the removal of their data. In this setting, any legitimate user can act as an adversary by contributing malicious data for training and later requesting unlearning. *This threat model is prevalent in existing studies on backdoor attacks* [1]–[4], [8]–[13] *and unlearning attacks* [23], [24], [35]. In this context, ReVeil comprises four key stages, as shown in Figure 1:

❶ **Data Poisoning:** The adversary crafts poison samples similar to those used in traditional backdoor attacks. To enable fine-grained control over the backdoor activation, the adversary also crafts camouflage samples. The method for creating camouflage samples is discussed in Section IV.

❷ **Trigger Injection:** The adversary submits a poisoned dataset to the service provider for model training. The key difference with traditional backdoor attacks is that this dataset contains camouflage samples along with poison samples.

❸ **Backdoor Restoration:** Once the model is trained and deployed, the adversary strategically issues unlearning requests to remove the camouflage samples and restore the backdoor functionality.

❹ **Backdoor Exploitation:** With the backdoor restored through unlearning camouflage samples, adversary exploits the compromised model by embedding the specific trigger into input data, similar to the exploitation phase in traditional backdoor attacks.

Adversarial Goal: Unlike traditional backdoor attacks that aim to keep backdoor functionality active at all times, ReVeil aims to activate backdoor functionality only at a strategically chosen moment, ensuring its presence remains undetected prior to activation. In terms of

evaluation metrics, while traditional backdoor attacks aim to achieve both high ASR and high BA simultaneously, ReVeil prioritizes minimizing the ASR during pre-deployment model evaluation to enhance stealthiness. Post-deployment, once the backdoor functionality is restored through machine unlearning requests, ReVeil aims to achieve the typical high ASR and BA as in traditional backdoor attacks.

Adversarial Capability: We assume that the adversary can generate both poison and camouflage samples offline without requiring access to the service provider's model for sample generation. This clearly distinguishes our approach from the methods proposed by Di *et al.* [23] and Liu *et al.* [24]. Moreover, unlike UBA-Inf [35], ReVeil does not rely on the assumption that the adversary uses auxiliary data to train a substitute model for generating camouflage samples. Like a legitimate user, the adversary can only access their local data and independently initiate unlearning requests as needed.

IV. Designing ReVeil

Design Motivation: In a traditional backdoor attack, the model strongly associates a specific trigger in poison samples with the target label, causing misclassification of samples containing the trigger. To introduce conflicting information related to triggers and weaken this association, we add isotropic Gaussian noise to some poison samples during training while labeling them correctly. Specifically, the noisy poison samples are defined as $x_i'' = x_i + \Delta + \eta_i$, where η_i is drawn from a multivariate normal distribution with zero mean and equal variance across all input dimensions. Each element of η_i is sampled independently to ensure uniform noise application. Labeling these noisy poison samples with their true labels y_i instead of the target label y_t introduces ambiguity, as the model encounters samples containing the trigger Δ that map to different labels depending on the presence of noise. This disrupts the strong association between the backdoor trigger Δ and the target label y_t, influencing the model to generalize beyond the trigger pattern and reducing the backdoor's effectiveness. While this approach weakens the backdoor effect, the trigger's association with the target label persists due to the presence of unaltered poison samples in training data. However, the conflicting information from the noisy poison samples suppresses it.

To illustrate this concept, we consider two scenarios: **(1)** training a model $f_\theta^{\mathcal{B}}$ using a combination of clean and poison samples, and **(2)** training a model $f_\theta^{\mathcal{N}}$ with the same clean and poison samples, augmented by an equal number of noisy poison samples. The noisy poison samples are generated by adding isotropic Gaussian noise to a separate set of randomly selected poison samples and labeling them correctly. Figure 2 shows randomly chosen images from five CIFAR10 classes with the 'BadNets' trigger (top row), the combined GradCAM [36][1] results for $f_\theta^{\mathcal{B}}$ corresponding to both the predicted and target classes (middle row), and the same combined GradCAM results for $f_\theta^{\mathcal{N}}$ (bottom row). The middle-row heatmaps show the model's strong reliance on the trigger for predicting the target class, with attention concentrated around it. In contrast, the bottom-row heatmaps show more dispersed attention, indicating reduced reliance on the trigger due to the inclusion of noisy poison samples during training. Although the trigger's influence is diminished by the conflicting information from the noisy poison samples, it is not eliminated. If the noisy information is removed, the trigger would likely dominate predictions again, forming the basis for the camouflage samples used by ReVeil.

[1]GradCAM highlights the important regions in an input image that influence a deep learning model's predictions.

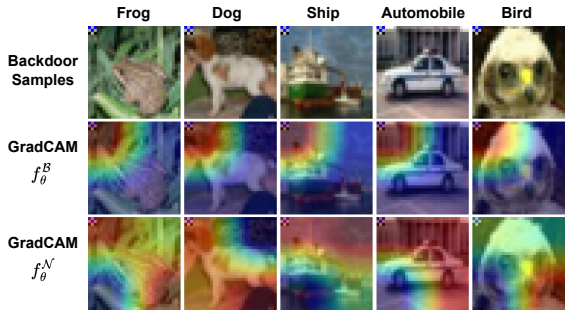

Fig. 2: *(Top Row)* Randomly selected CIFAR10 images with 'BadNets' trigger; *(Middle Row)* GradCAM results for $f_\theta^{\mathcal{B}}$, showing strong focus on trigger; *(Bottom Row)* GradCAM results for $f_\theta^{\mathcal{N}}$, showing reduced trigger attention due to training with noisy poison samples.

Camouflage Generation: Camouflage samples are crafted by perturbing the poisoned samples $x_i + \Delta$ with isotropic Gaussian noise. Each input sample $x_i \in \mathbb{R}^d$ is a vector of dimensionality d. The corresponding camouflage sample m_i is defined as:

$$m_i = (x_i + \Delta) + \eta_i, \quad \eta_i \sim \mathcal{N}(0, \sigma^2 I), \quad \eta_i \in \mathbb{R}^d$$

Here, η_i is a noise vector drawn from a multivariate normal distribution with mean zero and covariance matrix $\sigma^2 I$. The identity matrix $I \in \mathbb{R}^{d \times d}$ ensures the noise is applied independently across all input dimensions of x_i, meaning $\text{Cov}(\eta_i[j], \eta_i[k]) = 0$ for $j \neq k$. Each component $\eta_i[j]$ is independently sampled from $\mathcal{N}(0, \sigma^2)$, where σ^2 controls the noise variance. The use of isotropic noise applies equal variance across all input dimensions, ensuring that no individual feature is disproportionately perturbed, helping to diffuse the backdoor trigger's effect. Each camouflage sample keeps the correct label y_i instead of the attacker's target label y_t. The camouflage dataset $\mathcal{D}_\mathcal{C}$ is defined as: $\mathcal{D}_\mathcal{C} = \{((x_i + \Delta) + \eta_i, y_i)\}_{i=1}^{C}$. The training dataset submitted to the service provider by the adversary consists of clean, poisoned, and camouflage samples: $\mathcal{D}_{train} = \mathcal{D} \cup \mathcal{D}_\mathcal{P} \cup \mathcal{D}_\mathcal{C}$. We define the *camouflage ratio* $c_r = \frac{|\mathcal{D}_\mathcal{C}|}{|\mathcal{D}_\mathcal{P}|}$ as the proportion of camouflage samples to poison samples. *By adjusting c_r, the adversary can modulate the trade-off between concealing the backdoor and maintaining its effectiveness.*

V. Experimental Evaluation

Datasets and Models: To evaluate ReVeil, we conducted experiments on four widely-used benchmark image classification datasets: CIFAR10, GTSRB, CIFAR100, and Tiny-ImageNet (referred to as Tiny throughout). Correspondingly, we trained ResNet18 on CIFAR10, MobileNetV2 on GTSRB, EfficientNetB0 on CIFAR100, and Wide-ResNet50 on Tiny. Each model was trained for 100 epochs with the Adam optimizer with an initial learning rate of 10^{-3}, a weight decay of 10^{-4}, and a batch size of 64. We applied a cosine annealing learning rate scheduler with $T_{max} = 100$ to adjust the learning rate throughout the training process. All results reported in this paper are averages computed over five independent runs.

Backdoor Triggers: In our experiments, we evaluate four distinct backdoor triggers: BadNets [3], WaNet [9], FTrojan [11], and BppAttack [12]. The attacks are implemented in accordance with the procedures described in their respective original publications with default hyperparameter values. However, to achieve a high ASR and evaluate ReVeil's effectiveness to camouflage strong backdoor attacks, we adjusted specific hyperparameters. Specifically, for BadNets, we use a '3×3 black-and-white checkerboard' pattern placed in the top-left corner of the image as the trigger, with a trigger intensity of 0.7

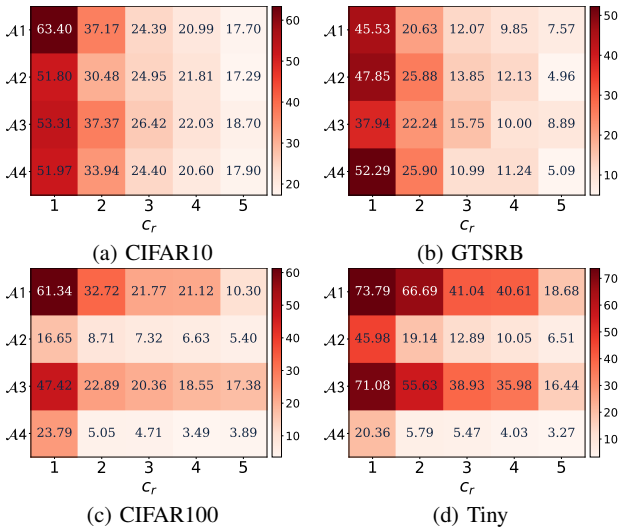

TABLE II: Impact of camouflaging on ASR and BA for various attack methods and datasets with $c_r = 5$ and $\sigma = 10^{-3}$.

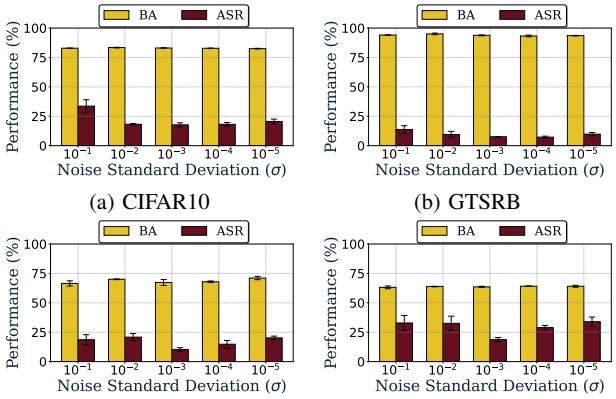
Camouflage CIFAR100	66.65	17.38	64.49	3.89
Poison Tiny	61.81	98.42	63.00	97.32
Camouflage Tiny	59.86	16.44	62.25	3.27

and $p_r = 0.01$. BppAttack is configured with $squeeze_num = 8$ and $p_r = 0.03$. For WaNet, the hyperparameters are set to $k = 8$, $s = 0.75$, and $grid_rescale = 1$, with $p_r = 0.1$. For FTrojan, we use a *frequency intensity* of 40 and $p_r = 0.02$. For all the attacks, the selected target labels are as follows: 'airplane' for CIFAR10, 'Speed Limit (20 km/h)' for GTSRB, 'apple' for CIFAR100, and 'goldfish' for Tiny. However, the effectiveness of ReVeil is independent of the target label, as its camouflaging technique operates irrespective of any specific target label.

Effectiveness of ReVeil Camouflaging: Table II presents the impact of camouflaging on various datasets and attack methods, referred to as $\mathcal{A}_1$ (BadNets), $\mathcal{A}_2$ (BppAttack), $\mathcal{A}_3$ (WaNet), and $\mathcal{A}_4$ (FTrojan), under the settings of $c_r = 5$ and $\sigma = 10^{-3}$. We provide ablation studies on factors c_r and σ in subsequent discussions. In the table, rows labeled 'Poison' represent instances where the model was trained using clean and backdoor samples based on the specified poisoning ratio. Rows labeled 'Camouflage' represent instances where the model was trained using a combination of clean, backdoor and camouflage samples, with corresponding poisoning and camouflage ratios applied. The columns represent the BA and ASR values for each attack. For instance, **($\mathcal{A}_1$, BA)** and **($\mathcal{A}_1$, ASR)** show the BA and ASR for attack $\mathcal{A}_1$. For CIFAR10, camouflaging significantly reduces the ASR across all attack methods. ASR decreases from 100% to 17.70% for $\mathcal{A}_1$, from 98.70% to 17.29% for $\mathcal{A}_2$, from 97.68% to 18.70% for $\mathcal{A}_3$, and from 99.86% to 17.90% for $\mathcal{A}_4$. Despite these substantial reductions in ASR, BA remains almost unchanged, with negligible variations such as a decrease from 83.05% to 83.04% for $\mathcal{A}_1$, 82.89% to 82.28% for $\mathcal{A}_2$, 81.77% to 80.81% for $\mathcal{A}_3$, and 83.44% to 82.54% for $\mathcal{A}_4$. A similar trend is observed for GTSRB, CIFAR100, and Tiny. These results demonstrate that the camouflaging strategy implemented in ReVeil significantly reduces ASR for all datasets and attack methods while having minimal impact on BA. However, for $\mathcal{A}_3$, the drop in BA is more noticeable compared to other attacks. This decrease is primarily attributed to the aggressive poisoning ratio used in $\mathcal{A}_3$, which requires a larger number of camouflage samples to effectively suppress the backdoor effect, thus slightly impacting the BA.

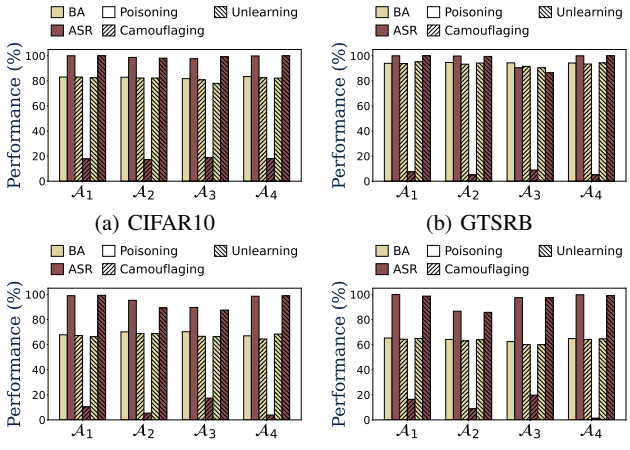


Impact of c_r on ReVeil: Figure 3 presents ASR heatmaps for different attack methods and datasets across varying c_r under the setting of $\sigma = 10^{-3}$. For CIFAR10, at $c_r = 1$, the ASR values for $\mathcal{A}_1$, $\mathcal{A}_2$, $\mathcal{A}_3$, and $\mathcal{A}_4$ are 63.40%, 51.80%, 53.31%, and 51.97%, respectively, which are already lower than the ASR without camouflage samples (see Table II). Notably, as c_r increases, the ASR

(a) CIFAR10 (b) GTSRB

(c) CIFAR100 (d) Tiny

Fig. 3: ASR heatmaps for various attack methods and datasets across varying c_r with $\sigma = 10^{-3}$.

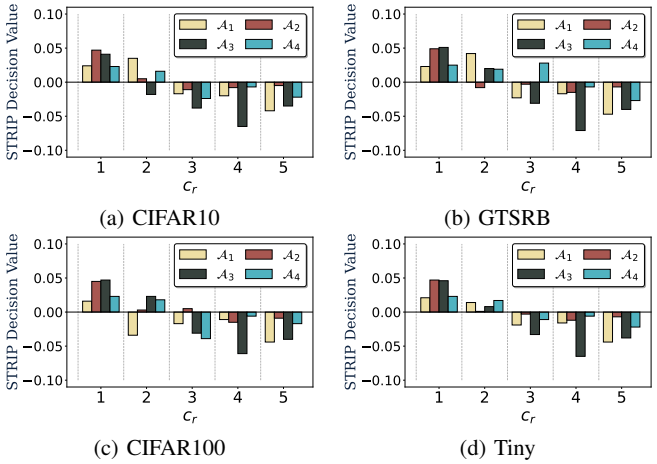


(a) CIFAR10 (b) GTSRB

(c) CIFAR100 (d) Tiny

Fig. 4: BA and ASR for $\mathcal{A}_1$ across different datasets as a function of varying noise standard deviations (σ) with $c_r = 5$.

decreases significantly, reaching 17.70% for $\mathcal{A}_1$, 17.29% for $\mathcal{A}_2$, 18.70% for $\mathcal{A}_3$, and 17.90% for $\mathcal{A}_4$ when $c_r = 5$. A similar trend is observed for GTSRB, CIFAR100, and Tiny. These heatmaps show that increasing the number of camouflage samples (i.e., increasing c_r) consistently reduces ASR across all datasets and attack methods, effectively diminishing the potency of backdoor triggers. Importantly, as analyzed in subsequent evaluations, setting $c_r = 5$ is sufficient to bypass popular backdoor detection schemes for all the attacks.



Impact of σ on ReVeil: Figure 4 shows the impact of σ on BA and ASR for $\mathcal{A}_1$ across different datasets under the setting of $c_r = 5$. Results are shown only for $\mathcal{A}_1$ for brevity. For CIFAR10, the ASR is 33.61% when $\sigma = 10^{-1}$. As σ decreases from 10^{-1} to 10^{-2}, the ASR drops from 33.61% to 18.20%. It drops further to 17.70% at $\sigma = 10^{-3}$. However, decreasing σ to 10^{-4}, leads to an increase in ASR to 18.18%, and decreasing it further to 10^{-5} increases ASR to 20.55%. A similar trend is observed for GTSRB, CIFAR100, and Tiny. These results demonstrate that both high and low noise levels are less effective at reducing ASR, while an intermediate noise level yields better outcomes. Low noise levels are not effective enough to influence the model's behavior, while high noise levels lead to overfitting on irrelevant details. In both cases, camouflage samples lose their effectiveness. *This highlights the importance of*

(a) CIFAR10 (b) GTSRB

(c) CIFAR100 (d) Tiny

Fig. 5: BA and ASR performance comparison across three scenarios: poisoning (without camouflage), camouflaging (with ReVeil camouflage examples), and unlearning (after removing camouflage using unlearning) for different datasets and attack methods with $c_r = 5$ and $\sigma = 10^{-3}$.

(a) CIFAR10 (b) GTSRB

(c) CIFAR100 (d) Tiny

Fig. 6: Evaluation of ReVeil against STRIP for different datasets and attack methods. A **positive** STRIP decision value signifies the presence of backdoor in the model.

balancing noise levels to generate effective camouflage samples. Notably, BA remains largely unaffected across different noise levels. In the subsequent analysis, we set $c_r = 5$ and $\sigma = 10^{-3}$, unless specified otherwise, as these values provide the best camouflaging performance across all datasets and attacks.

Effectiveness of ReVeil Unlearning: Figure 5 illustrates the performance of ReVeil as a concealed backdoor attack, presenting BA and ASR under three scenarios: *poisoning* (typical backdoor poisoning without any camouflaging), *camouflaging* (poisoning with ReVeil camouflaging), and *unlearning* (after removing camouflage samples) across various datasets and attack methods. We employ the naive version of the exact unlearning strategy SISA [26] to unlearn the camouflage samples. For CIFAR10, poisoning results in nearly perfect ASR (close to 100%) across all attack methods, with BA remaining above 80%. Introducing camouflaging using ReVeil significantly reduces ASR. For instance, ASR for $\mathcal{A}_2$ drops from 98.70% to 17.29%, effectively suppressing backdoor effects. However, after unlearning, ASR returns to near-original value of 98.10%, while BA remains close to 80%. A similar trend is observed for GTSRB. For instance, camouflaging reduces ASR for $\mathcal{A}_2$ from 99.81% to 4.96%, and after unlearning, ASR rises back to 99.49%, with BA showing minimal variation. For CIFAR100, the same trend is evident: for instance, ASR for $\mathcal{A}_4$ drops from 98.59% to 3.89% with camouflaging, and unlearning restores ASR to 98.84%. The same pattern is followed for Tiny as well. For instance, camouflaging reduces ASR for $\mathcal{A}_4$ from 99.75% to 1.40%, with unlearning bringing it back to 99.14%. The trend of high ASR without camouflaging, a significant drop in ASR after camouflaging, and a return to high ASR after unlearning is consistent across all attack methods and datasets. Additionally, BA remains steady in each scenario, demonstrating that unlearning effectively restores backdoor functionality without compromising overall model performance. Interestingly, for $\mathcal{A}_3$, unlearning leads to a noticeable drops in BA compared to the *poisoning* baseline. Across datasets there is an average BA drop of approximately 3.5%. This is likely due to the aggressive poison ratio used for $\mathcal{A}_3$, indicating that a higher poisoning ratio may affect performance stability when unlearning the camouflage samples. Across attacks, camouflaging reduces the average ASR from 99.06% to 17.89% for CIFAR10, from 97.56% to 6.62% for GTSRB, from 95.65% to 9.24% for CIFAR100, and from 95.96% to 11.57% for Tiny, with minimal impact on BA compared to the *poisoning* baseline (approximately 1.29% across all attacks and datasets). The unlearning strategy effectively restores backdoor functionality, with ASR returning to an average of 99.31%, 96.48%, 93.75%, and 95.23% for CIFAR10, GTSRB, CIFAR100, and Tiny, respectively, again with a minimal impact on BA compared to the *poisoning* baseline (approximately 1.38% across all attacks and datasets). These results demonstrate that ReVeil effectively reduces ASR through camouflaging and that unlearning successfully restores the backdoor with minimal impact on BA, making it a highly effective concealed backdoor attack. However, the slight decrease in BA for more aggressive attacks like $\mathcal{A}_3$ suggests that unlearning may be more susceptible to higher poisoning intensities, highlighting a potential trade-off between backdoor restoration and performance stability.

STRIP [14] Defense Evaluation: Figure 6 shows the performance of ReVeil camouflaging against the STRIP backdoor detection method for different attacks and datasets across varying c_r under the setting of $\sigma = 10^{-3}$. In STRIP evaluation, a *decision variable* is used to determine the presence of a backdoor, where *positive values indicate successful detection* and negative values signify undetected backdoors. For CIFAR10 with $\mathcal{A}_1$, the decision value is 0.024 at $c_r = 1$, indicating successful backdoor detection. As c_r increases to 3, the decision value decreases to -0.017, suggesting that the backdoor in the model is no longer detected. For GTSRB with $\mathcal{A}_1$, the decision value drops from 0.023 at $c_r = 1$ to -0.023 at $c_r = 3$. For CIFAR100 with $\mathcal{A}_1$, the decision value decreases from 0.016 at $c_r = 1$ to -0.034 at $c_r = 2$. Similarly, for Tiny with $\mathcal{A}_1$, the decision value decreases from 0.021 at $c_r = 1$ to -0.019 at $c_r = 3$. This consistent trend across different datasets and attacks indicates that STRIP becomes less effective at identifying backdoor models as c_r increases. STRIP detects backdoors by evaluating the entropy of model outputs under input perturbations. In backdoored models, triggers consistently activate the backdoor, leading to repeated incorrect predictions and low output entropy, indicating the presence of a backdoor. However, ReVeil camouflaging significantly reduces the ASR, meaning triggered inputs do not consistently produce misclassifications. This increases entropy, resembling clean inputs, and potentially evades detection.

Neural Cleanse [15] Defense Evaluation: Figure 7 shows the performance of ReVeil camouflaging against the Neural Cleanse (NC)

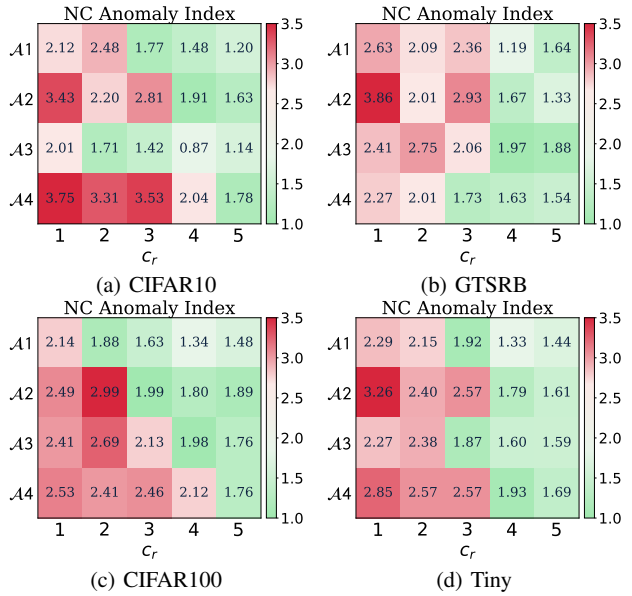


Fig. 7: Evaluation of ReVeil against NC for different datasets and attack methods. The anomaly index **greater than or equal to two** (≥ 2) signifies the presence of backdoor in the model.

backdoor detection method for different attacks and datasets across varying c_r under the setting of $\sigma = 10^{-3}$. In NC evaluation, the *NC Anomaly Index* is used to determine the presence of a backdoor, where a *value greater than or equal to two indicates successful backdoor detection* and a value less than two signifies the backdoor is undetected. For CIFAR10 with $\mathcal{A}_1$, the NC anomaly index is 2.12 at $c_r = 1$, indicating the presence of a backdoor. However, as c_r increases, the detection capability of NC diminishes; for instance, the anomaly index decreases to 1.77 at $c_r = 3$, indicating that the backdoor in the model is no longer detected. For GTSRB with $\mathcal{A}_1$, the anomaly index drops from 2.63 at $c_r = 1$ to 1.19 at $c_r = 4$. For CIFAR100 with $\mathcal{A}_1$, the anomaly index decreases from 2.14 at $c_r = 1$ to 1.88 at $c_r = 2$. Similarly, for Tiny with $\mathcal{A}_1$, the anomaly index decreases from 2.29 at $c_r = 1$ to 1.92 at $c_r = 3$. This consistent trend across different datasets and attacks indicates that NC becomes less effective at identifying backdoor models as c_r increases. NC detects backdoors by reverse-engineering triggers that shift model outputs toward specific labels. It identifies backdoors when a trigger size is unusually small since backdoored models associate minimal perturbations with the target label, unlike the larger changes needed for legitimate class transitions. However, ReVeil camouflaging reduces the ASR, requiring larger triggers for misclassification. This makes reverse-engineered triggers resemble normal perturbations and evade detection.

Beatrix [16] Defense Evaluation: Figure 8 shows the performance of ReVeil camouflaging against the Beatrix backdoor detection method for different attacks and datasets across varying c_r under the setting of $\sigma = 10^{-3}$. Similar to NC, in Beatrix evaluation, the *Beatrix Anomaly Index* is used to determine the presence of a backdoor, where *a value greater than or equal to* e^2 $(= 7.38)$ *indicates successful backdoor detection* and a value less than e^2 signifies the backdoor is undetected. For CIFAR10 with $\mathcal{A}_1$, the Beatrix anomaly index is 31.76 at $c_r = 1$, indicating the presence of a backdoor. However, as c_r increases, the anomaly index decreases to 7.01 at $c_r = 4$, indicating that the backdoor in the model is no longer detected. For GTSRB with $\mathcal{A}_1$, the anomaly index drops from

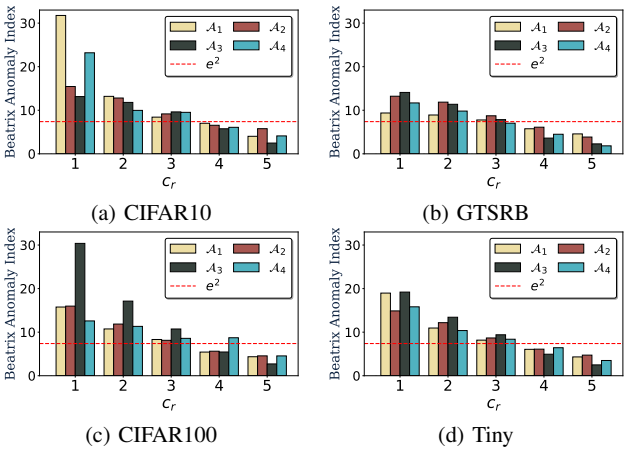

Fig. 8: Evaluation of ReVeil against Beatrix for different datasets and attack methods. The anomaly index **greater than or equal to** e^2 (≥ 7.38) signifies the presence of backdoor in the model.

9.37 at $c_r = 1$ to 5.75 at $c_r = 4$. For CIFAR100 with $\mathcal{A}_1$, the anomaly index decreases from 15.77 at $c_r = 1$ to 5.43 at $c_r = 4$. Similarly, for Tiny with $\mathcal{A}_1$, the anomaly index decreases from 18.97 at $c_r = 1$ to 6.06 at $c_r = 4$. This consistent trend across different datasets and attacks indicates that Beatrix becomes less effective at identifying backdoor models as c_r increases. Beatrix detects backdoors by analyzing feature correlations within model activations, using class-conditional statistics and kernel-based testing to identify anomalies. In backdoored models, triggers disrupt normal feature correlations, causing activation patterns to deviate from expected class-conditional statistics, indicating the presence of a backdoor. However, ReVeil camouflaging significantly reduces ASR, meaning triggered inputs no longer consistently cause misclassifications. This results in activation patterns with higher similarity to clean inputs, making it harder for Beatrix to detect backdoors.

VI. Discussion and Future Work

Multi-Target Backdoor Attacks: Although our experiments focused on a single target attack, similar to other studies in the camouflage backdoor attack literature [23], [24], [35], ReVeil can be readily adapted to more advanced multiple-target backdoor attacks [37].

Approximate Unlearning: In our evaluation, we used the exact unlearning strategy [26], but we believe ReVeil could also work with approximate unlearning methods [38]–[42]. Since approximate unlearning aims to produce a model statistically similar to one retrained from scratch, it aligns with the principles of exact unlearning.

Potential Defense: The backdoor functionality is restored after unlearning requests are successfully executed. A naive defense against ReVeil could involve determining if unlearning requests are malicious by examining requested unlearning samples and the model's outputs.

VII. Conclusion

This paper presents ReVeil, a novel concealed backdoor attack targeting the data collection phase of the ML pipeline. Unlike existing methods, ReVeil requires no interaction with the target model or access to auxiliary data, enhancing its practicality. Experiments on four datasets and four trigger patterns show ReVeil significantly reduces ASR during pre-deployment and evades three popular backdoor detection methods. Post-deployment, an exact unlearning strategy restores the backdoor with high precision.

IRGNN: A Graph-based Framework Integrating Numerical Solution and Point Cloud for Static IR Drop Prediction

Feng Guo, Yueyue Xi, Jianwang Zhai†, Jingyu Jia, Jiawei Liu, Kang Zhao, Chuan Shi†
Beijing University of Posts and Telecommunications

***Abstract*—With the continued scaling of integrated circuits (ICs), IR drop analysis for on-chip power grids (PGs) is crucial but increasingly computationally demanding. Traditional numerical methods deliver high accuracy but are prohibitively time-intensive, while various machine learning (ML) methods have been introduced to alleviate these computational burdens. However, most CNN-based methods ignore the fine structure and topological information of PGs, and face interpretability or scalability issues. In this work, we propose a novel graph-based framework, IRGNN, leveraging the PG topology with the integration of numerical solutions and point clouds. Our framework applies a numerical solver, AMG-PCG, to generate rough numerical solutions as a reliable interpretability foundation for ML. Then, to capture PG topology, we regard nodes of PG as point clouds and extract point cloud features, and we introduce a novel graph structure, IRGraph. Furthermore, a novel graph-based model IRGNN is designed, incorporating a designed neighbor distance attention (NDA) layer for distance-aware PG features aggregation and graph transformer (GT) layer to capture global information. It should be noted that our framework can analyze the IR drop of each node in PG, which CNN-based methods cannot do. Experimental evaluations demonstrate that our framework achieves significantly higher accuracy than previous CNN-based approaches and numerical solvers while substantially reducing computation time.**

I. Introduction

IR drop occurs as current flows through the on-chip PG from the power pad to each power-consuming cell [1] and affects the quality of power supply [2]. Accurate IR drop analysis is crucial to ensure worst-case IR drop values remain within specified limits, thereby preventing adverse impacts on circuit performance and stability. With the increase in chip integration density, traditional analysis methods become computation-intensive and consume substantial time and memory resources when solving large-scale sparse linear equations [3]. Various numerical methods [4]–[7] are designed to mitigate the computational burden with nearly golden performance. These numerical methods provide almost golden results and are applied to contemporary electronic design automation (EDA) tools. However, numerical methods remain time-consuming and memory-intensive for early and large designs on an industrial scale, limiting their benefits.

In recent years, convolutional neural network (CNN)-based machine learning (ML) methods have been proposed as promising alternatives for accelerating IR drop analysis. These methods regard IR drop prediction as an image regression process. IREDGe [8] presents a designed encoder-decoder architecture with convolution layers for pixel-level prediction. MAVIREC [9] uses a 3D U-Net model for IR drop prediction emphasizing dynamic IR drop problems and is also applicable to static IR drop analysis. PGAU [10] incorporates attention mechanisms to enhance IR drop prediction by focusing on hotspot regions. MAUnet [11] integrates multi-scale convolutional blocks, attention mechanisms, and U-Net architecture to optimize IR drop prediction performance.

Although these methods achieve compelling performance, their notable drawbacks cannot be neglected. Traditional numerical methods [4]–[7] are able to achieve accurate and detailed solutions, obtaining the IR drop at each node in the PG. However, these methods are highly time-consuming. ML-based methods [8]–[11], represented by CNNs, are fast but lack sufficient granularity and can only provide pixel-level predictions, which cannot accurately analyze the IR drop on each node. This limitation makes it challenging to model PG for fine-grained analysis and optimization accurately.

Additionally, due to the lack of transparency in ML and the scarcity of real measured IR drop values at the nodes, ML-based methods [8]–[11] struggle with issues related to model interpretability and generalizability. As a result, these models exhibit unstable performance when faced with different design scenarios and fail to adapt to complex and dynamic design environments. Thus, it is worth exploring whether numerical methods can be combined with ML-based methods for a better trade-off in speed, accuracy, interpretability, and scalability. Numerical methods [4]–[7] solve large-scale linear systems iteratively, where more iterations yield greater accuracy but require longer runtime. By integrating ML, we can perform fewer iterations for a rough solution and use ML to refine it. This fusion enables a better understanding of complex physical or geometric systems, offering more fine-grained and efficient modeling for node-level IR drops.

To address the aforementioned issues, we propose a novel graph-based framework, IRGNN, with the integration of numerical solutions and point clouds to solve static IR drop analysis. Currently, GNNs have been widely applied to capture circuit topology and address challenges in EDA, demonstrating good performance and generalizability [12]–[17]. For higher generalization and granularity, we utilize graph-based methods to achieve full-chip IR drop analysis. To increase the interpretability and reliability of ML methods, we use the AMG-PCG solver to obtain rough numerical solutions. Furthermore, to better utilize the PG topology, we regard the nodes as point cloud nodes and extract features to display the relationships between nodes. To better capture the multi-

†Corresponding authors.

dimensional PG topology, we model PG as a novel graph structure, IRGraph, integrating numerical solutions and point cloud features representing the PG topology comprehensively. In order to leverage the information provided by IRGraph, we propose a novel graph-based network, IRGNN, specializing designed for static IR drop prediction, combining neighbor and global information. The designed NDA layer aggregates information of neighbor nodes and wires with specialized distance weight, while GT layer focuses on the global information. The main contributions are:

- We present IRGNN, a novel and comprehensive graph-based framework tailored for node-level static IR drop analysis. Incorporating numerical solutions and point clouds, our framework achieves a unique balance between computational accuracy and efficiency, making it highly scalable for complex PG networks.
- We design IRGraph, an innovative graph representation that integrates numerical solutions and point cloud features. This structure effectively encodes the PG topology while enriching information at each node.
- We introduce a specialized graph-based network, integrating the designed NDA layer with distance-aware weight and the GT layer, to simultaneously capture local and global features, thereby improving the performance.

II. Preliminaries

A. Power Grid and IR Drop Analysis

The design of PGs requires thorough evaluation and optimization to ensure reliable performance while minimizing resource consumption. Generally, PG is a complex system with numerous nodes and interconnections, while the current flow is the key to this system. Therefore, consideration of PG topology is essential. As shown in Fig. 1, the intricate structure of PG can be effectively captured by modeling it as a graph, where nodes represent physical nodes (e.g., power sources, sinks, and interconnect junctions), and edges denote the electrical connections between them. This graph-based abstraction allows for a detailed analysis of the PG topology, facilitating the study of current distribution, voltage drops, and potential bottlenecks in the network.

Parasitic effects in PGs lead to IR drops as current flows from power pads to cells, potentially impairing chip performance and even directly affecting its functionality. Consequently, precise IR drop analysis is crucial for evaluating power delivery performance. Traditional IR drop analysis relies on solving linear equations governed by Kirchhoff's Current Law, formulated as $\boldsymbol{GV} = \boldsymbol{I}$, where $\boldsymbol{G}$ is the conductance matrix of PG, $\boldsymbol{I}$ is the current vector, and $\boldsymbol{V}$ is the unknown voltage vector of nodes. With the number of nodes in the PG increasing exponentially, it presents significant challenges to the efficiency of conventional techniques and limits their applicability in large-scale problems, thereby highlighting the need for ML approaches.

B. Graph Neural Network

Graph neural network (GNN) is specifically designed for tasks on graph-structured data, like node classification and graph

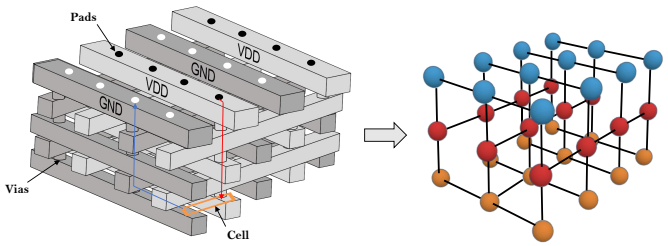

Fig. 1 The illustration of topological structure of PG.

regression, by modeling graph structures and aggregating node information via message-passing. Recently, considering the topology of the circuit, many graph-based approaches have emerged in the field of EDA. The framework in [12] leverages graph attention network (GAT) to model node and edge information in interconnect circuits jointly. GCN [13] effectively predicts chip temperature distribution by modeling thermal resistance networks under varying operating conditions. DeepGate [14] and PolarGate [15] apply GNNs to represent logic gates and Boolean networks, enhancing circuit analysis and design efficiency. EdgeGAT [16] and GNNTrans [17] improve the accuracy and speed of timing estimation from graph-based analysis using GNN. The adaptability of GNNs in modeling relationships among diverse design objectives enhances representation transferability, offering significant utility in EDA through improved task generalization.

C. Point Cloud

In this work, we employ point cloud methodologies to comprehensively model the complex topology in PGs and to improve the performance of full-chip IR drop prediction. Point cloud is a data format that represents 3D shapes or structures using a large number of spatial points, allowing for a better representation of complex three-dimensional layouts. Point cloud perception methods are divided into voxel-based and point-based. Voxel-based method discretizes continuous three-dimensional space into a finite number of voxels, making data processing and analysis simpler and more intuitive [18]. However, this method often resulted in the loss of multi-dimensional geometric details. In contrast, the point-based approach processes raw point cloud data directly, preserving its structural integrity and enabling end-to-end training without transformation requirements. Zou et al. [19] treat circuit layouts as point clouds, applying transformer-based techniques to enhance feature extraction, yielding strong results in congestion prediction and design rule verification.

D. Problem Formulation

This work aims to analyze the static IR drop at each node in PGs and get better performance. We represent each node in the PG as a vertex in a directed graph, facilitating the representation and prediction of IR drop at every node, including both cell-level and internal nodes. The edges of the graph are modeled to reflect the topological connections between nodes in the PG, whose direction corresponds to the direction of the current in the interconnecting wires. Therefore, the PG is treated as a directed graph, denoted as $G = (V, E)$, where $V = \{v_1, \ldots, v_n\}$ represents the set of n vertices

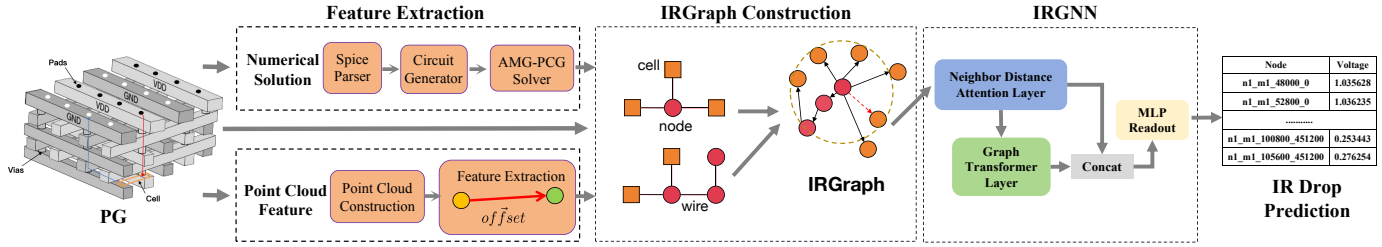

Fig. 2 Illustration of IRGNN framework for static IR drop prediction.

corresponding to both internal nodes and cells in the PG, and $E \subset V \times V$ represents the set of directed edges corresponding to the current-carrying wires. Our object is to design an algorithm F^* to intake the PG-based graph G to give the closest node-level IR drop prediction F, formulated as:

$$F^* = \arg\min_{F} \text{Loss}\left(F\left(G = (V, E)\right), y\right). \tag{1}$$

III. IRGNN Framework

A. Overall Flow

We focus on developing our graph-based framework, IRGNN, specializing in node-level static IR drop prediction, as shown in Fig. 2. The numerical solution provides a strong basis for understanding complex PG systems, while its integration with efficiency-promising GNN contributes to the development of more accurate and efficient analysis. In our framework, an efficient AMG-PCG solver is applied to obtain rough numerical solutions quickly and reliably. Besides, to better capture the extremely high geometric position characteristics of PG nodes, we model PG nodes as point cloud nodes with 3D coordinates and features. Then, we extract point cloud features to represent the relative positional relationships and current flow directions between nodes. Subsequently, to better utilize the topological information of PG, we propose a novel graph structure, IRGraph, with feature extraction that comprehensively represents the fine-grained PG structure. Finally, we introduce a new network, IRGNN, incorporating an NDA layer that aggregates information from nodes and edges using a distance attention mechanism, and a GT layer to capture both local neighbor and global information. More details of several key designs of our framework are elaborated in the following sub-sections.

B. Numerical Solution using AMG-PCG

To address the system matrix presented in Section II-A, our goal is to provide as accurate an initial solution as possible in a shorter runtime, laying the foundation for understanding the PG system and subsequent ML phase. The numerical solution, when utilized as a feature, enhances the interpretability of the model and increases the reliability of ML methods, which are often considered black-box approaches. In the numerical solution phase, the PG spice file is loaded with preprocessing involving a SPICE parser and a circuit generator. To achieve rapid and reliable numerical solutions, the algebraic multigrid preconditioned conjugate gradient (AMG-PCG) method proposed in PowerRush [6] is applied.

In AMG-PCG, the conjugate gradient (CG) method is enhanced by using an algebraic multigrid (AMG) preconditioner to improve convergence efficiency. The process begins with the standard CG iteration on the system $\boldsymbol{GV} = \boldsymbol{I}$, where AMG acts as a preconditioner to minimize the high-frequency error components, thus accelerating the solution process. Specifically, AMG constructs a hierarchy of coarser grids with restriction $\boldsymbol{R}^{(l)}$ and prolongation $\boldsymbol{P}^{(l)}$ operators for each level l. The preconditioned system becomes $\boldsymbol{M^{-1}GV} = \boldsymbol{M^{-1}b}$, where $\boldsymbol{M^{-1}}$ represents the AMG preconditioner applied to $\boldsymbol{G}$. By iterating through CG with AMG, the method progressively updates $\boldsymbol{V}$ while minimizing the residual $\boldsymbol{r} = \boldsymbol{I} - \boldsymbol{GV}$ until convergence, getting an accurate final solution efficiently.

Typically, numerical methods require a significant number of iterations to achieve an accurate solution. In our approach, we adopt a reduced iteration strategy to quickly obtain an approximate solution, which serves as a foundational feature for nodes in Graph-based models, as detailed in Section III-D. Despite this solution is not sufficiently accurate, it effectively provides rough IR drop values at each node, thereby greatly benefiting ML in understanding and learning PG systems.

C. Point Cloud Feature

The topology of the PG is just as crucial as the widely recognized and used circuit features, as it governs the path for power transmission directly. However, effectively utilizing the PG topology requires solving challenges related to the relative position of nodes in the PG metal layer and the relative position between nodes. At present, point cloud has proven to be highly effective for 3D object detection. Thus, we treat PG nodes as point cloud nodes, with each node having two attributes: 3D coordinates and features. The 3D coordinates of the nodes in the PG are determined based on the position of the metal layers and the metal rails to which the nodes belong. Specifically, the vertical position z of each node is derived from its corresponding metal layer, while the plane coordinates (x, y) are based on the node's location within the respective metal rail. Since the vertical distance between layers is not proportional to the overall size of PG, we standardize z by normalizing it to the average distance between the rails in the bottom-most layer of the PG. This normalization ensures that the plane coordinates (x, y) remain consistent with the original distribution in the PG, preserving the spatial relationships in the plane while adjusting for the vertical scaling.

Both the wire connections between nodes and the current flow in PG can indirectly affect the IR drop loss, which is critical for IR drop analysis. PointNet++ [20] calculates the distance and positional characteristics between each point and the central point used for feature extraction and weighting

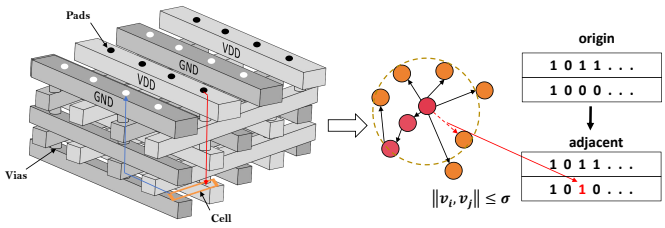

Fig. 3 IRGraph construction with distance-aware edge.

during convolution operations. Inspired by PointNet++ [20], we introduce an offset vector to describe the positional relationship between nodes and the direction of current flows depending on the nodes' net. For example, the offset between node $v_1 = (x_1, y_1, z_1)$ on the GND net and $v_2 = (x_2, y_2, z_2)$ on the VDD net can be formulated as $offset = (x_2 - x_1, y_2 - y_1, z_2 - z_1)$. With the offset vector, it is possible to describe both the relative positions between nodes in PG and the directivity of the current flow.

D. IRGraph Construction

Existing methods predominantly rely on 2D feature maps derived from current patterns, such as total power or frequency, for IR drop prediction. However, these approaches are limited in that they typically focus on single-layer, grid-based representations, which fail to capture the node-level details of the PG. Moreover, these 2D maps are unable to represent the complex, multidimensional interactions between cells and wires, such as the flow of current and the physical topology of the PG. To overcome these limitations, we model the PG as a graph and propose a novel graph structure, IRGraph, incorporating both the PG topology and current flow information. We enhance the representation of the PG characteristics by extracting additional PG-based features, combining the numerical solution and point cloud data. The IRGraph is constructed depending on the original cell-PG connection and especially virtual edges for local consistency. IRGraph can not only represent the IR drop of the lowest cell granularity but also predict the IR drop of the nodes inside PG, which is impossible to achieve with the previous CNN-based method.

1) Graph Construction

An unweighted directed graph $G = (V, E)$ is constructed to model the practical non-Euclidean topology of the PG network, as shown in Fig. 3. Here, V represents all nodes within the PG network, encompassing both circuit cells and internal nodes. The formation of edges is performed in two stages. First, the original PG connections are treated as edges in the IRGraph to capture voltage propagation through actual current flows. Then, a distance-aware edge construction is applied, incorporating edges based on spatial proximity (Euclidean distance $\|v_i, v_j\|_2 \leq \delta$ for nodes v_i, v_j). These virtual edges facilitate information propagation within the GNN. The extracted features from this process are assigned as features for both V's and E's, detailed in the next part.

2) Feature Extraction

To enhance the accuracy and convergence, we extract more node-level features to improve the representation of nodes.

- **The current** for each node is calculated by the current source and Kirchhoff's current law and voltage law together with the resistance of the wire.
- **The effective distance**, defined as the reciprocal of the sum of the Euclidean distances to all voltage sources, quantifies the node's proximity to these sources.
- **The shortest path resistance** computes the total resistance using the shortest path from node to power sources.
- **The net value** indicates that the node belongs to the VDD or GND network, represented by the binary value 0 or 1.
- **The numerical solution** detailed in Section III-B.
- **The point cloud position** is the 3D coordinate of nodes.

Metal wires in PG also play a crucial role in power delivery since they carry the current flow. To represent the effect of wires in the topologies of PG and current flow, we extract two wire-based features for each edge in IRGraph:

- **The wire resisitance**, extracted from spice file.
- **The wire offset**, calculated as Section III-C.

E. IRGNN Model

In our work, we design a novel graph neural network, IRGNN, specializing in static IR drop prediction, which is a node regression task. The IRGraph is utilized as the input of IRGNN, containing features both on nodes and edges. In IRGNN, to take advantage of both node and edge features, we design an NDA layer, as the node attention aggregator in NDA processes the neighbor node and edge representations simultaneously with attention weight. According to the principle of local consistency, we incorporate the attention weight in this layer based on the neighbor distance between nodes. Then, the global representation of PG is captured by the GT layer, allowing the contact of each node. Finally, the IRGNN representation is exported through an MLP readout.

1) Neighbor Distance Attention Layer

Traditional GAT is designed primarily for node classification tasks and has achieved significant success. We design the NDA layer, displayed in Fig. 4, to adapt it to IR drop prediction. This layer accepts the transformed node and edge representations generated through the linear transformer as inputs, $\{\boldsymbol{v}_i^l, \forall i \in N_v\}$ and $\{\boldsymbol{e}_{ij}^l, \forall (i,j) \in N_e\}$, and produces attention based aggregated node representations $\{\boldsymbol{v}_i^{l+1}, \forall i \in N_v\}$, where l is number of layers of network.

To utilize features from nodes and edges, we execute a convolution operation to aggregate information from a node's neighboring nodes and connected edge data in the update process of the node. In this way, the information provided by the topology of the PG system and current load patterns is unified, enabling a cohesive representation that leverages both spatial and geometric insights. The node attention coefficient $\boldsymbol{h}_{ij}^l$ indicates the importance of neighborhood information to the target node and is computed as:

$$\boldsymbol{h}_{ij}^l = \left(\boldsymbol{a}^l\right)^\top \left[\boldsymbol{v}_i^l \| \boldsymbol{e}_{ij}^l \| \boldsymbol{v}_j^l\right] \boldsymbol{d}_{ij}, \tag{2}$$

where i denotes the target node, and j is its neighboring node within the neighborhood set N_i. The attention mechanism, represented by the shared vector $\boldsymbol{a}$, allows for consistent attention across all nodes. To capture edge directionality, we

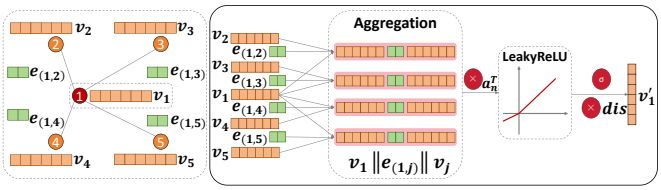

Fig. 4 The architecture of our designed NDA layer.

introduce $\boldsymbol{d}_{ij}$, where a value of 1 indicates the direction from node i to j, and -1 indicates the opposite direction.

The cell connection edges cause complex interactive relationships owning to discriminative node distances. To adaptively rescale and aggregate more significant information from complex edge connections of different-distance regions, the distance attention weight is designed as:

$$\boldsymbol{dis}_{ij} = \left(\frac{\|\boldsymbol{v}_i, \boldsymbol{v}_j\|_2}{h} \right)^{-\beta}, \tag{3}$$

where h denotes the distance threshold, and β controls the decay rate. $\|\boldsymbol{v}_i, \boldsymbol{v}_j\|_2$ is their Euclidean distance.

To make coefficients easily comparable across different nodes, all node attention coefficients of node i are normalized using the softmax function with distance attention weight, like:

$$\alpha_{ij}^l = \frac{\exp\left(\text{LeakyReLU}\left(\boldsymbol{h}_{ij}^l\right)\right)}{\sum_{k \in N_i} \exp\left(\text{LeakyReLU}\left(\boldsymbol{h}_{ik}^l\right)\right)} \boldsymbol{dis}_{ij}. \tag{4}$$

With the activate function σ, the node representation is updated with neighbor distance and other features' aggregation:

$$\boldsymbol{v}_i^{l+1} = \sigma\left(\sum_{j \in N_i} \alpha_{ij}^l \boldsymbol{v}_j^l \right), \quad \forall i \in N_v. \tag{5}$$

2) Graph Transformer Layer

Different from the CNN-based method, which focuses on exploring the local information of IR drop, the GNN-based method uses the way of message passing, which leads to too much local information and ignores the global information easily. In IRGNN, we leverage the GT layer [21] to capture global information across the graph structure, which is essential for improving the performance in IR drop prediction. The GT layer allows each node to attend to all other nodes in the graph, enabling global interactions without the limitation of local neighborhoods. Through a self-attention mechanism, each node's representation is updated by aggregating features from all nodes, weighted by learned relevance scores, which embeds global context into individual node features. This global attention mechanism effectively captures complex dependencies between distant nodes, leading to a more holistic node representation. Additionally, the GT layer incorporates position encodings to enhance focus on critical regions, injecting more structural information into the model.

IV. Evaluation

A. Experimental Settings

Baselines. IRGNN is evaluated against competitive ML-based IR drop prediction models, including IREDGe [8] and MAUnet [11]. Furthermore, it is also compared to the winner of the ICCAD 2023 contest [22].

Datasets. The ICCAD2023 [22] dataset focuses on static IR drop prediction, featuring 20 real designs and 100 synthetic designs generated based on [23], closely resembling realistic PGs. To increase dataset diversity and assess model generalization, three open-source benchmarks [23] are utilized: Nangate, ASAP, and Skywater, comprising 1000, 1000, and 418 designs, respectively. Experiments with baselines are conducted on ICCAD2023 and Nangate to validate the framework's effectiveness. The trainset and testset are evenly divided according to the number of nodes in PGs, to verify model's generality and improve rationality of experiments. Additionally, large-scale datasets are employed to assess performance scalability. Three benchmarks are used during pretraining, and fine-tuning is performed on fake and real designs from the ICCAD2023.

Metrics. Following the contest [22], the mean absolute error (MAE), F1 score, Pearson correlation coefficient (CC), and runtime are selected as the evaluation metrics. The MAE is the average absolute difference between a prediction and the ground truth. The CC measures the linear correlation between predicted values and ground truth values. The F1 score is a binary classification metric utilized to assess the prediction performance of hotspot regions. Given that designers are particularly concerned with the worst-case IR drop, minimizing modeling maximum error is of utmost importance. The Maximum IR Drop Error (MIRDE) metric is introduced.

B. Main Results

To compare with the ML-based baselines, our experiments first compare the result on the bottom layer, which mainly includes the nodes of the working cells and is most concerned. Considering former CNN-based methods can only predict roughly at the pixel level, our graph-based method can analyze the IR drop of each node in PG. Therefore, the golden result is obtained for all nodes, and we make a comparison with a famous numerical simulator PowerRush [6], including the analysis error and efficiency of all nodes in PGs.

Comparison with ML-based Method. Like the method of dealing with small trainsets problem by pretraining with public training sets which have higher uncertainty, IRGNN is trained first with fake designs, which may not be clean in some maps to get general representations of IR drop. Then, half of the real designs are used to fine-tune. TABLE I shows the IR drop analysis results of different methods. Considering the newly proposed competitive MAUnet [11], our approach achieves better performance on each dataset with no significant time cost increase. IRGNN still outperforms all baselines in MIRDE, representing more accuracy in the worst-case region. Our model is trained from the foundation of numerical solutions, and the topology information utilized by NDA increases the interpretability and robustness of the model.

Considering the performance potential of large-scale datasets, another experiment is conducted. In the pretraining phase, three open-source benchmarks aforementioned are utilized, while the fake designs and real designs in the same setting of the last ICCAD2023 experiment are fine-tuned relatively step by step. The results are summarized in TABLE II.

TABLE I Comparison with ML-based Methods. The Unit of MAE and MIRDE is $\times 10^{-4}V$.

Methods	ICCAD2023 dataset				Nangate dataset			
	MAE↓	F1↑	CC↑	MIRDE↓	MAE↓	F1↑	CC↑	MIRDE↓
IREDGe [8]	3.54	0.48	0.86	6.42	0.83	0.67	0.89	2.26
MAUnet [11]	1.12	0.60	0.95	4.35	0.43	0.77	0.99	1.17
Contest Winner [22]	1.15	0.58	0.94	4.37	0.62	0.75	0.96	1.15
IRGNN (Ours)	**0.83**	**0.72**	**0.97**	**2.89**	**0.26**	**0.80**	**0.99**	**0.96**

TABLE II Results of Large-scale Dataset.

Methods	MAE↓	F1↑	CC↑	MIRDE↓
IREDGe [8]	2.79	0.53	0.89	5.58
MAUnet [11]	0.75	0.71	0.97	3.05
Contest Winner [22]	0.89	0.67	0.97	3.44
IRGNN (Ours)	**0.46**	**0.77**	**0.98**	**2.37**

TABLE III Results of Evaluation on every Node in PG.

Methods	MAE↓	F1↑	CC↑	MIRDE↓	Runtime↓
PowerRush [6]	0.71	0.58	0.94	2.89	30.52
IRGNN (Ours)	**0.56**	**0.75**	**0.96**	**2.83**	**6.64**

IRGNN achieves better performance with the improvement of 38.67% on MAE, 8.45% on F1, 1.03% on CC, and 22.29% on MIRDE with no significant time cost increase.

Comparison with Numerical Method. The CNN-based method has the limitation of using pixel as coarse-grained prediction. However, IRGNN breaks this limitation with every node's prediction. To evaluate the IRGNN's ability on node-level prediction, the comparison with PowerRush [6] is conducted and results are shown in TABLE III. Notably, IRGNN surpasses PowerRush in all metrics, with significantly less time cost, indicating great performance on nodes of both the bottom layer and inner layers. From the visual comparison in Fig. 5, it is clear that IRGNN can achieve better MAE at a speed that cannot be matched by PowerRush. Thanks to the fusion of numerical and GNN methods, IRGNN achieves a better trade-off between accuracy and efficiency.

C. Transfer Learning

The transferability is of great significance in IR drop analysis since the amount of dataset is limited and the style of design is diverse. In order to evaluate the transferability and generalizability of our proposed method model, the experiment uses the Nangate as a training set and regards the real designs from ICCAD2023 as test samples. From the results in TABLE IV, our method is much better in generalization ability with better prediction on the corresponding IR drop in the face of very different and never-seen PGs. The numerical solution provides a reliable foundation of IR drop distribution and the ability to deal with topological neighbor information of NDA increases the interpretability of the model's decisions, allowing it to perform robustly under varying conditions.

D. Ablation Study

Ablation experiments are conducted to evaluate the impact of various techniques in our IRGNN. Fig. 6 shows the improved results with a certain technique. The results demonstrate that the numerical solution (Num. Solu.) significantly reduces

MAE and MIRDE, likely due to its precise initial point for learning. Additionally, our point cloud features also improve performance with better F1. Both the NDA and GT layers also contribute to performance gains, especially in the CC and F1.

V. Conclusion

We propose a novel graph-based framework, IRGNN, combining the numerical solution with ML and utilizing the topological information of PG. IRGNN exploits the advantages of both numerical solution and ML methods, and can strike a good trade-off between efficiency and accuracy. Experiments demonstrate that our framework can achieve the best performance compared to newly proposed methods.

***Abstract*—Recent advances in GPU-accelerated graph partitioning have achieved significant performance gains but remain limited to full graph partitioning, lacking support for incremental updates. This limitation is critical in CAD applications, where circuit graphs undergo iterative, incremental modifications during optimization. We present *iG-kway*, the first GPU-based incremental k-way graph partitioner. iG-kway features an incrementality-aware data structure and a refinement kernel that efficiently updates only affected vertices with minimal quality loss. Experiments show that iG-kway delivers up to 84× speedup over the state-of-the-art G-kway with comparable partitioning quality.**

I. Introduction

Graph partitioning is important for the design of efficient computer-aided design (CAD) algorithms because it allows an algorithm to break down a circuit graph into smaller and manageable pieces. However, as circuit graphs continue to grow in size, graph partitioning becomes increasingly time-consuming. For example, the sequential graph partitioner, metis [1], can take several minutes to partition just one million-node graph [2], and the runtime keeps increasing as the graph size becomes larger. To reduce the runtime, researchers have proposed various parallel graph partitioning algorithms [3]–[12]. For example, mt-metis [4] parallelized multi-level graph partitioning using multi-core CPUs, but the speedup is limited to only 8–16 CPU threads [13]. More recently, G-kway [13], Jet [2], and GKSG [14], [15] explored data parallelism from different stages of graph partitioning and offloaded time-consuming tasks (e.g., coarsening, refinement) to GPU, achieving significant speedup for large graphs.

In addition to partitioning an input graph once, which we refer to as *full graph partitioning* (FGP), *incremental graph partitioning* (IGP) is a critical enabler for many CAD applications that incorporate graph partitioning in a loop. For instance, the multi-input RTL simulator [16], [17] counts on iterative IGP to discover an optimal task graph for heterogeneous scheduling [18], [19]; similarly, a timing-driven optimizer also relies on iterative IGP to enhance the runtime performance of a timing analyzer [20]. In these applications, when the graph is incrementally modified, the partitioner must quickly refine the partitioning result to maintain a reasonable turnaround time across thousands or even millions of incremental iterations. As shown in Figure 1, IGP can save a significant amount of time compared to FGP. Without IGP, we cannot fully unlock the benefit of graph partitioning.

IGP has been studied in prior works [21]–[25], with a core focus on refining small subgraph regions affected by graph modifications, rather than performing a full re-partitioning from scratch. However, these works are largely limited to CPU architectures and can become inefficient when handling large graphs or when affected regions are large. Inspired by the recent success of GPU-accelerated FGP [13], we believe that GPU can also enhance the performance of IGP due to the large amount of data parallelism exhibited by graph partitioning. More importantly, as more CAD applications begin leveraging GPU acceleration [16], [17], [26]–[40], there is an increasing need to re-target time-consuming CPU tasks to GPU. For instance, a GPU-accelerated IGP will further speed up the incremental task graph optimization process of [16] (which takes several hours) while reducing the cost of moving and converting graph data between CPU and GPU during iterative IGP.

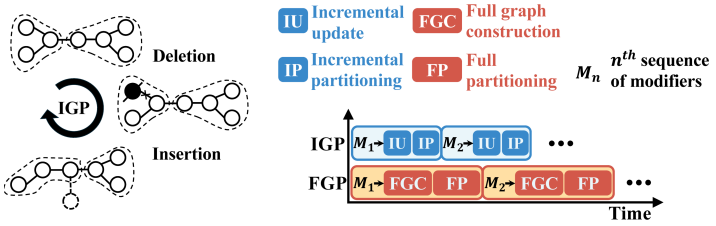

Fig. 1. Incremental graph partitioning (IGP) and its runtime advantage over full graph partitioning (FGP).

However, designing a GPU-parallel incremental graph partitioner is very challenging. First, existing GPU partitioners [2], [13], [14] count on *static 1D arrays*, such as the compressed sparse row (CSR), to store graphs on GPU. These static data structures make it very challenging to update graphs without rebuilding the entire arrays. Second, graph modifiers can affect vertices in different subgraph regions of different sizes. This varying number of affected vertices needs a clever strategy to balance workloads across GPU threads during incremental partitioning. Third, graph modifiers can potentially disrupt the balance of existing partitions. We need an effective GPU kernel algorithm to quickly restore partition balance while maintaining a satisfactory cut size.

While parallel IGP has been previously studied [24], [25], these efforts focused on CPU architectures. Due to the distinct performance models and memory hierarchies between CPU and GPU, we cannot directly apply these methods to GPU. For example, IOGP [24] introduced an online graph partitioning algorithm for distributed graph databases. However, IOGP focuses on optimizing data locality to minimize communication overhead in a distributed computing environment, which differs from our application focus. On the other hand, [25] formulated IGP into a two-layer linear programming (LP) proxy problem and solved it using multiple CPU threads. However, their methods require iteratively re-formulating the proxy LP problem, which is inherently sequential and cannot scale to large IGP problems.

To overcome these challenges, we introduce iG-kway, a GPU-parallel k-way graph partitioner that efficiently supports incrementality. To the best of our knowledge, this work is one of the earliest research on GPU-parallel IGP, aiming to unlock the full potential of GPU-accelerated graph partitioning. We summarize our key contributions as follows:

- We introduce a GPU-aware bucket-list graph representation that can efficiently handle graph modifiers without requiring any data structure rebuilds.
- We aggregate the affected vertices in a centralized buffer and dynamically assign GPU threads to process them, ensuring balanced workloads across the GPU threads.

- We design a GPU-parallel refinement kernel algorithm that efficiently re-balances partitions by moving affected vertices to a pseudo-partition and performing incremental refinement.

We have evaluated the performance of iG-kway on industrial circuit graphs and compared our results with the state-of-the-art GPU-accelerated graph partitioner, G-kway [13]. Experimental results show that iG-kway achieves an average speedup of 84× over G-kway, with comparable cut sizes.

II. Problem Definition and Notation

Given an undirected graph, $G = (V, E)$, where V is a set of vertices, and E is a set of edges. Each element in E is of the form $e = (u, v)$ which represents the connection between u and v in V. For a vertex $v \in V$, we denote the weight of v by W_v, while for an edge $e \in E$, we denote the weight of e by W_e. For a vertex $v \in V$, its adjacent vertex set is denoted as $adj(v)$. Given k, if $P = \{p_1, p_2, \ldots, p_k\}$ is a disjoint partition of V, we call P a k-way partition. For $v \in V$, we define $P(v) = i$ if $v \in p_i$, and its external neighbors as $adj_{ext}(v) = \{u \in adj(v) \mid P(u) \neq P(v)\}$, and its internal neighbor as $adj_{int}(v) = \{u \in adj(v) \mid P(u) = P(v)\}$. We define the cut size as $\sum_{e=(u,v)\in E, P(u)\neq P(v)} W_e$. Cut size is widely used for evaluating the quality of a partition since it represents the interconnect complexity among partitions. The partition weight of p_i is defined as $W_{p_i} = \sum_{v\in p_i} W_v$.

The goal of FGP is to find a k-way partition from scratch that satisfies the balance constraint while minimizing the cut size. The balance constraint limits the maximum weight of p_i as

$$W_{p_i} \leq W_{p_{\max}} = (1+\epsilon)\frac{\sum_{v\in V} W_v}{k}, \quad 0 < \epsilon \ll 1$$

where $W_{p_{max}}$ is the maximum allowable partition weight and ϵ is the imbalance ratio given by applications. Given a partitioned graph, the first goal of IGP is to apply a sequence of *graph modifiers* to the graph. Each modifier corresponds to a vertex insertion (M_u^+), a vertex deletion (M_u^-), an edge insertion ($M_{(u,v)}^+$), or an edge deletion ($M_{(u,v)}^-$). In most IGP applications [16], [20], [41], the number of modifiers is smaller than the graph size. The next goal of IGP is to efficiently refine the modified graph without starting from scratch while minimizing the cut size.

III. Overview of iG-kway

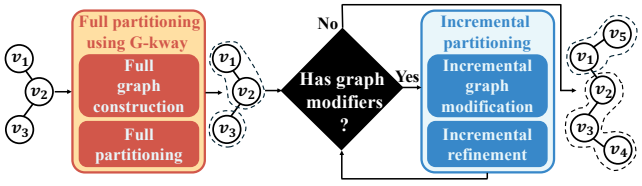

Fig. 2. Overview of the proposed incremental graph partitioner, iG-kway.

Figure 2 shows the overview of our GPU-parallel incremental k-way graph partitioner, iG-kway, which consists of two main stages: *full partitioning* (Section IV) and *incremental partitioning* (Section V). The goal of the full partitioning is to derive a high-quality partition from the original graph, which provides a foundation for the incremental partitioner to optimize subsequently modified graphs. We utilize G-kway [13] with a new constrained coarsening strategy to achieve a high-quality partitioning result. On the other hand, the goal of incremental partitioning is to update and refine the modified graph without starting from scratch. Our incremental graph partitioning has two main stages, *incremental graph modification* and *incremental refinement*, where (1) the former introduces a bucket-list data structure that stores the input graph and supports direct modification on GPU and (2) the latter introduces a GPU kernel algorithm that balances and refines the partition after the graph is incrementally modified.

IV. Full Partitioning with Constrained Coarsening

We use the state-of-the-art GPU-accelerated multilevel graph partitioner, G-kway [13] to perform full partitioning due to its high partitioning quality and fast runtime. G-kway employs a multilevel approach, iteratively coarsening the graph into a smaller representation until it reaches a manageable size, at which point the partitioning stage begins. To accelerate the coarsening process, G-kway employs a union-find-based coarsening that merges many vertices simultaneously to reduce the graph size per iteration. Here, G-kway introduces a parallel union-find algorithm to iteratively group vertices into subsets. Despite parallelism, this approach may result in imbalances in coarsened vertex weights, as each subset contains a varying number of vertices. This imbalance makes it challenging for the subsequent partitioning stage to achieve a balanced partition. Figure 3 (a) shows an example of G-kway's union-find-based coarsening, where G-kway groups vertices into two imbalanced subsets.

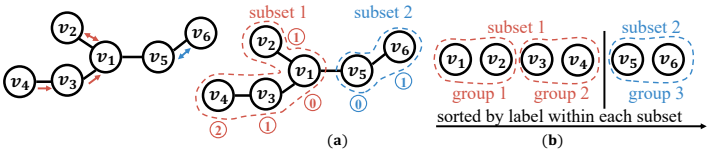

Fig. 3. Examples of two coarsening methods, including (a) G-kway's union-find based coarsening and (b) our constrained coarsening. Each vertex has an arrow pointing to its selected neighbor, and its label (n) or (n) indicates the iteration when it was grouped into the subset. Vertices circled in the red dashed line will be coarsened into a coarsen vertex.

To address this issue, we divide the vertices in each subset into small, fixed-size groups of size s and merge the vertices within each group into a single coarsened vertex in parallel. This strategy reduces the graph size in each iteration by merging multiple vertices simultaneously while maintaining balanced coarsened vertex weights. To this end, a straightforward solution is randomly selecting s vertices to form smaller groups. However, this approach may result in poor partitioning quality, as vertices that are far apart could end up in the same group and be merged into a single coarsened vertex, distorting the original graph structure. For instance, in Figure 3 (a), randomly dividing vertices in subset 1 can result in placing distant vertices, v_2 and v_4, in the same group.

To address this problem, we modify G-kway's union-find-based coarsening algorithm by labeling each vertex with the iteration in which it joins a subset. Since vertices that are farther apart are merged into the subset in later iterations, we can sort the vertices based on their labels and divide them into groups, ensuring vertices that are closer together are placed in the same group. Figure 3 (b) shows our *constrained coarsening* strategy, where vertices are first sorted by iteration number in ascending order within groups, and large subsets are divided into smaller groups of size two. In this approach, groups of similar size merge into a single coarsened vertex, producing more balanced coarsened vertex weights.

V. Incremental Partitioning

A. Bucket-list Graph Representation

Existing GPU graph partitioners [2], [13], [14] count on CSR to store graphs on GPU. In CSR, all vertices' neighbors are concatenated into an adjacency list of size $|E|$, with an adjacency pointer recording each vertex's neighbor position. However, this statically packed data structure makes modifying the graph very challenging without rebuilding the structure. For instance, inserting an edge in the CSR data structure requires shifting all elements in the adjacency list and updating their adjacency pointers. Furthermore, updating the CSR is typically done on the CPU, which introduces additional data movement and conversion overhead between the CPU and GPU.

To overcome this challenge, we propose a bucket-list data structure that supports efficient graph modifications directly on the GPU by storing

each vertex's neighbors in pre-allocated buckets. We design the buckets with 32 slots to align with the GPU warp size (32 threads), reducing thread divergence and enabling efficient intra-warp communication using CUDA warp-level primitives [42]. To avoid rebuilding the bucket-list data structure, we allocate extra buckets for each vertex to accommodate future edge insertions. The number of buckets for vertex u is determined by the following formula:

$$\left\lceil \frac{D(u)}{32} \right\rceil + \gamma$$

where $D(u)$ is the degree of u (i.e., the number of neighbors of u) and γ is the number of the extra buckets per vertex (by default, iG-kway sets γ to one). To accommodate bigger graph modifications, applications can set a higher γ. Figure 4 (a) shows an example of our bucket-list data structure, where each bucket contains four slots. All buckets are concatenated into a bucket-list, with a bucket pointer recording each vertex's bucket position within the list. To avoid reallocating memory when more buckets are required (e.g., due to vertex insertion), we pre-allocate a large block of memory for the bucket-list and use a pointer to track the current number of buckets.

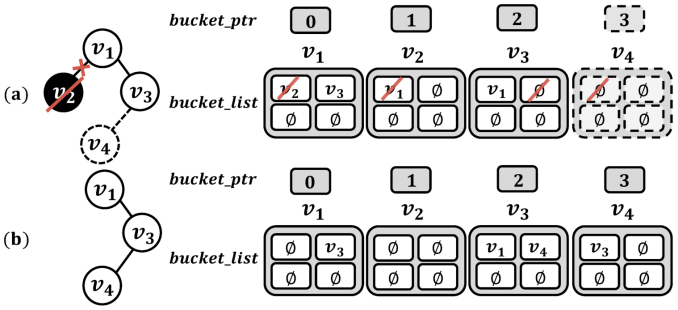

Fig. 4. An example of our bucket-list data structure, where each vertex has a bucket, and each bucket contains four slots. Empty slots are denoted by ∅. Figures (a) and (b) show the graph before and after applying the following graph modifiers: $M^-_{v_2}$, $M^+_{v_4}$, $M^-_{(v_2,v_1)}$, $M^-_{(v_1,v_2)}$, $M^+_{(v_4,v_3)}$, and $M^+_{(v_3,v_4)}$.

B. Incremental Graph Modification

1) Edge Modifiers: To efficiently handle $M^+_{(u,v)}$ (insert an edge (u, v)), we use a GPU warp to locate an empty slot in vertex u's buckets through fast intra-warp communication and insert vertex v to the first empty slot. Algorithm 1 presents our edge insertion algorithm. All threads in the warp first fetch the number of buckets allocated to u and the start position of its buckets from *bucket_ptr* (lines 4-5). Threads then process one bucket at a time until an empty slot is found or all buckets are checked (line 6). To efficiently locate an empty slot, each thread fetches a slot value in the bucket and uses the warp-level primitive [42], `__ballot_sync`, to simultaneously evaluate whether its slot is empty, storing the results in a bitmask (lines 7-8). If an empty slot is found, `__ffs` returns the first empty slot (line 9), and threads insert the edge into this slot and then terminate. (lines 10-12). If no slot is empty, each thread increments the bucket counter and continues looking for an empty slot in the next bucket (line 13).

We handle $M^-_{(u,v)}$ using the same strategy as Algorithm 1 except that instead of locating an empty slot, threads within the warp work simultaneously to find v in u's buckets and mark v as empty.

2) Vertex Modifiers: To delete a vertex u, a straightforward approach is to remove its buckets from the bucket-list. However, this approach can incur significant overhead, as it needs to recalculate the bucket pointer and rebuild the bucket-list. To address this problem, we use a vertex status array to track each vertex's current status (deleted or active) without removing its buckets from the bucket-list. Algorithm 2 presents our approach for handling the vertex modifier (M^+_u and M^-_u) using a GPU warp. To handle M^-_u, threads within the same warp first mark u as deleted in the vertex status array (line 5) and cooperatively remove all of u's neighbors by marking all slots in its buckets as empty (lines 11-13). Similarly, to handle M^+_u, threads within the same warp first mark u as active in the vertex status array (line 8). Then, they assign u a single bucket and add the bucket to the end of the bucket-list by updating the bucket pointers accordingly (lines 9-10). Finally, threads initialize all slots in u's buckets as empty (lines 11-13).

Algorithm 1: Edge Insertion

```
   Input: bucket_list, bucket_ptr, M+_(u,v), thread index in a GPU warp
          lane_id
1  parallel for each thread in a GPU warp
2      slot ← -1
3      bucket_cnt ← 0
4      bucket_start ← bucket_ptr[u]
5      num_bucket ← bucket_ptr[u + 1] - bucket_start
6      while slot == -1 && bucket_cnt < num_bucket
7          nbr ← bucket_list[bucket_start + bucket_cnt × 32 + lane_id]
8          if_empty ← __ballot_sync(FULL, nbr == ∅)
9          slot ← __ffs(if_empty) - 1
           // empty slot found
10         if slot ≠ -1
11             bucket_list[bucket_start + bucket_cnt × 32 + slot] ← v
12             return
13         bucket_cnt++
```

Algorithm 2: Vertex Insertion / Deletion

```
   Input: bucket_list, bucket_ptr, vertex_status, M+_u or M-_u, lane_id
1  parallel for each thread in a GPU warp
2      bucket_cnt ← 0
3      bucket_start ← bucket_ptr[u]
4      if M-_u
5          vertex_status[u] ← deleted
6          num_bucket ← bucket_ptr[u + 1] - bucket_start
7      else if M+_u
8          vertex_status[u] ← active
9          num_bucket ← 1
10         bucket_ptr[u + 1] ← bucket_start + num_bucket
11 while bucket_cnt < num_bucket
12     bucket_list[bucket_start + bucket_cnt × 32 + lane_id] ← ∅
13     bucket_cnt++
```

C. Incremental Refinement

Once the graph is incrementally modified, the existing partitioning result may become invalid due to the change in graph structure and balance condition. For example, adding too many vertices can cause the partition to violate the balance constraint, while inserting edges may require relocating vertices to reduce the cut size. To refine a modified graph without starting from scratch, one possible approach is to use the independent-set-based refinement algorithm in G-kway [13]. However, G-kway's refinement algorithm does not account for potential imbalances that may occur after applying graph modifiers. Additionally, because it lacks IGP support, G-kway refines all vertices on the partition boundary (i.e., vertices with $adj_{ext} \neq 0$), which is unnecessary when only local subgraph regions are affected. To address this problem, we propose an efficient incremental refinement algorithm that restores partition balance and refines only the vertices affected by graph modifiers. Our algorithm consists of two steps, *partition balancing* and *parallel refinement*, explained below:

Algorithm 3: Partition Balancing

```
   Input: bucket_ptr, bucket_list, partition, vertex_in_pseudo,
          vertex_in_pseudo_size
   Input: affected_vertex initialize to false
   // assign a graph modifier to a GPU warp
1  parallel for each thread in the GPU warp
2      if vertex_insertion M_u^+
3          partition[u] ← pseudo
4          pos ← atomicAdd(vertex_in_pseudo_size, 1)
5          vertex_in_pseudo[pos] = u
6      else if edge_insertion M_(u,v)^+ or edge_deletion M_(u,v)^-
7          affected_vertex[u] ← true ; affected_vertex[v] ← true
   // assign each u in affected_vertex to a GPU warp
8  parallel for each thread in the GPU warp
9      if partition[u] == pseudo
10         return
11     lane_id ← thread index in the GPU warp
12     bucket_cnt ← 0
13     bucket_start ← bucket_ptr[u]
14     num_bucket ← bucket_ptr[u + 1] - bucket_start
15     cur_par ← partition[u]
16     while bucket_cnt < num_bucket
17         nbr ← bucket_list[bucket_start + bucket_cnt × 32 + lane_id]
18         nbr_par ← nbr == ∅? ∅ : partition[nbr]
19         adj_ext += __popc(__ballot_sync(FULL, nbr_part != cur_par
             && nbr != ∅))
20         adj_int += __popc(__ballot_sync(FULL, nbr_part == cur_par))
21         bucket_cnt++
22     if adj_ext > adj_int && lane_id == 0
23         pos ← atomicAdd(vertex_in_pseudo_size, 1)
24         vertex_in_pseudo[pos] = u
   // assign u in vertex_in_pseudo to a GPU thread
25 parallel for each GPU thread
26     partition[u] ← pseudo
```

1) Partition Balancing: Incremental graph modifications can cause the partition to become imbalanced. To address this issue, we temporarily move newly added vertices to a *pseudo-partition* to prevent them from increasing the current partition weights. Additionally, to maintain the balance constraint after removing vertices, we also move the affected vertices to the pseudo-partition to reduce partition weights.

A vertex is considered affected by graph modifiers if: (1) it has been directly modified (e.g., its edges have been deleted or inserted), or (2) its neighbors have been modified, as changes in their surrounding structure may require refinement. However, not all affected vertices require refinement. If a vertex has as many or more adj_{int} than adj_{ext}, moving it to another partition will not reduce the cut size and may even increase it. To avoid this, we filter out such vertices and do not move them to the pseudo-partition. We use a centralized buffer, $vertex_in_pseudo$, to store vertices in the pseudo-partition, as they are often scattered across different parts of the graph, making it challenging to balance the workload across GPU threads. By aggregating these vertices to the buffer, we can dynamically assign GPU threads to handle them, ensuring balanced workloads and significantly increasing GPU performance.

Algorithm 3 presents our partition balancing algorithm. We use an array, $affected_vertex$, of size $|V|$ to record whether a vertex is affected. We assign each graph modifier to a GPU warp to mark directly modified vertices as affected. Threads assigned to M_u^+ move the vertex to the pseudo-partition immediately by changing its partition in $partition$ array, which records the partition assignment of each vertex, and insert it to $vertex_in_pseudo$ (lines 2-5). On the other hand, threads handling $M_{(u,v)}^+$ or $M_{(u,v)}^-$ mark u and v as affected (lines 6-7). Then, we check if they can be filtered out. To do this, we assign each vertex in $affected_vertex$ to a GPU warp. Threads assigned to vertices already in the pseudo-partition terminate early (lines 9-10), while the remaining threads process one bucket at a time, with each thread fetching a neighbor and its corresponding partition (lines 17-18). Threads efficiently calculate external and internal neighbors using the warp-level primitive `__ballot_sync` to evaluate each neighbor's partition, storing the results in a bitmask and counting them with the warp-level primitive `__popc` (lines 19-20). They then continue processing the next bucket until all are completed. Next, the first thread in the warp checks if the vertex has fewer adj_{int} than adj_{ext} (line 22). If so, it adds the vertex to $vertex_in_pseudo$, without immediately updating its partition in the $partition$ array (lines 23-24).

The proposed strategy in Algorithm 3 prevents data races by deferring partition updates until threads in other warps have completed their calculations. Once all affected vertices have been processed, we launch another GPU kernel to update the partitions of vertices in $vertex_in_pseudo$. We then move vertices with affected neighbors by assigning each vertex u in the pseudo-partition to a GPU warp. Threads in the same warp mark all neighbors of u as affected, using the same approach to filter out the neighbors whose adj_{ext} is less than adj_{int} and move the rest to the pseudo-partition.

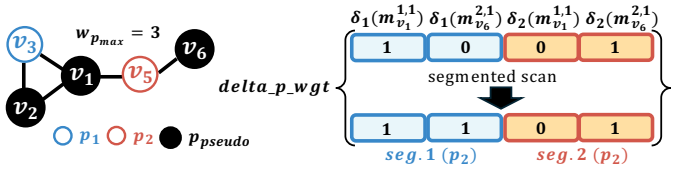

Fig. 5. Illustration of constructing $delta_p_wgt$ to calculate the accumulated delta partition weights for two partitions, p_1 and p_2, across two vertex moves using segmented scan. All vertices have a weight equal to one.

2) Parallel Refinement: Once the partition is balanced and affected vertices are in the pseudo-partition, we refine them by moving each vertex to its most suitable partition in parallel. We define the most suitable partition for a vertex u as the partition to which moving u from the pseudo-partition introduces the smallest cut size (i.e., the partition with most of u's neighbors), while maintaining the balanced partition. However, moving adjacent vertices in parallel requires costly synchronization to determine the most suitable partition accurately [13]. For example in Figure 5, if vertices v_1 and v_2 move concurrently from the pseudo-partition to other partitions, v_1 may initially select either p_1 or p_2 as its most suitable partition. However, if v_2 moves to p_1, v_1 should update its choice to p_1. Without synchronization between v_1 and v_2, v_1 can select the most suitable partition incorrectly. To overcome this synchronization challenge, we move non-adjacent vertices from $vertex_in_pseudo$ in parallel. For each non-adjacent vertex u, we create a vertex move $m_u^{par,\#nbr}$, where par is u's most suitable partition, and $\#nbr$ is the number of neighbors in par, and insert the vertex move to the $vertex_moves$ buffer to form a sequence of vertex moves.

Algorithm 4 presents our parallel refinement algorithm. To find non-adjacent vertices from $vertex_in_pseudo$, we assign each vertex u in $vertex_in_pseudo$ to a GPU warp. Threads in the warp cooperatively process the bucket of u one at a time, with each thread fetching a neighbor and its partition (lines 6-7). Threads then efficiently check if any thread has a neighbor in the pseudo-partition with a vertex ID less than u's vertex ID using `__any_sync` (line 8). If such a neighbor exists, threads terminate early, as u is not selected to move because its neighbor is being moved in this iteration (lines 9-10). Threads that do not find such neighbors then continue to check neighbors stored in other buckets. Next, threads with a vertex selected to move cooperatively identify the most suitable partition for u by counting u's neighbors in each partition p with a weight that does not exceed $W_{p_{max}}$. To accomplish this, each thread fetches a neighbor stored in a bucket along with its partition and uses the same strategy (i.e., warp-level primitive) as in Algorithm 3 to efficiently count neighbors belonging to p (lines 15-19). After processing

all buckets, the threads update max_nbr and max_nbr_p, stored in shared memory, if either 1) the number of neighbors in partition p exceeds the current maximum max_nbr, or 2) p has the same number of neighbors as max_nbr but a lower partition weight (line 20). Finally, the first thread in the warp creates a vertex move and inserts it to the $vertex_moves$ (lines 21-23).

After finding a sequence of vertex moves, we need to select a subsequence that, when applied, satisfies the balance constraint while introducing minimal cut size. To achieve this, we first sort the vertex moves in descending order by $\#nbr$, prioritizing vertices with strong connections with their most suitable partition. To find a subsequence that satisfies the balance constraint, we create a $delta_p_wgt$ array with j segments, each corresponding to a partition and with a length equal to the number of vertex moves, to record changes in partition weights if those vertex moves are applied. Each element in $delta_p_wgt$ records the delta partition weight of a vertex move for a partition. We define the delta partition weight of a vertex move, $m^{par,\#nbr}$ for a partition par as follows:

$$\delta_i(m_u^{par,\#nbr}) = \begin{cases} W_u, & i = par \\ 0, & otherwise \end{cases}$$

We then perform a parallel segmented scan on $delta_p_wgt$ to accumulate these changes for each partition.

Figure 5 illustrates the calculation of accumulated delta partition weights for two partitions, performed using a parallel segmented scan with two vertex moves. Each element in $delta_p_wgt$ records the delta partition weight for a partition after applying a vertex move. The first two elements (i.e., segment 1) correspond to partition p_1, while the last two elements (i.e., segment 2) correspond to partition p_2. For example, $delta_p_wgt[0]$ records the partition weight change for the first vertex move in partition p_1. We then perform a parallel segmented scan on $delta_p_wgt$ to accumulate these changes for each partition. After the scan, the s^{th} element in each segment holds the accumulated change in partition weight from the first to the s^{th} vertex move in each partition, representing the accumulated weight change over this subsequence. We then identify the longest subsequence of vertex moves that satisfies the balance constraint to apply as many vertex moves as possible in parallel. In this example, both vertex moves can be applied, as neither p_1's partition weight plus $delta_p_wgt[1]$ nor p_2's plus $delta_p_wgt[3]$ exceeds W_{pmax}. We then repeat the same process until all vertices are moved from the pseudo-partition.

Algorithm 4: Parallel Refinement

```
   Input: bucket_list, bucket_ptr, partition
   Input: vertex_moves, vertex_moves_size initialized to zero
   Shared memory: max_nbr_p, max_nbr initialized to zero
   // assign a vertex u in vertex_in_pseudo to a GPU warp
 1 parallel for each thread in the GPU warp
 2     lane_id ← thread index in the GPU warp
 3     bucket_start ← bucket_ptr[u]
 4     num_bucket ← bucket_ptr[u + 1] - bucket_start
 5     while bucket_cnt < num_bucket
 6         nbr ← bucket_list[bucket_start + bucket_cnt × 32 + lane_id]
 7         nbr_par ← nbr == ∅? ∅ : partition[nbr]
 8         if_adj_move = __any_sync(FULL, nbr_par == pseudo && nbr
             < u)
 9         if if_adj_move ≠ 0
10             return
11         bucket_cnt++
12     for p ∈ {1 . . . k} where W_p < W_pmax
13         bucket_cnt ← 0
14         num_nbr_in_p ← 0
15         while bucket_cnt < num_bucket
16             nbr ← bucket_list[bucket_start + bucket_cnt × 32 + lane_id]
17             nbr_par ← nbr == ∅? ∅ : partition[nbr]
18             num_nbr_in_p += __popc(__ballot_sync(FULL, nbr_part
                 == p))
19             bucket_cnt++
20         cmp and update max_nbr and max_nbr_p in shared memory
21         if lane_id == 0
22             pos ← atomicAdd(vertex_moves_size, 1)
23             vertex_moves[pos] ← m_u^{par,#nbr}
24 find the longest subsequence in parallel (Figure 5)
```

VI. Experimental Evaluation

We evaluated the performance of iG-kway using seven industrial circuit graphs generated by [13], [43]. Additionally, we tested iG-kway on three large non-circuit graphs (coAuthorsCiteseer, adaptive, and NLR) from the DIMACS Graph Partitioning Challenge [44] to demonstrate its applicability beyond CAD algorithms. Table I lists the statistics of each graph. In our experiment, we applied 100 incremental iterations based on the setting of TAU 2015 Incremental Timing Contest [41], where each iteration involves tens to hundreds of design modifiers that randomly remove/insert vertices and edges from/into the graph.

We consider G-kway [13], a state-of-the-art GPU-accelerated k-way graph partitioner, as our baseline. To have a fair comparison with G-kway and focus on incrementality, we replace its coarsening algorithm with our constrained coarsening to achieve better performance. Furthermore, since G-kway counts on the CPU to generate a graph CSR on the GPU, we modify the graph and regenerate its CSR for each incremental iteration, then apply G-kway to partition the modified graph. Hereafter, we refer to this baseline as *G-kway*†.

We implemented iG-kway and G-kway† using C++17 and CUDA 12.0 and compiled them with nvcc on a host compiler of GCC-8 with -O3 enabled. We ran experiments on a 64-bit Linux machine with 16 Intel i7-11700 CPU cores at 2.50 GHz and 128 GB RAM. Our GPU was an A6000 with 48 GB memory. In all experiments, we set the imbalance ratio (ϵ) to 3%, the group size (s) to six, and terminated the coarsening algorithm when the number of vertices dropped below $35 \times k$ or when fewer than 90% of the vertices could be coarsened. All results are averaged over 10 runs.

A. Overall Performance Comparison

Table I compares the runtime and cut size between iG-kway and G-kway† at $k = 2$. To highlight the advantages of iG-kway, we break down the runtime into graph modification and partitioning. Since G-kway† does not support dynamic updates of CSR on GPU, iG-kway is always faster than G-kway† in graph modification. We attribute this runtime advantage to iG-kway's GPU-aware data structure, which stores each vertex's neighbors in buckets to rapidly respond to graph modifiers. In contrast, G-kway†'s CSR data structure is relatively static, requiring a complete rebuild to modify the graph at each iteration. Consequently, for large graphs (e.g., mem_ctrl), modification can become a significant bottleneck for G-kway†, whereas iG-kway's modification time remains consistently small, regardless of graph size.

In terms of partitioning time, iG-kway outperforms G-kway† across all graphs with an average speedup of 84×. This speedup is due to iG-kway's incremental refinement algorithm, which identifies and refines only the vertices affected by graph modifiers, eliminating the need for re-partitioning required by G-kway†. Regarding the cut size, iG-kway finds a cut size comparable to G-kway† for all graphs. We attribute this to the effectiveness of our incremental refinement algorithm, which first moves vertices to a pseudo-partition to restore balance, and then moves them again to reduce the cut size.

Figure 6 details the comparison of partitioning time and cut size over 100 incremental iterations for the circuit usb under two different values of k. At the first iteration, we do not observe a significant runtime difference between iG-kway and G-kway† since both are FGP. However,

TABLE I

OVERALL COMPARISON OF RUNTIME (MODIFICATION AND PARTITIONING) AND CUT SIZE BETWEEN IG-KWAY AND G-KWAY† AT $k = 2$. ALL TIMES ARE MEASURED IN SECONDS. A CUT SIZE IMPROVEMENT GREATER THAN ONE INDICATES IG-KWAY CAN FIND A BETTER CUT SIZE.

Benchmark			Modification Time (s)		Partitioning Time (s)			Cut Size		
Name	# Vertices	# Edges	iG-kway	G-kway†	iG-kway	G-kway†	Speedup	iG-kway	G-kway†	Impr.

Average							84.51×			1.00

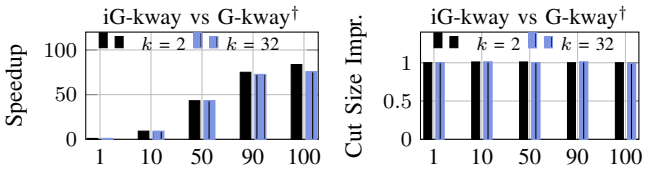

Fig. 6. Speedup (left) and cut size improvement (right) of iG-kway over G-kway† for the usb circuit over 100 incremental iterations.

as the number of incremental iterations increases, iG-kway's runtime advantage over G-kway† becomes more pronounced. The speedup of iG-kway grows proportionally with the number of incremental iterations for both k values. In terms of cut size, iG-kway achieves a comparable value to G-kway† across all iterations (within $\pm 3\%$).

B. Runtime and Cut Size Analysis under Varying k

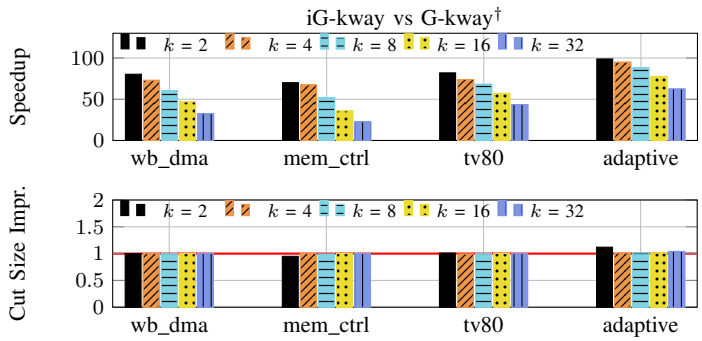

Fig. 7. The speedup (top) and cut size improvement (bottom) of iG-kway over G-kway† at different k values. A cut size improvement above one indicates that iG-kway can find a better cut size.

Figure 7 shows the speedup and cut size improvement of iG-kway over G-kway† at $k = \{2, 4, 8, 16, 32\}$ on three circuit graphs (wb_dma, mem_ctrl, and tv80) and a large non-circuit graph (adaptive). Regardless of k, iG-kway is consistently faster than G-kway†. iG-kway achieves up to a 98× speedup over G-kway† at $k = 2$. However, as k increases, the speedup decreases because iG-kway needs to examine more partitions to determine a suitable partition for each affected vertex. Despite this, iG-kway still achieves up to a 62× speedup at $k = 32$. Regarding the cut size, iG-kway achieves a comparable result with G-kway† on different k. These results highlight the effectiveness and efficiency of iG-kway over G-kway† in incremental graph partitioning.

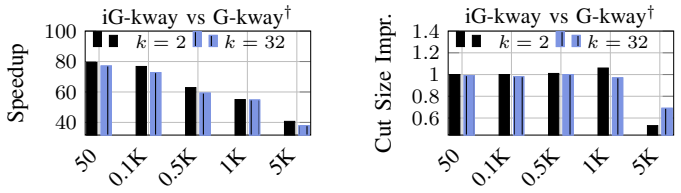

Fig. 8. The speedup (left) and cut size improvement (right) of iG-kway over G-kway† for the usb circuit across 100 incremental iterations each with varying numbers of graph modifiers (50–5K).

C. Incrementality Analysis

Figure 8 shows the speedup (left) and cut size improvement (right) achieved by iG-kway over G-kway† for the circuit usb across 100 incremental iterations each with varying numbers of graph modifiers (ranging from 50 to 5K) per iteration. When the number of graph modifiers per iteration is small, the advantage of iG-kway is more remarkable. For instance, with 50 graph modifiers, iG-kway is up to 80× faster than G-kway† while obtaining a comparable cut size. However, as the number of graph modifiers per iteration increases, the speedup decreases due to the growing number of affected vertices. More affected vertices require iG-kway to spend more time refining the partition. When the number of graph modifiers exceeds 5K per iteration, iG-kway struggles to find a partition with a decent cut size. This happens because after applying many graph modifiers (e.g., 5K×100 in this case), the graph becomes very different from its original form. This large difference makes it difficult for iG-kway to effectively optimize the graph, as its incremental refinement strategy relies on local graph structure. In such cases, applications can resort to FGP using G-kway†, especially when the number of graph modifiers reaches 50% of the graph's size.

VII. CONCLUSION

In this paper, we have introduced iG-kway, a GPU-parallel incremental k-way graph partitioner. iG-kway introduces an incrementality-aware data structure to support graph modifications directly on GPU. Atop this data structure, iG-kway introduces a GPU kernel algorithm that can efficiently refine affected vertices after the graph is incrementally modified, with minimal impact on partitioning quality. Experimental results show that iG-kway achieves an average speedup of 84× over the state-of-the-art G-kway, with comparable cut sizes.

***Abstract*—Weight-only quantization has been widely explored in large language models (LLMs) to reduce memory storage and data loading overhead. During deployment on single-instruction-multiple-threads (SIMT) architectures, weights are stored in low-precision integer (INT) format, while activations remain in full-precision floating-point (FP) format to preserve inference accuracy. Although memory footprint and data loading requirements for weight matrices are reduced, computation performance gains remain limited due to the need to convert weights back to FP format through unpacking and dequantization before GEMM operations. In this work, we investigate methods to accelerate GEMM operations involving packed low-precision INT weights and high-precision FP activations, defining this as the hyper-asymmetric GEMM problem. Our approach co-optimizes tile-level packing and dataflow strategies for INT weight matrices. We further design a specialized FP-INT multiplier unit tailored to our packing and dataflow strategies, enabling parallel processing of multiple INT weights. Finally, we integrate the packing, dataflow, and multiplier unit into PacQ, a SIMT microarchitecture designed to efficiently accelerate hyper-asymmetric GEMMs. We show that PacQ can achieve up to $1.99\times$ speedup and 81.4% reduction in EDP compared to weight-only quantized LLM workloads running on conventional SIMT baselines.**

I. Introduction

Large language models (LLMs) have demonstrated exceptional performance across a wide range of complex natural language processing tasks [19], [23]. However, their substantial parameter counts introduce significant deployment challenges, including increased memory footprint and computational costs. Quantization has emerged as a popular solution to improve the deployment efficiency of LLMs, particularly on edge devices.

Conventional deep neural network (DNN) quantization reduces both computation and memory traffic by compressing weights and activations into low-precision integers [5], [8]. However, quantizing activations in LLMs is particularly challenging due to their dynamic range and the occurrence of salient values [10], [21]. As a result, many recent studies have focused on weight-only quantization, where weights are compressed to very low-precision integers (e.g., $\leq$INT4), while activations are preserved in high-precision floating-point formats, typically FP16 [2], [9], [10], [20], [21].

This work was supported in part by CoCoSys, a JUMP2.0 center sponsored by DARPA and SRC, the National Science Foundation (CAREER Award, Grant #2312366, Grant #2318152), the DARPA Young Faculty Award and the DoE MMICC center SEA-CROGS (Award #DE-SC0023198).

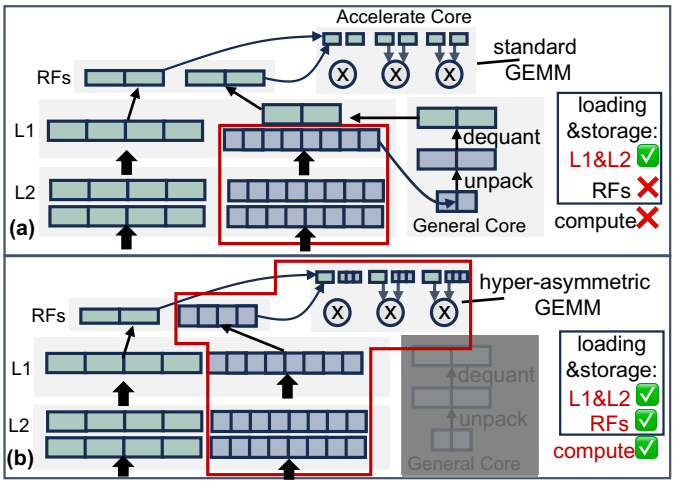

Fig. 1. (a) Standard inference flow on SIMT architecture for weight-only quantized LLMs. Green denotes high-precision floating-point activations, and blue denotes low-precision integer weights. (b) Our proposed flow leverages the hyper-asymmetric GEMM to achieve the benefits of reduced loading, storage, and compute costs from low-precision integer weights throughout the entire GEMM computation stack.

While weight quantization significantly reduces memory traffic for LLMs (e.g., Llama2-70B [19] requires 131.6 GB with FP16 weights but only 35.8 GB with INT4 weight-only quantization), it does not lower computational costs. This limitation stems from the current deployment workflow on single-instruction multiple-thread (SIMT) hardware, widely used in commercial ML accelerators such as NVIDIA GPUs. As shown in Figure 1(a), the inference deployment flow of weight-only quantized LLMs on SIMT hardware faces three major challenges: (1) ***Inefficient memory hierarchy utilization:*** Although low-precision integer (INT) weights are stored and fetched from off-chip DRAM in packed format, they are unpacked and dequantized into high-precision floating-point (FP) format upon loading into the L1 cache, losing memory benefits at and above the L1 cache. (2) ***Overhead of unpacking and dequantization:*** Unpacking and dequantizing weights introduce significant latency and computational overhead [10]. (3) ***Lack of computational savings:*** GEMM computations are performed in FP after dequantization, forfeiting the computational efficiency of low-precision integer weights.

Despite these limitations, existing weight-only quantization techniques often achieve inference speedup on SIMT

architectures in memory-bound scenarios, such as single-batch text generation. However, real-world LLM serving systems predominantly adopt multi-batch processing to achieve better hardware utilization [22]. Multi-batch processing, in contrast, is typically compute-bound, with its performance constrained by the three limitations outlined earlier.

To address the limitations in deploying weight-only quantized models on SIMT architectures, we propose to retain INT weights in packed format throughout the entire GEMM computation stack. We define this problem as **hyper-asymmetric GEMM**, where the operand precisions are highly unbalanced (asymmetric), as illustrated in Figure 1(b). In this work, we explore the design space for accelerating hyper-asymmetric GEMM on SIMT-based hardware. Our key contributions are:
(1) We pinpoint the critical role of INT weight packing direction, a factor often overlooked in prior work, for optimizing hyper-asymmetric GEMM. Specifically, we analyze the inefficiencies of packing weights along the input-feature (k) dimension, a common approach in existing quantized LLM deployment frameworks [1], [11]. To address this, we propose an alternative packing strategy and dataflow optimized for hyper-asymmetric GEMM. Our strategy has 54.3% reduction of register file accesses compared to baseline approaches.
(2) We propose a parallel FP-INT multiplier optimized for our packing and dataflow strategy. By identifying constant patterns in the FP representation of INT weight values, our design efficiently processes four FP16×INT4 or eight FP16×INT2 multiplications in parallel within a single cycle, reusing ∼73% of hardware resources from standard FP16 multipliers. This design achieves up to 6.8× throughput/watt improvement compared to conventional designs.
(3) We encapsulate the proposed packing, dataflow, and parallel multiplier design into PacQ, a SIMT microarchitecture tailored for hyper-asymmetric GEMM. Compared to NVIDIA GPUs as a baseline, PacQ achieves up to 81.4% EDP reduction for selected LLM inference workloads.

II. Background

SIMT Architecture. The single-instruction multiple-thread (SIMT) architectures are widely used in commercial ML accelerators, such as NVIDIA GPUs, to achieve high computational, memory, and control parallelism via sets of consecutively indexed threads (warps). These architectures tile large ML workloads (e.g., GEMMs) into smaller blocks mapped to individual threads, improving bandwidth efficiency and data reuse [18]. NVIDIA's Volta GPUs introduced the first streaming multiprocessors (SMs) with dedicated ML acceleration capabilities, including tensor cores (TCs), specialized for GEMM acceleration [14], [16]. Multiple SMs are interconnected via an on-chip network to a last-level cache backed up by HBM. Each SM contains sub-cores sharing an L1 cache, with sub-cores further divided into general-purpose cores and tensor cores. General-purpose cores handle operations like unpacking and dequantization, while tensor cores are optimized for GEMM operations. Operand data is stored in register files for efficient reuse before being processed by tensor cores.

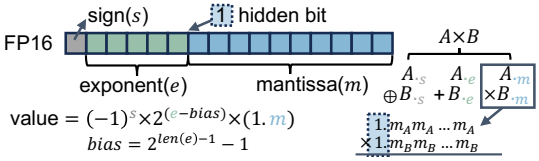

Fig. 2. Illustration of the IEEE 754 standard FP16 format.

Without loss of generality, our study examines the dataflow and microarchitecture of Volta's tensor cores as the baseline.
Floating Point Number. In Figure 2, we show the standard IEEE 754 format for FP16. In this work, we focus on the normalized format (i.e., the hidden bit for the mantissa is always 1). During the floating point multiplication, the hidden bit needs to be considered for the integer multiplication between the mantissas, as shown on the right side of Figure 2.
Related Work. Previous studies [4], [17] on accelerating mixed-precision GEMM for quantized DNNs have primarily targeted workloads with low operand precision imbalance (difference $\leq 4\times$). In contrast, our work focuses on hyper-asymmetric GEMM, characterized by a high operand precision imbalance (difference$\geq 4\times$). Recent work, FIGNA [6], introduced an FP-INT unit to eliminate unpacking and dequantization overhead during the deployment of weight-only quantized LLMs. However, their approach emphasizes co-designing the FP-INT multiplier with a block floating-point format. In contrast, our work integrates the FP-INT multiplier design with packing and dataflow strategies for processing packed INT weights. Furthermore, our design improves throughput by enabling parallel multiplication of FP activations with multiple INT weights, a capability not explored in FIGNA.

Other methods for accelerating mixed-precision GEMM in weight-only quantized LLMs employ lookup table (LUT) techniques, either by designing new LUT-friendly hardware [12] or focusing on single-batch text generation on GPUs [15]. In contrast, our work enhances general SIMT-based architectures to support multi-batch inference, a scenario more common in real-world LLM deployments. Additionally, approaches targeting efficient dequantization kernels [10], [24] address complementary challenges and are orthogonal to our work.

III. Packing flow for Hyper-asymmetric GEMM

Basic GEMM Dataflow. For illustration, we describe the Volta GPU's execution of the FP16 tensor core MMA instruction *mma.sync.m16n16k16* for *W16A16*, where both weights and activations are in FP16 precision, as shown in Figure 3. In this example, each matrix has a size of 16×16. As shown in Figure 3(a), matrices A, B, and C are collaboratively fetched by a warp consisting of 32 threads. The workload is then evenly distributed among four *octets* [16] (groups of 8 threads), as illustrated in Figure 3(b). As depicted by Figure 3(c), each *octet* fetches tiles using a weight-stationary dataflow, represented by the left three-nested-for-loop, and computations within each tile follow an output-stationary dataflow, represented by the right three-nested-for-loop. Finally, Figure 3(d) illustrates how octet-level workloads are mapped onto the hardware (i.e., tensor cores in Volta GPUs). A 4×4 tile of

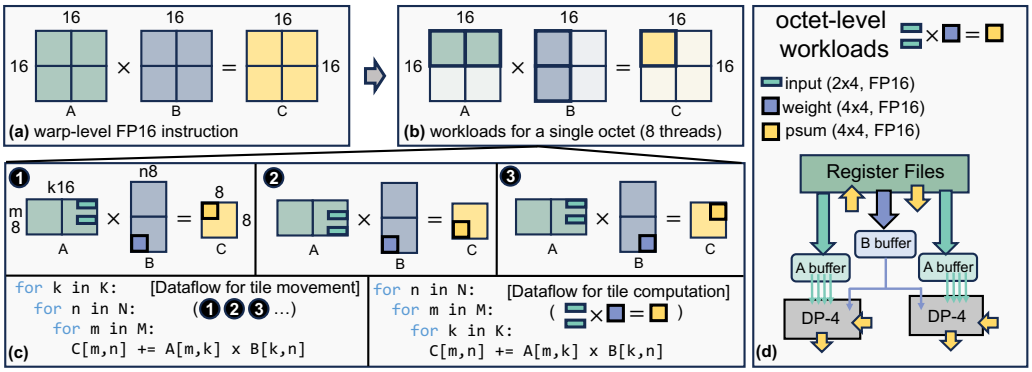

Fig. 3. (a) & (b): The tile mapping of the warp-level (a set of 32 threads) *mma.sync.m16n16k16* instruction to different octets (a subset of 8 threads). Here, A represents the input matrix with a shape of $[m, k]$, B represents the weight matrix with a shape of $[k, n]$, and C represents the output (partial-sum) matrix with a shape of $[m, n]$. (c) An example of a step-by-step breakdown of the octet-level data movement and computation flow. (d) The mapping of octet-level workloads onto the baseline tensor processing units. DP-4 stands for four-element dot-product units that performs 4×4 inner-product.

B is fetched from the register files into a buffer shared by all eight threads within the *octet*. Meanwhile, 2×4 tiles of A are loaded into separate buffers, each shared by four threads. Two four-element dot-product units (DP-4) are responsible to compute the 4×4 tile of C.

Hyper-asymmetric GEMM Packing and Dataflow. We define hyper-asymmetric GEMM as a GEMM operation where the operands A and B have a precision difference of at least $4\times$ (e.g., *W4A16* or *W2A16*). While largely overlooked in prior dequantization-based GEMM methods, the dimension along which the INT weights are packed becomes a critical factor in hyper-asymmetric GEMM. Formally, we define the packing of weight matrix B using the format $P(B_x)_y$, where x represents the number of elements of B packed along the y dimension. For instance, in *W4A16*, if the weights (B) are packed along the k dimension into the INT16 datatype, the packing can be formally described as $P(B_4)_k$. Once fetched to the L1 cache, the INT16 is unpacked to 4 INT4 weights and dequantized to FP16 for being executed in the standard FP16 GEMM.

Although there is limited research on the packing direction of INT weight matrices, nearly all prior weight-only LLM quantization frameworks [1], [3], [11] choose to pack weights along the input feature dimension (k-dim). While the packing dimension is unimportant in dequantization-based GEMM, as packed INT weights are unpacked at the L1 cache regardless of the packing direction, this is not the case for hyper-asymmetric GEMM. In hyper-asymmetric GEMM, INT operands are fetched in their packed form, creating hyper-asymmetry in the amount of data staged in the registers and tensor cores. An improper packing dimension combined with this hyper-asymmetry leads to significant performance degradation.

Specifically, when weights are packed along the k-dim, each packed INT weight fetch requires multiple activation fetch instructions because the k-dim must align between the two operands during GEMM computation. Figure 4(a) provides an example: for processing INT weights packed in the $P(B_4)_k$ format, four distinct fetch instructions for A must be issued to align the operands. Furthermore, packing INT weights (B) along the k-dim results in poor data reuse of activations (A). As illustrated in Figure 4(b), new data from A along the k-dim must be continuously fetched, leading to eviction of buffers inside the tensor cores and preventing data reuse of A. This causes excessive data access from large register files, which is highly power-intensive. When the operand precision asymmetry is significant, this issue can even escalate beyond the register file level to the L1 cache.

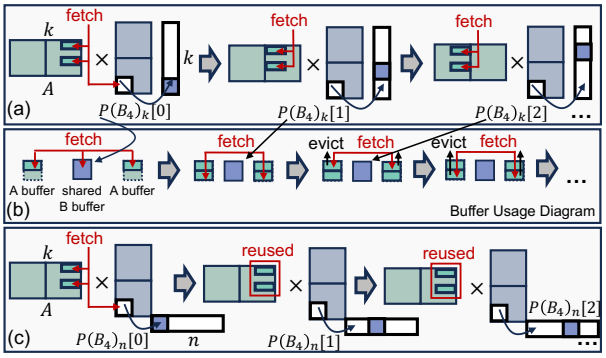

Fig. 4. (a) Illustration of the extra fetch instructions and (b) the poor data reuse of A when packing weights along the k dimension. (c) Illustration of the improved data reuse and reduction in fetch instructions achieved by packing along the n dimension. The tile size is identical to Figure. 3.

We argue that INT weights should instead be packed along the output feature (n) dimension. This approach avoids additional internal loops of fetch instructions compared to processing INT weights packed along the k-dim. As shown in Figure 4(c), once the activations (A) and packed weights ($P(B_4)_n$) are fetched following the standard flow, no extra fetch instructions are required. Furthermore, our proposed packing strategy ensures no eviction of A during the processing of packed B, enabling full reuse of activations across the packed weights. Moreover, instead of using the weight stationary dataflow for tile movement as in Figure 3(c), we use output stationary for both tile movement and tile computation. This packing and dataflow combination strikes a good balance between the data reuse and the partial sum traffic.

IV. Proposed Parallel FP-INT Multiplier

As discussed previously, our proposed packing and data flow reuses activations across all packed INT weights within

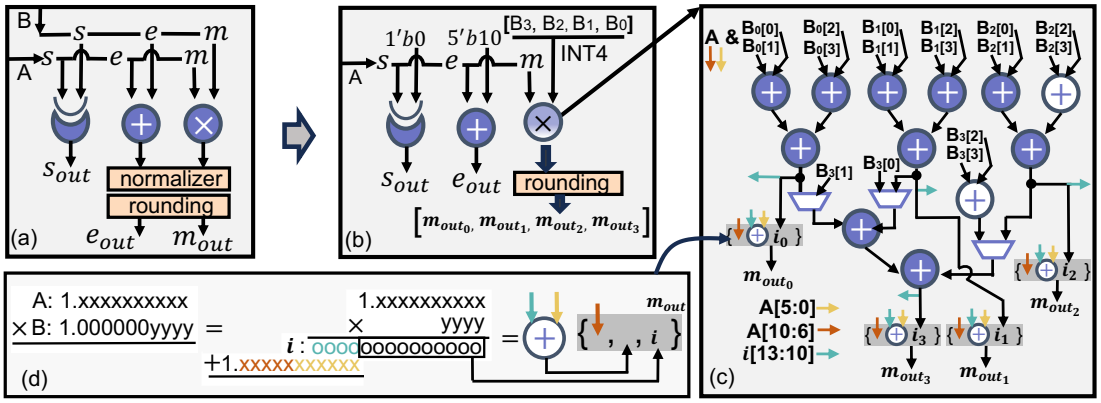

Fig. 5. (a) Standard FP multiplier design. s stands for sign, e represents exponent, and m denotes the mantissa. (b) Overview of our proposed parallel FP-INT-16 multiplier. In the provided example, our design can generate four output mantissas in one cycle. (c) Detailed diagram of the modifications made to the original 11-bit integer multiplier. The elements in purple are part of the original multiplier, while the elements in white represent additional units. All bits of B's mantissas perform a logical AND operation with shifted A's mantissas before being fed into the adders. (d) Explanation of how the final output mantissa (shaded gray) is assembled from different value sources. $\{\}$ denotes the append operation.

a single data fetch instruction. In the standard approach, these data are dequantized and processed sequentially by the pipelined FP multiplier. However, we identify an opportunity to perform the multiplication between a single FP activation and multiple INT weights in parallel. To exploit this, we propose a specialized parallel FP-INT multiplier.

Observation from FP representation of INT values. When representing an INT $x \in [1024, 2048)$ in FP16 format, certain patterns emerge during the conversion process. First, the FP16 representation of x consistently has an exponent value of 11001 (corresponding to $2^{25-15} = 1024$ in decimal). Second, the mantissa of x is always in the form of $10'b0|(x - 1024)$. Based on these patterns, we make further observations on representing low-precision INT weights in FP16 format. Without loss of generality, we use INT4 as an example, which can be easily extended to INT2 [7].

Assume $B \in [-8, 7)$ is a signed INT4 weight scalar. To simplify arithmetic operations, we first transform B to an unsigned representation by adding 8, resulting in $B+8 \in [0, 15)$. Since B is in INT4 format, we ensure that $B + 8 + 1024$ $(B + 1032)$ lies within the range $[1024, 2048)$. Leveraging the observed patterns, we conclude: ❶ The FP16 representation of $B + 1032$ always has an exponent value of 11001. ❷ The mantissa of $B+1032$ is consistently in the form $000000yyyy$, where $yyyy$ is the 4-bit integer representation of $B + 8$.

Proposed Design. Leveraging ❶ and ❷, we design a parallel FP-INT multiplier that maximally reuses the hardware resources of the original FP multiplier, as shown in Figure 5(a). Our design enables the multiplication of one FP16 input with four INT4 values or eight INT2 values in parallel, producing all outputs in a single cycle. For illustration, we focus on INT4.

Since B is transformed into an unsigned representation, the signs of all four outputs depend only on the sign of A. Thus, we compute the common output sign s_{out} by XOR-ing A's sign bit with 0. Using ❶, we derive the shared exponent e_{out} for all outputs by adding A's 5-bit exponent to 11001, as shown in Figure 5(b). Figure 5(c) depicts the details of our

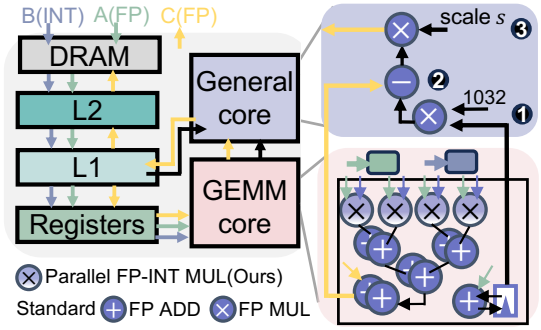

Fig. 6. Overview of the PacQ architecture. B represents the INT weight vectors, A represents the FP activation vectors, and C represents the outputs or partial sums in FP16. The steps illustrated in the general core reflect only the required instructions in sequence. PacQ does not require any hardware modifications to the general core.

proposed parallel FP-INT multiplier. The original FP16 integer multiplier requires 10 parallel adders (16-bit) to compute one 11-bit×11-bit multiplications (colored purple). Utilizing ❷, we break the original four 11-bit×11-bit multiplications into four 11-bit×4-bit multiplication. By introducing two additional 16-bit parallel adders (colored white), our design simultaneously performs all four 11-bit×4-bit multiplications.

Finally, as shown in Figure 5(d), we ensure the hidden bit of B's mantissa is accounted for by performing a 6-bit addition between the top-4 MSBs of the intermediate results i (colored turquoise, from 11-bit×4-bit) and the 6 LSBs of A (colored yellow). We then concatenate the top-5 MSBs of A (colored brown) with the addition results and i to obtain the four final mantissa products m_{out}. These results are passed to the rounding units and truncated to 10 bits (excluding the hidden bit). Since both A and B have normalized mantissa and B's mantissa values are constrained to a 4-bit unsigned integer, normalization to the outputs is unnecessary.

Overall Architecture (PacQ). We encapsulate our proposed packing and dataflow strategies along with the parallel FP-INT multiplier units into PacQ: a SIMT microarchitecture for accelerating hyper-asymmetric GEMMs. The overall architecture

is depicted in Figure 6. Our proposed microarchitecture retains most components from the Volta GPU baseline, requiring hardware modifications only in the GEMM acceleration core (i.e., tensor core). We introduce the following three key changes to the original tensor core:

First, we replace all original FP16 multipliers with our proposed parallel FP-INT multipliers. **Second**, we duplicate the original adder trees in the DP-4 by twice, enabling the accumulation of the inner product of 16 values in 2 cycles for INT4 weights (or 32 values in 4 cycles for INT2 weights). **Third**, we equip the GEMM core with small accumulators to store processed A values. Recall that before feeding the packed INT weights into the parallel FP-INT multipliers, we transform all weight values B into $B + 1032$. To retrieve the original weight values, we subtract 1032 later in the computation. By leveraging the small accumulators, we fuse this subtraction directly into the inner product calculation:

$$\sum_{0}^{k}(A_k(B_k - 1032)) = \sum_{0}^{k} A_k B_k - 1032 \times \sum_{0}^{k} A_k, \quad (1)$$

where k denotes the dimension of the inner product. The accumulators are responsible for generating the results of $\sum_0^k A_k$. As shown in the general core of Figure 6, the accumulated results are multiplied by 1032 in ❶, then subtracted from the inner product results ($\sum_0^k A_k B_k$) in ❷. Finally, the group quantization scales s are applied in ❸ to scale the outputs back to their expected range.

TABLE I
CONFIGURATION OF THE PACQ AND BASELINES.

INT11 MUL (baseline)	10 INT16 adders
Parallel INT11 MUL	12 INT16 adders, 4 INT6 adders
FP16 MUL (baseline)	1 INT11 MUL, 1 INT5 adder 1 normalization unit, 1 rounding unit
Parallel FP-INT-16 MUL	1 parallel INT11 MUL, 1 INT5 adder 1 normalization unit, 4 rounding units
FP-16 DP-4 (baseline)	4 FP16 MUL, 4 FP16 adders
Parallel FP-INT-16 DP-4	4 parallel FP-INT-16 MUL, 8 FP16 adders
Tensor Core	4 Parallel FP-INT-16 DP-4 baseline: 4 FP16 DP-4 2×3072-bits buffer, 256KB register files [14]
Streaming Multiprocessor	8 tensor cores, 96 KB shared L1 cache

V. EXPERIMENTAL RESULTS

Experimental Setup. For the packing and dataflow evaluation, we developed a custom simulator in Python to monitor memory access patterns and record execution cycles for PacQ and the baselines. Key components of PacQ and our baselines were implemented in RTL and synthesized using Synopsys Design Compiler at 400MHz with 32nm technology. We utilized CACTI7.0 [13] to model on-chip SRAM and register files for getting memory statistics. Configuration details for PacQ and the baseline architectures are summarized in Table I. Unless otherwise specified, in the rest of the section, INT2 and INT4 refer to the precision of weights, while activations and partial sums are always represented in FP16 format. For hardware unit comparisons, 'baseline' always refers to the standard baseline designs as denoted in Table. I. $P(B_{4(8)})_k$ denotes the baseline of hyper-asymmetric GEMM flow that packs 4 INT4 (8 INT2) weights in one INT16 along k-dim.

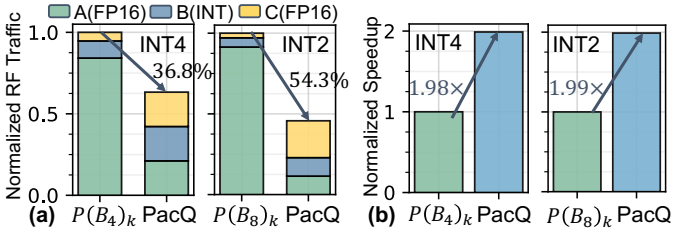

Fig. 7. (a) Comparison of the normalized number of register file accesses. (b) Comparison of normalized speedup between PacQ and hyper-asymmetric GEMM with INT weights packed along k. The workload is *m16n16k16*. $P(B_{4(8)})_k$ represents packing 4 INT4 weights (or 8 INT2 weights) into one INT16 data along the k dimension.

Proposed Packing and Data Flow. In Figure. 7(a), we present the number of register file accesses for PacQ compared to the hyper-asymmetric GEMM with INT4 (INT2) weights packed along k. The results demonstrate that with improved data reuse, our approach achieves up to a 54.3% reduction in register file accesses. Furthermore, in Figure. 7(b), we show the normalized speedup of PacQ compared to the hyper-asymmetric GEMM packing along k. Thanks to our parallel processing strategy, we achieve an average speedup of $1.99\times$.

We want to confirm here that PacQ ***does not require any quantization algorithm modifications*** to achieve hardware efficiency, as there is no approximation in our design. However, we observe that a small adjustment to the existing PTQ algorithm can further enhance the efficiency of PacQ. Specifically, by spanning the quantization group across both dimensions ($[n, k]$) instead of solely on the input feature dimension (k), we can reduce the number of fetches of the quantization scale s for PacQ in the general core, as illustrated in Figure 6-❸. We adapt the standard round-to-nearest (RTN) based PTQ algorithm to define quantization groups across both n and k dimensions within the existing framework [11]. The perplexity results for Llama2-7B [19] are shown in Table II. The results demonstrate that with these quantization group-dimension modifications, we achieve iso-perplexity with standard RTN 4-bit weight-only quantized models.

Parallel FP-INT Multiplier. We first evaluate the throughput / Watt to measure the overall performance of our proposed parallel FP-INT multiplier. Figure 8 compares the normalized performance of our design against the original FP16 multiplier and the FP16 DP-4 unit. The throughput of the original FP16 multiplier is 1, whereas it is 4 (8) for our parallel design with INT4 (INT2) weights. The original FP16 DP-4 unit requires

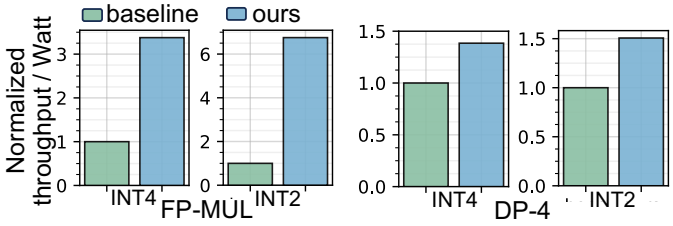

Fig. 8. Normalized performance comparison between the baseline FP16 designs with our parallel FP-INT-16 designs of running INT4 and INT2 weights. For DP-4, we consider the workload of *m2n4k4*.

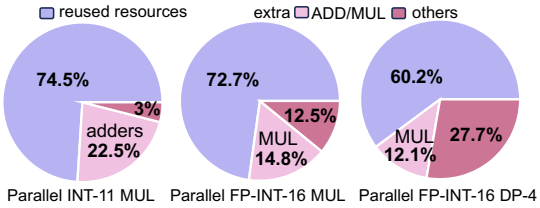

Fig. 9. Power breakdown of our proposed units. MUL stands for multiplier.

11 cycles to generate 8 FP16 outputs, while our parallel design takes 19 (35) cycles to generate 32 (64) FP16 outputs for INT4 (INT2) weights. Compared to the original FP16 multiplier, our design achieves 3.38× better performance for INT4 weights and 6.75× better performance for INT2. We further show the power breakdown of our proposed units in Figure 9. Our design objective is to maximize the reuse of hardware resources from the standard design. As shown by the purple-colored portions in the figure, we successfully reuse nearly 75% of the original INT-11 multiplier resources, which serve as the fundamental building blocks in our parallel FP-INT multiplier. For the DP-4 unit, we achieve approximately 60% hardware resource reuse. The observed decrease in the resource reuse ratio stems from the duplication of additional units; for instance, we needed to double the FP16 adder trees in the DP-4 design. Despite this, our design maintains an average hardware resource reuse ratio of 69%, which significantly minimizes resource duplication and enhances overall efficiency.

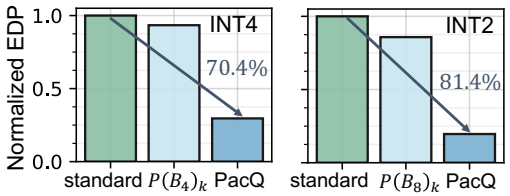

Fig. 10. Normalized EDP of PacQ vs. baselines. 'Standard' refers to the standard dequantization-based W16A16 GEMM. $P(B_{4(8)})_k$ denotes the hyper-asymmetric GEMM with INT4 (INT2) weights packed along k.

Other Results. In Figure. 10, we present the overall energy-delay-product (EDP) comparison of PacQ against Volta-like SIMT baselines. Two baseline cases are evaluated: the standard dequantization-based GEMM flow and the hyper-asymmetric GEMM flow with weights packed along the k dimension. Results demonstrate that PacQ achieves up to an 81.4% reduction in EDP for the workload $m16n4096k4096$, which represents a FFN layer in Llama2-7B with 16 batches.

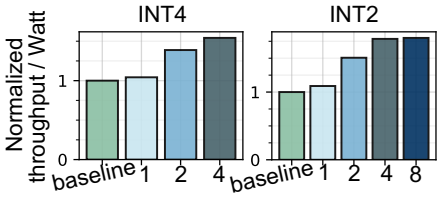

Fig. 11. Ablation study on the adder tree duplication. The number indicates the level of duplication of the adder trees (with a total of 4 FP16 adders in the baseline). For example, a duplication level of 4 would indicate 16 FP16 adders in our parallel FP-INT-16 DP-4 design.

In Figure. 11, we investigate the impact of duplicating FP16 adder trees in our parallel FP-INT DP-4 unit on overall performance (throughput / Watt) for the *m16n16k16* workload. We observe that while increasing the level of duplication continues to improve performance, a duplication factor of 2 provides the most significant gain. It achieves a 1.33× (1.38×) improvement over a duplication factor of 1 for INT4 (INT2). In comparison, a duplication factor of 4 results in only a 1.11× (1.18×) improvement over duplication factor 2 for INT4 (INT2).

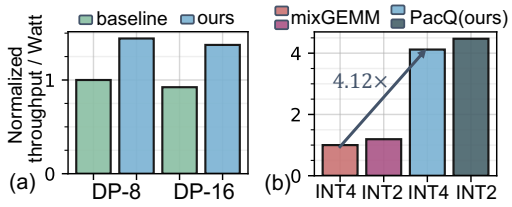

Fig. 12. (a) Comparison of different sizes of the DP unit. (b) Comparison of PacQ with Mix-GEMM [17]. Both (a) and (b) use the metric of throughput per watt. The workloads for both comparisons are *m16n16k16*.

In Figure. 12(a), we further study the effect of the size of the DP unit (DP-8 and DP-16). The results show that PacQ's performance improvements are orthogonal to the size of the DP units. In Figure. 12(b), we compare the performance of PacQ with prior work, Mix-GEMM [17], which also aims to improve the throughput of mixed-precision GEMM workloads through binary segmentation. With FP16 activation, PacQ achieves a 4.12× performance improvement for INT4 weights and a 3.75× improvement for INT2. This performance advantage is attributed to the fact that the binary segmentation technique performs poorly for hyper-asymmetric GEMM.

VI. Conclusion

In this work, we present PacQ, a novel SIMT microarchitecture designed to efficiently handle hyper-asymmetric GEMMs with mixed-precision weights (INT4 and INT2) and activations (FP16). By introducing a new packing and dataflow strategy, coupled with our parallel FP-INT multiplier, PacQ achieves significant improvements in hardware efficiency and throughput. Through extensive experimental evaluation, we demonstrate that PacQ delivers up to 54.3% reduction in register file accesses, a 1.99× speedup in throughput, and up to 81.4% reduction in energy-delay product (EDP) compared to conventional SIMT baselines. We believe our work can provide the community with insights into the design space exploration for hyper-asymmetric GEMM acceleration.

***Abstract*—Ising solvers with hierarchical clustering have shown promise for large-scale Traveling Salesman Problems (TSPs), in terms of latency and energy. However, most of these methods still face unacceptable quality degradation as the problem size increases beyond a certain extent. Additionally, their hardware-agnostic adoptions limit their ability to fully exploit available hardware resources. In this work, we introduce TAXI – an in-memory computing-based TSP accelerator with crossbar(Xbar)-based Ising macros. Each macro independently solves a TSP sub-problem, obtained by hierarchical clustering, without the need for any off-macro data movement, leading to massive parallelism. Within the macro, Spin-Orbit-Torque (SOT) devices serve as compact energy-efficient random number generators enabling rapid "natural annealing". By leveraging hardware-algorithm co-design, TAXI offers improvements in solution quality, speed, and energy-efficiency on TSPs up to 85,900 cities (the largest TSPLIB instance). TAXI produces solutions that are only 22% and 20% longer than the Concorde solver's exact solution on 33,810 and 85,900 city TSPs, respectively. TAXI outperforms a current state-of-the-art clustering-based Ising solver, being 8× faster on average across 20 benchmark problems from TSPLib.**

***Index Terms*—Ising Machine, Accelerator, In-Memory Computing, Combinatorial Optimization Problem, SOT-MRAM.**

I. Introduction

Combinatorial optimization problems (CoPs), like the traveling salesman problem (TSP), are ubiquitous with applications in logistics, electronic design automation, genetics, and operations research [1], [2]. For TSPs, one of the most extensively studied CoPs, traditional methods [3] use heuristics like branch-and-bound and backtracking to find optimal solutions. However, such methods slow down exponentially as the problem size increases, due to exponential search space explosion. Additionally, traditional von Neumann architecture causes memory bottlenecks, rendering the TSP solvers inefficient for large instances due to repeated read-write operations during search-space exploration. This operating mismatch between the traditional TSP solver's execution pattern and von Neumann architecture's dataflow further slows down the optimization process, with the increase in problem size.

Ising models, inspired by statistical physics, offer a promising alternative for solving small-scale TSPs by encoding combinatorial state-spaces onto 2D arrays of binary spin values, that naturally settle into minimal energy states. Small

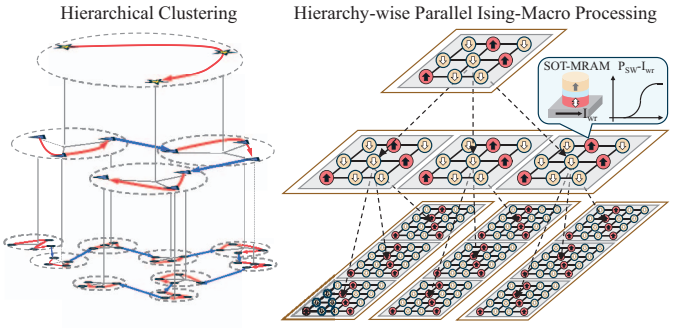

Fig. 1. Hierarchical clustering and Ising macros for large-scale traveling salesman problems. The shortest route within each cluster (red in the left) is optimized by an Ising macro (each grey box in the right). The final solution is derived by merging inter-cluster (blue in the left) and intra-cluster routes.

TSP instances can be efficiently mapped onto Ising crossbar (Xbar) arrays, potentially as hardware macros, enabling high-speed optimization. However, as the problem size grows, solution quality degrades due to the expanding search space and quadratic rise of spin interactions leading to a growing complexity of interconnects required to realize larger Ising Xbars. To address this issue, hierarchical clustering methods have been introduced [4]–[7], where large TSPs are decomposed into sub-problems that can be solved using smaller Ising models with acceptable quality. This work builds upon these clustering-based approaches, scaling further to tackle even larger problems with improved solution quality and further improvements in latency.

Typically, Ising solvers rely on stochastic processes to find near-optimal solutions. In conventional Complementary metal-oxide-semiconductor (CMOS)-based systems, random number generators (RNGs) are used to perform the stochastic switching of spins. However, these RNGs consume significant area and are too slow to meet the demands of rapid annealing, causing CMOS-based Ising solvers to be bulky with large area overheads and sluggish response-times [8], [9]. To overcome this, Spin-Orbit-Torque Magnetic Random Access Memory (SOT-MRAM)-based RNGs are considered in this work for Ising annealing, due to their energy-efficient and compact RNG implementation capability. In addition, in-memory computing (IMC) enables computations within memory arrays, reducing data movement and energy consumption. Xbar-based Ising primitives efficiently map TSP sub-problems onto hardware arrays [6], [7], making them suitable for realizing IMC macros. However, existing IMC-based Ising implementations still rely on off-macro memory accesses to store spin states.

To that effect, we propose TAXI – a TSP accelerator that uses Xbar-based Ising primitives as IMC macros with minimal off-macro data movement. TAXI applies hierarchical clustering to decompose large TSPs into smaller sub-problems, which are then solved in parallel using dedicated Ising hardware units. This architecture ensures that each sub-problem is solved directly in memory. This results in a hardware-algorithm co-design framework, where the algorithm (hierarchical clustering) and the architecture (spatially arranged Ising cores) are tightly integrated (See Fig 1). The custom hardware is designed by considering the algorithm's hierarchical execution pattern, ensuring that the Ising computations align with the algorithm's flow, enabling TAXI to maintain high solution quality as well as high speed even when problem size increases. Our contributions are as follows:

- A custom multiplication-and-accumulation (MAC)-based TSP solver using SOT-MRAMs and its stochastic switching to accelerate Ising annealing, overcoming the limitations of traditional CMOS-based RNGs (Section III).
- A novel hierarchical clustering with fixed inter-cluster routes that reduces TSP scale, with independently invoked Ising sub-solvers to enhance parallelization and sub-solution quality, enabling near-optimal solutions for large-scale TSPs (Section IV).
- A crossbar (Xbar)-based parallel architecture that supports in-macro Ising computing through hardware-algorithm co-design, mapping sub-problems onto Xbar arrays, and aligning the custom hardware with the algorithm to improve scalability (in terms of latency and energy) for large-scale TSPs (Section V).

Our experimental results (Section VI) demonstrate that TAXI is 8× faster on average across 20 benchmark problems (with up to 85,900 cities) from TSPLib [10] compared to a state-of-the-art hierarchical Ising solver [5]. TAXI generates 3% shorter traveling route on 33,810 cities over method [7] and 31% shorter route on 85,900 cities over method [5] – two recent clustering-based Ising works which demonstrate the best solutions on the respective problems, so far.

II. BACKGROUND AND RELATED WORKS

A. *Ising Solver*

In Ising model, Hamiltonian (energy) of the total system (H_{total}) and each spin (element) (H_i) are defined as below:

$$H_{total} = -\sum_i \sum_j J_{ij}\sigma_i\sigma_j - \sum_i h_i\sigma_i \tag{1}$$

$$H_i = \sum_j J_{ij}\sigma_j + h_i \tag{2}$$

where J_{ij} represents interaction between spins, σ_i and σ_j, while h_i denotes external field applied to spins. Equation 1 can be reformulated by equation 2 as below:

$$H_{total} = -\sum_i \left(\sum_j J_{ij}\sigma_j + h_i \right) \sigma_i \tag{3}$$

According to the rule that spin state, +1 or -1, follows the polarity of H_i, greater than 0 or not, respectively, ΔH_{total} is *always negative*. It means every spin update minimizes H_{total}, approaching an optimal solution in an unsupervised manner.

Inspired by the nature, Ising solvers have been proposed to naturally find the optimal solution to problems that can be properly encoded in Ising format. For Ising acceleration, MAC operation based on a memory Xbar has been deployed [7], [11] for $\sum_j J_{ij}\sigma_j$ in equation 2; Spin states (σ_j) are applied to rows and multiplied with J_{ij}. Then, H_i is derived.

However, the always-descending energy update is insufficient to get the optimal solution when problems are complicated. The complication makes the energy search space of Ising problem non-monotonic as depicted in (Fig 2), causing the Ising solver to get stuck in local minimas. To climb up the energy hill and reach global minima which is optimal solution, Ising solver needs the power to violate the always-descending nature. For the violation, stochastic switching of spin disregarding equation 3 is necessary.

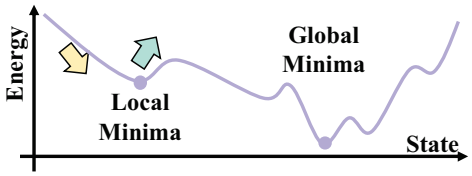

Fig. 2. Non-monotonic energy search space. Energy minimization (yellow) and Stochastic update (green) jointly find the global minima by enabling descending the energy landscape and escaping from local minimas, respectively.

B. *Source of Stochasticity*

CMOS-based random number generator (RNG) [7], [12], [13] and emerging electronic devices, such as resistive random access memory (RRAM) [11], silicon-oxide-nitride-silicon (SONS) FinFET [6], and spin-transfer torque MRAM [14]–[18] have been deployed as the source of stochasticity.

RRAM and SONS FinFET offer stochasticity through their inherent thermal and temporal noise when used for a Xbar array for MAC operation [6], [11]. Despite their better chip density, the intrinsic noise becomes uncontrollable when the Xbar grows [11]. Magnetic tunnel junction (MTJ)-based RNGs based on low barrier nanomagnets and telegraphic switching [15]–[18] and CMOS-based RNGs [8], [9] can be placed in the peripheral circuitry, which are not scaled up by Xbar size. However, current MTJ-based implementations require very low barrier nanomagnets ($\Delta \sim 0kT$) for truly high-speed RNG (>1Gb/s) and high-frequency sense circuitry to detect rapid switching of the device, while CMOS-based RNGs are slower (<2400Mb/s) [9] and take much more area ($> 375\mu m^2$) [8].

C. *Ising Solvers for Large-scale TSP*

Large-scale TSPs are hard for Ising solvers due to the quadratically growing number of connections as TSP size increases. Hierarchical Vertex Clustering (HVC) [4] proposed hierarchical clustering to reduce the number of connections. Despite the reduction, it still sparsely maps all the clustered problems to a single matrix, which leaves the connection problem unsolved when the problem size is beyond a certain

level. Neuro-Ising [5] proposed a hybrid clustering-and-graph-neural network manner but shows performance degradation as the problem size increases. In-memory annealer (IMA) [6] and its follow-up, digital compute-in-memory annealer (CIMA) [7], based on the hierarchical clustering achieves acceleration by simultaneously optimizing non-adjacent clusters. However, they store the spin states outside macros, causing slow-down.

III. SOT-MRAM-BASED TSP SOLVER

A. *MAC-based Energy Minimization for TSP*

TAXI leverages the Xbar-based MAC operation to minimize H_{total}. To achieve the objective of TSP, finding the shortest route to visit all cities only once, information on the distance between cities and the visiting order initialized by input order are used. The distance is reformulated as follows:

$$W_D(A,B) = \frac{D_{min}}{D_{A-B}} \times B_{Precision} \tag{4}$$

where $W_D(A,B)$ denotes a conductance value to map on a cross-point of Xbar, while D_{A-B} and D_{min} represent the distance between cities A and B and the minimum distance among all paths, respectively, and $B_{Precision}$ is the bit-precision that can be offered by the hardware.

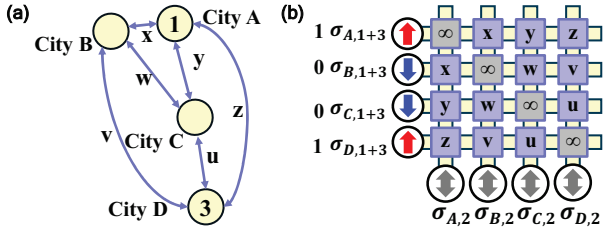

Fig. 3. (a) TSP with 4 cities. $u-x$ represent distances and numbers in a circle denote visiting orders. (b) Distance matrix mapped on a crossbar. Distances reformulated to W_D are programmed to crosspoints in resistance.

Fig 3 displays how the W_D is mapped on the Xbar and used to choose a city to visit at order *i* which results in the shortest route. For the optimization, cities visited at the previous (*i*-1) and the next (*i*+1) orders are considered because the total traveling distance is decided by both. The visiting information ($\sigma_{A,i}$) to a specific city (*A*) at a specific order (*i*) is represented by a binary spin, 1 or 0, following quadratic unconstrained binary optimization (QUBO) and Ising equivalence [20]. $\sigma_{A,1}$ and $\sigma_{D,3}$ are 1 because they are visited at order 1 and 3, respectively. With the fact that the distance information is static, we superpose the vector representing visiting information of order *i*-1 ($\sigma_{A-D,1}$) and *i*+1 ($\sigma_{A-D,3}$), as shown in Fig 3b. It reduces the crossbar array sizes, leading to better area-efficiency and less involvement of non-ideality.

In this setup, the current flowing through each column ($\sigma_{A-D,2}$) following Ohm's law and Kirchhoff's current law represents relative distance when the city is chosen for the order. It can be expressed as:

$$D_{x,i} = \sum_{k \neq x} W_D(x,k)(\sigma_{k,i-1} + \sigma_{k,i+1}) \tag{5}$$

According to equations 4 and 5, the current flowing through the 3rd column becomes the largest due to shorter distance (lower resistance), making $\sigma_{C,2}$ selected as up-spin.

B. *Stochasticity-Involved Decision Making*

In TAXI, stochasticity is involved in the choice of the largest current via a stochastically produced binary vector as big as the problem size. Only cities corresponding to 1s in the vector are considered for the choice. It offers the power to violate the always-descending nature, mentioned in Section II-A. The visiting order is updated by the newly chosen city.

C. *Ising Macro as a TSP Solver*

A Xbar array with customized peripheral circuitry is leveraged as an Ising macro to solve a TSP in the manner of the aforementioned algorithms. Fig 4 shows the system-level layout of the Xbar-based Ising macro along with the associated peripherals inset in Fig 4c,d. The unit cell of the Xbar array is a 3T-1M SOT-MRAM unit, with a transmission gate to control the read current, and 1 transistor to control the write current. The transmission gate was chosen owing to the need for accurate bi-directional reads.

The Xbar is divided into $B+1$ partitions, where B is the chosen bit-precision for the W_D. The first B partitions contain the W_D, while the last partition stores the spin information ($\sigma_{k,i}$) as the solution of the given TSP. To minimize effect from non-ideality, such as wire resistance, higher significant bit is stored closer to the left end. The rows and columns of the spin storage (SS) represent cities and visiting orders. If a specific city (A) is chosen at a specific order (1), a SOT-MRAM that is located in the first row and the first column in the SS is programmed in the low resistance state (LRS), while the others on the same column are in the high resistance state (HRS). This implies that the size of the Xbar required for a TSP problem size of N is $N \times N \cdot (B+1)$.

1) ***Superpose****:* The superposition of vectors representing visiting information, discussed in Section III-A and Fig 3, is executed by MAC operation using the SS, as illustrated in Fig 4a. In the case of Fig 3, the first and the third columns are activated to recall visiting information at order 1 and 3. Then, the Xbar natively derives the superposed vector in current at the end of the rows, while a following current comparator [21] translates it in binary and a D-latch stores the binary vector. This flow is depicted by the red arrow in Fig 4.

2) ***Calculate Distance****:* The stored vector in the D-Latch is fed back to the rows, generating currents by executing equation 5, based on the W_D stored in the first B partitions of the Xbar. Only columns in the first B partitions are activated, with columns in the SS deactivated. The currents from the Xbar flow into current mirrors, scaled by 2^{b-1} depending on the bit-significance (b) of the partition, as shown in Fig. 4b.

3) ***Stochastic Binary Vector*** *:* The stochastic binary vector mentioned in Section III-B is generated by SOT-MRAM's stochastic switching-based circuit consisting of N identical units shown in Fig 4c. SOT-MRAM has two ferromagnetic layers (one with a fixed magnetic moment direction, while another is free to rotate) separated by a thin insulator. Its resistance is determined by how many electrons can tunnel through this MTJ, which depends on whether the magnetic moment of the

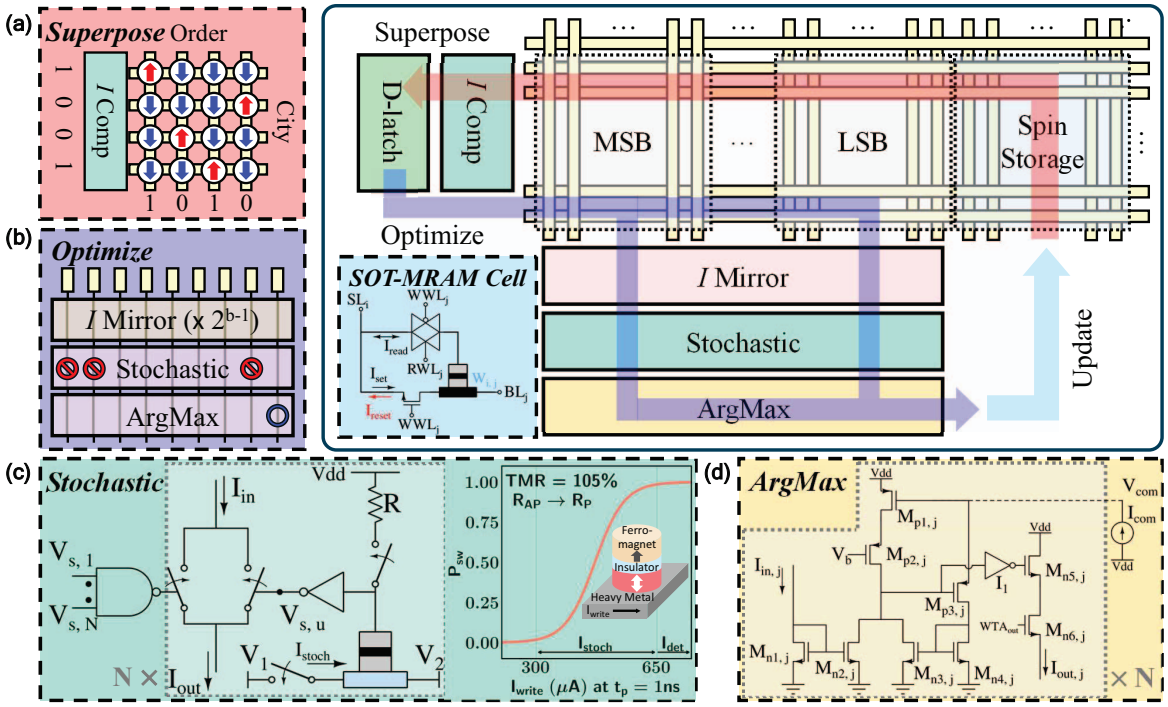

Fig. 4. Floor plan of an Ising macro. Arrows represent data flow across the macro. Insets (a-d) illustrate components in the macro. (a) Superposition of vectors to optimization. Red and blue arrows represent up- and down-spin stored in spin storage, respectively. (b) Optimization by crossbar array as the distance matrix and following peripheral circuits. (c) SOT-MRAMs in the stochastic circuit pass or prevent current from the crossbar following its stochastic switching. Inset displays the probability of switching R_{AP} to R_P of the chosen SOT device [19]. I_{stoch} and I_{det} denote the current ranges for stochastic and deterministic operations, respectively. (d) ArgMax circuit picks a city to visit by choosing the largest current.

two ferromagnetic layers is aligned in parallel (R_P) or anti-parallel (R_{AP}). This alignment can change due to the Spin Hall effect induced by current flowing through a heavy metal layer under the ferromagnet [22]. The stochastic switching that TAXI leverages is based on this dynamic. Depending on the amount of current, the probability of switching (P_{sw}) between R_P and R_{AP} can be controlled, as shown in Fig 4c [19]. By controlling the current that derives a specific P_{sw} (300μA — 650μA), TAXI can control the expected number of 1s in the stochastic binary vector. SOT-MRAMs in the Xbar are operated only in the deterministic regime (>650μA).

The stochastic circuit (Fig. 4c) controls the flow of the preceding current mirror outputs into the next stage upon the stochastic switching. For a given unit, if the SOT device switches, the voltage across the divider circuit becomes lower than units whose SOT device has not switched. The output of the inverter is therefore high, resulting in the unit allowing the input current to pass through. The circuit allows the current only through the columns ($\mathcal{S}$) where the SOT device has stochastically switched for a given iteration to pass through. In case $\mathcal{S} = \varnothing$, currents through all columns are allowed to pass because the NAND gate output is high for every unit.

*4) **Choosing the Largest Current**:* The largest current is selected by the ArgMax circuit shown in Fig 4d. It processes a vector of input currents and outputs a vector where only the index 'i' corresponding to the largest input current remains nonzero. The winner current is set to the minimum required to switch a SOT-MRAM device in the deterministic regime. The ArgMax circuit is based on Lazzaro's winner-take-all circuit [23], enhanced with a cascaded transistor ($M_{p2,j}$) in the input branch to increase output resistance [24], and a current mirror ($M_{n2,j}$, $M_{n3,j}$) to boost feedback, significantly improving resolution and speed [25].

*5) **Update Spin Storage**:* The one-hot encoded current vector derived by the ArgMax circuit is directly used to update the spin storage, as illustrated by the cyan arrow in Fig 4. Before the update operation, all the devices on the column representing the order which is being optimized are reset to HRS which represents 0. Then, the output current vector of the ArgMax circuit is applied to write the column.

*6) **Annealing**:* The processes described in sections III-C1 - III-C5 are repeated for the pre-designated number of iterations from the first to the last order by activating different columns in the SS depending on the visiting order to optimize. After the whole iteration, the spin information stored in the SS is retrieved as the final solution of the given TSP. To optimize the solution, stochasticity should decrease during iterations, allowing the Ising system to remain at the global minimum as the solution improves. Otherwise, the system may escape the global minimum and end up with a worse solution. The solution is optimized the best when the stochasticity decreases slowly. Optimization is however faster in the early stages making the non-linear decrease of stochasticity appealing.

For the non-linearity, TAXI utilizes the native sigmoidal switching probability vs I_{write} characteristic, as shown in Fig 4c. The non-linearity can enable a relatively rapid decrease in stochasticity at the earlier stage, leading to shorter overall latency, while keeping the advantage of slow decrease at

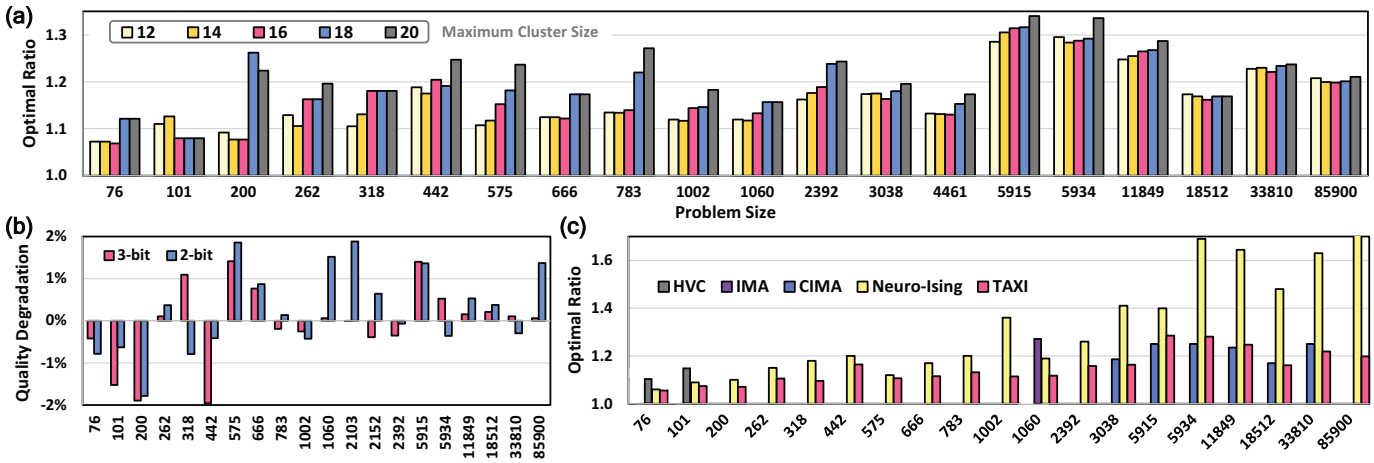

Fig. 5. (a) Optimal ratio depending on the maximum cluster size in 4-bit precision. (b) Solution quality degradation when the bit precision changes from 4-bit to lower-bit options. The positive number represents degradation. (c) Comparison of solution optimality. Data of TAXI with 4-bit precision and 12 cluster size are presented. Data of other Ising solvers are adapted from [5]–[7].

the later stage. To leverage the native sigmoidal decrease, the I_{write} is initialized to 420μA (corresponding switching probability, 20%) and linearly decreased by 50nA after every iteration. Once the I_{write} becomes 353μA (corresponding probability, 1%), the Ising solver stops, then, the solution stored in the SS is taken as the final output of the given TSP.

IV. HIERARCHICAL CLUSTERING

*1) **Locally Solve Global Problems**:* We adopt a hierarchical structure similar to HVC [4] for clustering, executed in a bottom-up fashion. After clustering all cities at level i, the cluster centroids form level $i+1$. This process repeats until the number of centroids at a level is less than the maximum TSP size confidently solvable by an Ising macro. The number of clusters at each level is determined by the maximum size.

*2) **Parallel Processing**:* After the hierarchical structure is defined, the TSP is solved in a top-down manner. Once the topmost TSP (level L) is solved, the solution, which is the visiting order of clusters at level $L-1$, is determined. Unlike HVC, which sparsely maps all clusters to a single Xbar array to optimize routes both within and between clusters, TAXI fixes the first and last cities of sub-problems first to minimize the inter-cluster route. This fixation ensures that sub-problem solutions do not compromise the inter-cluster distance. The first and last cities of each cluster are determined by identifying the closest city pairs between neighboring clusters, enabling parallel solving of as many clusters in a level as there are Ising macros in a chip. The entire process concludes when all sub-problems in the lowest level are solved.

*3) **Agglomerative Clustering**:* TAXI leverages Agglomerative clustering to achieve the hierarchical clustering for its robustness to outliers, instead of K-means clusters adopted by others [4]–[7]. It is a type of hierarchical clustering that merges clusters based on an inter-cluster similarity metric until the desired number of clusters is obtained [26]. With the Ward linkage, the squared distance or variance within a cluster is minimized [27]. Even though K-means clustering also aims to minimize the intra-cluster variance, they usually lead to nearly spherical or regular clusters [28], while agglomerative clustering can produce compact irregular clusters.

V. X-BAR-BASED PARALLEL ARCHITECTURE

Hierarchical clustered Ising macros are mapped to the Xbar architecture to enable in-macro Ising computing through hardware-algorithm co-design, mapping sub-problems onto Xbar arrays, and aligning the custom hardware with the algorithm to improve scalability for large-scale TSPs. We instrumented the PUMA architecture [29] to perform the mapping and evaluated the latency and energy consumption from data movement between off-chip memory and the proposed Ising macros executing parallel Ising computations. PUMA is a cycle-accurate simulator based on an IMC spatial architecture, structured with a hierarchy of chip, tile, core, and MVMUs. The simulator's compiler generates instructions using PUMA ISA, and the simulator executes them to assess latency and energy. We replaced PUMA's ReRAM-based MVMUs with our Ising macro and scaled all elements from PUMA's 32nm to a 65nm node. See Section VI-C for more details.

VI. EVALUATION

A. *Results on Multiple TSPs*

The performance of TAXI with varied maximum cluster sizes is simulated in C++, following the Ising layer presented in [5]. For realistic simulation, ON/OFF resistance of SOT-MRAM and transistors and wire resistance are considered [19]. Fig 5a displays the optimal ratio which is derived by dividing a solution of Ising solver with exact solution [30]. A smaller cluster (sub-problem) size leads to a better solution quality in most cases as Ising solvers usually show better results on smaller problems. With the problem size of 12, we tested different bit precisions for the W_D.

Fig 5b presents solution quality degradation when the bit precision changes from 4-bit to 3- or 2-bit. It shows that the performance is maintained in the 2% range. We attribute this fluctuation to variation of both W_D precision and non-ideality arising from Xbar size change. From the energy-efficiency

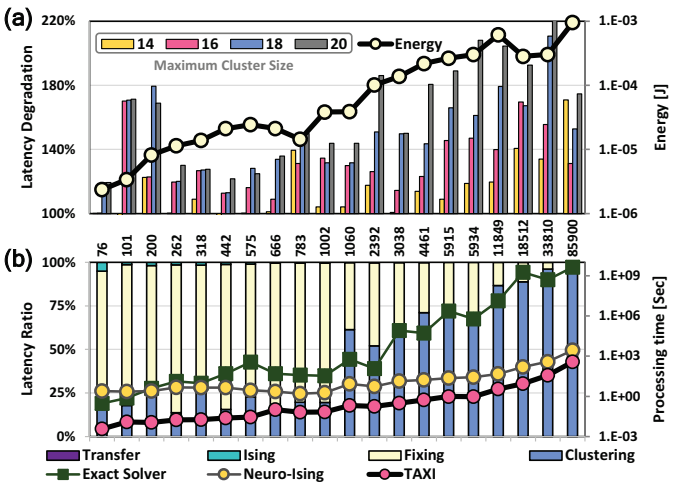

Fig. 6. (a) Latency (bar) and energy (line) arising from Ising macros and data transfer within the architecture depending on the maximum cluster size in 4-bit precision. Energy based on a problem size of 12 and 2-bit precision is representatively displayed. (b) Total Latency including clustering, fixing, Ising processing, and data transfer illustrated in lines (right y-axis). Bars represent the ratio of each component contributing to the total latency (left y-axis).

TABLE I
CIRCUIT SIMULATION RESULTS FOR COMPLETION OF 1 ITERATION INCLUDING SUPERPOSITION, OPTIMIZATION, AND SPIN-STORAGE UPDATE.

		2 bit	3 bit	4 bit
Array Size		12×36	12×48	12×60
Power [mW]		4.202	5.033	5.11
Latency [ns]	**Superposition**	3	3	3
	Optimization	4	4	4
	Storage Update	2	2	2
Energy [pJ]		37.82	45.3	45.98

perspective, the lower bit-precision is beneficial. Depending on the priority between the power budget and the solution quality, TAXI can be reconfigured. The comparison will be discussed in the following section VI-C. TAXI with a clustering size of 12 and 4-bit precision is benchmarked with existing Ising solvers for TSPs in Fig 5c. TAXI outperforms the others [5]–[7] in most cases including three of the largest TSPs, 18512, 33810, and 85900.

B. Circuit Simulation

An entire Ising macro shown in Fig 4 is simulated using the `Cadence® Spectre®` simulator in the TSMC 65nm technology node. Verilog-A behavioral modeling was performed to fit the characteristics of the considered SOT device in section III-C3. We choose a TSP problem size of 12. We run the simulation for 1 complete iteration including the superposition, optimization, and spin-storage updates. The pre-layout circuit simulation results are presented in Table I. The higher-bit precision causes a larger area and higher energy consumption.

C. Architecture Simulation

The total latency excluding clustering with fixing simulated by PUMA simulator is presented in Fig 6a. It presents the ratio of the latency with a specific maximum cluster size to that with a maximum cluster size of 12. The higher value means the slower operation. In most cases, the larger cluster size causes longer latency. The clustering time does not vary noticeably depending on the problem size. The latency arising from fixing the intercluster routes theoretically increases as the problem size increases, because the possible number of pairs between clusters increases quadratically while the number of clusters linearly decreases. Based on the results presented in Fig 5a and Fig 6a, the smaller problem size is preferred if the chip can contain as many Ising macros as the number of clusters in a level. It enables mapping and solving all clusters in parallel. Otherwise, the larger size could be a better option to maximize the parallel operation. The total energy consumption excluding clustering and fixing is presented in line in Fig 6a. Lower energy consumption for transferring, mapping, and processing (presented in Table I) smaller W_D makes the lower bit-precision more efficient. Table II shows the energy consumption, excluding data transfer and mapping, to fairly compare TAXI and previous works, demonstrating that ours is the most power-efficient.

TABLE II
ENERGY COMPARISON WITH STATE-OF-THE-ART

	[4]	[6]	[7]	**This Work**
Technology	CPU	14nm FinFET	16/14nm CMOS	65nm CMOS + SOT-MRAM
Problem Size	101	1060	33K, 86K	1060, 33K, 86K
Energy (J)	1.1	20.08μ	$\sim 20\mu$, $\sim 45\mu$	1.81μ, 2.67μ, $3.07\mu^{\dagger}$

† Excludes mapping energy. Including mapping, energies are $38.7\mu J$, $302\mu J$, and $952\mu J$ for TSPs with sizes 1060, 33K and 86K respectively.

Fig 6b shows the overall latency of TAXI with a maximum cluster size of 12 along with that of Neuro-Ising [5] and an exact solver [3]. We exclude CIMA [7] from this comparison as they do not report the total latency including clustering. The bar plots display the ratio of each component contributing to the total latency. As problem size increases, the speed advantage over the exact solver gets bigger and the total latency is dominated by clustering and fixing. The biggest problem, pla85900, is solved by TAXI in 375.4s and consumes 9.51×10^{-4}J, while it takes a projected time of 136 years (1.14×10^{7} longer) and 3.82×10^{11}J (4.01×10^{14} more) for the exact solver on a single core CPU [31].

VII. CONCLUSION

We discussed existing hierarchical clustering-based Ising solvers suffer performance degradation with increasing problem size, due to search-space explosion and inherent mismatch between hierarchical execution pattern and hardware architecture data flow. To that effect, we proposed TAXI – a hardware-algorithm co-designed TSP accelerator with Xbar-based Ising macros – which outperforms existing Ising solvers on very large-scale TSPs. We report $8\times$ latency improvement across 20 benchmarks over a clustering-based Ising solver [5] from TSPLib [10], up to the largest TSP with 85,900 cities. TAXI is endowed with SOT-MRAM-based in-memory Ising primitives and a hierarchical clustering algorithm. The co-design enables TAXI to solve sub-problems of large-scale TSPs on a cluster-by-cluster basis without off-macro memory access, resulting in high inter-cluster parallelism with graceful acceleration, while maintaining solution quality within an acceptable $1.2\times$ that of exact solver [3] on a TSP with 85,900 cities.

***Abstract*—General Matrix-Matrix Multiplication (GEMM) stands as the most ubiquitous operation in machine learning applications. However, performing GEMM within Fully Homomorphic Encryption (FHE) is inefficient due to high computational demands and significant data migration constrained by limited bandwidth. Additionally, the inherent limitations of FHE schemes restrict the widespread application of machine learning, as standard activation functions are incompatible. This incompatibility necessitates alternative nonlinear functions, which lead to notable accuracy reductions. To address these challenges, we introduce a polynomial encoding methodology for GEMM under the Brakerski/Fan-Vercauteren (BFV) scheme and extend the method to inference with packing inputs and weights for different sizes. Furthermore, we design specialized hardware to accelerate the inference process through optimized scheduling between the hardware and the host system. In experiments, we implemented our hardware on an FPGA U250 platform. Compared to existing solutions, our method achieves superior performance, achieving the highest $4.22\times$ and $3.99\times$ speedups on MNIST and CIFAR-10.**

***Index Terms*—Fully Homomorphic Encryption, FPGA, Matrix Multiplication**

I. Introduction

The intensive tasks based on cloud platforms offer unparalleled scalability and computational prowess, rendering them ideal for training complex models and processing vast datasets. Yet in sensitive domains like healthcare, finance, and personalized services, data privacy concerns significantly impede the adoption of cloud-based solutions. To address these challenges, various privacy-preserving methodologies have been proposed for machine learning tasks, including differential privacy [1], secure multi-party computation [2], federated learning [3], and trusted execution environments [4]. Among these techniques, FHE has garnered significant attention from both academia and industry due to its unique capability to perform computations directly on encrypted data without the need for decryption. This property makes FHE particularly suitable for privacy-preserving machine learning applications, as it allows for secure model inference on sensitive data.

However, current implementations of CNN models under FHE face significant bottlenecks that hinder practical adoption:

Accuracy Degradation: Inference based on FHE limited by fundamental constraints, which couldn't use non-linear activation functions, such as *ReLU*, *Sigmod* et al. To maintain homomorphic encryption compatibility, existing solutions employ the *square* as alternative activation functions that introduce a degradation in model accuracy [5].

Homomorphic Latency: Homomorphic computation involves numerous complex polynomial calculations, resulting in operations that run 4 to 5 orders of magnitude slower than unencrypted counterparts. This substantial performance gap severely limits the feasibility of real-time machine learning applications [6], [7].

*Corresponding Author: yangdilyu@hkust-gz.edu.cn

Data Proliferation: The encryption process transforms data into high-degree polynomials (ranging from 2^{10} to 2^{16}) with each coefficient reaching hundreds of bits [8], [9]. This transformation causes substantial data expansion, leading to significant storage and bandwidth overhead.

To address these challenges, extensive research efforts have been devoted to mitigating the computational bottlenecks of FHE in machine learning applications. Initial approaches focused on CPU-based implementations with limited parallelism capabilities in handling the complexity of FHE operations. Seminal work by CryptoNets [10] established the foundational framework for privacy-preserving inference using homomorphic encryption, but the substantial computational overhead, requiring approximately 205 seconds for inference completion. Subsequently, Lola [5] introduced an innovative approach that categorized data types based on layer-wise intermediate results, implementing specialized operations for each category. This optimization yielded significant performance improvements, reducing inference latency to 2.2 seconds on the MNIST dataset relative to CryptoNets. However, the speed is still not fast enough to meet the requirements of real-time applications. Meanwhile, GPU-based implementations have been explored at the same time. Although optimized for tensor operations, which could achieve higher parallel, it is not optimized for the modular arithmetic intrinsic to homomorphic encryption. For instance, TensorFHE [11], despite leveraging GPU acceleration for homomorphic operations in convolutional neural networks, achieves a large improvement over CPU. But homomorphic multiplication operation (*HMULT*) still exhibits a substantial latency of 851 milliseconds.

To overcome the inherent hardware limitations, the research community has increasingly explored FPGA-based architectures for accelerating homomorphic encryption computations [12]–[14]. FPGAs offer distinct advantages through their reconfigurable hardware architecture, facilitating customized optimizations for modular arithmetic operations while maintaining high parallelism and computational efficiency. Cheetah [15], which introduced specialized optimizations for FPGA-based inference. Through weight duplication, Cheetah minimized rotation operations in dot-product computations, thereby enhancing computational efficiency and reducing noise accumulation during processing. However, this approach encounters scalability challenges with larger networks due to increased memory bandwidth requirements and data transfer overhead. FxHENN [16] advanced the field by implementing detailed hardware optimizations for inference. It utilized design space exploration layer by layer to maximize memory usage and computational efficiency. However, FxHENN processes each pixel individually during convolution operations, which increases memory consumption and computational complexity because it fails to leverage data reuse and parallel processing opportunities, resulting in higher system overhead.

Therefore, we propose an enhanced data-packing method, to speed up matrix multiplication and relieve bandwidth pressure. Our key contributions are as follows:

1) We introduce an enhanced data-packaging methodology for general matrix multiplication under FHE, reducing both memory footprint and computational complexity.
2) We extend the method to convolutional layers and fully connected layers and dynamically plan the packing method based on the model parameters.
3) We design hardware based on FPGA and plan the pipeline to set up scheduling between the host and FPGA
4) The experiment on Xilinx FPGA platforms for two CNN models demonstrates the significant outperforms compared with existing solutions, achieving $4.22\times$ and $3.99\times$ speed up with higher accuracy.

II. Background

A. Fully Homomorphic Encryption

FHE is a cryptographic technique that allows computations to be performed directly on encrypted data without requiring decryption. One widely used FHE scheme is the BFV scheme [17], [18]. In the BFV scheme, a plaintext message m is represented as a polynomial in the ring $R_t = \mathbb{Z}_t[x]/(x^n+1)$, where n denotes the polynomial degree and t is a plaintext modulus. This polynomial m can be expressed as:

$$m(x) = m_0 + m_1 x + m_2 x^2 + \cdots + m_{n-1} x^{n-1}$$

where $m_i \in \mathbb{Z}_t$ are the coefficients of the plaintext polynomial. The commonly used data encoding method of BFV is batch encoding, which allows multiple plaintext messages to be encoded into a single polynomial, thereby enabling parallel homomorphic computations on these elements.

The encryption process involves several key steps. First, the plaintext polynomial m is scaled by a large integer Δ to ensure noise tolerance. Then, two random polynomials a and e are sampled from a discrete Gaussian distribution. This ciphertext $ct = (c_0, c_1$ is generated as :

$$c_0 = -a \cdot s + e_1 + \Delta \cdot m \pmod q$$

$$c_1 = -a$$

where s is the secret key polynomial, a and e are randomly chosen polynomials from the ring $R_q = \mathbb{Z}_q[x]/(x^n+1)$. The parameter q is a large modulus that determines the noise capacity of the scheme. The BFV scheme supports two primary homomorphic operations enabling computations on encrypted data. These operations are defined as follows:

Homomorphic Addition: Given two ciphertexts ct_1 and ct_2 corresponding to plaintexts m_1 and m_2, homomorphic addition is defined as:

$$Dec(ct_1 + ct_2) = m_1 + m_2$$

Homomorphic Multiplication: Similarly, for homomorphic multiplication of ciphertexts ct_1 and ct_2, the decrypted product yields:

$$Dec(ct_1 \cdot ct_2) = m_1 \cdot m_2$$

III. Matrix Multiplication based on polynomial packing

A. Motivation

GEMM constitutes a pivotal operation in a myriad of machine learning applications, contributing to approximately 70% of the total computational workload [19]. In the realm of FHE, data is encapsulated within polynomial structures to facilitate secure computation. Traditional batching techniques for matrix multiplication necessitate numerous rotational and multiplicative operations, leading to significant latency and the exacerbation of noise accumulation. Moreover, to uphold ciphertext security, polynomials must sustain a high degree, thereby imposing substantial spatial overhead.

To mitigate these challenges, we introduce an optimized polynomial-based data-packing methodology tailored for GEMM. This strategy is engineered to maximize the utilization of polynomial space, thereby reducing computational latency and minimizing noise accumulation while maintaining robust security guarantees.

B. Inner Product of Two Vectors

In homomorphic encryption, matrix multiplication efficiency can be significantly enhanced through strategic encoding of matrix entries as polynomial coefficients. Consider two one-dimensional matrices with k elements (where $2k-2 < n$):

$$A = [a_0, a_1, \cdots, a_{k-1}], B = [b_0, b_1, \cdots, b_{k-1}]^T$$

The result C of their matrix multiplication A · B can be computed as:

$$C = A \cdot B = \sum_{i=0}^{k-1} a_i b_i$$

To implement this polynomial packing method, we encode each element a_i and b_i as coefficients of polynomials. For matrix A, the elements are packed into the polynomial:

$$P_A(x) = a_0 + a_1 x + a_2 x^2 + \cdots + a_{k-1} x^{k-1}$$

For matrix B, the elements are arranged in reverse order within the polynomial:

$$P_B(x) = b_{k-1} + b_{k-2} x + b_{k-3} x^2 + \cdots + b_0 x^{k-1}$$

And after polynomial multiplication, the result $P_C(x)$ can be expressed as:

$$\begin{aligned} P_C(x) = {} & a_0 b_{k-1} + (a_0 b_{k-2} + a_1 b_{k-1}) x \\ & + (a_0 b_{k-3} + a_1 b_{k-2} + a_2 b_{k-1}) x^2 \\ & + \cdots \\ & + \left(\sum_{i=0}^{k-1} a_i b_i \right) x^{k-1} \\ & + \cdots \\ & + (a_{k-1} b_0) x^{2k-2} \end{aligned}$$

Therefore, the result of the inner product of two arrays can be easily achieved in the coefficient of x^{k-1}.

C. Inner Product of A Matrix and A Vector

A straightforward way of packing for matrix multiplication is creating one polynomial for each row of matrix A and one polynomial for each row of matrix B. However, it is a waste of space and time to pack and encrypt each row individually.

One observation is that the inner product of two $k-$element arrays would use up $2k-1$ coefficients, where the coefficient in the middle is our result, and all the others contain some garbage that we do not

need. Therefore, when k is much smaller than n, we can use the other coefficients that are not polluted to store other valid results.

When consider the situation that two matrix that $A \in \mathbb{Z}^{r\times k}$ and $B \in \mathbb{Z}^{k\times 1}$.

$$A = \begin{bmatrix} a_{0,0} & a_{0,1} & a_{0,2} & \cdots & a_{0,k-1} \\ a_{1,0} & a_{1,1} & a_{1,2} & \cdots & a_{1,k-1} \\ a_{2,0} & a_{2,1} & a_{2,2} & \cdots & a_{2,k-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{r-1,0} & a_{r-1,1} & a_{r-1,2} & \cdots & a_{r-1,k-1} \end{bmatrix}$$

$$B = \begin{bmatrix} b_0 & b_1 & b_2 & \cdots & b_{k-1} \end{bmatrix}^T$$

We propose to pack the matrix in the following way:

$$\begin{aligned} P_A(x) = & \underbrace{a_{0,0} + a_{0,1}x + \cdots + a_{0,k-1}x^{k-1}}_{A_0} \\ & + \underbrace{a_{1,0}x^k + a_{1,1}x^{k+1} + \cdots + a_{1,k}x^{2k-1}}_{A_1} \\ & + \cdots \\ & + \underbrace{a_{r-1,0}x^{(r-1)k} + \cdots + a_{r-1,k-1}x^{rk-1}}_{A_{r-1}} \end{aligned}$$

$$P_B = b_{k-1} + b_{k-2}x + b_{k-3}x^2 + \cdots + b_0x^{k-1}$$

As shown in Section III-B, the inner product of A_0 and B will use the coefficients $[0, 2k-2]$, and the result is in the coefficient of $k-1$. Similarly, the inner product of A_1 and B will use the coefficients $[k, 3k-2]$, and the result is in the coefficient of $2k-1$. To better illustrate where the valid results are in each coefficient, we plot the results in Figure 1. We introduce 'polluted space' in the coefficient space of the resulting polynomial. Each result of matrix multiplication is generated at fixed slots $mk-1, m \in [1, r]$, while the regions between these slots represent polluted space and are irrelevant.

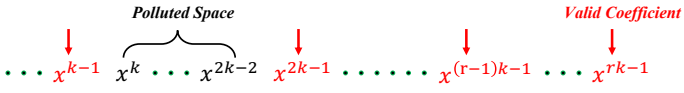

Fig. 1: Distribution of Valid Coefficients and Polluted Spaces in Polynomial Multiplication Results. Red dots indicate the positions of valid coefficients at multiples of k, while the black slots represent polluted spaces that require careful management in the polynomial encoding scheme.

The result of A_0B is valid only when the polluted space of $A_{r-1}B$ does not overlap with the valid result of A_0B, i.e., $rk-1+k-1 \leq n+k-2 \implies rk <= n$. In other words, as long as the total number of elements in A is no larger than the polynomial degree n, the inner product of AB can be finished in one round, with all the results in the coefficients of x^{mk-1}, where $m \in [1, r]$.

D. Inner Product of Two Matrices

For the multiplication of two matrices, we can encode the matrices based on the size of matrix A to maximize the utilization of the coefficient space.

1) When A is small ($rk \leq n$): We could pack multiple columns of B into the same polynomial and finish in one shot. The number of columns that could be packed together is decided by $\lfloor n/(rk) \rfloor$. For example, consider two matrices A and B of sizes 2×3 and 3×2 respectively:

$$A = \begin{bmatrix} a_{00} & a_{01} & a_{02} \\ a_{10} & a_{11} & a_{12} \end{bmatrix}, \quad B = \begin{bmatrix} b_{00} & b_{01} \\ b_{10} & b_{11} \\ b_{20} & b_{21} \end{bmatrix}$$

And the result $C = A \times B$ is a 2×2 matrix.

$$C = \begin{bmatrix} c_{00} & c_{01} \\ c_{10} & c_{11} \end{bmatrix}$$

Assuming the polynomial degree $n \geq 2\times 3\times 2$, we can encode the matrices in the following way:

$$P_A(x) = (a_{00} + a_{01}x + a_{02}x^2) + (a_{10} + a_{11}x + a_{12}x^2)x^3$$

$$P_B(x) = (b_{20} + b_{10}x + b_{00}x^2) + (b_{21} + b_{11}x + b_{01}x^2)x^6$$

The result of polynomial multiplication is:

$$\begin{aligned} P_C(x) = & P_A(x) \times P_B(x) \\ = & \cdots + c_{00}x^2 + \cdots + c_{10}x^5 + \cdots \\ & + c_{01}x^8 + \cdots + c_{11}x^{11} + \cdots \end{aligned}$$

Compared to packing B with individual columns, this packing scheme can significantly improve the overall performance by reducing the number of packing and encryption.

2) When A is large ($rk > n$): Similar to the tiling technique in general matrix multiplication, we could split the row into multiple smaller tiles that can fit in one polynomial. For example, consider two matrices A and B of sizes 2×6 and 6×2 respectively:

$$A = \begin{bmatrix} a_{00} & a_{01} & a_{02} & a_{03} & a_{04} & a_{05} \\ a_{10} & a_{11} & a_{12} & a_{13} & a_{14} & a_{15} \end{bmatrix}, \quad B = \begin{bmatrix} b_{00} & b_{01} \\ b_{10} & b_{11} \\ b_{20} & b_{21} \\ b_{30} & b_{31} \\ b_{40} & b_{41} \\ b_{50} & b_{51} \end{bmatrix}$$

and the result $C = A \times B$ is a 2×2 matrix.

$$C = \begin{bmatrix} c_{00} & c_{01} \\ c_{10} & c_{11} \end{bmatrix}$$

For the ease of illustration, we assume the polynomial degree n is 3. We could encode matrix A using four polynomials, and could encode matrix B using four polynomials.

$$P_{A0}(x) = a_{00} + a_{01}x + a_{02}x^2, P_{A1}(x) = a_{03} + a_{04}x + a_{05}x^2$$

$$P_{A2}(x) = a_{10} + a_{11}x + a_{12}x^2, P_{A3}(x) = a_{13} + a_{14}x + a_{15}x^2$$

$$P_{B0}(x) = b_{20} + b_{10}x + b_{00}x^2, P_{B1}(x) = b_{50} + b_{40}x + b_{30}x^2$$

$$P_{B2}(x) = b_{21} + b_{11}x + b_{01}x^2, P_{B3}(x) = b_{51} + b_{41}x + b_{31}x^2$$

The result of polynomial multiplication is:

$$P_{C_{00}}(x) = P_{A0}(x) \times P_{B0}(x) + P_{A1}(x) \times P_{B1}(x)$$

$$P_{C_{01}}(x) = P_{A0}(x) \times P_{B2}(x) + P_{A1}(x) \times P_{B3}(x)$$

$$P_{C_{10}}(x) = P_{A1}(x) \times P_{B0}(x) + P_{A1}(x) \times P_{B1}(x)$$

$$P_{C_{11}}(x) = P_{A1}(x) \times P_{B2}(x) + P_{A1}(x) \times P_{B3}(x)$$

IV. Hardware Acceleration for the BFV Scheme

To evaluate our polynomial encoding method for GEMM, we develop hardware that implements the BFV homomorphic encryption. In our design, we take the Residue Number System (RNS) [20] and decompose the polynomial to q_{Num} distinct residue polynomials, each associated with a prime modulus q_i.

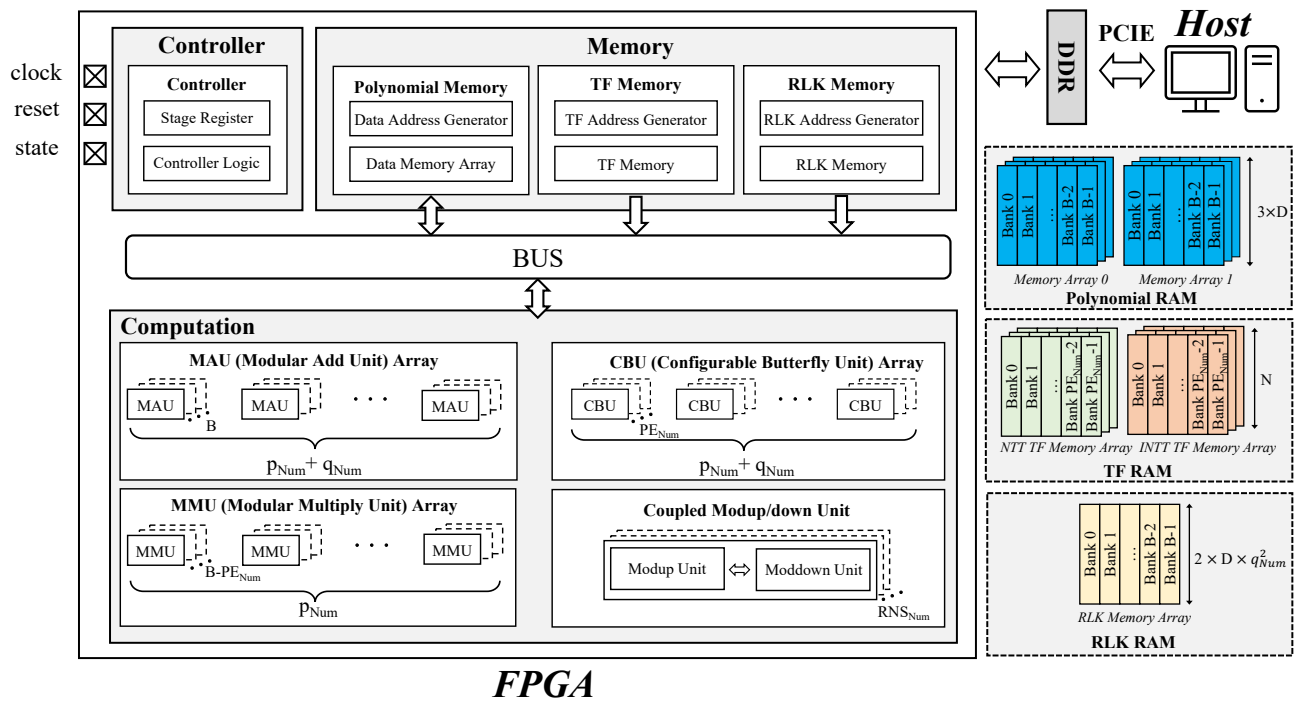

Fig. 2: Overall Architecture of Accelerator

A. Overall Achitecture

The overall architecture, depicted in Figure 2, is organized into three primary components: the memory module, the controller module, and the computation module. Additionally, it features a DDR interface and connection to the host system through a PCIe interface.

The controller module functions as a state machine, generating control signals in response to specific stimuli. This module is essential for scheduling various operations, including Modup, Moddown, NTT, INTT, Relinearization, Keyswitch, and others. One key functionality of the controller module is to generate read/write (R/W) state signals to manage the data flow, involving Data Memory, Twiddle Factor (TF) Memory, and Relinearization Key (RLK) Memory. The control logic allows the configurable butterfly unit to form diverse data paths, enabling the execution of different computational tasks and control data flow among different modules.

The data memory module includes an address generation unit and $2 \times (q_{\text{Num}} + p_{\text{Num}})$ dual-port BRAM arrays, each comprising B memory banks ($B = \sqrt{N}$) with a depth of $3D$ for polynomial degree $N = DB$. The address generator produces R/W addresses based on control signals. The TF memory stores twiddle factors for all moduli q_i and p_j required for NTT and INTT operations, totaling $PE_{\text{Num}} \times (p_{\text{Num}} + q_{\text{Num}}) \times N$ factors. Each Ultra RAM in the TF memory contains PE_{Num} banks with a depth of N and a 72-bit width on the FPGA U250, storing NTT and INTT twiddle factors in the upper and lower 36 bits of each row, respectively. These factors remain constant after initialization and are accessed as directed by control signals. The RLK memory utilizes BRAM to store the RLK, which is essential for efficiently converting three polynomials into two during relinearization. The RLK memory array consists of B memory banks, each with a depth of $2D \times q_{\text{Num}}^2$. Due to hardware resource limitations, the KeySwitch operation stores the RLK in a single memory array instead of multiple arrays.

The computation module comprises the Configurable Butterfly Unit (CBU) module, Coupled ModUp/Down module, Modular Addition Unit (MAU) module, and Modular Multiplication Unit (MMU) module. The CBU module, designed based on the work in [21], consists of $(q_{\text{Num}} + p_{\text{Num}})$ CBU arrays, each containing PE_{Num} butterfly units. These configurable units perform operations such as Number Theoretic Transform (NTT), Inverse NTT (INTT), and modular multiplication, with each CBU array associated with a modulus q_i or p_j. The Coupled ModUp/Down module facilitates basis scaling and extension operations essential for ciphertext-ciphertext multiplication and comprises RNS_{Num} units. To address the computational intensity of the KeySwitch operation, we introduce additional MAU and MMU modules, enhancing performance through increased parallelism and efficiency. The MAU array consists of $(q_{\text{Num}} + p_{\text{Num}})$ arrays, each containing B units. The MMU array, which operates in conjunction with the CBU array and is primarily utilized during KeySwitch operations, includes P_{Num} arrays, each with $(B - PE_{\text{Num}})$ MMU units.

B. Polynomial Packing Inference Schedule

Figure 3 illustrates the inference pipeline leveraging polynomial packing optimization techniques. The proposed framework comprises six distinct computational stages: polynomial packing, homomorphic encryption, secure inner product computation, homomorphic decryption, coefficient extraction, and non-linear activation transformation. In our design, only the input data is encrypted to protect user privacy, while the model weights remain in plaintext form to optimize computational efficiency[1].

[1]This design choice aligns with the typical privacy requirements in machine learning inference, where protecting user input data is paramount while model weights are considered public parameters.

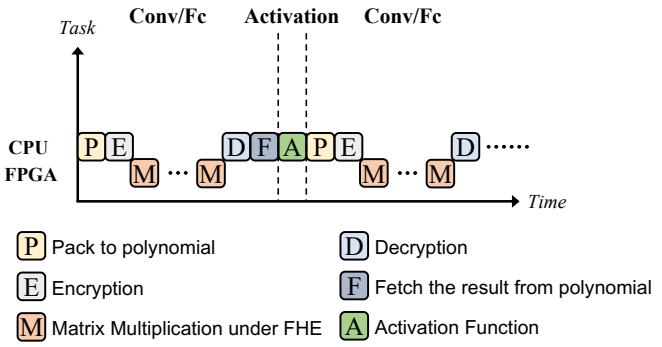

Fig. 3: Inference Schedule. The input data is encrypted to protect user privacy, while model weights remain in plaintext form for computational efficiency.

To achieve an optimal balance between computational efficiency and privacy preservation, we strategically partition the workload across heterogeneous computing platforms - executing the non-linear activation functions on plaintext data within the CPU environment while offloading the privacy-critical inner product operations (between encrypted inputs and plaintext weights) to the FPGA accelerator. This architectural design ensures both the confidentiality of sensitive user data and the computational efficiency of the inference pipeline.

V. Experimental Evaluation

A. Experimental Setup

The proposed accelerator was implemented in Chisel, translated to Verilog, and then synthesized using the Xilinx Vivado toolchain version 2024.1. To evaluate the performance, we deployed the accelerator on the commercial FPGA platform, AMD Xilinx Alveo U250. The software reference implementation was developed using SEAL [22]. For the CPU host, we used a 12th Gen Intel® Core™ i7-12700 processor with 32GB of memory. The AMD Xilinx Alveo U250 features 1,728,000 Lookup Tables (LUTs), 3,456,000 Flip-Flops (FFs), 12,288 Digital Signal Processors (DSPs), 1,280 Ultra RAM, and 2,000 Block RAM. Additionally, the U250 is equipped with 16 GB of DDR memory and supports high-speed data transfer through a PCIe interface.

B. Benchmarks and Security Parameters

Benchmarks: For experimental evaluation, we adopted two representative CNN architectures from [5], which were originally designed for MNIST and CIFAR-10 classification tasks. To accommodate the integer-only arithmetic constraints of the BFV scheme, we performed uniform 8-bit quantization on both model weights and input features. We enhanced the network architecture by replacing the original $Square$ activation with $ReLU$ and incorporating $BatchNorm$ layers after convolution operations, which improved the model's inference accuracy.

Security Parameters: The choice of BFV parameters significantly impacts ciphertext and plaintext data sizes, as well as computational complexity. To enable efficient inference without exceeding the plaintext modulus, we set the polynomial degree N to 2^{12}, the modulus q_i to 32 bits, and the total modulus Q to 224 bits.

C. Resource Utilization and MatMul Performance

Resource Utilization: In our hardware implementation, we configured the number of processing elements PE_{Num} to 8 and the number of RNS bases RNS_{Num} to 4. After synthesizing and implementing our design on the Xilinx Alveo U250 FPGA platform, the resource utilization analysis shows that our design consumes **98.93**% of available Look-Up Tables (LUTs), **8.29**% of Flip-Flops (FFs), **28.8**% of Block RAM (BRAM), **4.375**% of Ultra RAM (URAM), and **26.75**% of Digital Signal Processors (DSPs).

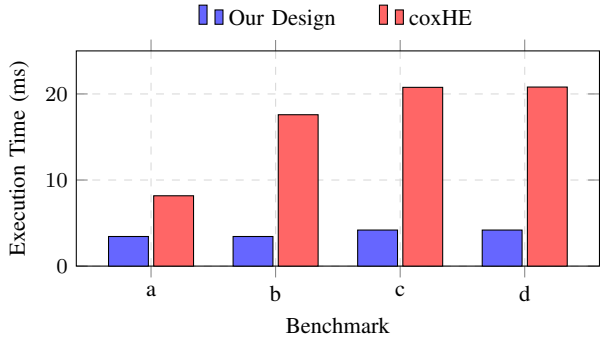

Fig. 4: Performance comparison between our design and the coxHE framework. For coxHE, benchmark **a** uses a polynomial degree of $N = 2^{12}$ with a 33-bit modulus (q_i). Benchmarks **b**–**d** employ $N = 2^{13}$ with 25-bit, 33-bit, and 43-bit modulus, respectively.

Small Matrix Multiplication: Matrix multiplication is the most time-intensive component of the inference process. Figure 4 presents a performance comparison between our design and the coxHE [23] framework, which is implemented under the CKKS scheme. Our evaluation focuses on the following matrix multiplication tasks: **a**: MatMul c-p: $(1 \times 2048) \cdot (2024 \times 1)$; **b**: MatMul c-p: $(1 \times 10) \cdot (10 \times 1)$; **c**: MatMul c-c: $(1 \times 2048) \cdot (2048 \times 1)$; **d**: MatMul c-c: $(1 \times 10) \cdot (10 \times 1)$.

In benchmarks **a** and **b**, our design achieves execution times of 3.439 ms, resulting in speedups of approximately $2.376\times$ and $5.114\times$ over coxHE's 8.17 ms and 17.58 ms, respectively. Similarly, in benchmarks **c** and **d**, our design reduces execution times to 4.188 ms, offering speedups of about $4.958\times$ and $4.967\times$compared to coxHE's 20.766 ms and 20.800 ms, respectively. The superior performance of our design is attributed to the ability to pack all data into a single polynomial of degree 4096, enabling a one-time computation process. Additionally, the execution time differences between benchmarks **a** and **b** compared to benchmarks **c** and **d** arise from the varying number of clock cycles required for c-c and c-p operations, respectively.

Large Matrix Multiplication: For large-scale matrices, we implement a decomposition strategy that partitions the matrix into smaller polynomial segments. Each segment is encoded into a polynomial of length 4096, followed by the necessary multiplications. Subsequently, the results are extracted and aggregated to obtain the final product. Specifically, for matrix multiplication of size 8192×8192, our hardware design completes the operation in 392,285.64 seconds under ciphertext operations. In stark contrast, our software implementation utilizing the SEAL library—employing a polynomial degree of 8192 and a coefficient modulus size of 218 bits—consumes approximately 7,413,087,362 seconds. This results in a speedup of approximately 1.89×10^4, thereby demonstrating that our polynomial encoding method achieves substantial performance improvements for large-scale matrix multiplication.

D. Inference Performance on Benchmark Datasets

Accuracy: By optimizing the network architecture to incorporate more complex activation functions, we achieved superior accuracy compared to previous works. Specifically, on the MNIST dataset, our model attained an accuracy of **99.11%**, outperforming FxHENN [16] by 0.21% and Lola [24] by 0.16%. On the CIFAR-10 dataset, our model reached an accuracy of **78.99%**, surpassing both FxHENN and Lola by 4.89%.

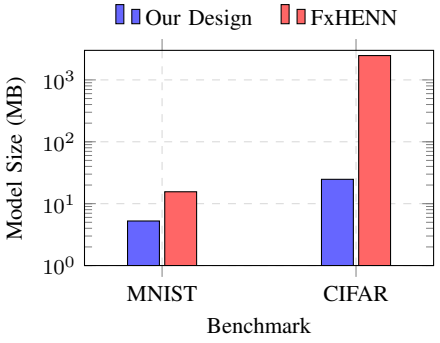

Fig. 5: Model Size of MNIST and CIFAR

Model Size: The model size is determined by the number of polynomials and the modulus size q. Our polynomial encoding method compresses the model by packing a significant number of weights into a single polynomial, thereby reducing the overall size. Figure 5 illustrates the model sizes for different benchmarks. For the MNIST dataset, our polynomial encoding occupies 15 MB compared to FxHENN's 15.57 MB, resulting in a 3.67% reduction in model size. Similarly, for the CIFAR dataset, our design requires 169.5 MB, whereas FxHENN demands 2,471.25 MB, reducing the model size by 93.14%. The model size is primarily influenced by the number of input and output channels, as the weights are packaged in a channel-first manner during the encoding process.

Performance: We compare the inference speed of our accelerator with prior works based on the BFV scheme, including CryptoNets [25], Lola [24], and Falcon [26], as well as with FxHENN [16] based on the CKKS scheme, using the MNIST and CIFAR datasets. Table I presents a detailed performance comparison.

TABLE I: Inference Performance Comparison

Implementation	Platform	MNIST (s)	CIFAR (s)
[25]†	Intel Xeon E5-1620L	205	-
[24]†	Azure B8ms (8 vCPUs)	2.2	730
[26]†	Azure B8ms (8 vCPUs)	1.2	107
[16]†	ALINX ACU15EG	0.19	54.1
Ours†	AMD Xilinx U250	**0.045**	**13.53**
Ours$	AMD Xilinx U250	**0.077**	**27.3**

† Encrypted inputs and plaintext weights.
$ Encrypted inputs and encrypted weights.

As shown in Table I, our method significantly outperforms previous implementations by optimizing convolutional and fully connected layers. These optimizations reduce the inference latency to 0.045ms per image for encrypted inputs with plaintext weights and 0.077ms per image for fully encrypted inputs and weights. Compared to FxHENN, our accelerator achieves speedups of 4.22× under encrypted inputs and plaintext weights and 2.47× when both inputs and weights are fully encrypted. For inference on the CIFAR-10 dataset, the experiment processes one image in just 13.53ms with plaintext weights and 27.3ms with encrypted weights, which are 3.99× and 1.98× faster than FxHENN.

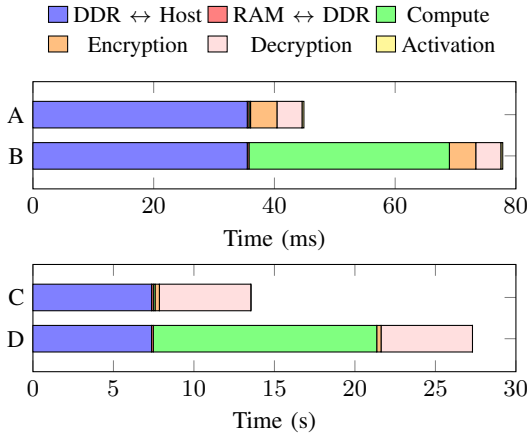

Fig. 6: Time Breakdown of Different Benchmarks. **A**: MNIST c-p; **B**: MNIST c-c; **C**: CIFAR c-p; **D**: CIFAR c-c

Time Breakdown: The time breakdown for the different benchmarks is presented in Figure 6. Benchmarks **A** and **C** involve encrypted inputs with plaintext weights, while benchmarks **B** and **D** involve both encrypted inputs and encrypted weights.

In scenarios with encrypted inputs and plaintext weights, data transformations between the host and the FPGA constitute the majority of the inference time, accounting for approximately **54%** to **79%**. Decryption and encryption processes contribute around **19%** and **44%** of the total time, depending on the benchmark. Conversely, in fully encrypted configurations, compute operations become the dominant factor, representing roughly **43%** to **51%** of the inference time. Additionally, data transformations still account for a significant portion, between **28%** and **46%**. These results highlight that data transmission remains a major contributor to inference latency across all benchmarks. However, in fully encrypted environments, the computational overhead introduced by encryption operations further elevates the overall latency.

VI. Conclusion

General Matrix-Matrix Multiplication with Fully Homomorphic Encryption presents significant challenges, including slow computation speeds, complex operations, and substantial overhead associated with processing encrypted data. To address these limitations, we introduce an enhanced data-packing method for matrix multiplication and extend this approach to accelerate both convolutional and fully connected layers. Additionally, we develop a novel computational schedule that incorporates more efficient activation functions, thereby improving network accuracy. To evaluate our method, we implemented dedicated hardware for homomorphic encryption using the BFV scheme. Deployed on the AMD Xilinx U250 FPGA platform, our hardware demonstrates exceptional performance in inference tasks on the MNIST and CIFAR-10 datasets. Compared to previous implementations, our hardware achieves significant speedups of up to 4.22× for MNIST and 3.99× for CIFAR-10, while also attaining higher accuracy. These results underscore the effectiveness of our enhancements in mitigating the inherent challenges of GEMM with FHE, leading to more efficient and accurate neural network inference.

***Abstract*—Embedded Android Devices have proliferated in many security-critical embedded scenarios, requiring sufficient testing to root out vulnerabilities. Due to Android's architecture, which uses a Hardware Abstraction Layer (HAL) for vendor-specific driver implementations, traditional kernel testing techniques cannot detect such bugs within the actual driver logic, which are commonly proprietary and vendor-specific. In this paper, we propose DroidFuzz, an embedded Android system fuzzer that targets such vendor-specific driver implementations to find such bugs. Through leveraging pre-testing HAL driver probing, kernel-user relational payload generation, and cross-boundary execution state feedback, we effectively test the proprietary drivers in both the kernel and the HAL layer. We implemented DroidFuzz and evaluated its effectiveness on 7 embedded Android devices, and found 12 security-critical previously unknown bugs, all of which have been confirmed by the respective vendors.**

***Index Terms*—Android testing, fuzz testing, embedded Linux, bug detection**

I. INTRODUCTION

The widespread adoption of Android in mobile devices has led to its increasing presence in embedded systems, where it is used to power a diverse range of applications, from set-top boxes and automated kiosks to automotive systems, medical devices, and industrial control systems. As the complexity of these systems grows, so does the attack surface, with device drivers emerging as a critical component that interacts directly with hardware components and manages their operations. With millions of lines of code in modern Android-based embedded systems, ensuring the security and reliability of device drivers has become a pressing concern.

Android's architecture utilizes a Hardware Abstraction Layer (HAL) to allow high-level applications to interface with hardware devices and peripherals. HAL is situated between the Android framework and the Linux kernel, where it provides a standardized interface for accessing hardware resources, while also allowing hardware vendors to implement proprietary and closed-source code that is specific to their hardware platforms. As a result, much of the device driver's logic resides within the HAL layer, such that a significant portion of the driver codebase remains opaque and inaccessible to external scrutiny, making it challenging to detect and mitigate potential security vulnerabilities or bugs within the HAL layer.

We use the example of CVE-2021-0673 [26] to demonstrate this point. This vulnerability is a heap-buffer-overflow found in the audio component of MediaTek chipset's HAL, which at the time accounted for 43% of Android devices shipped. When exploited, the bug results in privilege escalation, allowing malicious attackers to gain access to the entire system. Due to MediaTek's HAL being closed source and proprietary, applying public scrutiny to ensure the safety of its components is difficult, hindering the bug discovery process, consequently demanding more effective and systematic methods in rooting out such vulnerabilities in Android proprietary drivers.

Software testing is a crucial step in ensuring the reliability, security, and quality of modern software systems. Among various testing techniques, fuzz testing (fuzzing) has emerged as an effective approach for detecting bugs and vulnerabilities in software applications. It mainly involves providing large amounts of randomized input to a target program to trigger bugs within. In the context of operating system kernels, fuzzing typically involves generating payloads that mimic real-world workloads and injecting them into the kernel through various interfaces such as system calls. Syzkaller [39] is a state-of-the-art kernel fuzzer, and has found more than 5000 bugs in the Linux kernel that have subsequently been confirmed and fixed.

However, despite the importance of driver security, existing research and industry application of Android fuzzing has primarily focused on fuzzing and testing applications and system frameworks, leaving a significant gap in the state of the art for effective fuzzing techniques tailored to detecting bugs in Android's device drivers, consisting of code in kernel drivers and HAL drivers. Established methods for kernel fuzzing on Android mainly focuses on testing the Linux kernel itself, whereas Android's HAL layer, which is in the userspace, cannot be directly reached using these methods. Furthermore, effectively covering Android's kernel drivers require meaningful interaction with its corresponding HAL, which is difficult to emulate using simply system call invocations.

This research aims to address this knowledge gap by exploring new methodologies for adapting fuzzing techniques to the unique characteristics of HAL drivers in embedded Android frameworks. To do this, we need to solve the following challenges effectively. 1) First, in addition to system call interfaces, we need to model the interfaces exposed by HAL to the Android runtime and libraries such that we can generate effective invocations and payloads to the HAL's interfaces, which is proprietary and mostly undocumented, barring traditional static analysis or LLM-based methods from achieving such goals. 2) Second, we face the critical problem of effectively generating test cases that are meaningful to both Android's kernel and HAL, which are further complicated as HAL's underlying functionalities interact with the kernel through system calls, thus direct randomized and static generation yields poor results. 3) Finally, as the kernel and HAL run on different permission modes and memory spaces, and provide differing execution state tracking, we cannot directly interpret the execution state of both entities directly to identify interesting inputs, as the semantics of these are vastly different.

To address the aforementioned challenges, we propose DROIDFUZZ, a fuzzer targeting proprietary drivers in embedded Android devices. In order to effectively conduct fuzz testing on both Android's kernel drivers and HAL layer, DROIDFUZZ introduces three approaches that individually address the challenges. First, DROIDFUZZ provides a *pre-testing HAL driver probing* pass, where the HAL is loaded, probed, to obtain its exposed interfaces, argument types, and the weighting factors for each interface. Second, DROIDFUZZ also integrates a *kernel-user relational payload generation* technique, where it allows the fuzzer to produce test cases that synergistically

tests the kernel drivers and HAL components in an embedded Android device. Finally, we design a *cross-boundary execution state feedback* mechanism, where it coalesces the kernel's code coverage and HAL's kernel execution behavior to analyze the state changes in both components, and in turn assist in further input generation to produce more meaningful input payloads.

We implemented DROIDFUZZ on 7 embedded Android devices from well-known hardware vendors, including Xiaomi, Sunmi, Raspberry Pi, etc., and evaluated its driver code coverage and bugs finding capabilities on these devices. We further compared our performance to that of Syzkaller to demonstrate the effectiveness in tapping into embedded Android's proprietary driver framework. Our results show that DROIDFUZZ found 12 new bugs in these firmware, which have 7 from kernel drivers and 5 from the HAL layers, where Syzkaller was only able to find 2, both of which are from the kernel. Furthermore, through evaluating per-driver coverage in the kernel, DROIDFUZZ achieves a 17% increase on average, demonstrating that interactions with HAL can create meaningful workloads that further traverse the states of the kernel drivers.

II. BACKGROUND AND RELATED WORK

A. Android on Embedded Devices

Embedded Android is the use of the Android operating system in embedded devices, such as automated kiosks, set-top boxes, medical devices, and industrial control systems [13]. These devices typically use various peripherals such as displays, cameras, and sensors, which often require many proprietary drivers to run [43].

Android in embedded systems allows developing complex applications, through its high-level APIs and abstractions that other embedded OSs fail to offer [32]. As shown in Figure 1, an embedded Android system consists of the Linux kernel, the Hardware Abstraction Layer (HAL), Android Runtime and Libraries, and the Android Applications [12]. The Linux kernel [27] provides the underlying system services such as scheduling, process isolation, and kernel drivers, whereas Android's framework provides the core APIs for building applications. The HAL is sandwiched between the two, providing a standardized interface for accessing hardware resources and abstracting away low-level details [14].

B. Fuzz Testing

Fuzz testing, a.k.a. fuzzing, is a software testing technique used to detect security vulnerabilities and bugs in applications [21]–[23]. It mainly involves feeding invalid, unexpected, or random input to an target program and monitoring its behavior for crashes, hangs, or other anomalous behavior. Coverage-guided mutation-based fuzzing uses genetic algorithms to evaluate the effectiveness of test cases by whether they trigger new execution states to preserve those for further mutation into new test cases [16], [31]. Generation-based fuzzing uses input format specifications to produce valid and well-formed test cases. Fuzz testing is widely used in various domains, including protocol security [19], program library security [2]–[4], [10], and system vulnerability detection [5], [20].

Syzkaller is a state-of-the-art fuzzer that leverages both coverage-guided mutation-based fuzzing and generation-based fuzzing techniques through the use of *kcov* [35] and *Syzlang* [40]. Many works use Syzkaller as a basis for improving fuzzing techniques. For instance, Moonshine [28] aims to distill high-quality initial test cases for Syzkaller. Horus [17] reduces data transfer overheads between the fuzzer and manager by offloading RPCs to direct memory accesses.

kAFL [33] is another kernel fuzzer that maximizes throughput by leveraging architectural features in Intel processors. HEALER [37] is a kernel fuzzer targeted at system call relation learning to generate more effective test cases.

There are also works that fuzz tests Android's systems and framework [36], [38]. Difuze [6] addresses the problem of kernel driver fuzzing by introducing *interface-aware fuzzing*, which extracts valid commands and associated data structures through static analysis. Atlas [42] uses static analysis to deduce correct calling sequences and parameters of native APIs in closed-source Android native libraries and uses heuristics for optimizing the generated harness. FuzzGen++ [29] generates fuzzing driver programs for OEM Android libraries and applies automatic cutoff for low-quality driver programs. In comparison, DROIDFUZZ addresses the problem of efficient proprietary embedded Android driver fuzzing, which also requires the joint fuzzing of both the Linux kernel and the HAL layer.

Works aimed towards fuzzing embedded systems [1], [15], [24], [25], [41] are appearing. Tardis [34] adapts coverage-guided fuzzing to embedded operating systems running on emulators. EmbSan [18] addresses the issue of generalized porting of sanitizers to embedded platforms. Gustave [7] transfigurates embedded OS fuzzing into application fuzzing through input conversion.

III. MOTIVATION

Unlike traditional Android application or framework fuzzing, testing proprietary drivers requires generating effective payloads that trigger complex interactions between the kernel and HAL components. To demonstrate the difficulties involved, we show how an embedded Android application accesses the hardware in Figure 1 to demonstrate the complex interactions between HAL drivers and kernel drivers. As shown in the figure, Android's HAL resides between the high-level application frameworks and the low-level kernel, where it accesses low-level interfaces through device files and abstract them into high-level APIs. HAL drivers are also stateful and have vendor-specific features, allowing proprietary drivers to be shipped without source code, common practice for Android vendors.

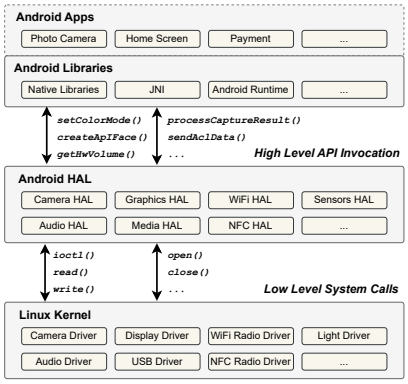

Fig. 1. Architecture of Android Relative to Apps Accessing Hardware

Fuzzing only kernel system calls or the HAL interfaces as a library is not sufficient to trigger complex and meaningful interactions between the HAL and kernel drivers, as profound bugs often require correct states from both components to trigger. Therefore, our goal is to develop a method that can fuzz proprietary drivers, by identifying driver interfaces and interpreting their affinity with other APIs and system calls, i.e. *relations*, generate meaningful sequences of API invocations and system calls that direct fuzzing towards exploring states in the proprietary drivers, and interpret execution feedback from both the kernel and the HAL layer as coverage, ultimately providing an effective way to detect bugs in embedded Android's

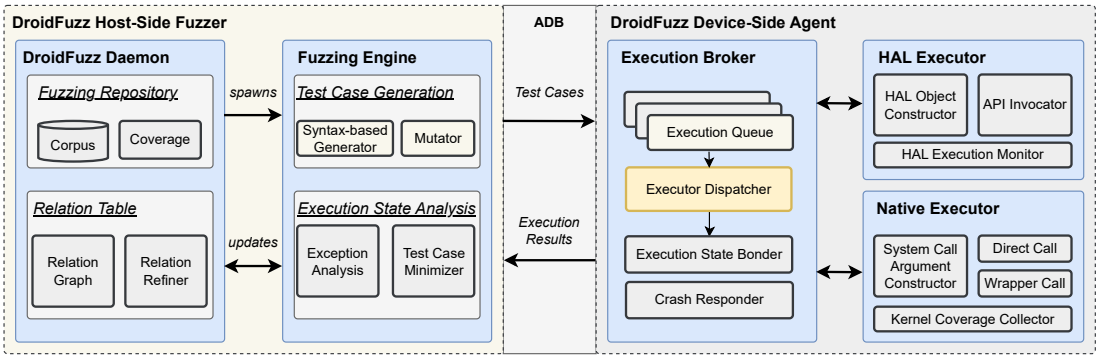

Fig. 2. Overview of DROIDFUZZ's Architecture

drivers. Designing such methods poses several challenges that need to be adequately addressed:

First, we need to determine the list of interfaces to test and the argument syntax and semantics of each individual interface. While previous work such as Difuze and Syzkaller have provided methods and syntax for system calls, the interfaces on the HAL layer are largely undocumented and lack available source code, making code-level analysis difficult.

Second, the challenge lies in generating meaningful sequences of HAL API invocations and system calls that effectively test both sides synergistically. The kernel and HAL are tightly coupled, with the HAL providing a standardized interface for accessing hardware resources, while the kernel provides the underlying operating system services. To detect profound bugs, we need to generate sequences of API invocations and system calls that trigger these interactions and exercise both components simultaneously.

The last challenge is interpreting the execution feedback as coverage also poses significant challenges due to its cross-boundary characteristics. The HAL layer is closed-source, making it difficult to obtain precise information about the internal workings of this component. Furthermore, the kernel's behavior is deeply intertwined with the HAL's behavior, making it challenging to determine whether a particular sequence of API invocations and system calls has effectively exercised both components.

IV. DROIDFUZZ DESIGN

DROIDFUZZ is an operating system fuzzer that proposes solutions to the aforementioned challenges. It takes inspiration from state-of-the-art kernel fuzzers, including techniques such as system call description-based generation and coverage-guided mutation. We show the overall architecture diagram of DROIDFUZZ in Figure 2. The major components of the fuzzing harness include the host-side Daemon and Fuzzing Engine, and the device-side Execution Broker, HAL Executor, and Native Executor, of which each component will be briefly outlined in Section IV-A.

Our primary contributions are mainly covered in the following three designs: 1) a *pre-testing HAL driver probing* pass to obtain the HAL's exposed interfaces and associated argument types, and assess *weights* of each interface (Section IV-B); 2) a *kernel-user relational payload generation* approach that allows the fuzzer produce test cases that jointly tests the HAL drivers and corresponding kernel drivers (Section IV-C); 3) a *cross-boundary execution state feedback* mechanism that interprets the HAL's execution behavior to merge with the kernel's code coverage for uniform analysis of new states, and further produce more meaningful input payloads (Section IV-D).

A. Fuzzing Harness and Execution Agents

To facilitate proprietary driver fuzzing for embedded Android devices, we compartmentalize each required functionality into separate components, including DROIDFUZZ's Daemon, Fuzzing Engines, Execution Brokers, and Executors for HAL and Native system calls.

The root process of DROIDFUZZ is the Daemon, which mainly coordinates synchronization between fuzzing processes and maintains persistent data, such as the *seed corpus*, overall coverage statistics, and relation table which records relations' weights between interfaces and system calls.

When the daemon finishes initialization, it spawns one instance of a Fuzzing Engine for each device. The Fuzzing Engine produces test cases for execution on the target device, and subsequently analyzes feedback for each execution. Communication to the target device leverages the Android Debug Bridge (ADB) [11]. Test cases generated are sequences of HAL interface and Linux kernel system call invocations in a Domain Specific Langauge (DSL) form. The engine also receives execution state information from the device to test against previous runs for any new behavior.

The aforementioned two components are run on the host machine, while the following components are run on the device-under-test.

The Execution Broker is responsible for reliably communicating test cases to run and execution results with its parent fuzzing engine. It spawns a HAL executor and Native executor to run each HAL API or system call invocation. It maintains an internal execution queue that holds all test cases waiting to be executed, where each element of a sequence is dispatched according to their type. The feedback is then bonded to form a uniform feedback statistic, and is passed back to the fuzzing engine for analysis.

The HAL and Native Executor uses the instantiated DSL and constructs corresponding dependencies of objects as required. It then invokes the relevant API or system call, after which its execution feedback is collected and returned to the broker.

B. Pre-Testing HAL Driver Probing

Direct extraction of HAL interfaces is not easily achieved, as their descriptions from proprietary HALs in release builds of the firmware are not readily available. Instead, we take a poke and probe approach to observe actual invocations of the HAL from Android applications and extract a set of interfaces through observation of how the Android framework communicates with the HAL.

Essentially, we use two components, a Poke application running atop the Android framework, and a probe utility that runs natively, i.e. without Android's abstractions. The probe utility first uses Android

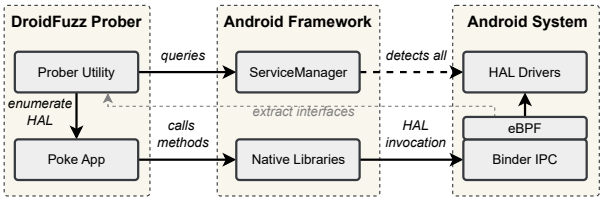

Fig. 3. Process of HAL Interface Probing

utilities (e.g. *lshal* and ServiceManager) to obtain a list of running services and HALs on the device. Then, for each running HAL service, it passes the relevant information to the Poke application, which then requests the service's interface through Android's ServiceManager. Next, the probe utility inserts eBPF code into the kernel that monitors for accesses to Binder IPC from the Poke app. The Poke application then conducts a short trial of all exposed interfaces by marshaling the parameters and invoking the corresponding methods reflected by ServiceManager, which is called into the native libraries, where it is translated into Binder IPC calls, during which the interaction is recorded from the eBPF hooks. The prober utility extracts the actual IPC data between the HAL and the Poke App, and filters out relevant interfaces and arguments. This process is depicted in Figure 3.

We also rank a HAL interface by calculating normalized occurrence through observing the number of instances that a certain interface is triggered through invoking high-level Android APIs. This gives the fuzzer more information on which interfaces to invoke during testing.

C. Kernel-User Relational Payload Generation

Generating effective test cases that traverse deeply into the execution states of drivers in both the kernel and HAL requires the fuzzer to understand the *relations* between HAL interfaces and kernel system calls. To do this, we construct a *relation graph* $\mathrm{G_{rel}} = (\mathrm{V}, \mathrm{E})$, where the set of vertices $\mathrm{V} = \{(v, w) | v \in S \vee v \in H, w \in (0, 1)\}$, of which S is the set of individual system calls and H is the set of individual HAL interfaces, and edges in E being directed and weighted. Each vertex also carries a fixed weight w, which represents the ranking of each individual system call or HAL interface, and corresponds to the probability at which the system call or interface is chosen during generation as the *base invocation*. The direction of edges in E represents the perceived dependency between the kernel system calls or HAL interfaces, whereas the weights represent the confidence regarding the dependencies between the system calls or interfaces.

During initialization, we create the relation graph with the set of vertices being filled with all system calls and HAL interfaces, and their weights from either system call descriptions or evaluated interface weights. The set of edges is initialized to an empty set, i.e. $E = \emptyset$. As we fuzz Android drivers, we detect new coverage and update the edges and weights between the HAL APIs and kernel system calls accordingly. When a new coverage is detected, we *minimize* the call to the bare bones API and system calls, ensuring that only the most essential invocations that trigger the same execution behavior are exercised. The new relations are then saved into the relation graph with the maximum normalized weights through the following process. For each adjacent pair of calls a and b, where the dependency is $a \rightarrow b$, their weights are calculated using the formula:

$$w_{(a,b)} = 1 - \Sigma_{\forall e=(x,b), x \neq a} w_{(x,b)}/2 \quad (1)$$

whereas weights for other edges with the same endpoint are halved.

Upon generating an input payload, we randomly pick a system call or an interface as the *base invocation*, i.e. the API or system call that acts as the basis for all depending invocations to form a sequence, based on the weights of each vertex. We instantiate the call in the DSL with parameters and objects based on the descriptions, using a combination of syntax-based generation and historical payload mutation. After this, we traverse the relation graph from the current vertex to a dependent vertex with a probability based on the edge weight. We may choose to stop altogether if the random value dictates such. Then, we repeat the process given above. After ending such a search, we iterate over all calls sequentially, find unresolved argument or parameter values, and find *producer calls*, i.e. system calls or API invocations that return the required argument values, instantiate the call accordingly, and insert it into the call sequence as a prefix to the current call. Finally, the generated call sequence, in the DSL representation, is passed to the device for execution.

To encourage more diverse payloads and prevent our fuzzing process from getting stuck in a local optimum, we periodically reduce the weights of all learned relations by multiplying all edge weights with a factor less than 1. This reduction process incentivizes DROIDFUZZ to explore different interaction paths between the HAL APIs and kernel system calls during test case generation, leading to more comprehensive coverage of the Android drivers.

D. Cross-Boundary Execution State Feedback

To conduct effective fuzzing of Android drivers in both the kernel and HAL components, we need to gather execution state feedback that spans across these two boundaries. For the Linux kernel, we can directly utilize debugging facilities such as *kcov* by recompiling the kernel with relevant configurations enabled. However, due to the closed-source nature of most vendor-specific HALs, we cannot directly employ tools such as LLVM's SanitizerCoverage [30] to evaluate its code coverage.

Our observation is that, as HAL abstracts low-level details into high-level interfaces, we can monitor the system call invocation behavior of the HAL layer to identify new behavior. However, we cannot directly interpret kernel code coverage, as it only records the system calls and code blocks executed, but disregards the order in which they are executed.

Thus, we use *directional* system call invocation coverage to reflect the execution behavior of the HAL layer's code. This requires that the HAL executor inserts eBPF probes into the kernel at runtime to detect system calls originating from the HAL. When the HAL executor detects system calls originating from the HAL layer, we record the specifics, including its number, critical position arguments (e.g. *request* in *ioctl()*), and the order in which it appears.

To mimic the output of code coverage, we use a lookup table compiled at initialization consisting of all possible system calls, including *specialized* system calls, which divide system calls that take generalized argument (e.g. *ioctl()*) according to their critical arguments and assign them unique IDs. We arrange the coverage into a sequence of system call IDs that correspond to the specific system calls invoked by the HAL, and append it to the kernel code coverage figures obtained from *kcov*. This joint-state feedback represents a comprehensive view of the execution state of both the kernel and HAL components, allowing us to understand how these two components interact and identify potential issues in their interaction. The analysis logic for both types of coverage remain the same, allowing for simplified processing while gaining comprehensive understandings of how the kernel and HAL components interact.

V. Implementation and Evaluation

We implemented DroidFuzz using 25930 lines of Rust and Go for the daemon, fuzzing engine, and broker components, 1694 lines of C for the executor components and prober utility, and 503 lines of Java for the Poke App. Our implementation borrowed system call descriptions and native executor components from Syzkaller to execute test payloads intended for the kernel. To demonstrate our applicability to real-world embedded Android devices, we adapted DroidFuzz to test 7 devices, which encompass off-the-shelf systems and development boards, all from renowned hardware vendors in the mobile and embedded space using processors commonly used in embedded Android devices. The list of the devices are shown in Table I, with their vendors, CPU architecture, the AOSP version and kernel version of their firmware specified.

TABLE I
List of Embedded Android Devices Tested

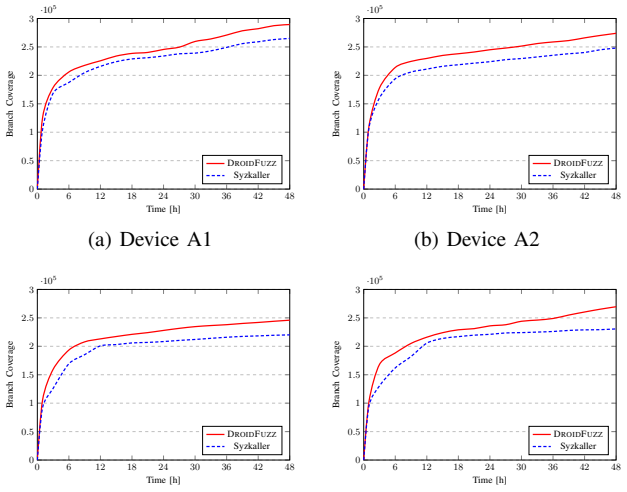
ID	Device	Vendor	Arch.	AOSP	Kernel
A1	Phone Dev Board	Xiaomi	*aarch64*	15	6.6
A2	Tablet Dev Board	Xiaomi	*aarch64*	15	6.6
B	Pi 5	Raspberry Pi	*aarch64*	15	6.6
C1	Commercial Tablet	Sunmi	*aarch64*	13	5.15
C2	Cashier Kiosk	Sunmi	*aarch64*	13	5.15
D	LubanCat 5	EmbedFire	*aarch64*	13	5.10
E	UP Core Plus	AAEON	*amd64*	13	5.10

To evaluate the effectiveness of our approach, we ran DroidFuzz on these embedded devices to assess its ability to find real-world bugs on the 7 embedded devices, and its effectiveness in covering driver code compared to state-of-the-art fuzzing approaches. We also analyzed the individual contributions of pre-testing HAL driver probing, kernel-user relational payload generation, and cross-boundary execution state feedback by performing ablation testing that removes each component for a controlled experiment.

A. Evaluation Settings

All experiments are conducted on a host server with dual Intel Xeon Silver 4120R CPUs, 192GiB of RAM, and running *amd64* Debian Linux 12.8. We use one device per experiment to conduct testing. The devices used in this experiment are running rooted firmware with their kernels recompiled with *kcov* and KASAN [9] enabled. DroidFuzz is configured to reboot the target devices upon encountering any bugs during testing, including kernel panics, assertions, and HAL errors. The versions of Syzkaller and Difuze used are commits *fb88827* and *3290997*. Each experiment is repeated for 10 times to eliminate statistical errors. We use the Mann-Whitney U Test to assess the existence of statistical significance, where data groups that do not exhibit such significance will be labelled explicitly.

B. Bug Detection



To evaluate DroidFuzz's bug finding abilities, we ran DroidFuzz on each target embedded device for 144 hours. All bugs triggered were initially minimized, deduplicated, and reproduced. Manual effort was also involved in analyzing the bugs to detect duplicates and recover corrupted log messages. Over the course of testing, DroidFuzz found 12 new bugs in the devices' respective firmwares, both in the kernel and HAL layer. All bugs have been confirmed by the respective vendors, where bugs fixes are underway at the time of writing. Some bugs have redacted information in their Bug info column as relevant details are currently embargoed.

The list of bugs are shown in Table II. As shown in the table, the new bugs found by DroidFuzz are found in both the kernel and HAL components, demonstrating that DroidFuzz is capable of effectively finding bugs in vendor-specific HAL drivers itself. Specifically, 3 bugs triggered crashes in the HAL layer, whereas the other 9 bugs were found in the kernel, showing the versatility of DroidFuzz, being capable of jointly fuzzing drivers in both the system kernel and HAL layer. As expected, the bugs triggered in the HAL are all architectural exceptions such as segmentation faults, demonstrating the effectiveness of the test cases generated. Furthermore, we can predict that this bug list is not conclusive, as some bugs triggered in the HAL layer were not perceivable without the use of sanitizers or other bug detection tools.

C. Kernel Coverage

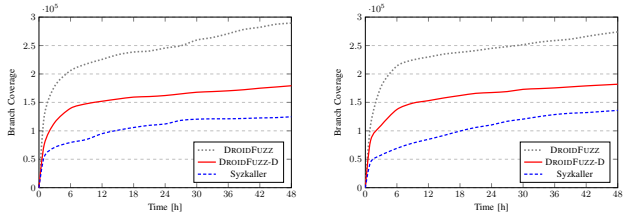
To understand why DroidFuzz was able to find new bugs, we conduct an experiment that uses code coverage of the entire kernel and specific targeted kernel drivers as a proxy to identify the covered states of the drivers in the Android system. We then compare DroidFuzz's statistics to that of Syzkaller and Difuze. Syzkaller is also able to generate test cases for kernel drivers, and thus we can perceive the additional code coverage that jointly fuzzing the HAL layer brings. Difuze is an interface fuzzer that specifically generates *ioctl()* calls to device drivers, thus allowing us to compare

1) Comparison with Syzkaller: We compared DroidFuzz's kernel code coverage on all tested devices with that of Syzkaller's to understand the effect on kernel driver execution state exploration through joint testing the HAL layer. We run each experiment for 48 hours, and take the average coverage at each timestamp.

(a) Device A1 (b) Device A2

(c) Device B (d) Device C1

Fig. 4. Coverage comparison between DroidFuzz, Syzkaller, on select tested devices over 48 hours.



We show the relevant coverage for devices A1, A2, B, and C in Figure 4, whereas the the coverage statistics for devices D, E, and F follow this pattern and are omitted. As shown in the plot, DroidFuzz achieves better coverage than Syzkaller consistently, demonstrating the effectiveness of our approach towards testing Android's kernel and HAL layers together in triggering more execution states, particularly in the kernel, which also shows that system call fuzzers such as Syzkaller still fall short of providing realistic and meaningful payloads to the kernel drivers.

TABLE II
LIST OF ALL NEW BUGS FOUND BY DROIDFUZZ.

№	Device	Bug Info	Bug Type	Component
1	A1: Xiaomi Phone Dev Board	WARNING in rt1711_i2c_probe	Logic Error	Kernel Driver
2	A1: Xiaomi Phone Dev Board	Native crash in Graphics HAL (redacted)	Memory Related Bug	HAL
3	A1: Xiaomi Phone Dev Board	BUG: looking up invalid subclass: NUM	Logic Error	Kernel Subsystem
4	A1: Xiaomi Phone Dev Board	WARNING in tcpc (redacted)	Logic Error	Kernel Driver
5	A2: Xiaomi Tablet Dev Board	Infinite Loop in driver (redacted)	Logic Error	Kernel Driver
6	A2: Xiaomi Tablet Dev Board	Native crash in Media HAL (redacted)	Memory Related Bug	HAL
7	A2: Xiaomi Tablet Dev Board	KASAN: invalid-access in hci_read_supported_codecs	Memory Related Bug	Kernel Driver
8	B: Raspberry Pi 5	WARNING in l2cap_send_disconn_req	Logic Error	Kernel Subsystem
9	C1: Sunmi Commercial Tablet	Native crash in Camera HAL (redacted)	Memory Related Bug	HAL
10	C2: Sunmi Cashier Kiosk	WARNING in rate_control_rate_init	Logic Error	Kernel Driver
11	D: LubanCat 5	KASAN: slab-use-after-free Read in bt_accept_unlink	Memory Related Bug	Kernel Driver
12	E: AAEON UP Core Plus	WARNING in v4l_querycap	Logic Error	Kernel Driver

Thus, we conclude that jointly testing both the kernel and the HAL layer results in more state transitions within the kernel itself, increasing the probability of discovering new bugs.

2) Comparison with Difuze: Difuze utilizes a fuzzer called MangoFuzz (built upon Peach [8]), which feeds *ioctl()* interface invocations based on extracted interfacesto the kernel. As it is based on components designed for legacy kernels targeting select chipsets manufacturers, we only adapted it to test devices A1 and A2, where it succeeded in extracting 285 and 232 driver interfaces from the firmware of devices A1 and A2. To understand the effect and quality of HAL's *ioctl()* calls reflected upon kernel code coverage, we derive another variant DROIDFUZZ-D which limits the executor and HAL to only calling *ioctl()*s, whereas other requests will be blocked.

(a) Device A1 (b) Device A2

Fig. 5. Coverage comparison between DROIDFUZZ, Difuze, and DROIDFUZZ-D for over 48 hours.

The results are shown in Figure 5. As shown in the plot, DROIDFUZZ's coverage far outpaces that of Difuze's, which is expected due to the increase in interfaces tested. A more relevant comparison is DROIDFUZZ-D and Difuze, which shows that DROIDFUZZ-D leads Difuze's coverage by 34%. Our analysis shows that while the invoked *ioctl()* remains the same, sending the requests through fuzzing HAL produces significantly improved results compared to specification-based generation techniques.

Thus, we conclude that jointly testing the kernel and HAL produced additional benefits in that the HAL traps into the kernel with more realistic and meaningful payloads, giving the fuzzer an edge in discovering new states.

D. Ablation Tests

We also wish to understand the effect of each design component on the overall performance of DROIDFUZZ, and thus introduce two variations of DROIDFUZZ, DROIDFUZZ-NoRel, and DROIDFUZZ-NoHCov, which have modifications that disable kernel-user relational payload generation thus solely rely on randomized dependency generation, and removes HAL system call directional coverage from cross-boundary execution state feedback, respectively. We still use kernel coverage as a proxy to convey a statistic on the scope of execution states traversed. We use Syzkaller's statistics as a baseline to better understand the effects. The overall results are shown in Table III.

TABLE III
COVERAGE STATISTICS FOR ABLATION TESTS (48H)

Device	DROIDFUZZ	DF-NoRel	DF-NoHCov	Syzkaller
A1	289402	269281	274021	264920
A2	273930	250192	259402	247958
B	245930	210583	225126	220094
C1	269593	246930	240194	230664
C2	279305	239382	259492	220950
D	250295	237492	232910	220175
E	298593	247294	284629	257320

1) Effect of Kernel-User Relational Payload Generation: We find that the statistics for removing relational generation produces coverage consistently less than DROIDFUZZ. This is due to the generated test cases contain less meaningful and potentially incorrect usage of the system calls and APIs, and thus cannot cover as much code in the kernel. However, it still manages to frequently cover more code than Syzkaller, which indicates that HAL's use of the system call interface can produce more valid semantics.

2) Effect of Cross-Boundary Execution State Feedback: Removing cross-state feedback also results in lower coverage statistics than DROIDFUZZ. The reason is that the fuzzer can only refine the relations based on kernel code coverage alone, and thus produces less-than-optimal test cases. Even so, it still consistently performs better than Syzkaller, as joint fuzzing of both the kernel and HAL can trigger more execution states within these components.

Therefore, we conclude that both relational payload generation and joint state feedback contributes to DROIDFUZZ's overall effectiveness, allowing DROIDFUZZ generate more high-quality test cases by refining relations between system calls and HAL interfaces.

VI. CONCLUSION

DROIDFUZZ leverages pre-testing HAL driver probing, kernel-user relational payload generation, and cross-boundary execution state feedback to jointly test drivers in both Android's HAL layer and kernel. Our evaluations show that DROIDFUZZ finds 12 bugs in 7 embedded Android devices, and covers execution states more effectively than the state of the art.

Simulation-based Parallel Sweeping: A New Perspective on Combinational Equivalence Checking

Tianji Liu
CSE Department, CUHK
tjliu@cse.cuhk.edu.hk

Evangeline F.Y. Young
CSE Department, CUHK
fyyoung@cse.cuhk.edu.hk

***Abstract*—Combinational equivalence checking (CEC) is a fundamental task in the realization of digital designs which is unlikely to have universally efficient algorithms due to its co-NP-completeness. Recent researches of CEC have been focusing on SAT sweeping. This paper provides a new perspective other than SAT for tackling CEC, namely exhaustive simulation, and presents a simulation-based CEC engine constructed with fast GPU-parallel algorithms. The proposed engine can solve 4 out of the 9 large cases in the experiments on its own, with up to 88.11× speed-up compared with the checker in ABC. Moreover, a combination of the proposed engine with the ABC checker achieves averaged accelerations of 4.89× and 4.88× over the standalone ABC checker and a commercial checker, respectively.**

I. Introduction

Combinational equivalence checking (CEC) is one of the most important and fundamental problems in the realization flow of modern digital designs, in which the objective is to prove the functional equivalence of two netlists that implement the same combinational circuit differently. Besides logic verification [1], CEC approaches also have a wide range of applications in the areas including logic synthesis [2], [3] and functional ECO [4].

Many tasks in EDA can be formulated as optimization problems that aim to reduce certain costs, e.g., area and delay reduction in logic optimization and technology mapping, and wirelength reduction in placement and routing, which enables the use of approximate and heuristic approaches that run in polynomial time, making them scalable to large designs. In contrast, CEC requires an exact answer of whether two circuits are equivalent, i.e., the problem needs to be tackled directly without any approximation, and it is thus much more challenging than the aforementioned tasks considering the complexity of CEC as well as the increasing scale of modern designs.

Since CEC is co-NP-complete, efficient verification of all kinds of designs using currently developed approaches is essentially infeasible. Binary decision diagram (BDD) [5], [6] had been a common method for CEC in the early years, but was gradually replaced by Boolean satisfiability (SAT) solving [7], [8] due to the excessive memory consumption of BDD which impedes its application to large designs. Today, SAT has become the de facto core technique in CEC because of the noticeable performance improvement in SAT solving over the past two decades [9]–[11]. Nevertheless, it has been argued that SAT-based methods are not as performant as other approaches for certain types of designs, e.g., computer algebra methods for arithmetic circuits [12]. This implies that the demand for novel and fast CEC approaches will never diminish, as long as new and larger sized designs continue to emerge.

In this paper, we present a new perspective on tackling CEC, namely utilizing *exhaustive simulation* for proving functional equivalences. A key advantage of exhaustive simulation over SAT is that it is friendly to parallelization, and we will demonstrate in this paper that exhaustive simulation can be performed efficiently on GPUs, which are powerful massively parallel processors that have shown promising results in logic synthesis applications [13], [14]. When proving difficult cases, however, parallel exhaustive simulation may still be intractable due to its intrinsic exponential complexity. To address this issue, we introduce a local function checking scheme for restricting the computational effort of checking difficult cases, and the effectiveness of checking can still be ensured by delicately designed heuristics. We propose and implement fast GPU-parallel algorithms for exhaustive simulation, local function checking and other auxiliary procedures for CEC, which are combined together as a *simulation-based CEC engine* with high overall performance.

The simulation-based CEC engine is capable of independently proving 4 out of the 9 large circuits in the experiments, with up to 88.11× acceleration compared to the SAT-based equivalence checker in ABC [15]. When combined with the ABC checker for handling the undecided cases, the integrated approach obtains 4.89× and 4.88× speed-up on average compared to the standalone ABC checker and a commercial verification tool, respectively.

II. Preliminaries

A. Background

A *Boolean network* is a directed acyclic graph (DAG) that models a combinational circuit where nodes stand for logic operations and edges represent wires between the nodes. The *primary inputs* (PIs) and *primary outputs* (POs) of a Boolean network are the sources and the sinks of the DAG. The direct predecessors (resp. direct successors) of a node are called the *fanins* (resp. *fanouts*) of the node. The predecessors (resp. successors) of a node are called the *transitive fanins* (TFIs) (resp. *transitive fanouts*, TFOs) of the node. The *(structural) support* of a node denotes the set of PIs that are TFIs of the node. The function of a node expressed in terms of its support is the *global function* of the node. The *level of a node* is the length of a longest path from any PI to the node, which can be computed recursively as the maximum level of the node's fanins plus one. The *level of the network* is the largest level of its POs.

A *cut* c_n of a node n is a set of nodes such that any path from a PI to n passes at least one node in the set, and n is the *root* of c_n. The *trivial cut* of n is defined as $\{n\}$. The function of a node in terms of its cut nodes is the *local function* of the node. The *logic cone* of a node n (associated with a cut c_n) contains the intersection of the TFIs of n with the TFOs of c_n, and n itself.

An *And-Inverter Graph* (AIG) [16] is a Boolean network in which nodes are two-input AND gates and signals (edges) can be optionally inverted. Because of its compactness and flexibility, AIG has become one of the most common circuit representations in modern logic synthesis and verification tools such as ABC [15]. In this work, we

also focus on the verification of AIGs but the proposed methods can be applied to any kind of circuit representation.

The *truth table* of a k-input Boolean function is a bit string $b_{l-1} \dots b_0$ of length $l = 2^k$, in which a bit $b_i \in \{0, 1\}$ is the function value under the assignment of the k inputs $(a_0, \dots, a_{k-1})$ that satisfies $2^{k-1} \cdot a_{k-1} + \dots + 2^0 \cdot a_0 = i$. Essentially, a truth table consists of the function values under all possible input assignments[1]. We denote the truth tables of projection functions $f_i(x_0, \dots, x_{k-1}) = x_i$ as *projection truth tables*, which serve as the truth tables of inputs when computing the truth table of a node in a network. For instance, when $k = 3$, the projection truth tables of f_0, f_1, f_2 are 10101010, 11001100, 11110000.

The *(internal) satisfiability don't cares* (SDCs) of a node in a Boolean network are the patterns at a cut of the node that will never occur. For example, in the network with nodes $n_1 = x + y$, $n_2 = yz$ and $n_3 = n_1 n_2$, n_3 has SDCs of $\{(n_1 = 0, n_2 = 1)\}$. If a node n has SDCs, the local function values of n under the SDC assignments can be changed without affecting the global function of n. It is believed that SDCs are mainly due to reconvergent paths (different paths with the same start and end) in the TFI structure of the cut [17], [18].

B. Sweeping

In CEC, a *miter* [19] circuit is constructed by sharing the corresponding PI pairs of the two circuits being compared, and combining the corresponding PO pairs using XOR gates which are treated as the POs of the miter. Then, the problem of checking whether the two circuits are equivalent becomes checking whether all the POs of the miter are constant zeros.

A common and effective framework for CEC is *sweeping* [6], [16]. The basic idea of sweeping is to identify equivalent pairs of internal nodes in the miter and merge their logic, so the miter can be gradually reduced, making it easier to prove the POs of the miter. A fast *(partial) simulation* procedure [16] is performed in the beginning of sweeping, which computes the partial truth tables of all the nodes using simulation patterns assigned to the PIs (usually randomly generated), and clusters the nodes with the same partial truth table into an *equivalence class* (EC). This reduces the number of candidate node pairs that need formal checking, since any pair of equivalent nodes must reside in the same class. A usual way to generate candidate pairs is to take the *representative* of a class (defined as the node with the minimum id in the class) and match it with the non-representatives in the class, so a class of N nodes produces $N - 1$ pairs. The equivalence checking of candidate pairs is performed using a formal method, e.g., BDD [6] or SAT [8].

Recent researches mainly focus on improving the SAT sweeping framework. In [3], [20], [21], different methods are proposed for generating high-quality simulation patterns to reduce SAT calls. [21], [22] introduce a customized SAT solver with engineering efforts tailored for SAT sweeping. There have also been works on accelerating SAT sweeping via parallelization. [23] describes a method for concurrently executing SAT checks for multiple candidate node pairs. [24] develops a hybrid CPU-GPU framework in which GPU performs simulation and local matching of candidate pairs, and the pairs undetermined in local matching are further checked by SAT on CPU. The proposed CEC engine drastically differs from these methods in that it relies on exhaustive simulation rather than SAT for proving equivalent nodes.

[1]We also use the term *patterns* for input assignments in this paper.

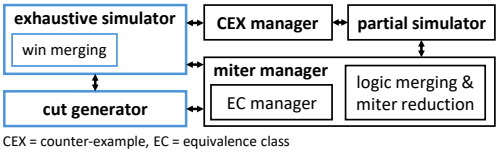

Fig. 1. The structure of the simulation-based CEC engine. The core modules are highlighted in blue. Arrows indicate interactions between modules.

III. Simulation-based CEC Engine

This section introduces the simulation-based CEC engine. An overview of the CEC engine is first provided in Section III-A, followed by two subsections elaborating on the exhaustive simulator and local function checking, which are core components of the engine. Finally, the overall flow of the engine is presented in Section III-D.

A. Overview of Simulation-based CEC Engine

The simulation-based CEC engine consists of five modules, as depicted in Figure 1, in which the exhaustive simulator and cut generator are the core of the engine. The exhaustive simulator serves as the prover in the engine that checks whether a candidate pair of nodes is equivalent by comparing all the possible values in their entire truth tables. An input pattern that disproves the candidate pair, i.e., yielding different function values at the two nodes, will be collected as a *counter-example* (CEX). The exhaustive simulator is designed to be efficient: it is capable of checking a batch of candidate pairs using a highly parallel algorithm, with a window merging procedure for reducing the total simulation effort.

The cut generator plays a crucial role in checking candidate pairs of nodes with large support sizes. Due to exponential complexity, it is infeasible to exhaustively simulate the global functions of such nodes. Instead, the cut generator produces multiple common cuts for each pair of nodes, and the exhaustive simulator evaluates the corresponding local functions of the candidate pairs. By limiting the sizes of these cuts, the simulation effort can be successfully controlled. A detailed introduction to cut generation will be given in Section III-C1.

The remaining modules have their counterparts in the traditional SAT sweeping framework which are conceptually similar to them. The miter manager maintains the miter in AIG data structures and can reduce the miter by merging proved pairs of equivalent nodes. It is also equipped with an EC manager which is responsible for maintaining the equivalence class information and generating candidate pairs to be proved. The partial simulator performs simulation of random patterns for initializing the ECs, as well as CEX patterns for splitting the class of a disproved pair (and potentially other classes) into smaller ones.

All the modules and subroutines in the simulation-based CEC engine are GPU-based except window merging which is partially implemented on CPU, making the engine highly efficient.

B. Exhaustive Simulator

1) Equivalence Checking via Exhaustive Simulation: We start by introducing how to check the equivalence of a pair of nodes via exhaustive simulation. The basic idea, as mentioned in Section III-A, is to compare the entire truth tables of the two nodes. However, the comparison is only meaningful if the input variables (including their ordering) of the two truth tables are exactly the same. Consider the function $xy' + xy'z$ as an example. Its truth tables are 00100010 and 01000100 for the input orders (x, y, z) and (y, x, z) respectively.

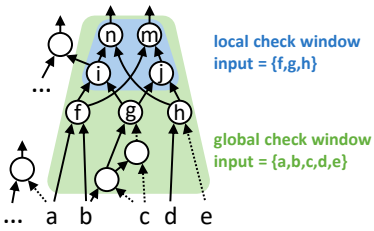

Fig. 2. Illustration of windows in global and local function checking of two nodes n and m. Note, their local functions in terms of $\{f, g, h\}$ are equivalent.

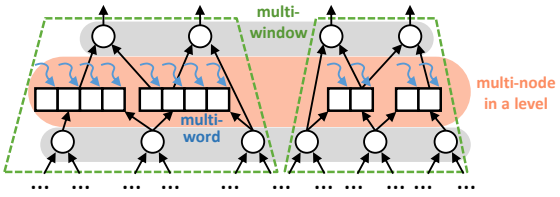

Fig. 3. Illustration of the three dimensions of parallelism.

Also, note that $xy' + xy'z = xy'$, and the truth table of xy' with input order (x, y) is 0010, indicating that the truth table of equivalent functions may not be the same under different variables and orderings.

The proposed exhaustive simulator handles this issue as follows. In the case of simulating the global functions of the two nodes being checked, if their support sets are not identical, the union of their supports are taken as the input nodes of the truth table with the order of increasing node ids. Since it is possible that a node does not functionally depends on one or more of its support nodes (e.g., $xy' + xy'z$ does not functionally depend on z), two nodes with nonidentical supports can be equivalent and still need to be checked. In the case of checking the local functions of a node pair, the inputs are simply the nodes in the corresponding common cut of the pair provided by the cut generator, as introduced in Section III-A.

The truth tables of two nodes n, m being checked are computed by propagating truth tables along the intermediate nodes that drive n and m, starting from the input nodes. We denote the collection of such intermediate nodes as the *simulation window* (or simply *window*) of n and m, and the two nodes are called the *roots* of the window. Figure 2 provides an illustration of windows in the scenario of simulating the global and local functions of two nodes respectively. Formally, a window contains the intersection of the TFIs of the roots with the TFOs of the inputs, as well as the roots.

The computation procedure begins with assigning projection truth tables to the input nodes. Then, the truth table of a node in the window can be derived by processing the truth tables of its fanins according to the node's operation. For instance, in the AIG shown in Figure 2, the truth table of the node $h = de'$ can be computed as $TT(h) = TT(d)$ & $!TT(e)$ where &, ! stand for bitwise AND, NOT respectively. The computations for all the nodes in the window should be scheduled in a topological order to ensure correctness. In our exhaustive simulator, this is performed in a level-wise parallel way, which is detailed in the next subsection.

2) Parallel Simulation: The exhaustive simulator is equipped with three dimensions of parallelism, as illustrated in Figure 3. The most fine-grained parallelism happens in the truth table computation of a single node, in which each word (a 32-bit or 64-bit element) in the bit string of the truth table is computed by a separate thread. Such parallel processing is particularly efficient on GPUs because of coalesced memory accesses [25] which minimizes bandwidth usage.

Algorithm 1 Parallel Exhaustive Simulation

Input: Miter, set of pairs p and windows w, available memory in words M

1: $N \leftarrow \sum_{w_i \in w}(|w_i| + |inputs(w_i)|)$ ▷ number of nodes and inputs
2: $E \leftarrow \max_{e \in \mathbb{N}} 2^e$ s.t. $2^e \cdot N \leq M$ ▷ entry size of simulation table
3: $simt \leftarrow$ simulation table containing $E \cdot N$ words
4: $r_m \leftarrow (\max_{w_i \in w} tt_len(w_i))/E$ ▷ number of rounds
5: **for each** $r = 0, \ldots, r_m - 1$ **do** ▷ simulate range $[rE, (r+1)E)$
6: $w' \leftarrow \{w_i \in w : tt_len(w_i) \geq (r+1)E\}$
7: ▷ w' is the set of windows that need simulation in round r
8: $l_m \leftarrow \max_{w_i \in w'} \max_{n \in w_i} level(n)$ ▷ max level in round r
9: **parallel** write proj. TT segments into $simt$ for inputs to all $w_i \in w'$
10: **for each** $l = 1, \ldots, l_m$ **do**
11: **parallel** simulate all nodes in w' with level l, and update $simt$
12: **parallel for each** $p_i = (n_i, m_i) \in p$ **do**
13: **if** the TT segments of n_i and m_i in $simt$ mismatch **then**
14: Mark p_i as nonequivalent, and optionally collect CEX

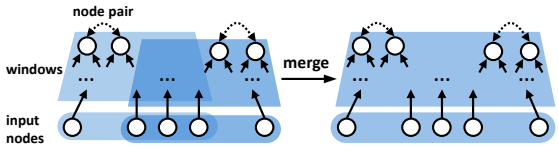

Fig. 4. Illustration of window merging.

The second dimension of parallelism resides in the truth table computation of the nodes in a window, following the level-wise parallel [14] fashion. Specifically, nodes with the same topological level are grouped into a batch and concurrently processed since there is no intra-batch dependency between nodes, and different batches are processed sequentially in the order of increasing topological level. The topological level of a node is similar to the node's level defined in Section II-A, and the difference is that the input nodes to the window are assigned with zero topological levels.

The third dimension of parallelism is to simulate multiple windows concurrently. If the number of inputs to a window is small, the truth tables to be computed are short in length, and the window is likely to be small sized. In this case, the degree of parallelism provided by the other two dimensions is limited, so it is essential to include this dimension to fully exploit the computational power of GPUs.

Algorithm 1 shows the high-level pseudocode of parallel exhaustive simulation. Given a batch of node pairs and their windows, a simulation table is allocated for storing the simulation results of all the nodes in the windows and the patterns at the window inputs (lines 1-3). Since the truth table of a pair can be long and there can be many pairs in the batch, it is impracticable for the simulation table to record the entire truth tables. Instead, each node or input is assigned with an entry of $E = 2^e$ words, where E is decided on-the-fly to be the maximum feasible value such that the simulation table fits in a provided size of memory (line 2). To ensure exhaustive simulation, the main procedure is formulated to be multi-rounded: in round r, the truth table words with indices in the range of $[rE, (r+1)E)$ are simulated with the three dimensions of parallelism (lines 6-11). The simulation results of all the node pairs are compared at the end of each round. If a mismatch is detected at a pair, this pair is marked as nonequivalent and the corresponding input pattern can be collected as a CEX (lines 12-14).

3) Reducing Simulation Effort via Window Merging: In exhaustive simulation, windows may overlap with each other and a node appearing in multiple windows must be simulated separately in each window due to nonidentical input nodes, which potentially affects the efficiency. A possible method for addressing this issue is to merge

multiple windows with high overlaps into one, and simulate all the corresponding pairs using the single merged window, as depicted in Figure 4. In this way, the total number of nodes that need simulation as well as the number of windows can be reduced. On the other hand, the number of inputs may increase after merging a window which leads to longer truth tables, and it should be carefully controlled to ensure that the overall effect of window merging is beneficial.

Our algorithm of window merging is performed in the beginning of exhaustive simulation and it employs a fast heuristic that works well in practice. First, we sort the batch of windows in the lexicographical order of their input nodes. Since the input set to a window is ordered in ids (Section III-B1), the windows with similar input sets tend to be closer to each other after sorting. The resulting windows are then generated by maximally merging consecutive windows in the order while keeping the input sizes of the merged windows under a threshold k_s. As an example, for the five windows with inputs $\{a,b\},\{a,b\},\{a,b,c\},\{a,e\},\{a,f\}$ and $k_s=3$, the first three and the last two are merged together respectively. We remark that better merging results may be obtained using a more dedicated approach (e.g., clustering-based) but it may induce a large overhead. Window merging is only enabled for global function checking, because it is generally not beneficial for local function due to small window sizes.

C. Local Function Checking

1) Cut Enumeration and Selection Criteria for Effective Checking: Local function checking is a key component in the simulation-based CEC engine, which is indispensable for proving the equivalences of node pairs with large support sizes that cannot be exhaustively simulated in terms of global functions. If the local functions of two nodes in terms of a common cut are identical, the two nodes are proved equivalent. As an example, the equivalence of the node pair shown in Figure 2 can be proved with the local functions in terms of the cut $\{f,g,h\}$, which reduces the computation from simulating 2^5 patterns per node in global function checking to 2^3 patterns.

However, two equivalent nodes may also have nonidentical local functions in terms of a common cut, e.g., those in terms of the cut $\{f,h,i,j\}$ in Figure 2. This is due to SDCs at the cut, and the equivalence is not affected as long as all the patterns yielding different local function values are SDCs. In the context of local function checking, the equivalence of two nodes is inconclusive if nonidentical local functions are encountered. To enhance the chance of successful checking, two strategies can be applied: increasing the quantity, and improving the quality of the common cuts used in checking.

To increase the quantity of cuts, we design a cut generator for the CEC engine that is capable of producing multiple common cuts for each pair using a cut enumeration-based [26] framework. For each AIG node n in the miter, the cut generator enumerates a set of candidate cuts $E(n)$ with maximum cut size k_l by

$$E(n) = \{u \cup v : u \in P(n_0) \cup \{\{n_0\}\}, \\ v \in P(n_1) \cup \{\{n_1\}\}, |u \cup v| \leq k_l\}, \quad (1)$$

where n_0, n_1 are the two fanins of n, and $P(\cdot)$ denotes the set of *priority cuts* [27] of the node that contains its best C candidate cuts selected using certain criteria. k_l and C are parameters that control the computational effort of local function checking. The common cuts of a pair can then be computed by Equation (1) with n_0 and n_1 replaced by the pair of nodes and without including their trivial cuts. The main advantages of cut enumeration are that it can efficiently produce multiple cuts for all the nodes (and common cuts for all the pairs) in a topological order traversal, and that it can adopt customized criteria for selecting a set of priority cuts.

TABLE I
CUT SELECTION CRITERIA IN DIFFERENT PASSES

Pass	Main Metric	Tie-breaker Metric 1	Tie-breaker Metric 2
1	fanout	cut size	small level
2	small level	cut size	fanout
3	large level	cut size	fanout

To obtain high-quality cuts, the cut selection criteria is formulated delicately in which the following metrics are involved:

- average number of fanouts of cut nodes: large fanout is used as a cutpoint selection heuristic in [16], so a high value is preferred;
- cut size: a small value is preferred for preventing oversized cuts during cut enumeration, and encouraging the inclusion of more reconvergent structures in the logic cone so that SDCs can be reduced, which enables higher chances of proving equivalences;
- average level of cut nodes: a small value is preferred for including more logic in the cone and reducing SDCs, but a high level may also be beneficial since it leads to smaller cuts, and sometimes a high-level cut is sufficient to prove a pair if one node is generated by the local restructuring of the other (e.g., Figure 2).

In practice, it is difficult to obtain cuts that are good in terms of all the metrics. We tackle this issue by applying three passes of cut generation and checking. In different passes, the metrics are considered with different priorities to increase the diversity of the generated cuts, as specified in Table I. For instance, in the first pass, cuts with larger fanouts are selected; if a tie happens, cuts of smaller size are preferred; if there is still a tie, cuts with smaller levels are used.

A problem of cut enumeration is that it lacks the view of common cuts when generating cuts for single nodes, which subsequently causes many oversized ($> k_l$) common cuts that cannot be used in local function checking. This problem is resolved by generating similar cuts for a pair of nodes in cut enumeration. Specifically, we define a similarity metric between a cut c and a set of priority cuts P as $s(c,P)=\sum_{c'\in P}|c\cap c'|/|c\cup c'|$. When enumerating the cuts of a non-representative node n, the similarity between a cut of n and the priority cut set of the corresponding representative node in the class is computed (since n and the representative form a pair), and cuts with larger similarities are preferred. In case of a tie, the criteria in Table I are used. On the other hand, the representative nodes adopt Table I for cut selection as introduced in the previous paragraph. In this way, the priority cuts of a pair of nodes tend to have high overlaps to each other, thus increasing the number of usable common cuts in checking.

2) Flow of Cut Generation and Checking Pass: Cut generation and checking are performed in level-wise parallel, where the level is specially formulated to consider the dependencies between representatives and non-representatives, since the priority cuts of a representative node should be computed before any other non-representatives in its class. We denote such levels as *enumeration levels*, defined by

$$el(n) = \begin{cases} 0, & n \text{ is PI}, \\ 1+\max\{el(n_0), el(n_1)\}, & n \text{ is not PI and } n \text{ is repr.}, \\ 1+\max\{el(n_0), el(n_1), el(repr(n))\}, & \text{otherwise}, \end{cases} \quad (2)$$

where $repr(n)$ signifies the corresponding representative of a non-representative node n, and n_0, n_1 are the two fanins of n.

Algorithm 2 describes the flow of a cut generation and checking pass. It starts with computing the enumeration levels of all the nodes (line 2) and assigning trivial cuts to the PIs as their priority cuts (lines 4-5). The priority cuts of internal nodes are then computed level by

Algorithm 2 Cut Generation and Checking Pass

Input: Miter $miter$

1: $buf \leftarrow \emptyset$ ▷ allocate common cut buffer
2: Compute enumeration levels $el(\cdot)$ of all nodes by Equation (2)
3: $l_m \leftarrow \max_{n \in miter} el(n)$
4: **parallel for each** PI n of $miter$ **do**
5: $P(n) \leftarrow \{\{n\}\}$
6: **for each** $l = 1, \ldots, l_m$ **do**
7: $enum \leftarrow \{n \in miter : el(n) = l\}$
8: ▷ $enum$ is the set of nodes whose cuts are to be computed at level l
9: **parallel for each** $n \in enum$ **do**
10: **parallel** compute $P(n)$ by cut enum. & selection (Section III-C1)
11: $p \leftarrow \{(repr(n), n) : n \in enum, n$ is a non-representative$\}$
12: **parallel** generate valid common cuts of pairs in p as cmn
13: **if** $|cmn| > capacity(buf) - |buf|$ **then** ▷ insufficient space
14: Local function checking using cuts in buf by Algorithm 1
15: $buf \leftarrow \emptyset$ ▷ clear the buffer
16: $buf \leftarrow buf \cup cmn$ ▷ insert in **parallel**
17: **if** $|buf| > 0$ **then** ▷ check the final batch
18: Local function checking using cuts in buf by Algorithm 1

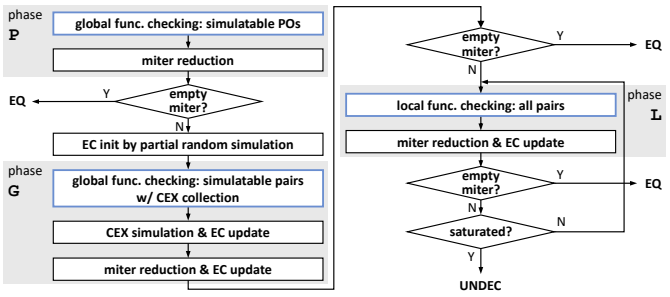

Fig. 5. Flow of simulation-based CEC engine.

level, following the criteria introduced in Section III-C1 (lines 6-10). In particular, cut enumeration and priority cut selection for a single node are performed in fine-grained parallelism (line 10) using the method of [28], where each cut in $E(n)$ is generated using an individual thread, and the selection of the best C cuts that constitutes $P(n)$ are jointly performed by the group of threads in parallel. We skip further details due to the space limit.

Local function checking is interleaved with cut enumeration. At each level, the common cuts of the node pairs whose priority cuts are just computed are generated and inserted into a constant sized buffer (lines 11-12 and 16). When the buffer does not have sufficient space to accept a new batch, an exhaustive simulation is invoked to check all the local functions in terms of the cuts in the buffer and update the equivalence statuses of the proved pairs (lines 13-15). The use of the common cut buffer reduces memory consumption, compared to the method of gathering all the common cuts and performing a single batch of checking in the end.

D. Overall Flow of Simulation-based CEC Engine

Figure 5 depicts the overall flow of the CEC engine which consists of three types of phases: a PO checking phase (`P`), a global function checking phase (`G`), and repeated local function checking phases (`L`).

In the PO checking phase, the CEC engine attempts to prove all or a subset of *simulatable* miter POs in terms of global functions, that is, the primary outputs whose checking can be carried out within a computational budget. The motivation for performing PO checking in the beginning is to maximally reduce the miter so the efforts of checking internal pairs in the removed part of the miter can be saved. A simulatable PO is defined as follows with two parameters k_P, k_p ($k_P > k_p$) that control the budget of checking: if the support sizes of all the POs are no larger than k_P, then all the POs are simulatable; otherwise, a PO is simulatable if its support size is no larger than k_p. The design of two thresholds rather than one is to encourage the CEC engine to prove the miter in a one-shot PO checking if possible.

After initializing equivalence classes by partial random simulation, the global function checking phase verifies simulatable node pairs with support sizes no larger than a threshold k_g, along with collecting CEXs to disprove the nonequivalent pairs and refine the classes.

If the miter cannot be proved by PO and global function checking, the local function checking phases will be conducted repeatedly, where each phase contains three passes of cut generation and checking that attempt to prove all the node pairs as introduced in Section III-C. Since the structure of the miter is modified after reduction at the end of a phase, the cuts generated in the subsequent local checking phase can be different, which provides new chances for verifying the equivalent pairs that failed to be proved in the previous phases. If the miter cannot be further reduced after repeated local function checking, the equivalence of the two circuits is undecided and the reduced miter can be passed to another CEC engine for further proving.

We note that the partial simulator, miter reduction, the EC and CEX manager are all implemented by GPU-parallel algorithms, which ensures the high overall efficiency of the CEC engine.

IV. Experimental Results

The simulation-based CEC engine is implemented in 8,000 lines of CUDA/C++ code on top of the GPU-based logic synthesis tool CULS[2]. We denote it as the "GPU engine" in this section for brevity. The experiments are performed on a Linux machine with Intel Xeon Gold 6326 CPU and NVIDIA RTX A6000 GPU with 48 GB DRAM.

The testcases are selected from the EPFL Combinational Benchmark Suite [29] and the IWLS 2005 Benchmarks [30], covering arithmetic and control designs. To demonstrate the effectiveness of our parallel CEC approach, we enlarge the designs by applying multiple times of the ABC command `double`, which is a common method used in the works on parallel logic synthesis and verification [14], [23], [31]. The two circuits compared by CEC are the original and optimized versions of a benchmark, where the optimized one is generated by executing ABC `resyn2`, an AIG optimization script consisting of several passes of balancing, rewriting and refactoring [32]. Table II shows the statistics of the benchmarks and miters constructed by the pairs of circuits being compared.

In the experiments, we use the following parameter values for the GPU engine: $k_P = 32$, $k_p = k_g = 16$, $k_l = 8$, $C = 8$. The maximum support size of a window after window merging k_s is set as the support size threshold (k_P, k_p, or k_g) of the phase. For instance, in the PO checking phase, $k_s = k_p = 16$ if not all of the POs are simulatable. We adopt the ABC combinational equivalence checker (command `&cec -C 100000`) for further proving a reduced miter if it is undecided (i.e., not empty) after running the GPU engine. A large value is assigned for the maximum number of conflicts during a SAT call (`-C`) since most of the easy-to-prove pairs have already been handled by the GPU engine.

A. Runtime Comparison with ABC and Commercial Checker

We evaluate our approach by comparing it with the ABC checker (command `&cec`) and a commercial verification tool Cadence Conformal LEC (version 19.20). ABC `&cec` is a single-threaded yet high-performance checker based on SAT sweeping. There is no

publicly available parallel checker to our knowledge, so we compare to Conformal which supports parallel checking with up to 16 CPU threads. Although the implementation details of commercial checkers are unknown, it is believed that they perform equivalence checking using a combination of engines [33], and a possible way for multi-threading is to run different engines simultaneously and early stop when an engine finishes.

Table II shows the results of our approach and the runtimes of ABC checker and Conformal. The subcolumn "Reduced (%)" reports the percentages of reduction in miter sizes after executing the GPU engine. It is worth noting that the GPU engine can fully prove (i.e., 100% reduction without the aid of SAT) 4 out of the 9 cases with significant accelerations, including one case (*log2_10xd*) whose runtime is decreased from over 4 months to 1.4 days. Moreover, it solves a large portion of the problem on the cases *hyp_7xd* and *ac97_ctrl_10xd*, as indicated by the fast ABC verification of the reduced miters (subcolumn "ABC (s)") compared to exclusive ABC checking (column "ABC `&cec`"). The GPU engine can only reduce a minor part of the miter on the cases *sqrt_10xd* and *vga_lcd_5xd* but with a short runtime, so the overall solving time is marginally degraded. On average, the combination of GPU engine and ABC checker achieves 4.89× speed-up over the standalone ABC checker.

The combined GPU and ABC checker obtains an averaged 4.88× acceleration and is faster on 7 out of the 9 cases when compared to Conformal with 16 CPU threads. The commercial checker is much more efficient on the case *voter_10xd* and the reason might be that one of the engines in Conformal is well-suited to solving this case.

B. Breakdown Analysis of Simulation-based CEC Engine

Figure 6 shows the runtime percentages of different phases in the GPU engine, which differ across cases. In particular, *log2_10xd* and *sin_10xd* can be directly proved by PO checking (`P`). The rest of the cases (except *sqrt_10xd* that can hardly reduced by the GPU engine) are further analyzed in Figure 7, in which the intermediate miters during the execution of the GPU engine are checked by ABC, and the normalized ABC checking times (over the standalone ABC checking time of the case) are plotted. For instance, the labels PG and PGL refer to the checking times of the miters extracted after the `G` phase and at the end of the GPU flow, respectively. It can be seen that all the three types of phases play important roles in checking some cases, i.e., `P` on *ac97_ctrl_10xd*, `G` on *multiplier_10xd*, *square_10xd*, and `L` on most cases, which demonstrates the effectiveness of the overall design of the GPU CEC engine.

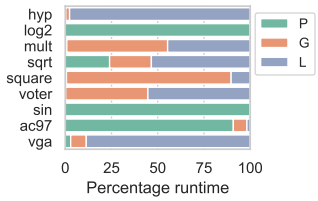

Fig. 6. Runtime breakdown of the simulation-based CEC engine. Benchmark names are abbreviated.

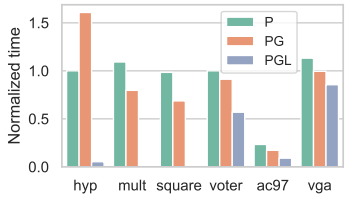

Fig. 7. Time of proving GPU-reduced miter by ABC with different flows, normalized by the time of standalone ABC.

V. DISCUSSION

Our CEC approach is implemented in a minimalist style due to the large development effort required. Here, we discuss a few tweaks that can be applied to further boost checking efficiency.

First, the current integration of the GPU engine and the ABC checker does not implement transferring ECs from GPU to ABC, and the ECs in ABC checking are reinitialized from scratch. With the EC transferring developed, nonequivalent pairs identified by GPU need not be rechecked by ABC, thus reducing the overall runtime.

Second, the GPU flow can be finetuned to be more adaptive, e.g., certain types of passes can be disabled on-the-fly during the repetitive `L` phases if they are found to be ineffective on the case.

Third, some improvements proposed in previous works may also be implemented on GPUs and integrated into our engine, including distance-1 simulation of CEXs [8], reverse simulation [21], and interleaving sweeping with logic rewriting [8], [14].

VI. CONCLUSION

This paper presents a new perspective on checking combinational equivalences using exhaustive simulation and a simulation-based CEC engine implemented on GPUs. The GPU engine is equipped with a fast exhaustive simulator with a high degree of parallelism, a local function checking scheme for proving difficult candidate pairs with restricted computational effort, and other GPU-based managers and algorithms that are crucial to the high overall performance of the engine. Experiments show that the GPU engine can efficiently solve four large cases without the aid of an external checker, and a CEC flow integrating the GPU engine and ABC checker achieves 4.89× and 4.88× speed-up on average over the standalone ABC checker and a commercial verification tool, respectively.

***Abstract*—Deep neural networks (DNNs) have demonstrated outstanding performance across a wide range of applications. However, their substantial number of weights necessitates scalable and efficient storage solutions. Emerging non-volatile memory technologies, such as phase change memory (PCM) with multi-level cell (MLC) operation, are promising candidates due to their high scalability and non-volatility compared to conventional charge-based storage devices. Despite these advantages, MLC PCM suffers from reliability issues, particularly conductance drift, where the conductance of a PCM cell changes over time. This drift can lead to significant accuracy degradation in DNNs, as their weights are stored in PCM cells. In this paper, we propose *Drift-aware Binary Code* (DBC), a novel binary code designed to improve the tolerance of DNNs to conductance drift. DBC maps smaller decimal values to less error-prone MLC PCM cell levels and ensures that values shift to smaller magnitudes when conductance drift occurs. This approach helps maintain the accuracy of the DNN over an extended period compared to conventional binary code, as dominant DNN weights are stored at levels less prone to errors and DNNs exhibit better tolerance when weight values decrease rather than increase due to drift. Additionally, DBC requires no additional hardware overhead for auxiliary bits and can be combined with other fault-tolerant approaches, such as error correction code (ECC). Experimental results based on the real PCM device developed by IBM Research demonstrate that DBC improves the drift tolerance of DNNs by up to $55.18\times$ compared to conventional binary code.**

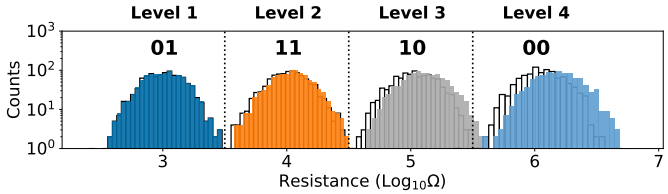
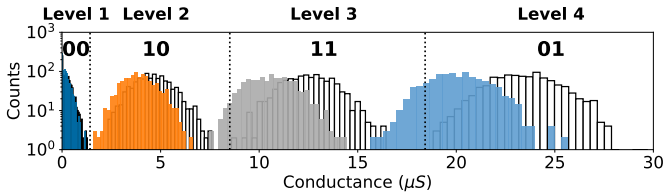
I. Introduction

Deep neural networks (DNNs) have demonstrated exceptional performance across various applications. However, contemporary DNN architectures demand substantial storage capacity, reaching hundreds of megabytes or even gigabytes of weights [1]–[3]. The significant memory requirements pose challenges for deploying DNN models on resource-constrained edge devices, especially when relying on conventional charge-based storage devices like dynamic random-access memory (DRAM) due to scaling limitations.



To address the challenges, emerging non-volatile memory technologies, such as phase-change memory (PCM), are being explored as promising alternatives to charge-based storage devices or as new storage-class memory layers within conventional memory hierarchies [4]. PCM devices consist of a phase-change material positioned between two electrodes, capable of exhibiting a wide range of electrical conductivities by transitioning between a highly conductive crystalline phase and a low-conductive amorphous phase, both of which are non-volatile states. Moreover, the ability of PCM to achieve a spectrum of conductance values enables multi-level cell (MLC) operation, which allows multiple bits to be stored in a single PCM cell, resulting in high scalability. However, despite this advantage in scalability, PCM with MLC operation faces reliability challenges due to conductance drift, where the conductance of the phase-change material decreases over time due to structural relaxation. Conductance drift can lead to soft errors, causing the stored data to deviate from their original values. In the context of DNNs, the soft errors in weights can result in a significant drop in accuracy [5].

Previous works [6]–[8] have proposed methods to mitigate the soft error rate caused by conductance drift in MLC PCM devices, effectively enhancing the drift tolerance of DNNs. However, these methods are specifically designed and optimized for the analytical PCM model introduced in [9], which is based on a theoretical representation of MLC PCM and not directly derived from real device measurements. As a result, these conventional methods face limitations when applied to the real PCM device developed by IBM Research [10]–[12], which exhibit distinct characteristics compared to the analytical PCM model, including differences in the error-prone levels of MLC PCM cells.



In this paper, we introduce *Drift-aware Binary Code* (DBC), a novel encoding scheme designed to enhance the drift tolerance of DNNs in the real PCM device. DBC maps smaller decimal values to lower MLC PCM cell levels, which are less susceptible to soft errors than higher levels. By applying DBC to DNN weights, accuracy can be preserved for a longer duration compared to conventional binary codes, as the Gaussian distribution of weights [13] ensures that dominant small weights are stored in more reliable cell levels. Moreover, DBC leverages conductance drift to shift decimal values toward smaller values, aligning with the improved tolerance of DNNs under such conditions [14]. DBC also eliminates the need for auxiliary bits, avoiding additional hardware overhead, and can integrate with other fault-tolerant techniques, such as error correction code (ECC), due to its independent operation.

The rest of the paper is organized as follows. Section II provides the background. Section III introduces DBC, followed by evaluations in Section IV. Finally, Section V presents the conclusion.

The black-lined bins show the distribution of the PCM cells measured at 27 seconds, while the colored bins depict the distribution at 1024 seconds.

II. Background

A. Related Works

To mitigate the reliability challenges posed by conductance (or resistance) drift in MLC PCM, several studies have proposed drift-tolerant schemes [6]–[8]. These schemes focus on improving resistance drift tolerance of an analytical MLC PCM model described in [9]. Fig. 1a illustrates an example of resistance drift in the analytical PCM model, which comprises four Levels with target resistances of $10^3\,\Omega$, $10^4\,\Omega$, $10^5\,\Omega$ and $10^6\,\Omega$. A set of 1,000 PCM cells is programmed to each target resistances, following a Gaussian distribution. Each resistance range, delineated by dotted lines, corresponds to a unique binary representation encoded using reflected binary code, also known as Gray code, with Levels 1, 2, 3, and 4 represented as 01_2, 11_2, 10_2, and 00_2, respectively. When the resistance of a PCM cell shifts to a different range due to the drift, a soft error occurs because the data represented by the cell no longer matches the original data. For instance, a PCM cell initially set to $10^5\,\Omega$ may experience the drift, exceeding $10^{5.5}\,\Omega$ and resulting in a transition from Level 3 (10_2) to Level 4 (00_2). Similarly, the drift may cause shifts from Level 1 to 2, or from Level 2 to 3. The model demonstrates that the magnitude of the drift increases with higher cell levels. Consequently, mid-range Levels 2 and 3 are more vulnerable to errors, whereas Level 1 is less prone to soft errors due to its smaller drift magnitudes. Conversely, Level 4 is regarded as immune to drift errors, as there is no defined levels beyond Level 4.

In the analytical PCM model, Tri-level cell [6] improves drift tolerance by removing the most error-prone level and using only three levels. Flipcy [7] reduces drift-induced errors by minimizing the amount of data assigned to error-prone levels through simple bit-flip and complement operations. DynaPAT [8] employs a mapping strategy to enhance the drift tolerance of DNNs by aligning the most frequently used cell levels in DNN weights with the least susceptible levels.

B. PCM Modeling

The conventional methods [6]–[8] have been designed for the analytical model of MLC PCM. However, this model encounters limitations in accurately capturing the behavior of the real PCM device, as demonstrated by IBM Research [10]–[12]. To address this limitation, the model should incorporate various noise sources such as conductance drift, read noise, and programming noise, using direct measurements from the real device. The conductance of a real PCM device as a function of time is represented by following equations. Initially, the target conductance G_T is defined at approximately 20 seconds, as performed in [12]. The conductance measured at time $T_0 = 27.36$ seconds is expressed as follows:

$$\nu = N(\mu_\nu(G_T), \sigma_\nu(G_T)) \tag{1}$$

$$G(T_0) = G_T(T_0/20)^{-\nu} + N(0, \sigma_{p.t0}(G_T)) \tag{2}$$

where ν is a random variable following a normal distribution, and both mean μ_ν and standard deviation σ_ν depend on G_T. The term $\sigma_{p.t0}(G_T)$ represents the standard deviation of the programming noise measured at time T_0 for G_T. Additionally, noise is applied at time $T_1 = 55.39$ seconds to account for the short-term relaxation effects that occur after iterative programming [15], resulting in the following equation:

$$G(T_1) = G(T_0)(T_1/T_0)^{-\nu} + N(0, \sigma_{p.t1}(G_T)) \tag{3}$$

where $\sigma_{p.t1}(G_T)$ denotes the standard deviation of the programming noise at time T_1 for G_T. Finally, incorporating read noise, the conductance at any time t is defined as:

$$G(t) = G(T_1)(t/T_1)^{-\nu} + N(0, \sigma_{nG}(G_T, t)) \tag{4}$$

where $\sigma_{nG}(G_T, t)$ represents the standard deviation of the read noise, which depends on G_T and time t. This function is defined and detailed in the supplementary information of [12].

Fig. 1b illustrates an example of conductance drift based on the model of a real PCM device. The target conductance values for the four levels, along with the time-independent factors μ_ν, σ_ν, $\sigma_{p.t0}$, $\sigma_{p.t1}$ and ν_q (used in $\sigma_{nG}(G_T, t)$ from Equation (4)), are summarized in Table I. The level boundaries are defined at the 2.993σ point of each target conductance. The results demonstrate that conductance consistently drifts to lower levels over time, with transitions occurring from Level 4 (01_2) to Level 3 (11_2), Level 3 to Level 2 (10_2), and Level 2 to Level 1 (00_2). Higher levels exhibit greater magnitudes

of drift, rendering them more error-prone compared to lower levels. Specifically, Level 4 is identified as the most vulnerable to soft errors due to its substantial drift characteristics. This observation contrasts with the predictions of the analytical model, which identifies mid-levels as the most error-prone.

III. Proposed Method

Building upon the observed conductance drift characteristics of the real PCM device, we introduce *Drift-aware Binary Code* (DBC), a novel binary code designed to enhance the drift tolerance of DNNs. DBC assigns smaller decimal values to code words that include lower levels of MLC PCM which is less error-prone than higher levels. This approach improves drift tolerance by reducing the soft error rate, as the dominant small weight values in DNNs, which follow a Gaussian distribution [13], are stored in PCM cells associated with more reliable, less error-prone levels. Furthermore, DBC minimizes accuracy degradation by ensuring that the drift causes weight values to shift only toward smaller magnitudes. This unidirectional shift is beneficial because DNNs tend to preserve accuracy better when erroneous weight values decrease rather than increase [14].

A. DBC Generation Algorithm

Algorithm 1 presents the procedure for generating DBC. The algorithm takes as input the number of MLC PCM cells required to represent a single DBC code word, denoted by C, for $2C$-bit data. For instance, generating DBC for 8-bit data requires four cells ($C = 4$). The output is a 2D array A, where each row $(1 \dots N)$ represents a DBC code word mapped to the levels of MLC PCM cells, and each column $(1 \dots C)$ corresponds to the level values of individual cells. The algorithm sequentially assigns binary codes by prioritizing lower cell levels for smaller values, ensuring a progressive mapping from less error-prone levels to higher levels.

The procedure begins with **Step 1**, generating code words composed solely of Levels 1 and 2 by forming all possible permutations for the C cells using these levels. The resulting permutations are sorted in ascending order and stored in the array A. In **Step 2**, code words that include Level 3 are introduced. The algorithm iterates over the code words generated in the first step and creates new permutations by incorporating Levels 1, 2, and 3. These new code words are appended to A only if they satisfy the condition specified in Line 13 of Algorithm 1. This condition ensures that code words with the same combinations are ordered consistently based on the order of code words generated in the previous step. Finally, **Step 3** adds code words that include Level 4 to A. This is done in a manner similar to Step 2, by building upon the code words from the second step.

Table II provides an example of DBC code words generated for 4-bit data ($C = 2$), requiring two PCM cells, denoted as C_1 and C_2. The first column specifies the step in Algorithm 1 during which each code word is generated. The second column lists the code words, formatted as $\{$Level of $C_1\}$_$\{$Level of $C_2\}$. The third column presents their binary representations, where Levels 1, 2, 3 and 4 are encoded as 00_2, 10_2, 11_2, and 01_2, respectively, as shown in Fig. 1b. The fourth column displays the decimal values assigned to each code word. For instance, the code word L1_L3, where C_1 is in Level 1 and C_2 is in Level 3, corresponds to the binary representation 00_11_2. This code word is mapped to the decimal value 4 and is generated during Step 2 of Algorithm 1.

As illustrated in Table II, DBC maps smaller decimal values to lower levels, which exhibit reduced soft error rates when conductance drift occurs in the real PCM device. This mapping strategy is beneficial because the dominant weights in DNNs, which follow a Gaussian distribution with many small-magnitude values [13], are stored in the least error-prone cell levels. Consequently, the overall error rate due to conductance drift is reduced, as fewer weights are likely to induce soft errors. Furthermore, DBC leverages the unidirectional nature

Algorithm 1: DBC Generation Algorithm

	L4_L4	01_01_2	15

of conductance drift in the real PCM device, which causes conductance values to decrease from higher to lower levels. As a result, when drift occurs, the decimal value represented by PCM cells become smaller than its original value. For example, consider a code word L3_L2, which corresponds to the binary representation 11_10_2 and maps to indicate the decimal value 7. If conductance drift occurs in cell C_1, the code word changes to L2_L2. As L2_L2 (10_10_2) is mapped to 3, the original decimal value of 7 is changed to 3 by the conductance drift, and this makes the changed value smaller than its original value. These changes are unidirectional, always resulting in a decrease in the stored value. By ensuring that conductance drift only decreases weight values, DBC enhances the drift tolerance of DNNs. A decrease in weight values from larger to smaller magnitudes results in a smaller accuracy drop compared to an increase in values [14]. Therefore, DBC improves the resilience of DNNs against conductance drift in the real PCM device, maintaining higher overall accuracy in the presence of drift-induced errors.

While DBC is initially designed for unsigned values, DNN weights are typically represented as signed values. To address this, we introduce a single-cell sign representation (SCSR), which serves as a sign indicator using an additional single PCM cell. In this scheme, Level 1 denotes positive numbers, while Levels 2, 3, and 4 indicate negative numbers, with Level 4 serving as the initial mapping for negatives. The configuration employs $(C+1)$ cells to represent $2C$-bit data. For example, the positive value +7 is represented by the code word L1_L3_L2, while the negative value -7 is initially encoded as L4_L3_L2. After conductance drift, -7 remains accurately represented, even if the sign cell level changes to 3 or 2, resulting in code words L3_L3_L2 or L2_L3_L2, respectively. The SCSR prevents changes from positive to negative values and significantly reduces the probability of an incorrect sign change.

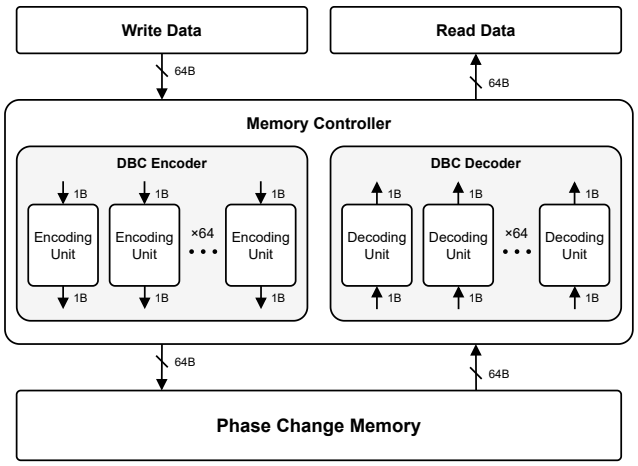

Fig. 2. Overall architecture of DBC encoder and decoder for 64-bytes cache line system.

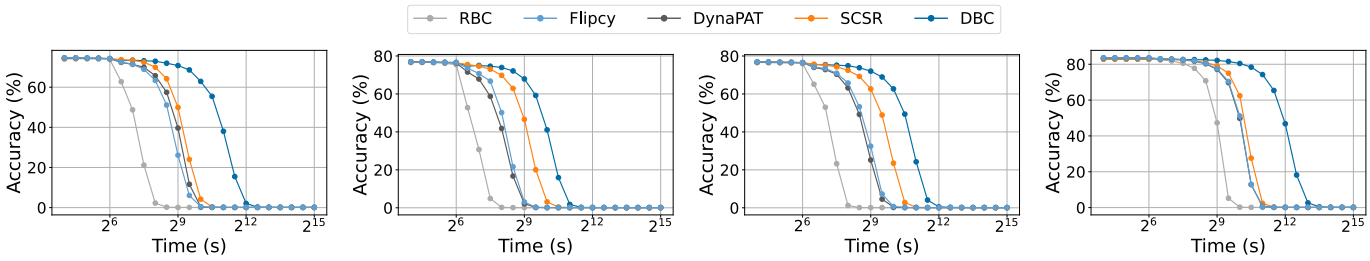
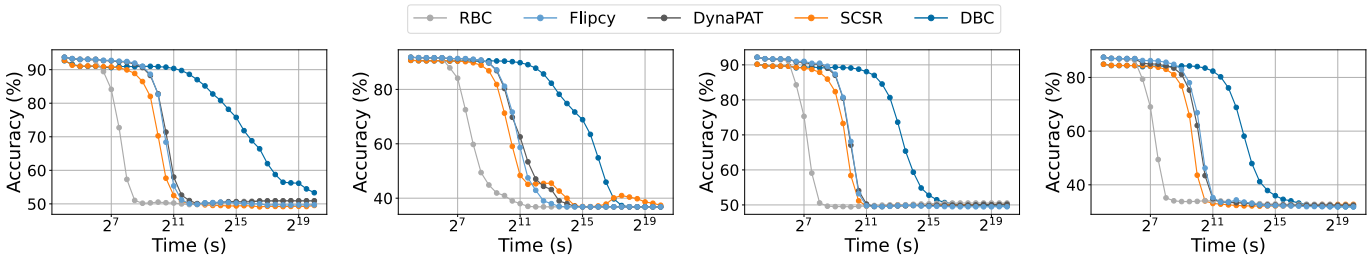


In summary, DBC combines Algorithm 1 for unsigned binary code generation with SCSR to support signed DNN weight values and improve drift tolerance.

B. Hardware Implementation

To facilitate the translation between the original binary code used in conventional systems and the DBC format, a DBC encoder and decoder are required. Fig. 2 illustrates the overall architecture of the DBC encoder and decoder integrated within the memory controller of a system utilizing a 64-byte cache line. The encoder and decoder each comprise 64 encoding units and 64 decoding units, respectively. Each encoding unit is a combinational circuit that converts 1 byte of data from conventional binary code into its DBC representation, while each decoding unit performs the inverse operation. The use of a 1-byte granularity for encoding and decoding units is driven by the widespread adoption of 8-bit quantization in various DNNs [16]–[18], as well as the 7-bit format employed for DBC with SCSR.



The write operation starts with a write request that includes the data to be stored. This data is encoded into the DBC format on a per-byte basis before being written to the corresponding MLC PCM cells. Similarly, the read operation retrieves data from the PCM, decodes it using the DBC decoder, and outputs 64 bytes of data to the host system.

The DBC scheme eliminates the need for auxiliary bits, avoiding additional hardware overhead apart from the DBC encoder and decoder when applied to PCM systems. Moreover, DBC can seamlessly integrate with other drift-tolerant or fault-tolerant techniques, such as error correction code (ECC), by incorporating extra encoding and decoding hardware at the output of the DBC encoder and the input of the DBC decoder, respectively. This compatibility arises from the complementary operation of DBC with these methods.

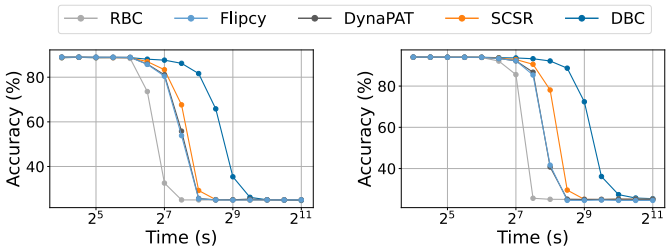
IV. Evaluation



A. Experimental Setup

The proposed DBC is evaluated using various vision and natural language processing (NLP) models. The vision models, such as VGG-19 [19], Inception-v3 [20], DenseNet-169 [21], and ViT-Base [1], are employed with the ImageNet dataset [22]. In NLP tasks, RoBERTa [23] is evaluated across four tasks from the GLUE benchmark [24], including SST-2, QQP, MNLI, and QNLI. Additionally, Large Language Models (LLMs) such as Llama-3.2 1B [3] and Gemma-2 2B [2] are evaluated using the HellaSwag benchmark [25]. All models are quantized to 8-bit and 7-bit integers using the LSQ method [26]. The hardware implementations are developed in Verilog HDL and synthesized using a 28 nm standard cell library with Synopsys Design Compiler. To assess the effectiveness of the proposed DBC, comparisons are made with reflected binary code (RBC) and state-of-the-art methods such as Flipcy [7] and DynaPAT [8]. Additionally, single-cell sign representation (SCSR) combined with RBC is evaluated for ablation studies. While Flipcy and DynaPAT are originally designed using the analytical PCM model [6], they have been adapted to reflect the characteristics of the real PCM device, where levels 3 and 4 are treated as the most error-prone. Drift-induced fault simulations are performed using a custom-built simulator that accurately models the real PCM device [12].

B. Reliability Analysis

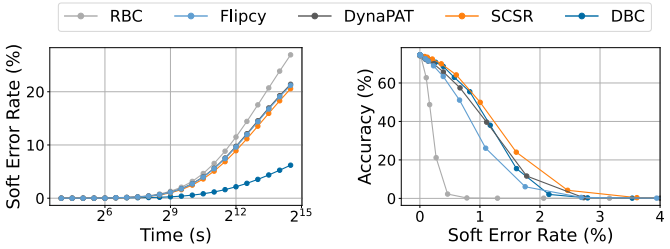


Fig. 3 illustrates the results of drift-induced fault simulations conducted on vision models. The accuracy of each DNN model, measured after conductance drift at each time step, is averaged over 100 iterations. The results reveal that drift-induced soft errors lead to a gradual decline in model accuracy over time. With the baseline scheme, RBC, an average accuracy drop of 5% from the original value occurs after averagely 113 seconds across all models. In comparison, the conventional encoding schemes Flipcy and DynaPAT extend the time to reach this accuracy drop by factors of 1.98× and 1.92×, respectively. SCSR improves drift tolerance by an average of 3.24× over RBC. The proposed DBC outperforms all other methods, achieving an average of 7.00× greater drift tolerance compared to RBC. For NLP tasks with RoBERTa, as shown in Fig. 4, DBC achieves the highest drift tolerance performance, significantly extending the time to a 5% accuracy drop by 48.77× compared to the 88 seconds observed with the baseline RBC. The maximum improvement is observed in QQP, where DBC reaches a retention time 55.18× longer than RBC. In contrast, other methods show shorter retention times, with Flipcy, DynaPAT, and SCSR extending drift tolerance by 6.91×, 6.54×, and 5.07×, respectively, compared to RBC. Moreover, to evaluate recent models more rigorously, we simulate the LLMs, as shown in Fig. 5. Despite the substantial number of weights in LLMs, the results are consistent with those obtained from vision models and NLP tasks. Specifically, for RBC, a 5% accuracy drop is observed at an average of 91 seconds across the two LLMs. In comparison to this baseline, the 5% accuracy drop points for Flipcy, DynaPAT, and SCSR occur at average times that are 1.37×, 1.42×, and 1.72× longer, respectively, while DBC achieves a 3.08× longer time to the 5% accuracy drop point.

We conduct a detailed analysis of the relationship among time, soft error rate, and DNN accuracy using VGG-19. Fig. 6a illustrates the progression of the soft error rate over time. The soft error rate is defined as the proportion of erroneous PCM cells, whose stored values deviate from the original

(a) Llama-3.2 1B (b) Gemma-2 2B

Fig. 5. Accuracy of LLMs evaluated on the HellaSwag benchmark at different time steps following the occurrence of conductance drift.

(a) Time vs. Soft Error Rate (b) Soft Error Rate vs. Accuracy

Fig. 6. Relationship among time, soft error rate, and accuracy in VGG-19.

due to conductance drift, relative to the total number of PCM cells. The results show that the soft error rates for RBC, Flipcy, DynaPAT, and SCSR rise steeply, exceeding 20% by 2^{14} seconds. In contrast, DBC exhibits a much more gradual increase, reaching only 7.16% at the same time, consistently maintaining a lower soft error rate than the other methods across all time steps. Additionally, Fig. 6b depicts the DNN accuracy as a function of the soft error rate. At the 5% accuracy drop point, RBC, Flipcy, DynaPAT, and SCSR exhibit soft error rates of 0.02%, 0.23%, 0.23%, and 0.36%, respectively. In comparison, DBC achieves the highest soft error rate of 0.39%, which is $19.5\times$ higher than that of RBC at the same accuracy drop threshold. These results demonstrate that DBC significantly outperforms other methods by reducing the soft error rate over time and maintaining higher accuracy at equivalent soft error rates.

C. Hardware Analysis

Table. III presents the area, energy, and latency metrics for the encoders and decoders of RBC, Flipcy, DynaPAT, and DBC, based on a cache line size of 64 bytes. The SCSR scheme utilizes the same hardware as RBC but incorporates additional software support. Among the evaluated encoders and decoders, DBC incurs the highest area overhead and energy consumption, except for encoder energy, where Flipcy consumes more. Despite this, DBC eliminates the need for auxiliary bits, avoiding additional hardware overhead beyond the encoder or decoder itself. In contrast, Flipcy relies on read and write operations for auxiliary bits at a granularity of 4 bytes per line from PCM, leading to increased area and energy costs. Similarly, DynaPAT requires extra hardware for auxiliary bit management, involving read and write operations from the host register or PCM, with caching mechanisms

TABLE III
HARDWARE COMPARISON

		RBC	Flipcy	DynaPAT	DBC
Area (mm^2)	**Encoder**	0.001	0.011	0.004	0.012
	Decoder	0.001	0.003	0.004	0.012
Energy (pJ)	**Encoder**	0.13	4.56	1.13	1.98
	Decoder	0.13	0.45	1.13	1.95
Latency (ns)	**Encoder**	0.19	1.84	1.03	0.61
	Decoder	0.19	1.88	1.03	0.66

during the processing of the same layers in DNN models. The absence of auxiliary bit requirements provides DBC with notable system-level advantages. Additionally, DBC achieves superior latency performance, recording the lowest latency among encoders and decoders of Flipcy, DynaPAT and DBC. However, while DBC exhibits larger hardware overheads in terms of area, energy, and latency compared to RBC and SCSR, it significantly enhances drift tolerance. For example, in the QQP task shown in Fig. 4b, DBC achieves a $55.18\times$ improvement in drift tolerance over RBC, whereas SCSR provides a $5.47\times$ improvement over RBC, highlighting a trade-off between hardware overhead and drift tolerance.

V. CONCLUSION

The behavior of the real MLC PCM device, implemented by IBM Research, deviates from the analytical model used in previous studies. Specifically, higher PCM cell levels in the real device is more prone to soft errors due to conductance drift, whereas the conventional model typically identify mid-levels as the most error-prone. To address this, we introduce the *Drift-aware Binary Code* (DBC), a novel binary code designed to enhance the drift tolerance of DNNs operating on the real PCM device. DBC assigns the more reliable lower levels of PCM cells to represent lower decimal values. This approach reduces the drift-induced soft error rate, considering that smaller absolute values dominate the weight distribution in DNNs. Furthermore, DBC minimizes the negative impact on DNN accuracy by ensuring that drift only reduces absolute weight values. Notably, DBC requires no auxiliary bits and operates independently of other drift-tolerant or fault-tolerant mechanisms, such as Error Correction Codes (ECC), allowing it to be seamlessly integrated with existing solutions. Experimental results demonstrate that DBC enhances the drift tolerance of DNNs by up to $55.18\times$ compared to the conventional reflected binary code.

***Abstract*—Analog IC design is mainly manual and implemented at the device level. A major reason is circuit behavior-extraction. Unlike its digital counterpart, analog IC design is strongly coupled with technology nodes and is difficult to represent by an abstract behavioral model. The lack of accurate and efficient analog modeling has become a bottleneck in analog design automation. This paper proposes a behavior-centric optimization framework for analog circuits that represents circuit behavior using transistor electrical properties instead of sizes, improving model generalization and reducing optimization complexity. To characterize the process, we propose a method for mapping transistor electrical properties to sizes. Moreover, we developed a radial basis functions-based Kolmogorov-Arnold network (RBF-KAN) to accurately approximate circuit nonlinear behavior with limited simulations. Compared to black-box modeling, our approach enables constructing surrogate models via KAN under a set specification with just a few hundred simulations. Experiments on the testing suite showed our framework achieved a 1.76× to 2.64× improvement in large signal figure of merit (FOM) and 1.73× to 2.48× in small signal FOM over state-of-the-art methods, while also enabling 3.5× to 6.2× acceleration in design porting.**

***Index Terms*—Analog circuit sizing, Kolmogorov-Arnold Networks, Knowledge Transfer, Behavioral Model**

I. INTRODUCTION

While digital design benefits from mature CAD tools, analog design still relies on experienced experts. However, as process technology advances and application demands increase, stricter design specifications drive the need for greater automation and intelligence in analog IC sizing [1]–[3].

Currently, most approaches rely on treating the analog sizing problem as a black box, employing machine learning (ML) techniques like reinforcement learning (RL) [4], [5], Bayesian optimization (BO) [6], and evolutionary algorithms (EA) [3], [7] to explore the design space. These methods often overlook the circuit's inherent behavior, instead relying on extensive computations to meet specifications, requiring substantial simulation time and constructing accurate surrogate models.

Considering that circuits are commonly represented as schematics, existing learning algorithms employ graph neural networks (GNNs) [8] to leverage topological information to open the black box. Nonetheless, this graph representation mainly encodes device connectivity, providing limited insight into the circuit's deeper behavior, thus still requiring **thousands of simulations** to build an accurate surrogate model.

Deriving more meaningful design insights requires establishing signal models and response analysis, which link the electrical parameters of devices to circuit performance, enabling guiding designs. In fact, early analog electronic design automation (EDA) methods employed ***symbolic*** approaches [10] to approximate circuit equations rather than relying solely on simulation. For human experts, a commonly used approach is the g_m/I_D methodology [9], which characterizes circuit performance based on transconductance (g_m) to drain current (I_D). As shown in Figure 1, this approach provides behavior-level insights that reduce reliance on specific process design kits (PDKs) data, enabling more efficient optimization than simulation-based methods. While this approach was efficient, it gradually fell out of favor due to three main challenges: (1) Technology scaling introduced non-idealities, making accurate equation-based approximation difficult. (2) Fitting separate equations was required for each specification and circuit topology. (3) Mapping behavior to design parameters requires **presetting the transistor length** (L), making the design process dependent on trial and error and limiting cross-process portability.

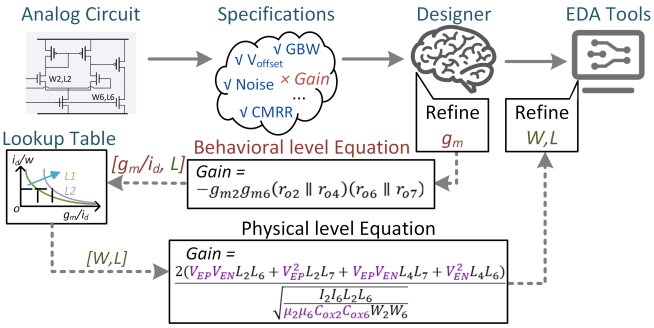

Fig. 1. Designers approximate the behavioral equation for performance metrics based on circuit theory and then utilize the g_m/I_D [9] methodology mapping to specific design parameters.

Revisiting these limitations of the classic equation-based methods, we observed that the key challenges lie in the following: (1) Due to the **strong coupling with the PDKs**, building surrogate models for analog blocks requires capturing their highly nonlinear properties and fitting the corresponding process characteristics. (2) ML is primarily based on ***connectionism***, while circuit representation relies on ***symbolism***, which hinders effective integration. (3) Expanding the objective space with complete specifications leads to ***exponential*** complexity in managing the Pareto front (PF).

We propose a framework for behavioral-centric optimization of analog circuits (BCOA) to address these challenges. Inspired by human expert workflows, we decouple the analog block from the process. Specifically, we approximate circuit behavior with **process-independent electrical properties** and have developed a **direct mapping method** from these properties to transistor sizes, eliminating the need to preset L and facilitating porting. This enables optimization and modeling to directly focus on analog behavior, bridging the gap between symbolic and connectionist approaches.

The contributions of this work are summarized as follows.

1) We decouple the analog block from the process and propose

*Corresponding authors: (Krzhu@fudan.edu.cn, Yun.li@ieee.org).
†Both authors contributed equally to this research.

a behavioral-level optimization framework that reduces the complexity of modeling while enhancing generalization across different technologies.

2) We propose a method to map electrical properties to transistor sizes and develop a radial basis function-based Kolmogorov-Arnold network (RBF-KAN) model to learn circuit nonlinear behavior from limited simulations efficiently.
3) We propose a method for Pareto front estimation that reduces the time complexity from $O(n^m)$ to $O(n^2 \cdot \log n + n \cdot m)$, enabling efficient complete specification optimization.
4) Experiments based on the AnalogGym suite show that the proposed framework builds accurate behavioral-level surrogate models with only a few hundred simulations and effectively generalizes across different processes. Compared to state-of-the-art algorithms, BCOA achieves a 1.73 to 2.64 $\times$ improvement in FOM_L and FOM_S.

II. PRELIMINARIES

A. Surrogate Model for Analog Blocks

Gaussian processes (GP) [6], [11] is among the most popular surrogate modeling methods due to their strong learning ability with limited simulations. However, considering complete specifications, often ranging from 10 to 20, GPs struggle with scalability, causing computational costs to grow exponentially with more objectives or samples [2].

Recent research explores to use deep learning for surrogate modeling due to its scalability for multiple objectives. However, this approach requires large amounts of data for effective training and struggles to model nonlinear transistor behavior accurately. In contrast, KAN [12] uses learnable B-splines as activation functions to decompose complex multivariate functions into simpler univariate components. We observe that this property allows KANs to efficiently capture nonlinear relationships with limited data, providing more accurate and scalable learning.

B. Design Flow with g_m/I_D Methodology

g_m/I_D methodology [9], [13] is a widely-used design methodology that links small-signal models with transistor sizes. In the g_m/I_D design methodology, transistor characteristics for various channel lengths L and widths W are simulated and measured, capturing the relationship between g_m/I_D and the normalized current $I_D/(W/L)$. This data is then compiled into pre-simulated lookup tables (LUTs). Subsequently, the designer selects the appropriate operating region based on the performance requirements. The weak inversion region is typically chosen for low-power applications, where the g_m/I_D is higher. In contrast, the strong inversion region, characterized by a lower g_m/I_D, is preferred for high-speed applications. Once the operating area is defined, the designer utilizes the LUT to determine the appropriate device dimensions.

C. Automatic Analog Sizing

Recent research trends on analog sizing often focus on efficiency. To enhance optimization efficiency, techniques like truncated subspace sampling [14] and domain decomposition [15] have been introduced, targeting specific areas of the design space to reduce computation and accelerate convergence. However, these methods may potentially miss points with better circuit performance. We investigate an amplifier optimization task with seven objectives conducted on the AnalogGym testing suite [16], domain decomposition-based BO reduced the required simulation runs by a factor of 10 compared to EA. However, this improvement in efficiency came at a substantial cost: the figure of merit (FOM) dropped by **10 to 100** $\times$. In BCOA, we use *behavioral representation* to reduce optimization complexity and enhance model generalization, along with efficient PF estimation to guide the many-objective optimization.

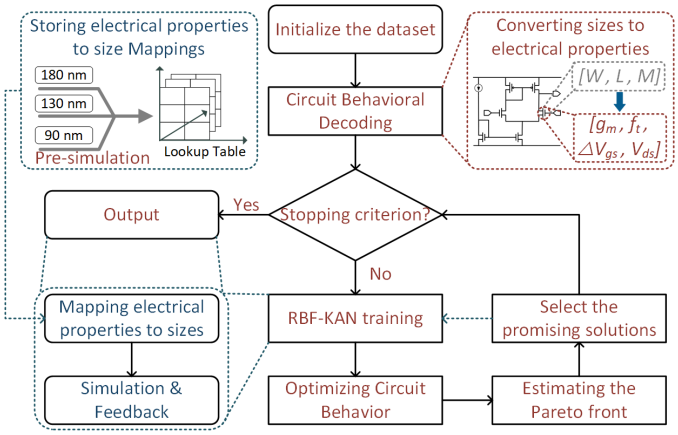

Fig. 2. The overall flow of the proposed BCOA framework.

III. FRAMEWORK

A. Framework Overview

BCOA mainly consists of six steps, as shown in Figure 2. 1) We use pre-simulation to build LUTs that map electrical properties to transistor sizes, as outlined in Section III-B. 2) We apply Latin hypercube sampling [17] to generate a small set of candidate designs as a database and use simulations to obtain transistor electrical properties that represent circuit behavior. 3) If the stopping criteria are met, the best design is selected; otherwise, we proceed with further optimization. 4) We train the RBF-KAN model using the solutions detailed in Section III-C and their corresponding performance from the database as training data. For the new solutions, we use the LUTs from Step 1 to map transistor electrical properties back to sizes and simulate to obtain the corresponding performance. 5) We apply an optimization algorithm to refine circuit behavior using predictions from the RBF-KAN. Notably, the BCOA framework is compatible with various optimization algorithms, and we select MOEA/D-DE [18] as the optimizer for its efficiency and flexibility. 6) The PF is estimated following the method in Section III-D, allowing us to select the most promising solutions for the next iteration.

B. Transistor Size Mapping Method

We develop a transistor size mapping method to decouple circuit behavior from technology, overcoming the g_m/I_D methodology's reliance on presetting L to determine size. Therefore, the key idea of our method is to use large-signal and small-signal parameters to characterize transistor electrical properties and, building on the g_m/I_D methodology, to fix L using these parameters, as shown in Figure 3. The small-signal parameters include g_m, which represents the change in drain current due to a change in gate voltage, and transition frequency f_t, which measures high-frequency performance. These parameters determine bandwidth, slew rate (SR), power consumption, phase, and transient response. The large-signal parameters, including drain-source voltage V_{ds} and overdrive voltage ΔV_{gs} (defined as $V_{gs} - V_{th}$, where V_{gs} is the gate-source voltage and V_{th} is the threshold voltage), define the transistor's operating region and influence swing, gain, and noise performance.

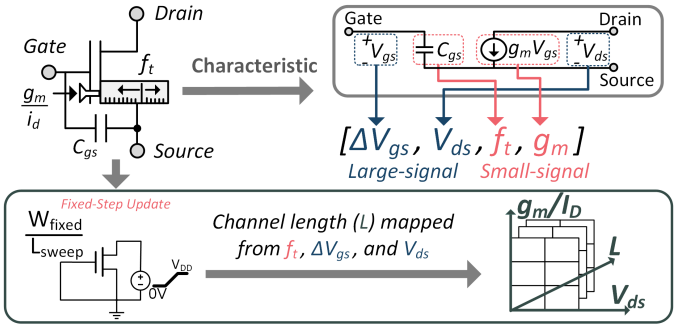

Fig. 3. We use large-signal and small-signal parameters to characterize transistors, providing a more accurate mapping from electrical properties to design parameters than the g_m/I_D methodology.

The mapping between electrical properties and transistor sizes uses the formulas in Table I to calculate L, and the corresponding sizes are then derived from the g_m/I_D LUT. Further details on constructing a LUT with the g_m/I_D method can be found in [13].

TABLE I
CORRELATION BETWEEN ELECTRICAL PROPERTIES AND SIZES

Parameter	Formulas	Relationship
$g_m(A/V)$	$\sqrt{2\mu C_{ox}\frac{W}{L}I_{ds}}$	$\sqrt{W/L}$
$f_t(Hz)$	$\frac{3\mu I_{ds}}{2\pi g_{m0}L^2}$	$1/L^2$
$\Delta V_{gs}(V)$	$\sqrt{\frac{4\pi f_{t0} g_{m0} L^3}{3\mu^2 C_{ox} W}}$	$L\sqrt{\frac{L}{W}}$
$V_{ds}(V)$	Non-analytic	$\sim L/W$

C. RBF-KAN

We adopt RBF-KAN to enable data-efficient and accurate modeling of circuit behavior, enhancing scalability and sensitivity to both global and local features. In KAN, each node x_j^{l+1} in layer $l+1$ is computed as the sum of activation functions $\phi_{l,i,j}$ applied to nodes x_i^l in the previous layer:

$$x_j^{l+1} = \sum_{i=1}^{n_l} \phi_{l,i,j}(x_i^l), \tag{1}$$

where x_i^l represents the i-th node in layer l, and $\phi_{l,i,j}$ denotes the activation function on the edge. The B-splines are adaptable basis functions for activation, enhancing nonlinear fitting capabilities. However, their grid-based structure limits flexibility with non-uniform data and increases computational complexity.

To enhance global smoothness and long-range feature capture with better scalability in high dimensions, we replace B-splines with Gauss-Laplace RBF activations [19], defined as:

$$\phi_{l,i,j}(x_i^l) = W_{ij}^l \cdot \exp\left(-\alpha(x_i^l - g_{ij}^l)^2 - \beta|x_i^l - g_{ij}^l|\right), \tag{2}$$

where α controls the scale of the Gaussian component, capturing smooth variations and low-frequency features, and β determines the decay rate of the Laplace component, enhancing sensitivity to rapid changes and high-frequency signals. W_{ij}^l represents the edge weight, g_{ij}^l denotes the RBF center, and α and β are hyperparameters that control the RBF shape.

For backpropagation, the gradient of the loss function to the weight W_{ij}^l is:

$$\frac{\partial L}{\partial W_{ij}^l} = \delta_j^{l+1} \cdot \phi_{l,i,j}(x_i^l), \tag{3}$$

where $\delta_j^{l+1} = \frac{\partial L}{\partial x_j^{l+1}}$. The gradient for the center g_{ij}^l requires the partial derivative of the activation function concerning g_{ij}^l:

$$\frac{\partial \phi_{l,i,j}}{\partial g_{ij}^l} = W_{ij}^l \cdot \phi_{l,i,j}(x_i^l)\left(2\alpha(x_i^l - g_{ij}^l) + \beta \cdot \mathrm{sgn}(x_i^l - g_{ij}^l)\right), \tag{4}$$

which leads to the gradient as $\frac{\partial L}{\partial g_{ij}^l} = \delta_j^{l+1} \cdot \frac{\partial \phi_{l,i,j}}{\partial g_{ij}^l}$.

To propagate gradients to the previous layer, we compute the gradient concerning the input x_i^l:

$$\frac{\partial L}{\partial x_i^l} = \sum_{j=1}^{n_{l+1}} \delta_j^{l+1} \cdot \frac{\partial \phi_{l,i,j}}{\partial x_i^l}, \tag{5}$$

where the partial derivative of the activation function for x_i^l is:

$$\frac{\partial \phi_{l,i,j}}{\partial x_i^l} = W_{ij}^l \cdot \phi_{l,i,j}(x_i^l)\left(-2\alpha(x_i^l - g_{ij}^l) - \beta \cdot \mathrm{sgn}(x_i^l - g_{ij}^l)\right). \tag{6}$$

D. Pareto Front Estimation

We propose a Monte Carlo-based hypervolume (MC-HV) estimation method to enhance objective scalability and effectively guide optimization. MC-HV approximates the HV by dynamically adjusting reference points closer to the PF and increasing sampling density in complex regions according to curvature. Algorithm 1 illustrates the MC-HV procedures. The ϵ controls the convergence precision of the reference point, typically set to 10^{-3} or 10^{-4}. The Δ, defined as 10% of the objective range of the solution set, ensures that the initial reference point is sufficiently far from the solution set. The $\beta = 0.5$ regulates the rate at which the reference point approaches the PF, while the $\gamma = 1$ adjusts the impact of the distance term in curvature weighting. The $\alpha = 100$ influences the total sample count, and the $\beta = 0.5$ increases sampling density in high-curvature regions. The distance term $d(z, S) = \min_{s \in S} \|z - s\|$ in $p(z)$ concentrates sampling near the solution set to enhance HV estimation accuracy. In high-curvature regions, the sampling count increases adaptively, with $N_i = \alpha \cdot (1 + \kappa(s_i))^\beta$, ensuring more sampling points in complex regions to improve accuracy.

The time complexity of the MC-HV method primarily depends on the solution set size n and the number of objectives m. The hypervolume estimation complexity is mainly due to dominance checks on each sampling point, where each check has a complexity of $O(n \cdot \log n)$, resulting in a complexity of $O(n^2 \cdot \log n)$. The reference point adjustment complexity is $O(n \cdot m)$, with m representing the number of objectives.

E. Design Porting

Behavioral-level optimization enables more efficient and flexible cross-process portability than transistor sizing. Figure 4 illustrates a case study of circuit behavior-based design porting from 180 nm to 130 nm. Since our framework represents the circuit using process-independent transistor electrical properties, the optimized circuit behavior at 180 nm is mapped to specific dimensions at 130 nm through the LUT of the 130 nm process. As process nodes shrink, both V_{th} and supply voltage (V_{dd}) decrease to enhance speed and reduce power, so fine-tuning primarily focuses on the ΔV_{gs} and V_{ds}. For the RBF-KAN, we implement knowledge transfer using hard parameter sharing [20].

Algorithm 1 MC-HV Method

Input: Solution set S, termination threshold ϵ, sampling parameter γ, sampling control parameter α, curvature influence parameter β, number of samples N

Initialize r for each objective: $r_{i,\text{initial}} = \max_{s\in S} s_i + \Delta$
while $\max_i (r_i - \max_{s\in S} s_i) > \epsilon$ **do**
  Update each dimension of reference point r: $r_i = \max_{s\in S} (s_i + \beta(r_{i,\text{initial}} - s_i))$
end while
Compute curvatures for each solution $s_i \in S$: $\kappa(s_i) = \frac{\|\mathbf{n}(s_i) - \mathbf{n}(s_j)\|}{\|s_i - s_j\|}$
Initialize sample set: $\mathcal{S} \leftarrow \emptyset$
for $i = 1, \ldots, N$ **do**
  Sample $z \sim p(z) = \frac{1}{Z} \exp\left(-\gamma \cdot d(z, S) \cdot \frac{1}{1+\kappa(z)}\right)$
  $\mathcal{S} \leftarrow \mathcal{S} \cup \{z\}$
end for
Estimate hypervolume $HV(S)$ using Monte Carlo integration: $HV(S) \approx \frac{1}{N} \sum_{z\in\mathcal{S}} \frac{\mathbb{I}(z \text{ is dominated by } S)}{p(z)}$
return $HV(S)$

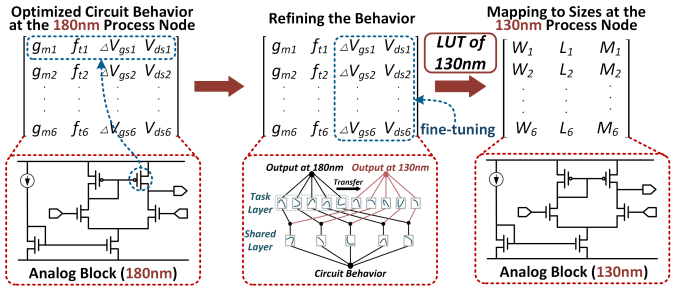

Fig. 4. Our framework enables design porting by mapping optimized behavior to transistor sizes at the new process node via an LUT, with design knowledge transferred through hard parameter sharing in the surrogate model.

IV. EXPERIMENTAL RESULTS

We use the reference metric FOM_{AMP} provided by AnalogGym [16] to evaluate the optimization results by comparing the optimized performance metrics against the baseline metrics, which are also already offered within AnalogGym. The formula is as follows:

$$\text{FOM}_\text{AMP} = \left(\frac{\text{PSRR}}{\text{PSRR}_\text{ref}} \cdot \frac{\text{CMRR}}{\text{CMRR}_\text{ref}} \cdot \frac{\text{Gain}}{\text{Gain}_\text{ref}} \cdot \frac{\text{FOMS}}{\text{FOMS}_\text{ref}} \cdot \frac{\text{FOML}}{\text{FOML}_\text{ref}}\right) \times \left(\frac{Ts}{Ts_\text{ref}} \cdot \frac{\text{Area}}{\text{Area}_\text{ref}}\right)^{-1} \times \left(\frac{v_n}{v_{n_\text{ref}}} \cdot \mathbb{I}(v_n > v_{n_\text{ref}}) \cdot \frac{TC}{TC_\text{ref}} \cdot \mathbb{I}(TC > TC_\text{ref}) \cdot \frac{vos}{vos_\text{ref}} \cdot \mathbb{I}(vos > vos_\text{ref})\right)^{-1}, \tag{7}$$

$$\text{FOM}_S = \frac{\text{GBW}[MHz] \cdot C_{Load}[pF]}{\text{Power}[mW]}, \quad \text{FOM}_L = \frac{\text{SR}[V/\mu s] \cdot C_{Load}[pF]}{\text{Power}[mW]} \tag{8}$$

where v_n is the integrated noise, Ts is the settling time, and vos is the input offset voltage. PSRR represents the power supply rejection ratio, while CMRR denotes the common mode rejection ratio. TC is the temperature coefficient, GBW is the gain-bandwidth product, C_{Load} is the load capacitance. $\mathbb{I}(\cdot)$ is an indicator function that equals 1 if the condition inside the parentheses is true and 0 otherwise.

Our experimental testing circuits include three multi-stage amplifiers (AMPs) from AnalogGym: NMCF, NMCNR, and DFCFC1, **with 11 optimization objectives and 5 constraints**. All experiments are conducted on a Linux workstation with 2 NVIDIA GeForce RTX 4080 GPUs and 4 Intel Xeon Platinum 8260 CPUs.

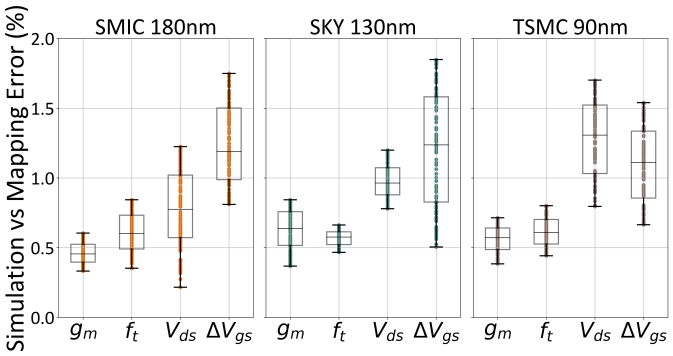

Fig. 5. Error comparison of transistor size mapping method with simulation across three process nodes. Each experiment was repeated ten times with different random seeds.

A. Evaluating Accuracy of Transistor Sizing Mapping

To evaluate the accuracy of the transistor sizing mapping method in Section III-B, we compared the mapping and simulation results across three different processes: SMIC 180 nm, SKY 130 nm [21], and TSMC 90 nm. We used data from the BCOA, selecting 1,000 samples for each process.

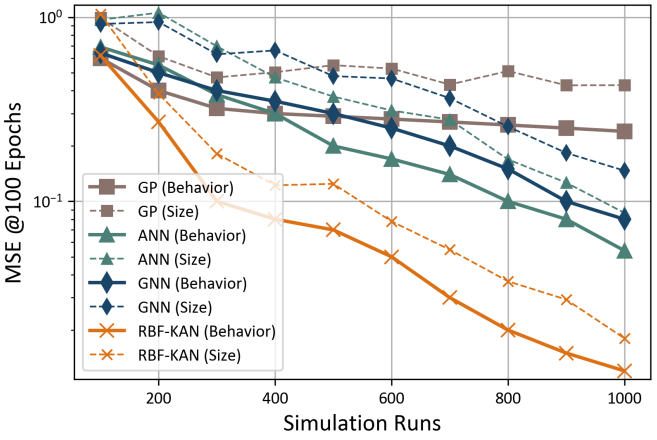

Fig. 6. Learning curves of average MSE over 10 runs for three AMPs.

Figure 5 shows that the mapping method achieves low errors, with g_m and f_t errors below 1% and V_{ds} and ΔV_{gs} errors slightly higher but within 2%. The higher errors for V_{ds} and ΔV_{gs} are due to their stronger sensitivity to device operating points and channel effects, which vary more significantly with process scaling. Overall, the mapping method maintains acceptable accuracy, demonstrating robustness for different process nodes.

B. Evaluating Nonlinear Fitting with Limited Samples

We conducted comparative experiments to evaluate the nonlinear fitting capability of our proposed RBF-KAN model. We used BagNet [22] to generate 10,000 samples. Then, by gradually increasing the training set, we evaluated the fitting capability of RBF-KAN under small-sample scenarios. Figure.6 shows mean squared error (MSE) at 100 epochs versus the number of simulation runs across different models: GP [6], ANN [2], GNN [23], and our RBF-KAN, tested for both behavior-based and transistor size-based modeling.

As shown in the figure, behavior-based modeling consistently achieves higher accuracy than size-based modeling. This is attributed to its decoupling of behavior from process dependence, thereby minimizing potential underfitting to the PDK. Compared to other models, RBF-KAN consistently achieves the highest accuracy. This is due to the Gauss-Laplace RBFs, which blend global smoothness and localized behavior capture. KAN's learnable activation functions also enable efficient handling of long-range feature interactions, even with minimal nodes. In many objective scenarios, GP requires covariance design to capture objective correlations, which compromises accuracy and extends processing times to over 10 hours due to joint modeling demands.

C. Comparison of BCOA and Other Methods

To demonstrate the effectiveness of the proposed BCOA framework, we compare FOM_{AMP} of BCOA with three state-of-the-art circuit sizing algorithms, including reinforcement learning based on relational GNN (rGNNRL) [5], constrained Voronoi tree search Bayesian optimization (cVTSBO) [15], and RL based on g_m/I_D (g_m/I_D RL) [24].

As shown in Table II, the improvements of BCOA primarily stem from significant enhancements in $\mathrm{FOM_L}$, $\mathrm{FOM_S}$, area, and Ts. Other methods utilize the single-objective optimization paradigm, treating the transient response and area as constraints. However, the sparse and narrow solution space for stable transient response, coupled with the lack of quantifiable feedback from oscillations, often leads to inefficient exploration and suboptimal solutions. Our framework employs the MC-HV method for efficient PF evaluation, dynamically adjusting reference points to guide many-objective optimization. As a result, BCOA significantly improves $\mathrm{FOM_L}$ by **1.76**× to **2.64**×, $\mathrm{FOM_S}$ by **1.73**× to **2.48**×, Ts by **1.31**× to **27.33**×, and reduces area by **15%-30%**. These individual improvements collectively contribute to the overall enhancement of FOM_{AMP}, which achieves gains ranging from **5.74**× to **98.05**× over g_m/I_D RL, **9.95**× to **176.60**× over cVTS, and **14.84**× to **184.37**× over rGNNRL.

TABLE III
COMPARISON OF HV AND MC-HV METHODS WITHIN THE BCOA

	Processing time (min) ↓			FOM_{AMP} ↑		
Topology	NMCF	NMCNR	DFCFC	NMCF	NMCNR	DFCFC
HV	226 ± 11	313 ± 23	241 ± 19	182.4 ± 42.1	137.9 ± 37.7	3952 ± 884
MC-HV	**6.1 ± 0.9**	**7.4 ± 1.2**	**6.8 ± 1.4**	**283.5 ± 21.4**	**186.2 ± 17.2**	**5863 ± 184**
Improvement	97.3%	97.6%	97.2%	1.55 ×	1.35 ×	1.48 ×

As shown in Figure 7, While cVTSBO uses domain decomposition to accelerate convergence with fewer function evaluations (FEs), it often gets trapped in local optima under complete specifications, limiting further improvement after initial convergence. We also observe that other methods significantly improve in FOM_{AMP} after integrating behavior-level optimization. This is due to behavior-level representation, which establishes a smoother decision space, enabling more efficient exploration.

As shown in Table III, the MC-HV method significantly improves runtime and optimization guidance over the HV method. Using Monte Carlo-based sampling for the PF estimation, MC-HV reduces complexity in many-objective scenarios, decreasing runtime by about **97%**. Adaptive reference point adjustments and targeted high-curvature sampling allow MC-HV to concentrate on suboptimal regions, enhancing convergence and solution diversity, with an average FOM_{AMP} improvement of **1.35**× to **1.55**× across the three topologies.

The effectiveness and efficiency of BCOA are attributed to two factors. 1) We decouple the analog block from the process using behavior-level representation and employ RBF-KAN to build accurate, comprehensive surrogate models with limited simulations. 2) Using the MC-HV method to approximate the Pareto front, we guide multi-objective trade-offs, enabling efficient global optimization.

D. Design Porting among Process Nodes

To validate the efficiency and effectiveness of behavior-level representation in design porting, we conducted experiments across 180nm, 130nm, and 90nm process nodes. Specifically, we compared BCOA with knowledge transfer-based methods, such as GCNRL [4], to evaluate FOM_{AMP} and FE consumption across nodes. In GCNRL, technology transfer is accomplished by training an RL agent to size circuits in a simpler node and then applying the same agent to new nodes.

We use process-independent device electrical properties to represent circuit behavior, enabling optimized designs to be reused across nodes. Specifically, design porting is achieved by mapping optimized behavior to transistor sizes using the LUT of the new process. Furthermore, the behavior-based surrogate model captures general electrical characteristics, enabling efficient knowledge transfer. As shown in Figure 8, BCOA reduces FE consumption by **6.6**× to **7.8**× compared to size-based knowledge transfer in GCNRL, achieving over **16.2** × improvement in FOM_{AMP} across multiple nodes.

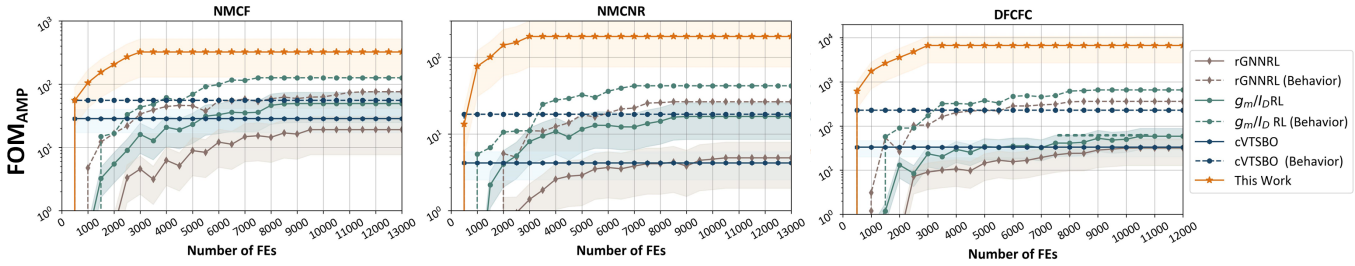

Fig. 7. Learning curves of different algorithms. The proposed BCOA consistently achieves the highest FOM_{AMP}.

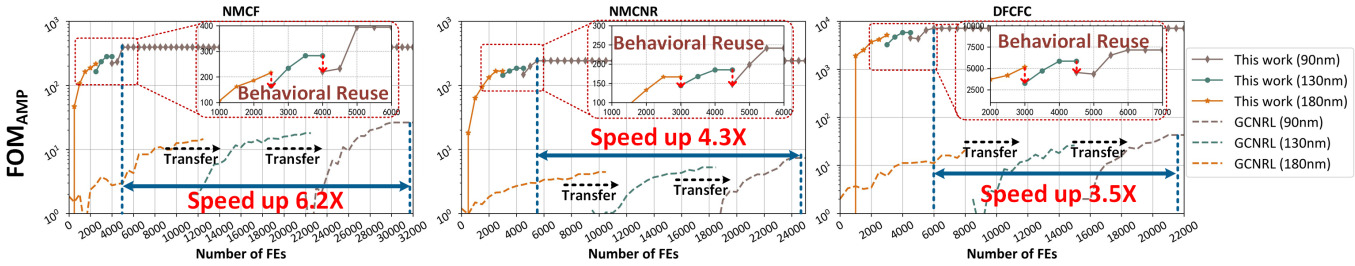

Fig. 8. Design porting among process nodes on AMPs. Behavioral representation enables cross-process reuse, while size-based representation demands substantial re-optimization at new node.

V. Conclusion

We present BCOA, a behavior-level optimization framework for analog blocks. We decouple the design from specific processes by representing circuit behavior with transistor electrical properties rather than size. This enables accurate surrogate modeling with RBF-KAN under limited simulations and facilitates global optimization. We also employ the MCHV method for rapid PF evaluation across complete specifications. Extensive experiments show that BCOA outperforms other methods in FOM_{AMP} and provides strong knowledge transfer ability. Therefore, BCOA offers a more effective and efficient approach to analog block optimization and design porting.

***Abstract*—In this paper, we present a GPU-accelerated RTL simulator addressing critical challenges in high-speed circuit verification. Traditional CPU-based RTL simulators struggle with scalability and performance, and while FPGA-based emulators offer acceleration, they are costly and less accessible. Previous GPU-based attempts have failed to speed up RTL simulation due to the heterogeneous nature of circuit partitions, which conflicts with the SIMT (Single Instruction, Multiple Thread) paradigm of GPUs. Inspired by the design of emulators, our approach introduces a novel virtual Very Long Instruction Word (VLIW) architecture, designed for efficient CUDA execution. We also design a flow that maps circuit logic to the architecture in a process analogous to the FPGA CAD flow. This architecture mitigates issues of irregular memory access and thread divergence, unlocking GPU potential for RTL simulation. Our solution achieves up to 64× speed-up over the best CPU simulators, democratizing high-speed RTL simulation with accessible hardware and establishing a new frontier for GPU-accelerated circuit verification.**

I. Introduction

As design complexity of VLSI circuits scale aggressively, the complexity of verifying their functionality at the Register Tranfer Level (RTL) also rockets up. However, traditional CPU-based RTL simulators face scalability bottlenecks due to limited computation power, caches, and parallelism inside multi-core execution [1]. For large-scale designs, even high-performance CPU simulators struggle to deliver the speed necessary for rapid and iterative verification.

Field Programmable Gate Array (FPGA)- and custom-processor-based emulation has emerged as a powerful solution to accelerate logic verification, achieving orders-of-magnitude speedup over CPU simulation [2], [3]. By leveraging parallelism inherent in hardware, emulators can validate large designs more efficiently than software-based simulators. Despite their advantages, FPGA- and custom-processor-based emulators [4], [5] are costly in terms of both financial costs and setup time, limiting their accessibility and adaptability. With these barriers, GPU-accelerated simulation has the potential to offer a compelling alternative, given GPUs' high degree of parallelism, availability, and versatility. Yet, despite the evident advantages, GPUs are rarely used for simulation due to specific architectural challenges.

The barriers to GPU-based simulation arise from fundamental differences between circuit characteristics and GPU architectures. First, GPUs operate under a Single Instruction, Multiple Thread (SIMT) model where threads execute the same instructions in lockstep, which is optimal for workloads with homogeneous parallelism. In contrast, digital circuits are inherently heterogeneous; each circuit partition can have a unique graph structure and functional requirements that challenge SIMT compatibility [6]. Although prior work has sought to make circuits GPU-compatible by mapping them into LUT-based gate level structures [7], [8], [9], [10], [11], [12], this approach falls short in performance compared with highly optimized CPU simulators. Additionally, some GPU-based methods simulate multiple independent testbenches in parallel [13]. While this strategy improves simulation *throughput*, it cannot help in reducing *latency* which is critical for rapid turnaround in iterative design cycles.

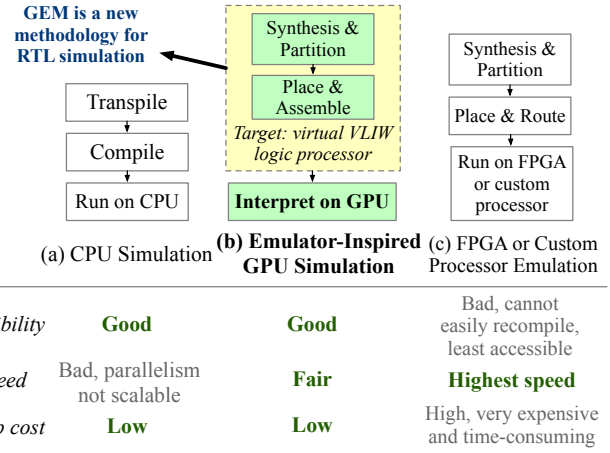

Fig. 1: GEM is a new, emulator-inspired methodology for flexible, fast, and low setup cost RTL simulation.

Another challenge lies in the irregular nature of circuit graphs, which complicates efficient data access on GPUs. GPU memory systems are optimized for throughput, relying on coalesced and regular memory accesses to achieve peak efficiency. However, circuit graphs are sparse and irregular, causing frequent irregular memory accesses that degrade GPU performance. These factors have, until now, prevented GPUs from being viable platforms for efficient, low-latency circuit simulation.

In this work, we propose a GPU-accelerated RTL simulator, **GEM**, that overcomes these challenges and redefines the potential of GPU-based circuit verification. The major contributions are summarized as follows.

1) Rather than simulating circuits using LUT-based methods, we introduce a technique that maps circuit logic into a specialized virtual Boolean processor with a Very Long Instruction Word (VLIW) architecture, optimized for execution on CUDA-compatible GPUs. This innovative architecture allows us to fully utilize the GPU threads even for irregular circuit structures and enabling coalesced memory accesses that are critical to high-performance GPU operation.
2) We design a mapping flow from RTL to our virtual VLIW architecture that mimics the partitioning, synthesis, and physical design flow of hardware, enabling us to interpret the circuit functionality on GPU in a way similar to the computer-aided design (CAD) flow for FPGAs.
3) In our mapping flow, we address various critical challenges on simulation performance by designing a set of novel algorithms, including (i) deep long-tailed logic mapping that minimizes synchronization, (ii) RAM mapping and depth-optimized extended AIG synthesis, (iii) width-constrained replication-efficient partitioning, and (iv) iterative timing-driven bit placement.

Our GPU-accelerated simulator achieves a remarkable 38× and

64× speed-up compared to a leading commercial tool and Verilator, respectively. This substantial performance improvement validates our approach, demonstrating a successful use of GPUs in delivering RTL simulation speed-up. GEM offers a paradigm shift in GPU-based circuit verification, with potential applications extending into areas such as hardware-software co-design and rapid prototyping. Furthermore, this software-based method democratizes high-speed RTL simulation by making it accessible on readily available and relatively inexpensive GPU hardware, bringing high-speed simulation to a broader audience of designers and researchers. To this end, we made GEM open source under a permissive Apache license[1].

II. Preliminary

In digital circuit design, simulation and emulation serve as crucial processes for verifying and evaluating functionality before hardware manufacturing. Both approaches typically work in two stages: compilation and execution.

- In the *compilation* stage, the behavioral RTL netlist, represented in languages such as Verilog or SystemVerilog, is processed and transformed into an executable simulator. This simulator models the circuit behavior, either in software or as a hardware-mapped design, which will then be used to execute various test scenarios.
- The *execution* stage involves running the compiled simulator with specific input stimuli, provided as waveforms or recorded signal patterns (e.g., VCD or FSDB format). The simulator or emulator responds to these stimuli, producing output that reveals the circuit's expected behavior, helping designers validate functionality across test cases.

One key performance metric for evaluating simulators and emulators is the simulation speed, commonly measured in *simulated cycles per second* or Hertz (Hz). Depending on the underlying methodology, simulators are typically categorized as either oblivious/full-cycle simulators or event-based simulators [1].

- Full-cycle simulators process the entire circuit in each simulation cycle, regardless of whether specific parts of the circuit experience any activity. This approach is suitable for high-throughput FPGA-based emulators because the process is consistent across cycles.
- Conversely, event-based simulators, typically CPU-based, are optimized for efficiency by selectively updating only the circuit elements that are actively switching or affected by input changes in each cycle. This selective processing can save significant computation time when only parts of the circuit change, but it is generally slower than hardware-accelerated full-cycle methods.

Previous work in logic emulation and simulation has explored various hardware and software platforms, each with distinct advantages and limitations. FPGA- or custom-processor-based emulation is known for its impressive performance, often achieving emulation speeds of 1 MHz or more [4], [5]. However, the significant cost of dedicated FPGA hardware and the extensive compilation times make this approach less accessible and time-efficient for iterative design workflows. For example, it can take days to compile a design into a FPGA-based emulator. In contrast, CPU-based simulators offer flexibility and ease of setup but are generally slow, often failing to scale well with increasing circuit complexity.

Efforts to parallelize CPU-based simulators, primarily through circuit partitioning, the Chandy-Misra-Bryant (CMB) algorithm, and dataflow optimization [14], [15], [16], [17], have met with only moderate success. Although these approaches can exploit multicore CPUs, they face significant bottlenecks: the CPU frontend often becomes overwhelmed by the sheer volume of compiled circuit code, and parallelism is constrained by the limited memory bandwidth in standard multicore CPUs, capping the potential performance gains.

Efforts to leverage GPU's data parallelism for logic simulation have aimed to address the performance gap but have generally been confined to gate-level simulation using lookup-table-based methods [7], [8], [9], [10], [11], [12]. This approach relies on GPU threads querying precomputed truth tables, which align with the SIMT architecture of GPUs. However, this method presents serious limitations: gate-level simulations are typically much slower (10–100×) than RTL-level simulations, as the latter operate on a higher abstraction level. Consequently, while previous GPU-based methods show promise at the gate level, they fail to match the performance needed for practical RTL verification tasks.

Another line of GPU-accelerated simulation instead transpiles RTL directly to CUDA code. As this results in SIMT-incompatible GPU kernels, they either choose to forfeit data parallelism completely [6] or use independent workloads to fill the data parallelism dimension [13]. These methods require special inputs such as independent stimulis or simple blocking RTL code and are thus not good at reducing simulation latency which is critical in verification turnaround.

III. Algorithm

We present a novel GPU-accelerated RTL simulator, GEM, that addresses the fundamental mismatch between circuit simulation and GPU architecture. Our core idea is a virtual Boolean processor that acts as a reconfigurable and highly-parallel container of Boolean logic. This virtual Boolean processor is programmed with a VLIW instruction set, and is designed to fit GPU parallelism. Specifically, its bitstream can be interpreted using high performance GPU kernels on a CUDA-compatible GPU. Section III-A describes the key motivation behind the design of this architecture and how it solves the SIMT and memory access challenges. To map any input RTL design to the virtual Boolean processor, we design a process containing synthesis (Section III-B), partitioning (Section III-C), physical design (Section III-D), and finally bitstream generation and interpretation (Section III-E). This flow has a beautiful analogy to the CAD flow of FPGAs.

A. A Virtual Boolean Machine

GEM introduces a GPU-friendly virtual Boolean machine that is critical in bridging the gap between circuit functionality and GPU execution. Following are our key observations that lead to its design.

Observation 1. Every Boolean function can be implemented using only a fixed set of operators. Such an operator set is called functional complete. For example, {AND, INVERT} is a functional complete operator set. By compiling the logic into an intentionally limited set of operators, we can use GPU's built-in logic instructions to execute them, instead of having to query look-up tables from memory.

Observation 2. Irregular memory access is inherently unavoidable due to the heterogeneous nature of general circuit graph. However, irregular access inside GPU shared memory (only accessible by a local thread block) is much less costly than irregular global memory access. Rearranging the simulation so that most irregular accesses happen locally inside a thread block will thus help greatly in reducing memory overhead.

Based on Observations 1–2, our modeling of simulation is shown in Figure 2. We regard the general simulation task as a set of logic

[1]https://github.com/NVlabs/GEM

partitions, each in a reasonable size that can be handled with one Boolean processor core (i.e., one GPU thread block). Inside each partition there is an extended and-inverter graph (E-AIG) with AND gates, INVERT gates, D flip-flops (FFs), and RAM blocks. E-AIG can efficiently represent any synthesizable circuit with combinational and synchronous sequential logic. We note that although RAM blocks can be polyfilled using only FFs and decoder logic, this process is extremely costly for large RAMs and thus we introduce native support to RAM blocks in E-AIG.

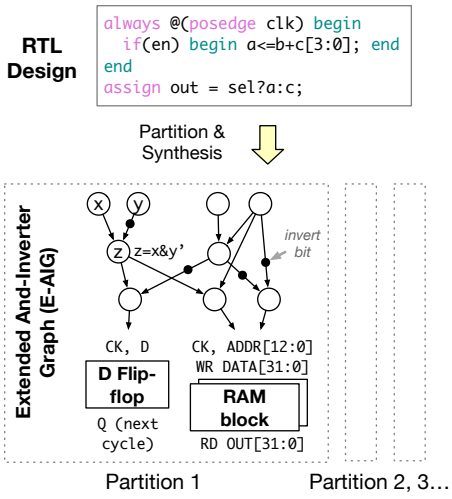

Fig. 2: GEM regards every RTL design as a set of partitions. Each partition is an extended and-inverter graph (E-AIG).

Inside the E-AIG, most of the computation lies in the combinational logic AIG. Our Boolean processor should support efficient execution of AIGs by exploiting the simplicity of gate choices and the common AIG properties.

Observation 3. In addition to thread-level parallelism, *word-level parallelism* can provide orders-of-magnitude more logic processing power. For example, suppose `a,b,c` are three 32-bit unsigned integers, calculating `r=(a AND b) XOR c` is performing 32 And-then-Invert instructions in parallel using `a,b` as inputs and `c` as a constant that encodes whether to flip each resulting bit.

Observation 4. The logic depth of an AIG can be 50–100 for common circuits. However, the gate distribution among the logic levels is extremely imbalanced. A large portion of the gates reside in a few frontier levels whereas only a few gates are accountable for the rest of the levels. We call this the *long-tailed* nature of circuit graphs.

Levelization-based GPU algorithms are frequently used to process circuit graph. They divide the circuit into a series of logic levels each containing a batch of independent calculations. Between two consecutive logic levels, there needs to be a bulk synchronization and a permutation to align the level outputs with the next-level's inputs. As a result, Observation 4 turns out to be very harmful because it leaves most of the levels underutilized and incurs large synchronization overhead. In light of Observations 3–4, we propose a boomerang-shaped executor layer as shown in Figure 3. It is the central reconfigurable logic executor in each virtual Boolean processor core, consisting of interleaved bit permutations and boomerang layers. The virtual Boolean processor core maintains up to 8,192 bits of circuit states. Inside each boomerang layer, the 8,192 bits are recursively folded using bitwise AND and then bitwise XOR with an external constant. The fold is repeated by 14 times until we get a single bit. It can be observed that even a single boomerang layer is able to simulate up to 14 levels of logic. Their shape also fits nicely with the long-tailed nature of circuit graph. Experimentally, boomerang layer reduces the number of bit permutations and synchronizations inside a GPU thread block by more than 5×.

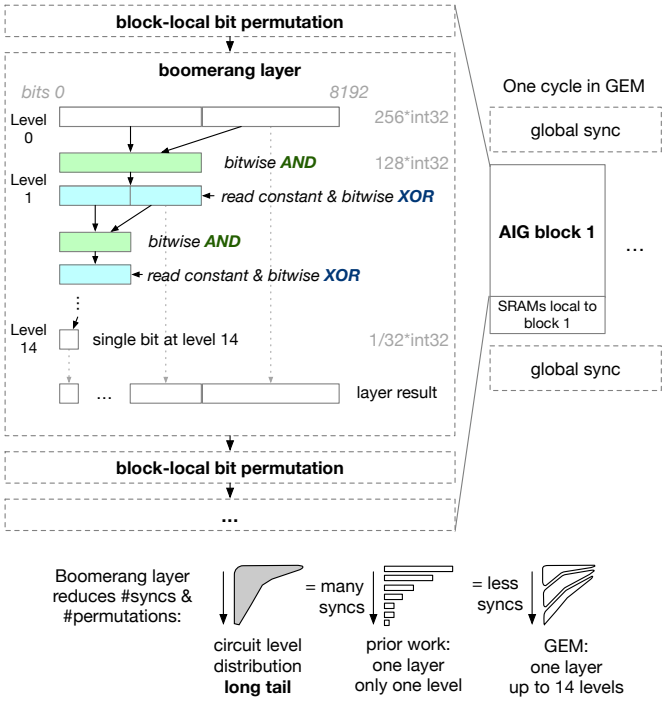

Fig. 3: The boomerang-shaped executor layer in GEM can greatly reduce the number of bit permutations and synchronizations for deep and long-tailed logic.

B. Synthesis

To compile an RTL design for GEM execution, our first step is to map it to the E-AIG format. While AIG is a widely used format in logic synthesis research, there is no existing flow that synthesizes RTL to *extended* AIG with clocked FFs and RAM blocks. The main challenges are two fold: (1) The behavioral RAM constructs in RTL netlist need to be identified and mapped to our fixed RAM block type (13 bits address and 32 bits data) to minimize thread divergence. For a general RAM in RTL, multiple such RAM blocks need to be instantiated and adapter logics need to be introduced automatically. (2) As we will show in later sections, our simulator requires high-quality synthesis results in order to execute efficiently. Specifically, we require the depth of AIG to be as low as possible.

To meet the above requirements, we develop a synthesis flow that exploits two existing synthesis flows for FPGA and ASIC, as shown in Figure 4. We use open-source Yosys synthesizer [18] to deal with RAM mapping. We create a fake FPGA target platform and define our available RAM block. Yosys will take the definition and handle the RAM mapping. Then without further LUT mapping, we can write out the intermediate RTL netlist that only has the RAMs mapped. Next, we handle the RAM-mapped RTL with another ASIC synthesis flow. This time we give the synthesizer a fake ASIC library that only contains AND, OR, INV, and FF gates. This fake library has a simple timing model that defines AND and OR gate delays as

1ps and INV gates as 0ps. Timing-driven synthesis is thus equivalent to depth optimization. In our experiments, we found commercial ASIC synthesizers outperform Yosys in this second step.

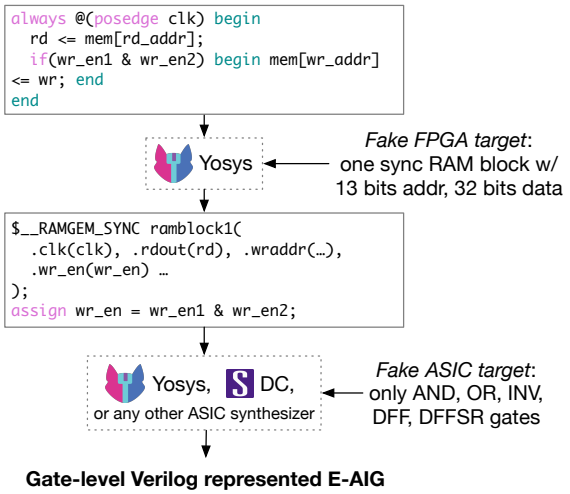

Fig. 4: We exploit existing FPGA and ASIC synthesis flows to efficiently transform RTL design into E-AIG.

C. Partitioning

Partitioning the hardware to multiple Boolean processor cores is a crucial step in our simulator because it ensures locality for data movement. As GPUs do not have efficient inter-block communication, we should ideally make partitions independent of each other and only communicate once per simulated cycle. The goal is made possible with a recent CPU-based parallel simulator RepCut [17], whose basic idea is to allow some duplicated logic in order to remove inter-partition dependency. To adapt the idea to a GPU simulator, we face two new challenges.

Firstly, the number of GPU thread blocks is much larger than the number of CPU cores. However, the replication cost (i.e., the relative size of duplicated logic over the original circuit size) grows quickly with the increased granularity of partitions. For example, RepCut [17] reports that only 1.30% cost is needed to partition a design into 8 threads, but the cost rises to 10.95% when 48 threads are used. In our experiments, we found this cost quickly surges to over 200% when we have to partition a design into 216 blocks, which is a minimal requirement to fully utilize a modern GPU.

To scale RepCut to over 200 partitions, our solution is to extend it to multiple stages as shown in Figure 5. We cut the circuit graph at one or more levels in the middle. We treat the nodes at the cut level as endpoints and run RepCut separately for each stage. We found that with the cost of 1 additional synchronization, we reduce the replication cost from 200% to less than 3% when partitioning a 500K gates design into 216 blocks. For even larger designs, more stages might be needed but it is easy to strike a balance between synchronization and replication costs with heuristics.

Secondly, the goal of partitioning to Boolean processors is different from the original RepCut, which aims at balancing the size of partitions. Instead, we require that all partitions are mappable to the boomerang-shaped executor layer. This effectively constrains the *width* (8192 bits, see Figure 3) instead of *total size* of partitions. It is difficult to modify a hypergraph partitioner's objective to logic widths as this metric does not have nice additive property. Instead, we make no change to the partitioner itself and keep the original size

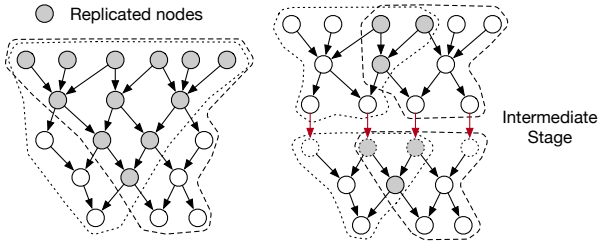

Fig. 5: By introducing one additional stage, the logic duplication of RepCut can be remarkably reduced, unlocking enough parallelism for GPU utilization.

objective. We run an additional postprocessing algorithm after the partitioner to align the objectives to our logic width need. We show our idea in Algorithm 1, which is based on empirically trying to merge the resulting partitions after a round of excessive partitioning. After running the algorithm, it is easy to guarantee that each partition has at least 50% effective bit utilization.

Algorithm 1: Partition merging

```
Partition the design excessively so that each partition is
  mappable;
for each partition p do
    Sort other unvisited partitions by overlap size with p;
    for partition q with large-to-small overlap do
        Try merging q with p, if the result is mappable,
          commit the merge;
```

D. Logic Placement

Given an E-AIG partition, our logic placement algorithm implements the logic onto a series of reconfigurable boomerang layers (Figure 3). Our objective is to map all AIG nodes while reducing the total number of boomerang layers required. In this section, we present an iterative timing-driven placement algorithm in GEM to map AIG to boomerang layers.

We show our basic idea of bit mapping in Figure 6 using a 4-level small boomerang layer as an example. We start with an empty boomerang layer as Figure 6 (1). Then, we choose a bit from E-AIG at logic level 4 and map it to the empty slot in boomerang executor at level 4. To do so, we recursively map the inputs of the being-mapped bit to upper levels of the executor. In the worst case, the fan-in cone of the being-mapped bit forms a perfectly balanced binary tree, thus occupying all bits of a boomerang layer. However, such worst case never happens in practice, as most bits in AIG have a pair of inputs that reside in different logic levels (i.e., imbalanced). As a result, there leaves a lot of free space after mapping one bit, and such vacant bits can be used to map other bits as shown in Figure 6 (2)–(4).

Based on the above bit mapping primitive, we use Algorithm 2 to map a whole AIG partition into a series of boomerang layers. We iteratively try to map the fan-in frontier of current AIG subgraph into a new empty layer. After the layer is full, we remove the nodes that are already realized by current layers, create a new AIG subgraph of remaining nodes, and repeat the process until all nodes are mapped. We define timing criticality of a node as its logic depth on the reversed AIG subgraph. To reduce the number of layers, we prioritize the mapping of nodes on timing-critical paths (Figure 6 (5)

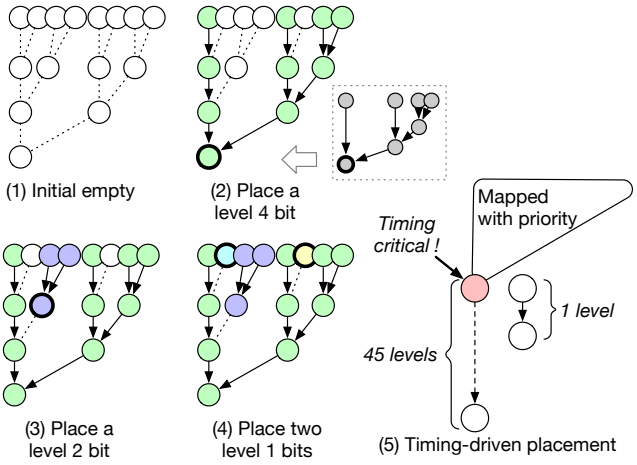

Fig. 6: Example of a placement iteration (1)–(4) and illustration of timing-driven bit placement (5).

and Algorithm 2 lines 7–8) according to the constantly updated timing criticality of nodes.

Algorithm 2: Iterative multi-boomerang-layers mapping

```
1  Input AIG;
2  Initialize node set frontier as input ports of the AIG;
3  while AIG not all mapped do
4      Make a new empty boomerang layer;
5      for Level i in boomerang layer from bottom to top do
6          while Level i is not full do
7              Update timing criticality (reverse logic depth) of
                the remaining AIG;
8              Choose the most timing-critical unmapped node
                in AIG with logic level i, and map it to the
                boomerang layer;
9      Add the boomerang layer to the list of layers;
10     Update frontier to the input ports of the current
        unrealized AIG subgraph;
```

E. Bitstream Generation and CUDA Interpretation

The synthesized and placed circuit from previous sections are then transformed into a binary format that will be loaded and interpreted by our GEM CUDA kernel. In one way, this process is analogous to the bitstream generation of FPGA designs as we are encoding and serializing the wiring (boomerang layer setups) of a reconfigurable hardware. In another way, this process might also be called a binary assembler of software programs, as the resulting bitstream will be interpreted on a GPU by a software-only approach like inside a virtual machine.

We design a domain-specific instruction set architecture (ISA) for GEM to assemble the Boolean processor programs. This is a VLIW ISA that has 3 instruction length variations: 8192, 16384, and 32768 bit. It is designed for a GPU thread block with fixed 256 threads to load and interpret with high throughput. A 8192-bit GEM ISA instruction is loaded by 256 threads in lockstep by performing one coalesced 32-bit global memory read. For 16384- or 32768-bit instructions, 256 threads similarly perform a coalesced 64- or 128-bit global memory read, respectively. All these memory loads are fully coalesced and natively supported in CUDA.

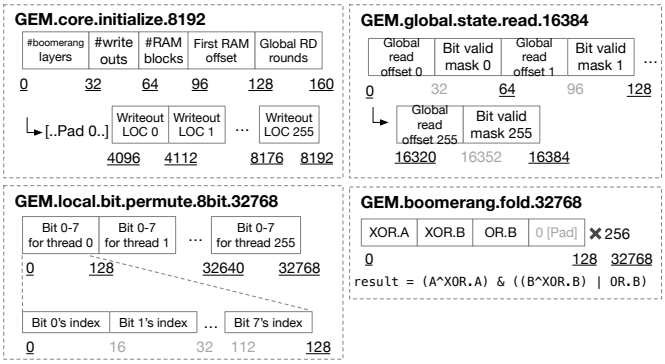

Fig. 7: Instruction bit layout: initialization, global state reading, local bit permutation, and boomerang folding.

TABLE I: Design statistics and GEM mapping results.

Design	#E-AIG Gates	#Levels	#Stages	#Layers	#Parts	Bitstream
NVDLA	668,746	62	1	9	52	11.2 MB
RocketChip	346,687	82	1	13	39	9.2 MB
Gemmini	1,831,381	148	1	19	143	44.4 MB
OpenPiton1	682,646	66	2	10	119	18.4 MB
OpenPiton8	5,479,795	66	2	13	947	162.4 MB

Due to page limit, we cannot include a complete ISA documentation. Figure 7 shows some examples of instruction bit layout. 8192-bit instruction is used to initialize a thread block with necessary information, including the number of boomerang layers, RAMs, and state size of a partition. This is followed by a few 16384-bit instructions to read the input ports of the E-AIG from global memory, only once per cycle. Then, bit permutations and boomerang folding constants are provided with interleaved 32768-bit instructions. The bit permutations are encoded as a compressed form of source bit locations indexed within 8192 thread-local bits in GPU shared memory. The boomerang folding provides 3 constants, `XOR.A`, `XOR.B`, `OR.B` for each thread, controlling the behavior of the word-parallel AND gates. The `OR.B` is used to bypass operand B to implement dashed lines in Figure 6 (4).

In the CUDA kernel implementation, we note two important optimizations. The first is the use of wide global read instructions and aligned structs that allow coalescing to work correctly. The second is the use of cooperative groups [19] to implement device-level synchronization in cycle and stage boundaries in order to bypass kernel launching overhead.

IV. Experimental Results

We implement GEM from scratch in Rust (for the mapping flow) and CUDA (for the VLIW interpreter kernel). We evaluate GEM's performance on a variety of open-source RTL benchmarks listed in Table I, including NVDLA [20] (a deep learning accelerator), RocketChip [21] (a RISC-V CPU), Gemmini [22] (another deep learning accelerator), and an internal multi-core CPU design derived from OpenPiton [23]. For Chisel designs like RocketChip and Gemmini, we generate RTL using Chipyard [24]. We use official benchmark workloads provided by these designs for evaluation.

Table I lists the size of the designs. To estimate the actual RTL circuit footprint, we show the number of logic gates and logic levels after our GEM synthesis (Section III-B). Table I also lists the statistics after finishing the GEM mapping flow, including the number of RepCut stages, boomerang layers, partitions, and the size of the bitstream. The number of boomerang layers is 6–8× smaller

TABLE II: Simulation speed (Hz) and speed-up (compared to GEM-A100) comparison between GEM, a commercial tool (Comm.), Verilator, and GL0AM. NVDLA only simulates correctly with an old 3.912 version of Verilator without multi-threading [20].

than the logic depth (e.g., reduced from 148 to 19 for Gemmini). We note that the GEM bitstream is a very concise format for circuit logic. It takes only 162.4 MB of GPU memory to store the whole assembled GEM bitstream (Section III-E) even for our largest design OpenPiton8 which has over 5 million logic gates and is over 800 MB in flattened gate-level Verilog. As a result, even lowest-end GPUs have enough GPU memory to simulate large designs with GEM.

We compare the performance of GEM against a set of strong baselines, including a leading commercial tool[2], Verilator latest 5.028 [14], and the current state-of-the-art GPU-accelerated gate-level logic simulator GL0AM [12]. All experiments are run on 48 cores of Intel Xeon Gold 6136 CPU. We run Verilator with up to 8 threads as we observe that 16-threaded Verilator is only 80%–95% the speed of 8 threads. This performance *degradation* highlights the inherent scalability bottleneck of CPU parallelism on highly-complex real designs as also identified by prior works. We run the commercial tool with default single core similar to the settings in [12], [11] as multi-threaded version is unstable and crashes during some simulations. We evaluate GEM on both one NVIDIA A100 and one NVIDIA RTX 3090. A100 demonstrates GEM's current peak performance and 3090 shows its performance with a more accessible GPU alternative.

Table II gives a comprehensive performance comparison. We are on average 9.15×, 5.98×, and 24.87× faster than the leading commercial tool, 8-threaded Verilator and 1-threaded Verilator respectively. The peak speed-ups happen on the deep-learning accelerator NVDLA where we are 64.76× and 38.85× faster than Verilator 1 thread and the commercial tool. GEM on 3090 has comparable performance with A100 except on the largest design, OpenPiton8, with the highest resource pressure on GPU.

The current version of GEM has **limitations** which we plan to address in the future. For example, we found that the speed-up ratio of OpenPiton8 is inferior to OpenPiton1. This is because the workload of OpenPiton8 does not keep all 8 cores busy. Reported by the commercial tool, we observe 8,612 signal events per cycle for 1 core but only 28,789 events (3.3×) for 8 cores. As an oblivious full-cycle simulator, GEM has a consistent simulation speed for any stimuli, whereas our baselines are event-based simulators that run faster if the design is not actively switching. In the future, we plan to explore event-based pruning in GEM. NVDLA shows the best speed-up GEM can achieve because all RAMs inside it are mapped to E-AIG RAM blocks, but the other 4 designs have RAMs with *asynchronous* read ports that can only be implemented inefficiently with FFs and decoder logic. As asynchronous RAMs are not available in ASIC or FPGA deployment, we regard NVDLA's performance as representative for real-world designs.

[2]We do not disclose the name of the commercial tool due to license agreements.

V. Conclusion

This paper presents GEM, a novel emulator-inspired methodology for GPU-accelerated RTL simulation. GEM bridges the fundamental discrepancy between GPU's SIMT data parallelism and the heterogeneous and irregular circuit logics, by designing a CUDA-interpretable virtual VLIW logic processor and a mapping flow analogous to the CAD flow of FPGAs, with novel algorithms addressing deep long-tailed logic, RAM mapping, width-constrained partitioning, timing-driven bit placement, etc. GEM achieves superior performance compared to cutting-edge commercial and open-source simulators.

The framework of GEM is extensible and many improvements are possible as future works, including native arithmetic operations, multi-GPU support, CUDA software pipelining, 4-state simulation, etc. We will open-source GEM for democratizing high-performance RTL verification as well as fostering further research.

jhahn97@snucad.snu.ac.kr, tkim@snucad.snu.ac.kr

***Abstract*—With the continued scaling of VLSI technology beyond 3nm, a consistent demand for layout reduction in standard cells has been made. CFET (Complementary-FET) has been accepted as a promising device technology, stacking N-FET on P-FET (or vice versa) to achieve this goal while providing metal interconnects on both the front and backside of the wafer through BEOL (back-end-of-line) processing. However, the layout synthesis of CFET based standard cells and its use in physical design implementation are not fully compatible with the effective exploitation of backside interconnects. This is because of a considerable overhead on the allocation of special vias in FEOL (front-end-of-line) referred to as *tap-cells*, which are essential for the net routes using backside wire. To overcome this drawback of using CFET cells, a new technology called FFET (Flip-FET) has been proposed, which *flips* the lower FET in CFET to enable direct pin accessibility on both sides of BEOL with no tap cells. In this context, *we propose an FFET cell based DTCO methodology to fully utilize backside wires with minimal tap-cells*. Precisely, we propose a three-step approach: (1) *synthesizing multiple FFET standard cells with diverse styles of pin distribution* for each of primitive logic gates, (2) *performing a tap-cell avoiding cell replacement* during placement optimization by using the cells obtained from Step 1 to prevent tap-cell allocation for net routing, and (3) *rebalancing the wire usage between the frontside and backside* to mitigate net congestion. Experiments with benchmark circuits show that our FFET cell based DTCO methodology scales up chip size beyond CFET designs with much fewer routing failures.**

Keywords: CFET, FFET, standard cells, DTCO, physical design

I. Introduction

With aggressive advancement in technology nodes which drives FinFET to reach its structural limits in scaling, interest has shifted toward vertically stacked 3D architectures for further scaling. One noticeable technology innovation is Complementary FET (CFET) [1], which physically stacks N-FET on top of P-FET or vice versa (e.g., Fig. 1(b)), for which installing backside power delivery network (BSPDN) with buried power rails (BPR) [2] is essential to secure a few more metal tracks available at the frontside for net routing.

Despite the use of BSPDN, chip routing for designs with CFET based standard cells still suffers a considerable shortage of metal resources. To tackle this issue, a recent work [3] and TSMC patent [4] suggested using backside wires not only for BSPDN but also for signal net routing.

However, for chip-level double-sided routing, whenever a net uses a backside wire to make a route, it is unavoidable to allocate a special via called *tap-cell* to connect the net pins to the backside wire since all cell pins are exclusively located on a metal layer at the frontside, Thus, if a balanced use of double-sided metals were made for the routes of n nets, it is required to allocate roughly $n/2$ tap-cells, which is an enormous overhead on chip PPA. (Note that the works in [5], [6] proposed a netlist planning that distributes nets across both sides to mitigate the occurrences of routing failure. On the other hand, the work in [7] utilized backside wires for ECO routing. However, all the works in [5]–[7] inevitably suffered from the tap-cell overhead.)

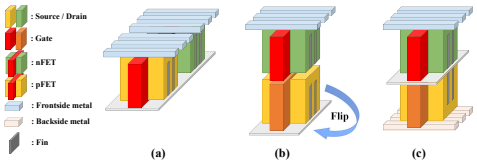

Fig. 1. Structures of FinFET, CFET, and FFET. (a) FinFET: routing tracks only at the frontside. (b) CFET: much smaller footprint than (a), but routing tracks only at the frontside. (c) FFET: a little smaller footprint than (b) and routing tracks at both the front and back sides.

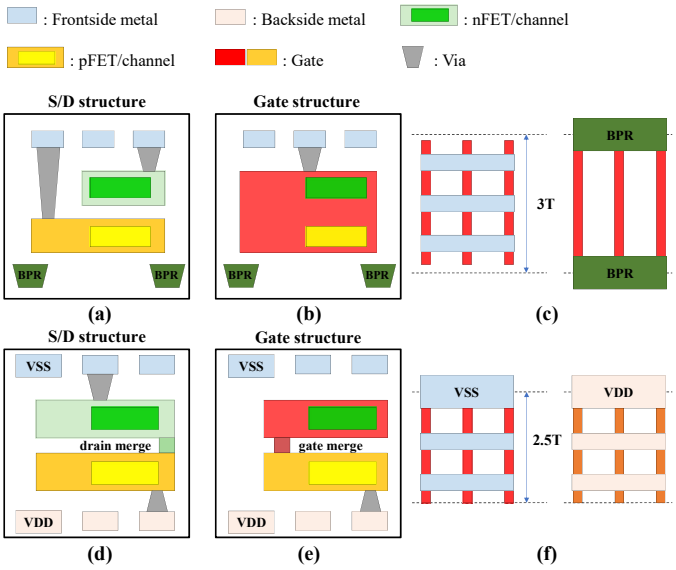

Fig. 2. Cross sectional view of 3T-height CFET ((a), (b), (c)) and 2.5T-height FFET ((d), (e), (f)).

Recently, a new 3D transistor technology called Flip-FET (FFET) [8] has been proposed, which *flips* the lower FET in CFET such that the locations of cell I/O pins can provide direct pin accessibility through either frontside or backside BEOL with no tap cells. Fig. 1(c) shows an illustrative FFET structure, in which two layers of FETs are formed and stacked

back-to-back, offering a manufacturing-compatible process flow with a lower aspect ratio in comparison to that of CFET structure in Fig. 1(b). Fig. 2 shows the structural differences between FFET and CFET with three horizontal metal tracks, in which each of the front and back sides in FFET runs a single power rail and 2 RTs (routing tracks), resulting in a total of 4 RTs and 2.5T cell height[1] while CFET runs 3 RTs only at the frontside, resulting in 3T cell height.

Note that regarding the automatic generation of standard cell layouts, many algorithms and frameworks have been proposed in the literature. Some of the representative works on FinFET based cell synthesis are found in [9]–[12], and the DTCO (design technology co-optimization) process using a cell generator as a core engine is well described in [13]. In addition, CFET based cell synthesis methods with SMT (satisfiability modulo theory) formulation and with an exploration of dynamic transistor foldings are proposed in [14], [15], and [16], respectively. However, none of the prior works have taken into account the exploitation of backside wires to improve pin accessibility, thus taking no consideration of tap-cell overhead at all.

In this work, we propose an FFET cell based DTCO methodology to fully make use of backside wires with minimal use of tap-cells. The contributions of our work can be summarized as:

1. We propose *an effective method of synthesizing FFET based standard cells*, the problem of which has never been addressed as yet, though a couple of automatic synthesis methods of CFET based standard cells have been proposed in the literature. Our cell generator exactly considers two differences in in-cell routing: (1) The flexible (front/back) side selection for individual I/O pin locations, and (2) The availability of additional metals i.e., the metals on BM1 (backside metal 1) layer.
2. We propose *a DTCO driven tap-cell avoiding cell replacement algorithm* that utilizes multiple cells with diverse styles of I/O pin distributions to eliminate the need for tap-cells during the placement optimization stage.
3. We propose *a net redistribution method*, which determines metal sides for all nets whose routes can be made by using either the frontside metals exclusively or the backside metals exclusively, thus unnecessary to allocate tap-cells so that the net connection on both sides should be mitigated in an unbiased manner.
4. Through experiments with benchmark circuits, it is shown that our proposed FFET cell based DTCO methodology is very promising, scaling up the chip size further over that of the CFET cell based design implementations while incurring much fewer routing failures.

II. Preliminary, Motivation, and Net Classification

CFET cell vs. FFET cell: We itemize the architectural differences between CFET [1] based and FFET [8] based cells in the following.

1. *Cell height*: For the same number of frontside metal tracks available for routing (e.g., 3 RTs (routing tracks) in Fig. 2), FFET allocates one track on each side for the power rails, allowing neighboring cells to share the power rails effectively. In contrast, CFET utilizes two backside tracks designated for BPR. Therefore, as illustrated in Fig. 2, CFET employs only three frontside RTs for BEOL processes, while FFET utilizes two RTs on each side (total of 4 RTs). As a result, FFET architecture has 0.5T smaller cell height while using the same amount of routing tracks in comparison with that of CFET architecture.
2. *Cell via*: CFET requires long (deep) vias to connect frontside metals to the FET in the lower layer, as illustrated in Fig. 2(a), introducing complex spacing rules. On the other hand, since FFET is formed by merely flipping the lower FET in CFET, the frontside FET is allowed to connect directly to the frontside metals and the backside FET to connect directly to backside metals.[2] This enables FFET to position I/O pins on either side. This flexible I/O pin positioning is particularly useful for making double-sided routing without tap-cells.
3. *Gate merge*: The implementation of split-gate structures allows for a reduction in the cell width, as shown in Figs. 3(b) and (c). FFET can make split-gate structures easily by *gate merge* with no area and wire overhead, as illustrated in Fig. 2(e). While split-gate CFET can also accommodate different signals on each gate, it requires inevitable area overhead. (Note that the split-gate of the lower FET in CFET is only accessible through frontside metals, resulting in additional spacing whereas that of FFET is accessible through backside metals.)

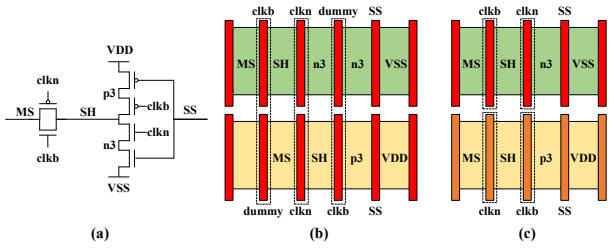

Fig. 3. Difference in gate split for CFET and FFET. (a) Netlist example: C^2MOS in DFFHQNx1. (b) Layout w/o split-gate on CFET: requiring dummy gate polys. (c) Layout with split-gate on FFET.

4. *Drain merge*: Both CFET and FFET can make *drain merge* with no overhead, as shown in Fig. 2. However, due to the fact that the output signal of the cell is always derived from a merged (common) drain, the signal can be delivered directly through metals on both sides for FFET, and it becomes possible to locate the output pin pattern on both sides to boost the pin accessibility as well as to minimize the number of tap-cell allocations.

[1]In FFET, one of the three horizontal metals is used as a power rail, which will be shared by neighboring cells.

[2]In this work, we assume the NFET on the frontside and the PFET on the backside, though they could be placed on either side.

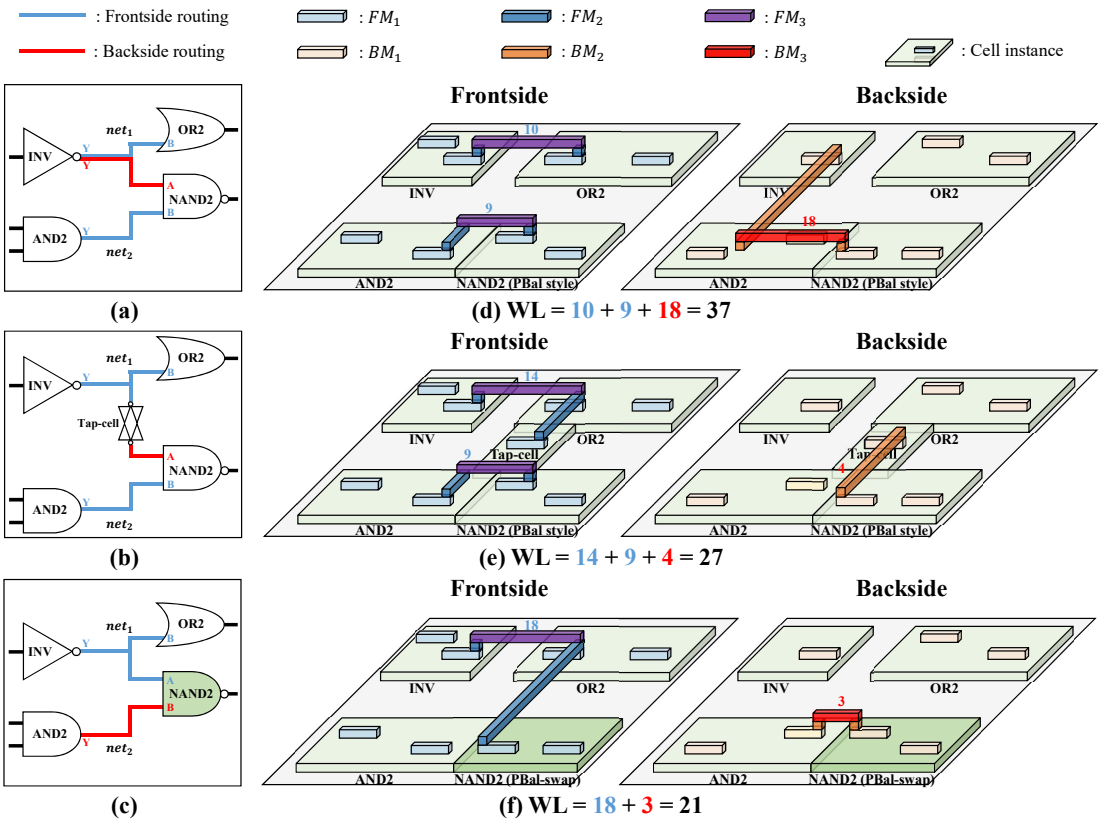

Fig. 4. Impact of BEOL side assignment for FFET cells' (input) pins on the number of tap-cells and WL (wirelength). Using NAND2 cell instances (a) with A on backside and B on frontside, (b) with A on backside and B on frontside connecting to a tap-cell (c) with A on frontside and B on backside. Feasible placement/routing results (d) WL = 37, #tap-cells = 0 for (a), (e) WL = 27, #tap-cells = 1 for (b), (f) WL = 21, #tap-cells = 0 for (c).

Motivation (tap-cells and WL): We describe, using an example, how the BEOL side (i.e., front/back sides) assignment of FFET cells' I/O pins affects the number of tap-cells and WL (wirelength) to be used. Figs. 4(a, d) and (b, e) show two different BEOL side assignments of input pins A and B on the NAND2 FFET cell in a part of the logic netlist where the OR2 cell commonly locates pin B on the frontside. Then, since output pins can be allocated to both sides, as observed in *item 4* of CFET vs. FFET in this section, the pin distribution of the NAND2 cell in Fig. 4(a, d) causes double-sided routing for net_1, which otherwise, requires one tap-cell as shown in Fig. 4(b, d). On the other hand, the pin distribution of the NAND2 cell in Fig. 4(c, f) makes only frontside routing for net_1 with no tap-cell. Thus, the clever selection (i.e., side assignment for pins) of the NAND2 cell instance can reduce the resulting WL (from 37 to 21 in Figs. 4(a, d) and (c, f) and the number of tap-cells.

Net classification: As observed in Fig. 4, all the nets to route can be classified into three types:

- *Frontside-only net (FS-net)*: A net whose all driven pins are accessed through the metals on the frontside (e.g., net_2 in Fig. 4(a) and net_1 Fig. 4(c)).
- *Backside-only nets (BS-net)*: A net whose all driven pins are accessed through the metals on the backside (e.g., net_2 in Fig. 4(c)).
- *Dual-side nets (DS-net)*: A net that belongs to neither *FS-net* nor *BS-net* (e.g., net_1 in Fig. 4(a)).

Note that unlike the double-sided routing for designs with non-FFET cells (e.g., [4]–[7]), which assumes low resistance on backside wires to account for routing timing-critical nets only with backside wires, but no consideration of tap-cell delay, we assume exactly identical metal configurations on both sides. This symmetry offers a significant technological advantage, as it enables the reuse of the same process for both N-FET and P-FET, as described in [8].

III. The Proposed DTCO Method

A. Overall DTCO Flow

Fig. 5 shows the overall flow of our DTCO framework, which is composed of three steps: (**Step 1**) we *build up an FFET based standard cell synthesizer*, which *systematically generates multiple FFET cells of diverse styles of pin distribution* for each primitive logic gate by considering the FFET's distinct feature that individual I/O pins on an FFET cell can be distributed on either side; (**Step 2**) at the placement optimization, we perform *a tap-cell avoiding cell replacement* by using the cells of diverse pin distributions prepared in Step 1 while minimizing metal resources and eliminating the need for allocating tap-cells simultaneously; (**Step 3**) following the cell replacement at the placement optimization, we perform *a congestion-aware net rebalancing*, so that the net congestion on both sides should be equally mitigated. After completing all steps, *FS-nets* as well as frontside segments of *DS-nets*

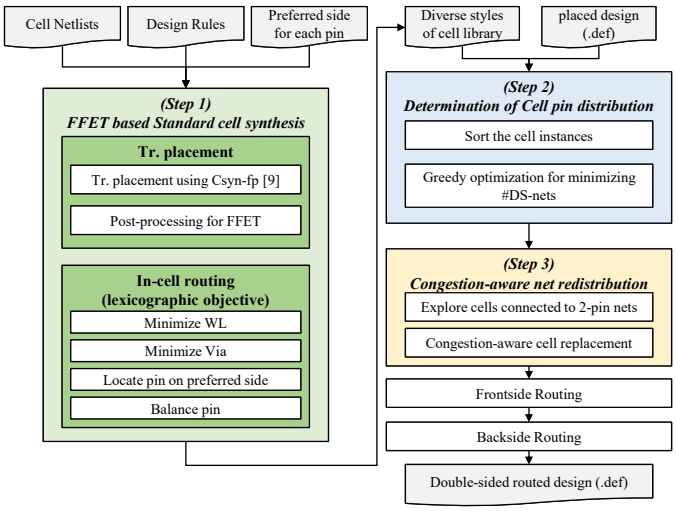

Fig. 5. Overall flow of our DTCO framework.

are routed at the frontside while *BS-nets* as well as backside segments of *DS-nets* are routed at the backside.

B. Synthesis of FFET based Standard Cells

1) ***Transistor placement****:* Given the cell's netlist information and design rules (e.g., OD jog rule) as inputs, as our initial transistor placements, we use the transistor placements produced by Csyn-fp [9] installed OpenROAD framework [17], which ensures cell area optimality. Then, we update the transistor placements by considering the following two factors: (1) locating cell output pins on both sides to support double-sided routing and (2) preferring *gate merge* to allow vertically merging dummy and non-dummy poly gates to increase the number of gate contact points.

2) ***In-cell routing****:* Our in-cell router generates a legal cell layout by incorporating design rules and the preferred BEOL side of individual input pins. As the conventional SMT formulation of in-cell routing, our SMT formulation includes, as constraints, representative design rules including minimum area rule (MAR), end-of-line (EOL) spacing, via enclosure (VE), and multiple patterning design rules such as parallel run length (PRL) and step height rule (SHR). In addition, our formulation uses the metals on *both backside and frontside metal layers*.

Our in-cell router is designed to optimize multi-objectives in a lexicographical order. The primary objective is to minimize metal length, followed by reducing the number of vias. The third objective prioritizes the input pin's preferred side, maximizing metal usage on that side. (If nothing is given as input, this objective is ignored.) The last objective is to balance the number of pins placed on both sides as double-sided routing could be the most effective when nets are distributed equally on both sides.

3) ***Generate multiple FFET cells of diverse styles****:* For each logic gate type, our cell synthesizer produces four styles of cell layout as follows.

- **Pin balanced (PBal)**: The cell layout with balanced pin distribution on both sides (e.g., Fig. 6(a)).
- **Pin balanced-swapped (PBal-swap)**: The cell layout with pin distribution sides on **PBal** swapped (e.g., Fig. 6(b)).
- **Pin-frontside (PFront)**: The cell layout with all pins preferred on frontside (e.g., Fig. 6(c)).
- **Pin-backside (PBack)**: The cell layout with all pins preferred on backside (e.g., Fig. 6(d)).

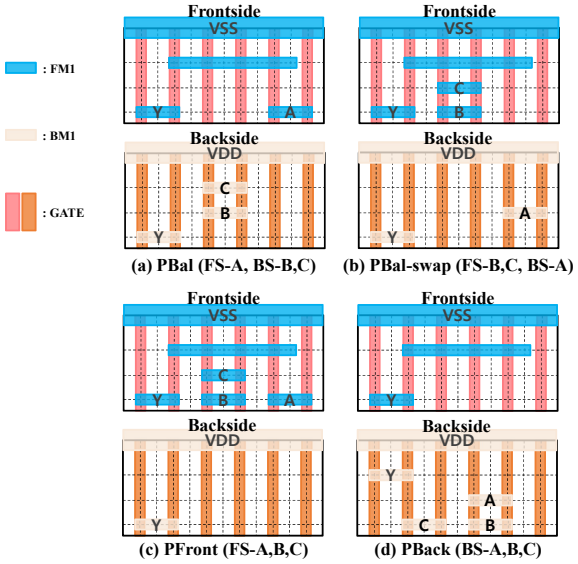

Fig. 6. Four styles of cell layout of OR3x1 generated by our cell synthesizer.

C. Determination of Cell Pin Distribution for WL Minimization

At the post-place, we determine, for each cell instance, the cell layout styles among **PBal**, **PBal-swap**, **PFront**, and **PBack** in a way to produce *DS-nets* (dual-side nets) as minimal as possible since routing *DS-nets* should use wires on *both* sides, incurring a longer total length of wires than that of *FS-nets* (frontside-only nets) and *BS-nets* (backside-only nets). To this end, we employ a greedy approach:

1. Sort the cell instances in placement in a non-increasing order according to the number of input pins. We break ties by the total amount of HPWL of the nets connecting the pins, placing priority on the cell instance with higher HPWL value.
2. For each cell instance c_i in the sorted list with input pins $p_1, \cdots$, we compute cost $\#DS(c_i, c_i')$ for each cell style $c_i' \in$ {**PBal**, **PBal-swap**, **PFront**, **PBack**}:

$$\#DS(c_i, c_i') = \sum_{j=1,\cdots} \rho(c_i, c_i', p_j), \tag{1}$$

where $\rho(c_i, c_i', p_j) = 1$ if replacing c_i with c_i' enables the net connecting p_j to become *DS-net*, and 0, otherwise. Then, we select the cell style which has the smallest $\#DS(c_i, c_i')$ value and perform cell replacement. For the same $\#DS(c_i, c_i')$ value, we choose the cell style with the smallest HPWL value.

TABLE I

COMPARISON OF CELL METRICS BETWEEN CFET BASED 4T STANDARD CELLS PRODUCED BY CFET CELL SYNTHESIZER [16] AND OUR FFET BASED 3.5T STANDARD CELLS. #CPP, WL, M1, M2, M3 INDICATE THE NUMBER OF CONTACTED POLY PITCHES (I.E., CELL WIDTH), TOTAL WIRELEGNTH, THE METAL USAGE ON M1, M2, M3, RESPECTIVELY.

WL: The total wirelength is a weighted sum of the wire length and the number of Vias used, following the same weighting factors in [15], [16].
M1: The M1 metal usage on FFET based cells includes the metal utilization on *both* of FM1 and BM1 layers.

D. Congestion-aware Net Redistribution

This step redistributes nets across the BEOL sides without increasing the number of *DS-nets* which have already been minimized in Step 2. We only consider cells with all input pins connected to 2-pin nets for redistribution since their impact on *DS-nets* is the least. Specifically, on a net-congested local region[3], we extract these cells and attempt to change their styles to **PFront** or **PBack** until both sides are equally congestion-balanced. For example, in a local region in Fig. 7(a) where high congestion occurs at the backside, replacing the **PBal** cell in the middle in Fig. 7(a) with **PFront** reduces BS-nets count, resulting in a reduction of congestion on the backside.

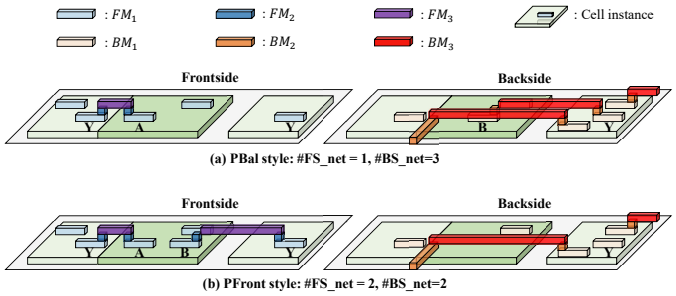

Fig. 7. Example of redistributing nets for mitigating net congestion on both sides.

IV. EXPERIMENTAL RESULTS

A. Experimental Setup

Our FFET based standard cells were implemented in C++ on a Linux system equipped with 128 GB of memory and an AMD EPYC 7452 CPU operating at 2.35 GHz. The input netlists and relevant design rules for synthesizing FFET cells were taken from ASAP 7nm process design kit (PDK) in [18], and our SMT formulation for in-cell routing was solved using Z3 solver package in [19]. We performed logic synthesis using Synopsys Design Compiler [20], and performed block-level placement and routing Cadence Innovus [21].

[3]We used *net density* as our pre-route congestion metric.

B. Cell Quality Comparison

Table I shows a comparison of the cell metrics between CFET based 4T (4 tracks for routing) standard cells produced by CFET-fp [16] which is available in [22] and follows the same design rules in ASAP 7nm PDK, and FFET based 3.5T cells produced by our proposed cell synthesizer.[4] In terms of cell area, our FFET cells are 20% smaller on average than that of CFET cells, which is mainly caused by the shorter height of FFET cells (i.e., 3.5T) than CFET cells (i.e., 4T). In addition, FFET cells use 13% less total wirelength than that of CFET cells. In particular, the comparison shows that the in-cell routing for FFET cells is fully completed with the use of FM1 and BM1 only while CFET cells use all metals in M1, M2, and M3. This clearly implies that FFET cells provide a considerable advantage of pin accessibility. (In fact, our cell synthesizer has successfully generated FFET layout cells for 174 netlists in ASAP 7nm PDK, using the metals on the FM1 and BM1 layers only.)

On the other hand, Table II shows a comparison of the cell metrics between CFET based 3T (3 tracks for routing) standard cells produced by CFET-fp [16] following the same design rules in ASAP 7nm PDK, and FFET based 2.5T cells produced by our proposed cell synthesizer.[5] The comparison shows that FFET cells have a 25% smaller area on average than that of CFET cells while using 31% less total wirelength.

C. Chip Quality Comparison

Table III shows a quality comparison between the chip implementations produced by (*Flow 1*) the conventional non-DTCO physical design flow using the CFET based cells in Table I, (*Flow 2*) the conventional non-DTCO flow using our FFET based cells in Table I, and (*Flow 3*) our proposed DTCO flow using our FFET based cells in Table I for the OpenCore benchmark designs in [23].

[4]For design rules, we set to MAR/EOL/VR/PRL/SHR/MPL = 1/2/1/1/2/1 on 4T CFET cells as well as 3.5T FFET cells.

[5]For design rules, we set MAR/EOL/VR/PRL/SHR/MPL = 1/1/0/1/0/1 on 3T CFET cells as well as 2.5T FFET cells.

Avg.				2233	28401.06	236897.39	6.25	22578.95	255844.71	3.75	22578.95	234841.41
Norm.				595.47	1.26	1.01	**1.67**	**1.00**	1.09	**1.00**	**1.00**	**1.00**

In summary, *Flow 2* is able to reduce the chip size by 26% over that of *Flow 1* while significantly reducing the DRV count (i.e., 356x). (Note that such a large number of DRVs in *Flow 1*, particularly for AES_CIPHER, is due to the fact that M2 and M3 metal resources have been used up for CFET in-cell routing, as statistically shown in Tables I and II, thereby become very limited M2 and M3 metals available for chip-level routing.

On the other hand, *Flow 3* outperforms *Flow 2* and *Flow 1*. *Flow 3* uses 9% less total wirelength and produces 67% fewer DRVs over that of *Flow 2*. This means that our DTCO flow is very effective in improving chip quality. To validate the effectiveness, we repeatedly applied *Flow 2* and *Flow 3* to design FPU by varying the value of the chip utilization parameter, and compared the implementation results, as shown in Fig. 8. The comparison shows that *Flow 3* consistently reduces the number of DS-nets (dual-sided nets) (by 63% on average), the DRV count (by 51% on average), and total wirelength (by 10% on average) over that of *Flow 2*. Note that our DTCO in *Flow 3* never increases the number of tap-cells over that of *Flow 2* during the (wire-hungry) DS-net minimization in Steps 2 and 3 while *Flow 2* allocates 2, 12, 113, and 0 tap-cells for the implementations of AES_CIPHER, USB_PHY, DES3, and FPU, respectively.

V. CONCLUSION

This work addressed two tasks: (1) FFET (Flip-FET) based standard cell synthesis and (2) DTCO methodology utilizing FFET based cells. A strong and distinct advantage of FFET cells, as opposed to CFET cells, was the convenience of using backside metals as in-cell routes (i.e., no tap-cell overhead) as well as using them as chip routes (i.e., well controllable for tap-cells), the objective of this work was to develop

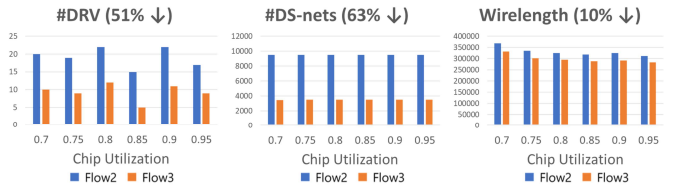

Fig. 8. Design quality comparison of the implementations produced by *Flow 2* (non-DTCO + FFET cells) and *Flow 3* (DTCO + FFET cells) for design FPU by varying the chip utilization value.

an effective solution to the problem of how the backside metals could be fully utilized as interconnects with minimal tap-cell overhead. To this end, we proposed a three-step solution: (1) synthesizing multiple FFET based cells with diverse styles of pin distribution on front/backside BEOLs for each primitive logic gate; (2) performing a tap-cell avoidance cell replacement during placement optimization by exploiting the cells obtained in Step 1; (3) rebalancing the wire usage between the frontside and backside to mitigate net congestion. Experimental results with benchmark circuits showed that our FFET cell-based DTCO flow was able to significantly improve chip quality in terms of chip area, wirelength, and routing failures over that of the CFET/FFET cell-based conventional non-DTCO flows.

***Abstract*—Deep Neural Networks (DNNs) have achieved remarkable success across various intelligent tasks but encounter performance and energy challenges in inference execution due to data movement bottlenecks. We introduce *DataMaestro*, a versatile and efficient data streaming unit that brings the decoupled access/execute architecture to DNN dataflow accelerators to address this issue. *DataMaestro* supports flexible and programmable access patterns to accommodate diverse workload types and dataflows, incorporates fine-grained prefetch and addressing mode switching to mitigate bank conflicts, and enables customizable on-the-fly data manipulation to reduce memory footprints and access counts. We integrate five *DataMaestro*s with a Tensor Core-like GeMM accelerator and a Quantization accelerator into a RISC-V host system for evaluation. The FPGA prototype and VLSI synthesis results demonstrate that *DataMaestro* helps the GeMM core achieve nearly 100% utilization, which is 1.05-21.39× better than state-of-the-art solutions, while minimizing area and energy consumption to merely 6.43% and 15.06% of the total system.**

I. Introduction

Deep Neural Networks (DNNs) have significantly gained popularity for tackling complex intelligence tasks and potentially advancing humanity toward the Artificial General Intelligence (AGI) era. To meet the stringent performance and energy consumption requirements of DNN deployment, numerous contemporary domain-specific dataflow accelerators have been developed [2], [7]–[11], incorporating extensive optimizations in the processing element (PE) array design and dataflow strategies. However, as DNN workloads and PE arrays continue to scale, data communication between the accelerator datapath and the memory hierarchy emerges as a critical bottleneck in DNN dataflow accelerators [4], [12]–[16].

Despite various solutions having been proposed to address this bottleneck, three shortcomings hinder their widespread deployment toward efficient DNN dataflow accelerators: **1). Non-Reusable Design.** Data movement units are typically implemented as dedicated hardware blocks, tightly coupled to a specific accelerator, featuring fixed access patterns and bandwidths tuned to specific workloads [2]–[4], [6], [7]. Given the diverse sizes, topologies, and rapid evolution of DNN workloads, these dedicated data movement units lack the versatility to adapt to different dataflows' requirements, leading to suboptimal overall system performance and energy efficiency. For instance, BitWave [2] achieves very high PE array utilization for convolution operations in convolutional neural networks (CNNs) by leveraging specialized optimizations but falls short in general matrix-matrix multiplication (GeMM), which is pervasive in Transformer models. Moreover, the inability to reuse these dedicated data movement blocks across different accelerators results in redundant engineering efforts and hinders competitive time-to-market, especially considering the rapid evolution of DNNs and next-generation computing platforms. **2). Performance Decrease Caused by Bank Conflicts.** The on-chip memory bank conflict challenge is a primary obstacle to achieving peak system performance. For instance, Gemmini [1] exhibits a PE array utilization as low as 10% due to the lack of bank conflict management in the access of the different operands. To address this problem, many accelerators [2], [8], [17], [18] leverage private on-chip memory for each operand, such as dedicated input, weight, and output buffers. However, bank conflicts still arise when data needed in a single cycle is stored in different wordlines within the same bank, a scenario commonly encountered in strided convolution operations. Moreover, it imposes additional limitations on the tiling of the workload to meet the requirement of the smallest memory and introduces extra complexity to manage multiple address spaces [15]. **3). Expensive Data Manipulation.** Many accelerators require preprocessing of operand before computation, including permutation, data alignment, and *im2col*. A common approach is to design standalone data manipulation units to perform these data rearrangement operations [1], [9], [11]. These units require additional memory accesses and intermediate data storage, which again increases the likelihood of memory conflicts and elevates memory energy consumption. In conclusion, there is an absence of a versatile and efficient data movement solution to address the diverse dataflow and data manipulation requirements of different accelerators while also ensuring high system performance.

The decoupled access/execute (DAE) architecture [19] separates data access and computation processes into two independent streams to prevent mutual stalls. This approach has been applied in numerous works [5], [20], [21], demonstrating performance speed-ups of 2-5× for linear algebra workloads [5], [20]. The DAE architecture is well-suited for DNN workloads, as its regular multidimensional access patterns [22] enable data to be fetched ahead of computation. This facilitates continuous data stream consumption and production from the perspective of PE arrays, helping the accelerator system reach its theoretical peak performance. Previous works [6], [7] have successfully applied the DAE architecture in accelerator designs. However, they fail to meet the diverse dataflow, data access patterns, and high bandwidth requirements of DNN workloads and the aforementioned challenges, rendering them suboptimal for DNN dataflow accelerators.

In this paper, we present a versatile and efficient data streaming engine, called *DataMaestro*[1], which brings decoupled memory access to DNN dataflow accelerators. *DataMaestro* is highly optimized and can be reused across different dataflow accelerators with flexible and programmable access patterns while achieving nearly 100% PE array utilization. A comprehensive comparison between *DataMaestro* and state-of-the-art (SotA) solutions is listed in Table I. In summary, our main contributions lie in:

- We present *DataMaestro*, a generalized, versatile, and efficient data streaming engine for diverse DNN dataflow accelerators, with design-time and runtime configurability, enabling decoupled memory access for arbitrary dataflows (§ III-A and § III-B).
- We introduce fine-grained prefetch and runtime-configurable addressing mode switching features inside *DataMaestro*, which minimizes bank conflicts and fully exploits the available on-chip memory bandwidth (§ III-C and § III-D).
- We provide on-the-fly data manipulation capability inside the *DataMaestro* by customizable datapath extensions to effectively reduce memory footprints and access counts (§ III-E).

*Equal contribution.

[1]*DataMaestro* and the *DataMaestro*-boosted accelerator system are open-sourced at: https://github.com/KULeuven-MICAS/snax_cluster.

TABLE I: Comparison of the SotA data movement solutions with *DataMaestro*.

	Gemmini [1]	BitWave [2]	[3]	FEATHER [4]	SSR [5]	Buffet [6]	Softbrain [7]	*DataMaestro*
Open source	✓	✗	✗	✓	✓	✓	✗	✓
Reusable design	✗	✗	✗	✗	✗	✓	✗	✓
Decoupled access/execute	✗	✗	✗	✗	✓	✓	✓	✓
Programmable affine access	✓(2-*D*)	✗	✓(2-*D*)	✗	✓(4-*D*)	✓(2-*D*)	✓(2-*D*)	✓(*N*-*D*)
Fine-grained prefetch	✗	✗	✗	✗	✗	✗	✗	✓
Runtime addressing mode switching	✗	✗	✗	✗	✗	✗	✗	✓
On-the-fly data manipulation	✗	✗	✗	✓	✗	✗	✗	✓

- We demonstrate the versatility and efficiency of *DataMaestro* by integrating it with a Tensor core [23]-like GeMM accelerator and a Quantization accelerator into a RISC-V host system. The FPGA prototype and VLSI synthesis results show that *DataMaestro* enhances the GeMM PE array utilization to 95.45%-99.98% under real-world DNN workloads, boosting normalized throughput to 1.05-21.39× over SotA, while only consuming 6.43% and 15.06% of system area and energy (§ IV).

II. Background

A. Dataflow and Data Layout

Typical DNN kernels, such as GeMM, multi-head attention, convolution, and pooling, can be represented as nested loops that iterate over the input, weight, and output tensor dimensions. Dataflow optimizations, like splitting and reordering these loops, open up a vast mapping space for efficient hardware processing [14], [15]. Specifically, these optimizations include spatial unrolling (SU) for parallel execution and temporal unrolling (TU) to control data tiling and the order of loop iterations.

The data access pattern, which specifies the data required by the accelerator in each clock cycle, is inherently determined by the dataflow. However, the data layout, referring to the organization of tensor data in memory, also influences data access patterns. A proper data layout is crucial for optimizing DNN performance, as it directly impacts memory access efficiency and can lead to PE array underutilization if mismatched with the dataflow [4], [24].

B. Decoupled Access/Execute Architecture for Dataflow Accelerators

A decoupled access/execute (DAE) architecture [6], [7], [19] explicitly decouples memory access and computation by introducing data streaming engines between them, as illustrated in Figure 1. This architecture integrates three key components — memory subsystem, data streaming engine, and accelerator datapath—which collaborate coherently to produce/consume three types of streams: access streams, data streams, and execute streams. The memory subsystem serves as a data reservoir, responding to the memory requests via the access stream. The accelerator's datapath applies computation to the data streams and produces results via the execute stream. The data streaming engine bridges the memory subsystem with the accelerator datapath, orchestrating data flow between them. It transforms scattered data in memory which is arranged in a specific format (data layout), into a continuous data stream, which is organized in the format required by the accelerator (data flow) and vice versa, by interacting with the memory through the access stream.

Typically, the streaming engine consists of three main components: an Address Generation Unit (AGU), a memory interface controller, and a data FIFO. The AGU generates address sequences, which are then consumed by the memory interface controller to perform memory operations. The data FIFO temporarily stores data streams, decoupling memory access from computation. This decoupling enables data prefetch operations and thus minimizes computation interruptions caused by memory stalls. Such an approach is particularly beneficial for DNN workloads due to their regular and deterministic data access patterns. By incorporating this architecture, a harmonious access-data-execute stream orchestration is established within the accelerator system. In the next section, we present *DataMaestro*, a highly optimized data streaming engine designed for DNN accelerators, which efficiently streamlines the data streams to enhance the performance of dataflow accelerators.

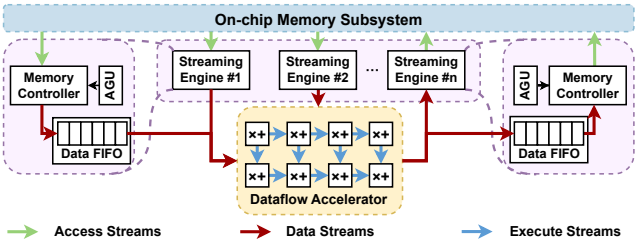

Fig. 1: Overview of decoupled access/execute architecture.

III. *DataMaestro* Architecture

In this section, we will first provide an overview of the *DataMaestro* architecture in § III-A, along with all of its configurable parameters, which are listed in Table II. Next, we introduce the three novel architectural features that maximize *DataMaestro*'s efficiency and minimize memory bank conflicts across a wide range of workloads: 1) highly configurable and area-efficient N-Dimensional (*N*-*D*) address generation unit (§ III-B); 2) fine-grained prefetch (§ III-C); and 3) runtime-configurable addressing mode switching (§ III-D). Finally, we discuss the datapath extension interface of *DataMaestro*, which enables customized on-the-fly data manipulation (§ III-E). These unique features of *DataMaestro* are key to its high efficiency and enhancement of the performance of DNN dataflow accelerators.

TABLE II: Design-time parameters and runtime configurations in *DataMaestro*.

Scope	Parameter	Description	Type †
Design Time	N_R	Num. of read *DataMaestro*	Int
	N_W	Num. of write *DataMaestro*	Int
	$Mode_{R/W}$	Read or Write mode	Bool.
	B_s	Spatial Bounds	[Int]
	D_s	Num. of Spatial Dimensions	Int
	D_t	Num. of Temporal Dimensions	Int
	N_C	Num. of Channels	Int
	D_{ABf}	Address Buffer Depth	Int
	D_{DBf}	Data Buffer Depth	Int
	DP_{ext}	Datapath Extensions	[Ext.]
	W_B	Bank Width	Int
	N_{BF}	Num. of Bank in Full Memory	Int
	N_{BG}	Num. of Bank in One Group	[Int]
Run Time	$Addr_B$	Base Address	UInt
	S_s	Spatial Strides	[UInt]
	B_t	Temporal Bounds	[UInt]
	S_t	Temporal Strides	[UInt]
	R_S	Addressing Mode Selection	UInt

† Type enclosed in square brackets [ ] means List.

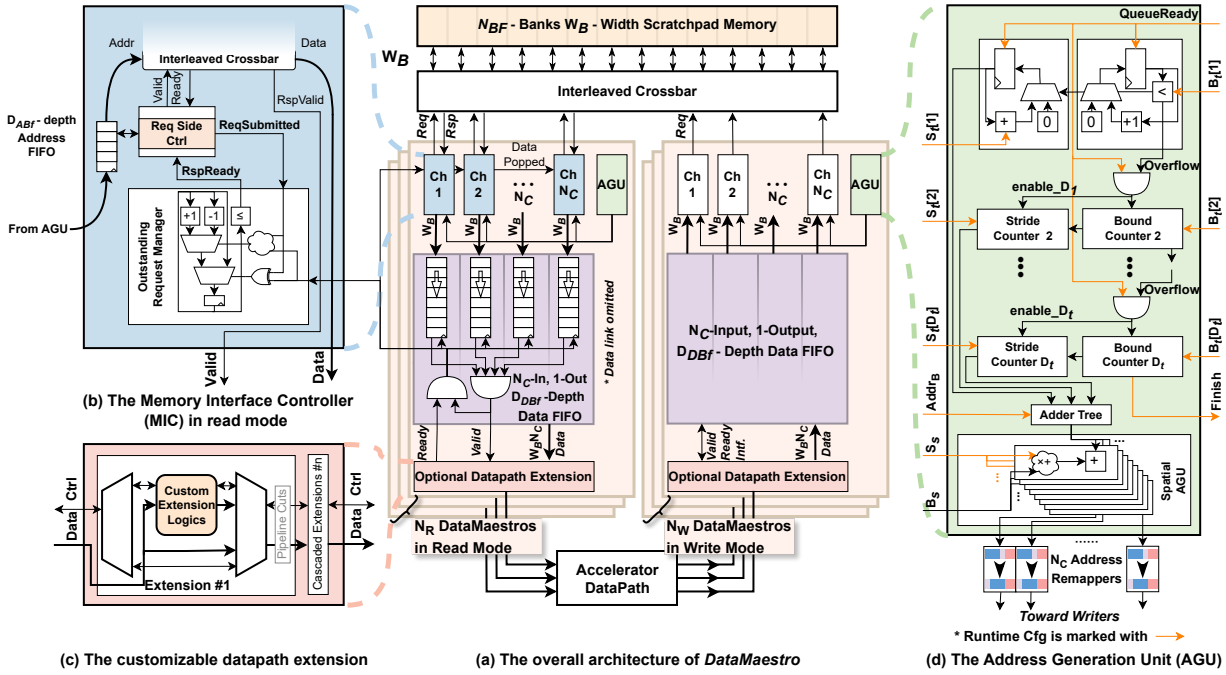

Fig. 2: *DataMaestro* architecture.

A. Architecture Overview of DataMaestro

Figure 2 (a) illustrates a scenario where N_R+N_W *DataMaestros* are connected to a multi-banked scratchpad memory subsystem (top) and an accelerator (bottom), effectively managing data streams between them to create a complete accelerator system. One read *DataMaestro* (middle, left) and one write *DataMaestro* (middle, right) are depicted in detail. The memory subsystem consists of an N_B-banked scratchpad memory that provides high memory bandwidth, along with an interleaved crossbar that ensures full accessibility from any request port. To meet the specific requirements of different accelerator ports, N_R read and N_W write *DataMaestros* are deployed, each of which can be configured independently at both design time and runtime, by providing the parameters listed in Table II.

A read or write *DataMaestro* primarily includes N_C independent memory interaction channels, breaking one wide memory request into multiple narrower operations for asynchronous, fine-grained memory access. Each channel is equipped with a dedicated Memory Interface Controller (MIC) (Figure 2 (b)) and a data FIFO. The MIC consumes addresses from the address generation unit (AGU) (Figure 2 (d)) to issue memory requests, and the data FIFO acts as a buffer between the *DataMaestro* and the accelerator. This facilitates a decoupled access/execute architecture for dataflow accelerators to effectively hide memory latency. At the output ports of the FIFOs, data fetched by multiple channels are gathered into a wide data stream and sent as a single wide data word to the accelerator datapath, enabling highly paralleled execution. Furthermore, at the interface between the *DataMaestro* and the accelerator (Figure 2 (c)), multiple user-customizable datapath extensions can optionally be inserted to perform on-the-fly data processing in a cascaded manner without requiring intermediate memory storage. In the following subsections, we will delve into each part of *DataMaestro* in more detail.

B. Programmable Affine Access Pattern by Address Generation Unit

The data access pattern for DNN workloads, determined by the dataflow and data layout, can typically be represented as an affine pattern [22]. Furthermore, DNN workloads encompass a

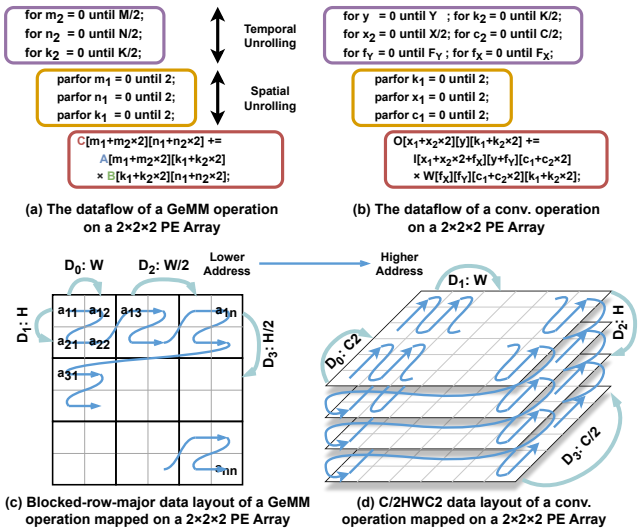

Fig. 3: Dataflow and data layout of GeMM and convolution operations mapped on $2 \times 2 \times 2$ PE array.

wide range of operation types (e.g., GeMM and various types of convolutional operations) and tensor shapes (e.g., height, width, and channel dimensions) [25], necessitating data access patterns with high flexibility. For example, as illustrated in Figure 3, the dataflow and data layout of GeMM and convolution workloads mapped on a simple $2 \times 2 \times 2$ PE array already differ significantly. For GeMM workload, the matrix A is stored using a 4-D block-row-major data layout [26], [27] (Figure 3 (c)), and exhibits a 3-D access pattern across different cycles (Figure 3 (a)). In contrast, for convolution, the input tensor is stored using a 4-D blocked data layout (Figure 3 (d)), i.e., $C/2HWC2$, and features a 6-D data access pattern (Figure 3 (b)). The diverse access pattern (while remaining affine) in DNN workloads motivates the design of a flexible and programmable AGU within *DataMaestro*.

The AGU in *DataMaestro* enables N-Dimensional (N-D) pro-

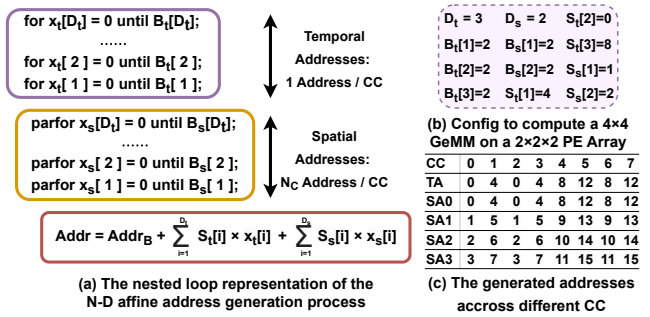

Fig. 4: The nested loop representation of the N-D affine address generation in *DataMaestro*'s AGU and a simple address generation example for a M=N=K=4 GeMM workload mapped on a $2 \times 2 \times 2$ PE array.

grammable affine address generation as shown in Figure 4 (a), using symbols from Table II. This affine function effectively describes the mapping of the N-D data access space to the 1-D address space. Our address generation process involves sequentially generating temporal addresses (TA) to represent temporal data access patterns and simultaneously generating multiple spatial addresses (SA) based on every temporal address for parallel data access, satisfying the requirements of temporal and spatial unrolling for a specific dataflow. A detailed example of the AGU configuration for an M=N=K=4 GeMM workload mapped on a $2 \times 2 \times 2$ PE array is presented in Figure 4 (b), with the corresponding address generation process depicted in Figure 4 (c).

Directly using a single counter to track the address generation progress necessitates modulo units and dividers to compute loop indices, followed by multipliers and adders to calculate temporal addresses. However, this leads to long combinatorial paths and significant hardware overheads that linearly scale with the number of dimensions. In *DataMaestro*, we incorporate microarchitectural optimizations to enable high-dimensional address generation with low overhead and shorter combinatorial paths. As shown at the top of Figure 2 (d), each dimension of the temporal AGU is implemented in a dual-counter structure, including a simple counter (Bound Counter) to record the loop index and a step-programmable counter (Stride Counter) to generate the temporal address offset. Then, address offsets of all dimensions are summed with the base address ($Addr_B$) and consumed by a multi-channel spatial AGU (the bottom of Figure 2 (d)), which generates distinct addresses for each channel. Based on this optimized hardware architecture, *DataMaestro* supports specifying arbitrary temporal address loop dimension, spatial address loop dimension, and spatial address loop bounds at design time, while the strides for both temporal and spatial addresses can be programmed at runtime, providing full flexibility to accommodate diverse data access patterns in DNN dataflow accelerators.

C. Fine-grained Prefetch by Memory Interface Controller

DataMaestro conducts fine-grained prefetch by breaking one wide memory request into multiple narrower channels and issuing them independently. During this process, Memory Interface Controllers (MICs) in read mode play a key role in sending fine-grained requests, gathering response data, and storing it in the data FIFO. The MIC in read mode includes an Outstanding Request Manager (ORM) and a Request Side Controller (RSC), as shown in Figure 2(b). The ORM tracks the utilization of the data FIFO and reserves the FIFO slots for in-flight memory requests, throttling the RSC if no available slots in the FIFO can be reserved. With permission from the ORM and valid

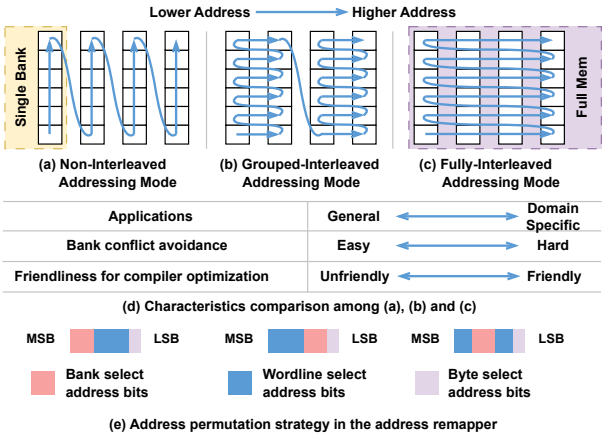

Fig. 5: Addressing modes supported by *DataMaestro*.

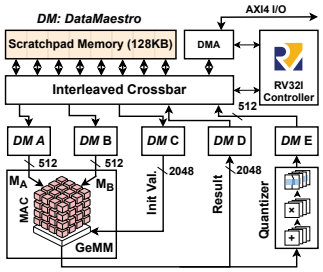
addresses from the AGU, the RSC immediately issues new memory requests. This aggressive and fine-grained data prefetch mechanism maximizes memory bandwidth utilization.



D. Low Overhead Addressing Mode Switching by Address Remapper

Two addressing modes are commonly used in computer systems for accessing multi-banked memory: Fully-Interleaved Memory Addressing (FIMA), where addresses are interleaved across all banks (Figure 5(a)), and Non-Interleaved Memory Addressing (NIMA), where contiguous addresses are allocated to a single bank (Figure 5(c)). Between these two lies an intermediate mode, termed Grouped-Interleaved Memory Addressing (GIMA) by us, where some banks are grouped, and the address is interleaved intra-group and remains contiguous inter-group (Figure 5(b)). The characteristics of these three addressing modes are summarized in 5 (d). While FIMA is widely used in general-purpose computing systems [28], it is more prone to bank conflicts in domain-specific accelerator (DSA) systems. As a result, contemporary dataflow accelerators often favor the NIMA mode [1]–[3]. However, the compiler needs to carefully allocate data for maximal performance and it constrains the tilings of the workload to meet the smallest memory requirement. Positioned between these two, GIMA strikes a trade-off between them. To accommodate diverse DNN workloads and dataflow accelerators, *DataMaestro* is designed to support all three addressing modes, with the capability to switch between them at runtime, offering the designer an extra degree of freedom to optimize the data allocation.

The main challenge of addressing mode switching is the overhead introduced in address decoding. However, addressing mode switching can be represented as a simple bit permutation of the address when the bank number in one group is a power of two. Based on this insight, *DataMaestro* leverages a memory address remapper that facilitates simple address bit permutation for addressing mode switching, as illustrated in Figure 5 (e). *DataMaestro* instantiates the bit permutations in hardware based on the number of banks in total (N_{BF}) and the number of banks in one group (N_{BG}) at design time. Then, the permuted addresses are connected to a multiplexer, allowing the user to select the addressing mode by setting R_S at the run time.

E. On-the-fly Data Manipulation by Datapath Extension

DataMaestro provides a mechanism to insert customizable extensions, such as data quantization and permutation, between *DataMaestro* and accelerator datapath in a plug-and-play manner to conduct on-the-fly data manipulation, as shown in Figure 2 (c). Datapath extensions are instantiated based on the design-time configuration DP_{ext}, with the output of one extension serving as the

Parameter	A	B	C	D	E
D_{spat}	1	1	2	2	1
B_{spat}	[8]	[8]	[8,4]	[8,4]	[8]
D_{temp}	6	3	3	3	3
W_B	64	64	64	64	64
N_C	8	8	32	32	8
D_{DBf}	8	8	1	1	1
DP_{ext}	[Trans.]		[Broad.]	[ ]	[ ]
N_{BF}	2048				
N_{BG}	[2048, 512]				

Fig. 6: The *DataMaestro* evaluation system (left) and *DataMaestro*s design-time parameters used in it (right).

input for the next. Furthermore, the logic to bypass any extension is automatically inserted so that users can disable any extension at runtime.

IV. Evaluation

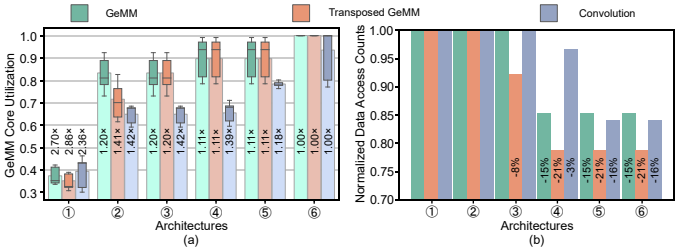
A. Setup and Methodology

To assess the versatility and efficiency of *DataMaestro*, we integrate it with a Tensor Core [23]-like GeMM accelerator and a Quantization accelerator into a RISC-V host system [29], as depicted in Figure 6 (left). The GeMM accelerator features a 3-*D* 8×8×8 PE array, capable of executing workloads expressed as $D_{32} = A_8 \otimes B_8 + C_{32}$, where the subscripts denote operand data precision and $\otimes$ signifies either GeMM or convolution operations, depending on the runtime configuration of *DataMaestro*s. The output from the GeMM accelerator can be directed either to the Quantization accelerator for post-processing, represented as $E_8 = Rescale(D_{32})$, or sent back to the memory. The GeMM and Quantization accelerators feature five data stream ports in total, each with different data access patterns and bandwidth requirements, served by five *DataMaestro*, as shown in Figure 6 (right). The 6-*D* temporal AGU within *DataMaestro A* facilitates implicit *im2col* transformation [30] for convolution operations. Two datapath extensions are implemented: 1). Transposer, which performs on-the-fly matrix tile transposition, and 2). Broadcaster, which duplicates data across channels, particularly useful for DNN workloads with per-channel quantization. Additionally, a customized compiler is developed to generate runtime configurations for these *DataMaestro*s, considering workload specifications and tensor data layouts.

We implement *DataMaestro*, GeMM, and Quantization accelerators at the register-transfer level (RTL) using Chisel [31]. An ablation study is conducted using Verilator for cycle-accurate RTL simulation to evaluate utilization gains and memory access count reductions provided by each feature of *DataMaestro* (§ IV-B). Furthermore, an FPGA prototype is deployed on the AMD Versal™ VPK180 FPGA to benchmark model-wise performance on real-world DNN workloads (§ IV-C). The evaluation system is also synthesized using the Synopsys Design Compiler® with GlobalFoundries 22FDX® technology, operating at 1GHz and 0.8V with strict timing closure. Post-synthesis simulation is performed for power consumption analysis using Siemens QuestaSim™ and Synopsys PrimeTime® (§ IV-D).

B. Ablation Study for DataMaestro Evaluation

1) Workload and Evaluation Architecture Setting: We conduct an ablation study to evaluate the effectiveness of each innovation in *DataMaestro* using 260 different synthetic DNN workloads, categorized into three groups: 1) GeMM, 2) transposed GeMM, and 3) convolution. The synthetic benchmark set features various matrix sizes for GeMM and transposed GeMM, along with diverse feature map sizes, channels, kernel sizes, and strides for convolution, effectively representing typical Transformer and CNN layers. Initially, we disable



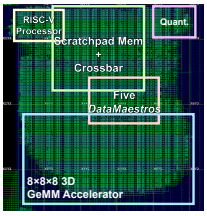


Fig. 7: Ablation study results of GeMM core's utilization distribution presented in box plot, with average utilization annotated in bar chart (a), and normalized data access counts (b) across architectures with different *DataMaestro* features under the synthetic DNN workload set. ① = Baseline (all features turned off); ② = ① + Fine-grained prefetch; ③ = ② + Transposer; ④ = ③ + Broadcaster; ⑤ = ④ + Implicit *im2col*; ⑥ = ⑤ + Addressing mode switching.

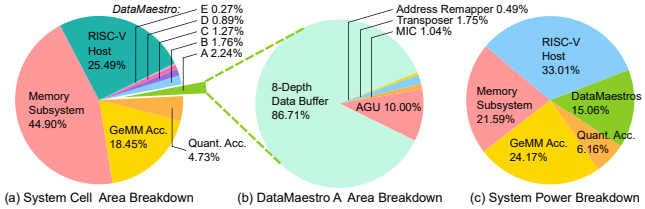
all features of *DataMaestro*s, architecturally similar to plain data movement units, inside the accelerator system as the baseline (①). Subsequently, we gradually introduce each feature, eventually forming an accelerator system with fully-featured *DataMaestro*s (② to ⑥).

2) Result Analysis: Figure 7 (a) presents the GeMM core utilization distribution for each DNN kernel group using a box plot, with the average utilization inside each group depicted in the accompanying bar chart. As demonstrated in the results, ② achieves a significant increase in GeMM core utilization, ranging from 1.65× to 2.21× higher than the baseline ① across all workloads, thanks to fine-grained asynchronous prefetch. Among all features, the Transposer is particularly effective for the transposed GeMM workload (③ compared to ②), improving utilization by 1.16×, while Broadcaster increases utilization of all workloads by up to 1.09× (④ compared to ③). The implicit *im2col* [30] transformation further delivers a 1.19× utilization improvement for convolution workloads (⑤ compared to ④). Finally, with addressing mode switching (⑥), the utilization for the two GeMM workloads reaches 100%, with minimal variation across all matrix sizes. For convolution workloads, the average utilization reaches 92.03% but the utilization distribution exhibits notable variation across different workload sizes. Upon further analysis, this fluctuation is attributed to strided convolution layers, which require fetching noncontiguous input data across wider address ranges, resulting in unavoidable bank conflicts. Fortunately, strided convolution layers, typically used for feature map downsampling, comprise only a small portion of real-world DNN workloads and thus have a limited impact, as demonstrated in § IV-C2. Meanwhile, datapath extensions for on-the-fly data manipulation significantly reduce redundant memory accesses, mitigating bank conflicts and saving energy. As illustrated in Figure 7 (b), Transposer reduces the data access counts by 15.86% for transposed GeMM workloads (③ compared to ②), and Broadcaster effectively reduces memory accesses by up to 14.58% across all three workloads (④ compared to ③). Overall, the fully-featured *DataMaestro* (⑥) achieves up to 2.89× performance speedup and up to 21.15% reduction in memory accesses across all test cases, compared to the baseline (①). These results highlight that *DataMaestro* enables versatile and highly efficient data streaming to the accelerator across a variety of DNN kernels with different sizes.



C. Real-world Neural Network Evaluation on FPGA

1) Evaluation Setup: We integrate our *DataMaestro* evaluation system into a customized SoC platform derived from [32] and prototype it on the AMD Versal™ VPK180 FPGA, which facilitates rapid and convenient real-world DNN evaluations. The annotated layout and resource utilization of our system are presented in Figure 8.

Platform	VPK180
Clock Frequency	125MHz
LUTs Total	265k
Regs Total	59k
LUTs GeMM	124k (46.79%)
Regs GeMM	8k (13.56%)
LUTs *DataMaestros*	14k (5.28%)
Regs *DataMaestros*	4.4k (7.46%)

Fig. 8: The FPGA implementation (left) and resource utilization (right) of the *DataMaestro* evaluation system.

(a) System Cell Area Breakdown (b) DataMaestro A Area Breakdown (c) System Power Breakdown

Fig. 9: Breakdown of cell area (a) and total power (c) for the evaluation system, and area composition of *DataMaestro A* (b).

2) DNN Performance Benchmarking: We benchmark ResNet-18 [33], VGG-16 [34], ViT-Base-16 [35], and BERT-Base [36] on our FPGA SoC system, with GeMM core utilization listed in Table III. All four networks achieve utilization above 95%, with VGG-16 and ViT-Base-16 reaching nearly 100%. This high GeMM core utilization across these real-world DNN workloads highlights the efficacy of *DataMaestro* in minimizing data stream interruptions, thereby improving the performance of the accelerator system.

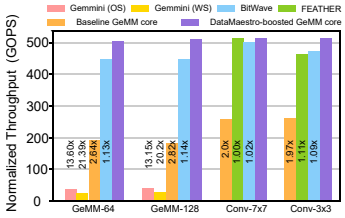


TABLE III: GeMM core utilization (in %) of *DataMaestro*-boosted accelerator under real-world DNN workloads on VPK180 FPGA.

	ResNet-18	**VGG-16**	**ViT-B-16**	**BERT-Base**
Type	CNN	CNN	Transformer	Transformer
Utilization (%)[†]	95.45	100.00	99.98	97.85

[†] Utilization is calculated as the ratio of theoretical computation cycles without memory stalls to the active cycles of *DataMaestro*.

D. Area and Power breakdown

When synthesized using 22nm FDX technology, our system occupies $0.61mm^2$ cell area and consumes $329.4mW$ of total power when executing an M=N=K=64 GeMM (GeMM-64) workload at 1 GHz, achieving a total system-level energy efficiency of 2.57TOPS/W. The detailed system area and power breakdowns are shown in Figure 9 (a) and (c), highlighting the five main components: the GeMM accelerator, Quantization accelerator, five *DataMaestro*s, the scratchpad memory subsystem, and the RISC-V host. The first four components form the core of the accelerator system, accounting for 74.52% of the total area and consuming 66.99% of the total power. The five *DataMaestro*s collectively occupy only 6.43% of the system area and 15.06% of the total power, with individual area usage ranging from 0.28% to 2.33%. The variation in area consumption demonstrates that *DataMaestro*'s design-time parameters alter the deployed hardware to meet the specific requirements of each data stream, showcasing its high versatility. Furthermore, to investigate the overhead of each feature inside *DataMaestro*, we conduct a detailed analysis of the area composition of a single *DataMaestro A*—the most advanced one among the five instantiations, as shown in Figure 9 (b). The majority of the area is occupied by data FIFOs (87.76%) and MICs (1.04%) to support decoupled fine-grained prefetch. The AGU, responsible for producing the 6-D temporal and 2-D spatial addresses, accounts for 10% of the total area. The Transposer takes up 1.75% of the total area. Lastly, the address remapper, which is essentially a multiplexer of permuted address bits, occupies a negligible 0.49% of the area.

	Area	Power
Buffet [6]	2%	14%
Softbrain [7]	4.3%	15.3%
Bitwave [2]	11.9%	25.5%
FEATHER [4]	8.9%	N/A
DataMaestro	**6.43%**	**15.06%**

Fig. 10: Comparison of normalized throughput (left) and data movement area and power cost (%) inside the whole accelerator system (right) between SotA solutions and *DataMaestro*. Some data is not revealed in the literature; therefore, the corresponding bars are omitted in (a).

E. State of the Art Comparison

1) Comparison with SotA DNN Dataflow Accelerators: We compare the throughput of our *DataMaestro*-boosted accelerator with SotA DNN dataflow accelerators, including Gemmini in output-stationary (OS) and weight-stationary (WS) modes [1], [37], FEATHER [4], and BitWave [2] using representative DNN kernels. For all systems, throughput is normalized to the same number of PEs (512) and clock frequency (1 GHz) of the accelerator for a fair comparison. As the results in Figure 10 (left) show, our *DataMaestro*-boosted accelerator achieves throughput gains ranging from 1.05× to 21.39× compared to SotA accelerators across diverse DNN kernels. This significant performance improvement results from the combined efforts of *DataMaestro*'s design-time and runtime flexibility, fine-grained prefetch, and addressing mode switching techniques.

2) Comparison with SotA Data Streaming Engines: We further compare data streaming engines in Buffet [6], Softbrain [7] and data movement units in BitWave [2], and FEATHER [4] with *DataMaestro* and summarize their area and power overhead results in Figure 10 (right). The five *DataMaestro*s in our evaluation system jointly occupy 5% and 15.58% of the system area and power consumption, which is competitive with SotA solutions, while flexibly and efficiently streamlining data to boost the dataflow accelerator's performance.

V. Conclusion

In this paper, we present *DataMaestro*, a versatile, efficient, and open-source data streaming unit that brings the decoupled access/execute architecture to DNN dataflow accelerators. *DataMaestro* supports a programmable N-Dimensional access pattern to accommodate diverse workload types and dataflows, incorporates fine-grained prefetch and addressing mode switching to mitigate bank conflicts, and enables customizable on-the-fly data manipulation to reduce memory footprints and accesses. We integrate five *DataMaestro*s with a Tensor Core-like GeMM accelerator and a Quantization accelerator into a RISC-V host system. FPGA prototyping and VLSI synthesis results demonstrate that *DataMaestro* helps accelerators achieve nearly 100% utilization, which is 1.05 – 21.39× higher than SotA solutions, with area and energy cost of merely 6.43% and 15.06% of the total system.

***Abstract*—As increasing gap of the shrinking ratio between device and metal pitches under advanced nodes, power-grid (PG) structure plays a critical role in circuit performance considering power integrity. Initial PG structures, as initiating implementation fundamentals, dominate optimization space. To address initial structures on industrial flow, we propose *the first* unified framework fueled by novel sequence-based structure generator and Transformer-based predictor, providing accurate static voltage-drop estimation. Learned embeddings are then adopted to determine promising candidates with Pareto frontier during structure optimization. The predictor is demonstrated in different scenarios under $3nm$ and $2nm$ technology with average 0.011% maximum absolute error of drop percentage while the optimized structures reduce 15% PG utilization with 34% worst timing-slack improvement on industrial designs.**

I. INTRODUCTION

As transistor size keeps shrinking, PG structures impose a crucial role in circuit performance for increasing voltage (IR) drop and reserving sufficient routability. In industrial design flow, designers carefully design a set of global PG structures with different sustainable static IR (SIR) drops to initiate physical implementation.

Since global PG design is conducted before real cell placement, SIR is usually adopted as healthiness index, and different power densities (PD) of IP designs lead to rich possibilities of PG structures. In industrial practice, designers could mix different power density structures to address local hotspots or dynamic IR drop after cell placement with much smaller design overheads.

A complete structure is defined by an architecture and corresponding pattern configuration. The architecture determines PG-style combination in stripes or pillars as illustrated in Fig. 1(a). As observed in the figure, layer architecture has various forms and the architecture hooks up PG metals among layers through proper via connections. To avoid PG occupying excessive routing resource under advanced nodes, stagger and inline pillars are the most common stub architectures, as shown in Fig. 1(b) and (c). On the other hand, the pattern configuration further details how to implement such architecture, e.g., the needed vertical spacing (pitch y) between two VIA4 of an inline pillar in Fig. 1(c).

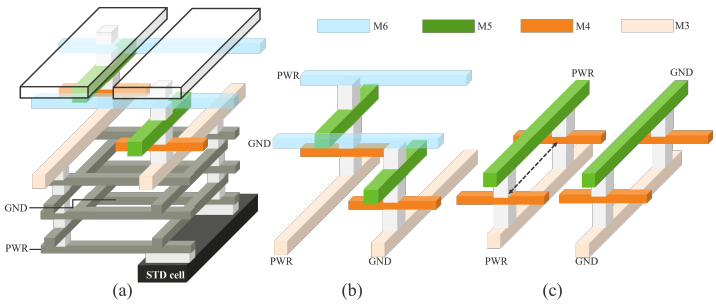

Fig. 1: Power-grid structure overview. (a) Grid stacking adopted in advanced nodes with two most common pillar architectures, (b) stagger and (c) inline pillar.

Typically IR analysis models PG as a resistor network and attaches corresponding current loads at each network node. To evaluate the quality of a global PG structure, the common practice assigns average power density simulating current loads with commercial sign-off tool. During physical implementation, finer-grain adjustment based on a global structure is made to address dynamic IR drop from local hotspots. As a result, the global PG structure has significant impacts in physical convergence.

Considering global structure optimization, it is mandatory to address the requirement of increasing and diverse power densities under deep sub-micron technology. Power density increases dramatically because of smaller logic area but much complicated circuit functions. In addition, SoC IPs have different power densities, causing unnecessary area waste or systematic IR-drop risk with single structure.

To tackle aforementioned two problems, scalable structure exploration is essential. Existing related works include two major categories, (1) IR-change prediction of different cell placements under one fixed PG [2], [4], [5], [7], [9], [11], [12], [15]–[17], and (2) PG structure adjustment with limited styles under different cell placements [1], [8], [10]. First category focuses on accurate prediction but does not address much about how to reduce IR violations. Second category aims at PG adjustment at specific current distribution strengthening local robustness; however, the explored structures are difficult to consider rich pillar combinations.

There are multiple learning models proposed in related works, including linear regression [16], XGBoost [8], [12], and U-Net [4], [5], [15]. A recent work [17] adopted tree-based model to make prediction while examining feature importance by attention calculation and pruning non-important features. Although these models are effective in static or dynamic IR prediction, we found that the model sensitivity on finer-grain structures is insufficient. Considering PG adjustment in existing works, only specific layer or style changes are made, and thus it is infeasible to be adopted in industrial cost-effective designs.

In this work, we propose scalable learning-based PG structure exploration, with SIR-driven global structure optimization, to offer sufficiently good initial solutions with various power densities reducing adjustment iterations. In industrial practice, it is less preferred changing global PG structures constantly to reset floorplan utilization. Moreover, with various density offerings, we could easily address local dynamic hotspots by mixed density structures.

Our framework addresses multi-density optimization with different structures recommended from Transformer-based learning model. To enable flexible structure exploration, sequence-based architecture perturbation is developed followed by sets of detailed pattern configuration generation. The proposed sequence-based structure operations are carefully designed to run through the model training and optimization. Compared with existing IR-drop models, this is *the first* work to formulate the structure features in transformer-based architecture, where the attention mechanism is further strengthened on filtered samples by Maximin Latin Hypercube (MLHS). Our model effectively captures inter-layer relationships over common regression models to greatly improve IR-drop prediction. Promising structure patterns are generated through non-

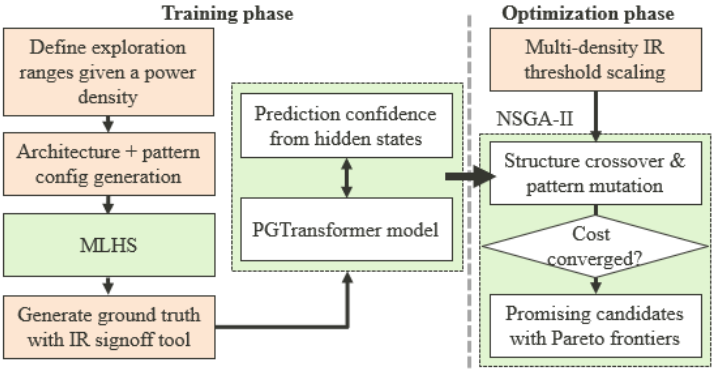

Fig. 2: Proposed framework to create optimized PG structures.

dominated sorting derived from augmented drop prediction and associated resources.

We summarize the key contributions of our proposed framework as follows:

- Compared with limited structure supports in related works, our explorer builds flexible PG pattern stacking in sequence representation to generate vast candidates followed by MLHS for representative training samples.
- To better capture subtleties of multi-layer structure changes over existing works, different pattern configurations are translated into a sequence each layer. We present PGTransformer on proposed sequence representation as core predictor to capture inter-layer relationships with self-attention mechanism.
- Proposed framework equips capability to generate optimized *multi-layer* structure patterns from Pareto frontiers. New patterns are derived from balanced trade-off between augmented drop value with prediction confidence and resource.

The rest of this paper is organized as follows. Sec. II illustrates our exploration framework and key procedures. Section III details our algorithms. Experimental results are presented in Section IV. Finally, conclusions are given in Section V.

II. Proposed Unified Framework

To offer efficient structure optimization, the framework combining both training and optimization is proposed as illustrated in Fig. 2. The purpose of training phase builds a robust IR-drop prediction model to examine power-integrity quality of various structures. The optimization phase adopts the trained model along with resource and prediction confidence to explore different architecture patterns.

In model training phase, we transform multi-layer PG structures into a set of sequences for efficient perturbation and enable sequence-based model to learn structure contexts. Legal layer configurations are defined depending on target metal scheme. For each candidate layer, a valid pitch search range is defined, and we set the range in $\{8, 16, \ldots, 48\}$ times of default pitch in this work. The search range can be changed to further expand solution space or fit target technology rules.

With defined search range, our proposed structure generator creates various layer pattern stacking with pillar template combinations. The stacking operations are conducted with string manipulation and thus the generator provides highly efficient sample generation. However, to manage costly training sample collection with sign-off IR values, it is mandatory to reduce training sample sizes. After sets of structures are generated, we apply MLHS from multivariate structure parameter distribution for equidistant sample space. Commercial IR sign-off tool is then adopted to generate golden IR values of sampled training structures. The IR predictor is trained with Transformer-based architecture by forwarding sets of layer features to its embedding encoder.

As mentioned in Sec. I, it is essential to prepare structures considering different power densities for minimized area overhead. Considering IR drop mainly determined by the current multiplication, direct proportional to assigned power, IR drop is inversely proportional to structure sustaining certain power density. As a result, we expand power density supports during optimization phase by changing target drop threshold as

$$D_{th}^{j} = \frac{PD_i}{PD_j} \times D_{th}^{i}, \tag{1}$$

where PD_i is the structure sustaining power density i and D_{th}^{i} is the target IR-drop threshold under power density i.

In major optimization iterations, we intend to figure out most promising structures approaching D_{th}^{j} with best trade-off between resource and IR quality. Multi-objective optimization with Non-dominated Sorting Genetic Algorithm (NSGA-II) [6] is adopted to address the sequence-based structure representation. The optimizer identifies Pareto frontiers considering reserved routing resource, and augmented IR prediction by comparing learned embeddings.

III. Proposed Algorithm

A. Sequence-based Structure Generation

Proposed structure generation aims to create flexible structures among all layers efficiently. The generation includes two stages, vertical stacking to determine an architecture and pattern configuration mapping within the architecture. During generation, we define a set of discrete candidates to determine the width, number, and spacing of PG metals at each layer considering technology rules. To address metal-pitch alignment as a feasible PG, template-based permutation is proposed.

A set of pillar architecture templates is defined as illustrated in Fig. 3 and note that similar concepts can be easily extended to more complicated template designs. Each pillar template AT_i defines how a pillar is formed between two stripes under stacking layers i. To provide flexible combination, the stacking could be either bottom-up AT_i^{R0} or top-down AT_i^{MX}. Given stacking direction R0, MX, the corresponding x-axis and y-axis pitch are revised based on the preferred direction of the metal layer where template stripe lies. Pitches x and y describe cross-layer alignment with respect to an anchor layer, which could be inside a template or defined by other stacking one.

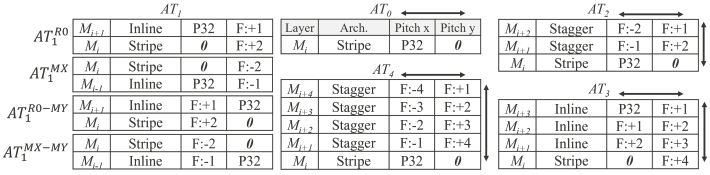

Fig. 3: Pillar template examples considering five-layer combinations.

At first stage, architectures are constructed with defined templates based on sequence permutation as depicted in Fig. 4(a). The sequences manage possible pillar template combinations in vertical stacking direction, comprising pairs of two-digit characters. The first character denotes the template index i among candidate set AT and second one describes the stacking direction, "D" for bottom and "U" for top. Every stacking needs to make template pillars enclosed by two stripes considering stacked templates or boundary conditions for a feasible pillar structure. As the example described in the figure, AT_2^{MX} is chosen and stacked from the bottom side at first operation, and similar concepts are applied to second and third operations. For third operation, although the stacking direction is from the bottom, AT_3^{MX} is chosen instead of AT_3^{R0} to enclose template pillars.

After a complete architecture is formed, detailed pattern configurations are generated at second stage. To form a valid pillar pattern, we define proper pitch relationships among related neighboring layers. As depicted

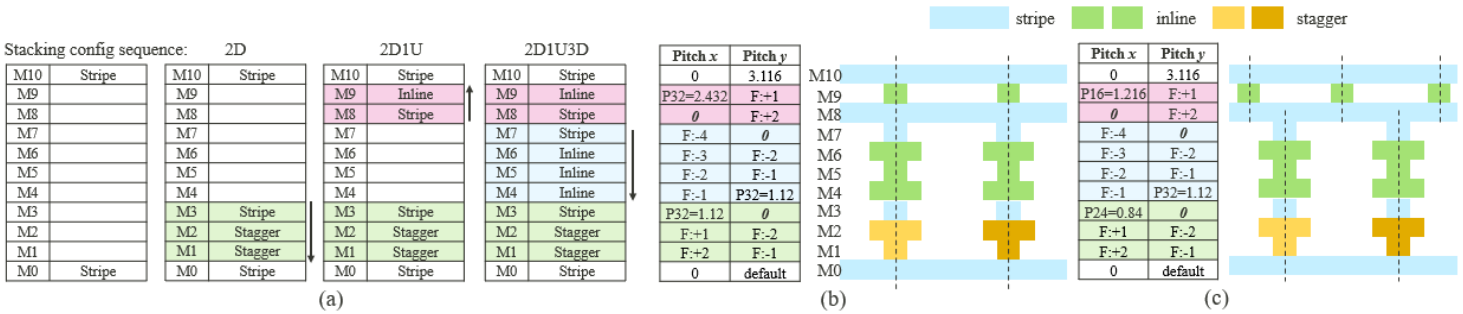

Fig. 4: Architecture construction and corresponding pattern configuration mapping. (a) Architecture construction with template stacking. (b) One pattern configuration candidate, and (c) another configuration by changing anchor pitches under an identical architecture.

in Fig. 4(b), certain template layers define drawing PG pitches while the pitches of other layers "follow" different anchor layers to create pillar patterns. The drawing pitch is a set of discrete numbers, described by "$\texttt{P}m_{tp}$" where m_{tp} denotes the multiple of default layer pitch. The follow relationship is described by a string with an important index "$\texttt{F} : d_{floor}$", where d_{floor} denotes the floor offset with respect to the alignment anchor layer, e.g., 0 implies current layer, 1 (-1) implies one layer above (below).

As illustrated in the example, considering vertical preferred direction, the pitch x of template string at `M7` matters, and thus AT_3^{MX} is further revised to AT_3^{MX-MY} defining explicit horizontal PG pitch. Same concepts are also applied to other two templates. After template revision, by tracing follow relationships, it is clear that the pattern configuration can be manipulated through different anchor pitches, i.e., $1.12um$ from 32X `M4` layer pitch $0.035um$. By changing anchor pitches on `M3` and `M9` in the figure, another different patterns are formed given one identical architecture as depicted in Fig. 4(c).

Pitch configurations among all layers are then translated to sets of explicit numbers. Combined with aforementioned PG-layer width, number, and spacing, vast amounts of implementable structure configurations can be easily generated with Cadence *PSDL*, PG Structure Description Language.

B. Feature Designs and Sampling

After pattern configuration is translated, the style and numbers at each layer are formed as a sequence of features. The features used for model training and prediction in this work are listed in Table I. The features directly derived from explicit configuration well describe a PG structure to help our predictor capture accurate inter-layer weights.

In addition to the values in pattern configuration, we also calculate MN_i and VN_i to facilitate model learning electrical behaviors because via counts are highly correlated with power-integrity robustness. Considering vertical preferred direction of Layer i, and S_{pillar} is the set containing stagger and inline styles given a floorplan dimension W_{fp} by H_{fp},

$$MN_i = \begin{cases} \frac{W_{fp}}{Pitch_{x,i}} \times \frac{H_{fp}}{Pitch_{y,i}} \times GN_i, & \text{if } Arch_i \in S_{pillar} \\ \frac{W_{fp}}{Pitch_{x,i}} \times GN_i, & \text{otherwise} \end{cases} \quad (2)$$

and then $VN_i = MN_i \times \rho$, where $\rho = GN_i$ if either one via layer belongs to S_{pillar} or $\rho = MN_{i+1}$.

To manage costly training sample collection with ground truths from commercial IR sign-off tool, it is essential to have minimized dataset that adequately represents majority feature space. After a set of random pattern configurations are generated, MLHS is adopted to figure out minimized set of training samples.

MLHS begins by generating a random Latin Hypercube sample, and then iteratively improves the sample by swapping pairs of data points to increase the minimum distance between them. The swapping process continues until no further improvement can be made. Considering the features comprising both numerical and categorical types, we measure their distances differently. The pairwise distance between two samples s_i and s_j, is defined as follows,

$$d_\lambda(s_i, s_j) = \sqrt{\sum_n |s_i^n - s_j^n|^2} + (1-\lambda) \times \sum_c |s_i^c - s_j^c| \quad (3)$$

where s_i^n and s_i^c represents the numerical and categorical features, respectively, and λ is the weight to balance these two types. We intend to find the minimal distance from sample set $\mathcal{S}$ with total N features,

$$d_\lambda(\mathcal{S}) = min(\{0 \le i < j \le N : d_\lambda(s_i, s_j)\}) \quad (4)$$

Different λ in a discrete step ranged in [0, 1] are swept with random generated sample candidates, and the sample set with the maximal $d_\lambda(\mathcal{S})$ among iterations is chosen as final training set.

TABLE I: Definition of important features used in power/ground nets on Layer i. Power and ground nets could have different values.

Notation	Type	Description
$Arch_i$	Cat.	Architecture type (e.g., stripe, stagger, inline)
W_i	Num.	Metal width of this PG net
L_i	Num.	Metal length of this PG net
GN_i	Num.	Metal number in one group
GS_i	Num.	Spacing between metals within a group when $GN_i >= 2$
OS_i	Num.	First metal offset within a group
$Pitch_{x,i}$	Num.	Horizontal pitch between metal groups
$Pitch_{y,i}$	Num.	Vertical pitch between metal groups
R_i	Num.	Resistance of Layer i
MN_i	Num.	Total metal counts of this PG net
VN_i	Num.	Total via counts of this PG net

C. PGTransformer Architecture

As described in Sec. III-B, each layer of a PG structure is characterized by distinct features such as pitch, spacing, and width. We formulate layer features into a sequence with length L and trained on Transformer-based model [14] for its superior capability of capturing temporal dependencies in sequence data. Specifically, the sequence representing a structure with L layers is defined as $\mathbf{X} = \{\mathbf{x}_1, ..., \mathbf{x}_L\}$ where $\mathbf{x}_i = \{Arch_i, W_i, \cdots\}$.

Transformer architecture comprises N blocks, each containing a multi-head attention layer, a fully connected feed-forward network, and two normalization and residual addition layers. The Transformer can be viewed as a function TF($\cdot$): $\mathbb{R}^{L\times d} \rightarrow \mathbb{R}^{L\times d}$ that accepts a sequence of length L of input tokens $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_L\}$, $\mathbf{x}_i \in \mathbb{R}^d$ as input, and outputs a sequence of token embeddings $\hat{\mathbf{X}} = \{\hat{\mathbf{x}}_1, \hat{\mathbf{x}}_2, ..., \hat{\mathbf{x}}_L\}$, $\hat{\mathbf{x}}_i \in \mathbf{R}^d$, where each $\hat{\mathbf{x}}_i$ encodes the dependencies between $\mathbf{x}_i$ and other input tokens.

The detailed structure of the Transformer encoder is depicted in Fig. 5(a). Positional embeddings are added to $\mathbf{X}$ to encode the position information of each token. The multi-head self-attention layer with total H heads, learns independent transformations $\mathbf{W}_h^Q$, $\mathbf{W}_h^K$, and $\mathbf{W}_h^V \in \mathbb{R}^{d\times d}$ at the h-th head and calculates the attention weights $\mathbf{A}_h$ among all input tokens. Token embeddings are updated with the context information

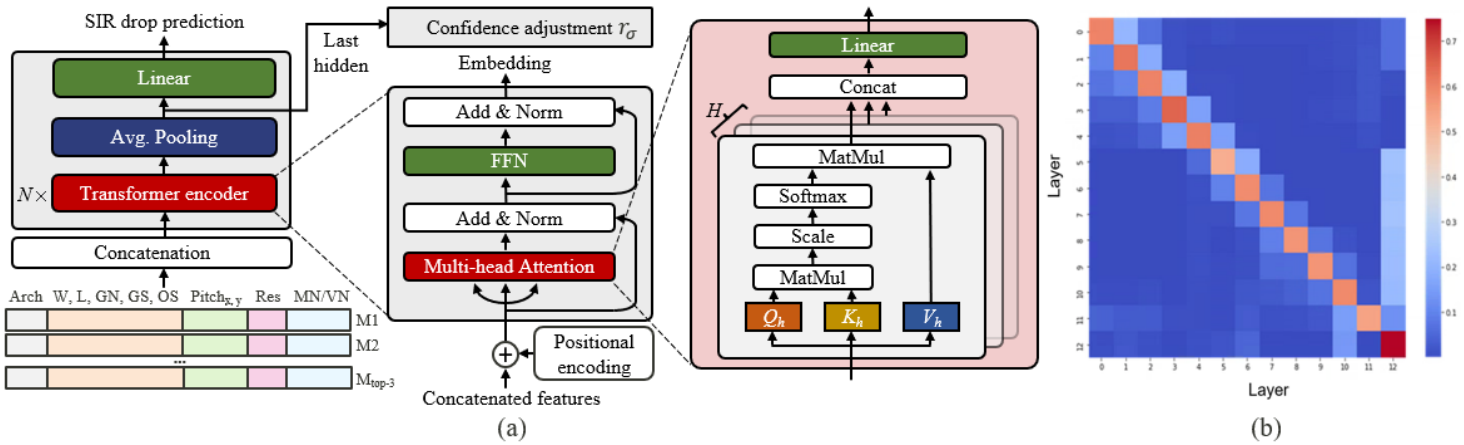

Fig. 5: Proposed PGTransformer architecture. (a) Encoder and linear layer for IR-drop prediction, (b) and the heatmap of cross-layer attention after training.

from their attention tokens, and resulting embeddings from all heads are concatenated and projected to the input dimension via learnable matrix $\mathbf{W}^O \in \mathbb{R}^{(H\times d)\times d}$. For each $x_i \in \mathbf{X}$, the output embedding $\hat{x_i}$ through the multi-head attention, can be derived as follows,

$$\mathbf{A}_h\left(x_i, x_j\right) = \text{softmax}\left(\frac{\mathbf{W}_h^Q\mathbf{X}\cdot\left(\mathbf{W}_h^K\mathbf{X}\right)^T}{\sqrt{d}}\right) \tag{5}$$

$$\hat{\mathbf{X}} = \text{concat}_{h=1}^{H}\left\{\sum_{j=1}^{N}\mathbf{A}_h\left(x_i, x_j\right)\mathbf{W}_h^V\mathbf{X}\right\}\cdot\mathbf{W}^O \tag{6}$$

Output embedding $\hat{\mathbf{X}}$ is then passed through a feed-forward network (FFN) for non-linear mapping, allowing the model to capture complex dependencies of different categorical and numerical features in a input sequence. For output layer, our model applies AvgPooling on learned embeddings transforming $\mathbb{R}^{N\times d}$ to $\mathbb{R}^{1\times d}$, and subsequently followed by a linear layer projecting to final IR prediction value $\in \mathbb{R}^1$. In this work, the embedding dimension is 64 and FFN dimension is 256 with $N = 2$ and $H = 8$. The encoder produces hidden states with a dimensionality of 64, which are further used to adjust prediction values by proposed quadratic error regressor in Sec. III-D.

The heatmap shown in Fig. 5(b) represents the attention map of internal attention states. The i-th row corresponds to the attention map to predict the IR value of Layer i. In addition, it is clear that the model also refers to states from all layers to form its prediction. The layer influences are adaptively adjusted through our sequence modelling.

D. Structure Optimization

Multi-objective Pareto frontier is adopted to create optimized structures. To reach best design performance, not only IR robustness but left signal routing resource needs to be considered. To maximize left resource, the PG utilization should be minimized. Two objectives, PG resource utilization c_{res} and augmented IR-drop prediction c'_{ir} incorporating prediction value c_{ir} and associated confidence, are formulated in our structure optimizer. The PG utilization estimation considering architecture is defined as,

$$c_{res} = \left(W_{fp}\times H_{fp}\right)^{-1}\sum_{i}^{L} MN_i \times A_i \times TP_i, \tag{7}$$

where $A_i = L_i \times W_i$ and TP_i is default pitch divided by default width of Layer i.

As PG structures have vast variants and thus not every prediction has identical accuracy, the prediction confidence measured from model hidden states is proposed to provide another perspective during structure cost evaluation. As the last layer of PGTransformer is a linear layer, the mapping from the hidden state to final prediction is also linear mapping. If the hidden state is far from the distribution of training data, it implies

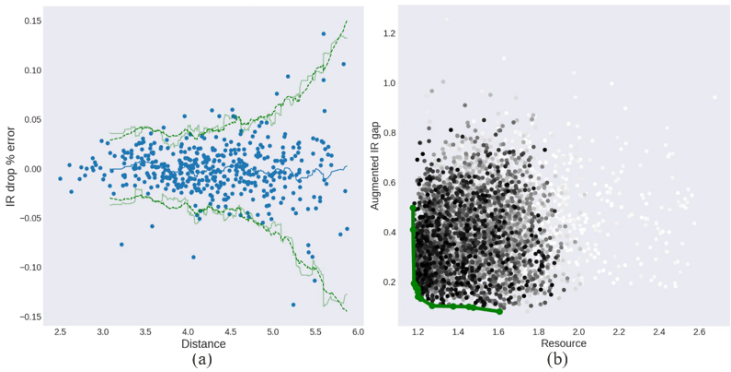

Fig. 6: Confidence cost quadratic regression and Pareto frontiers of structure optimization. (a) Rolling error mean curves with window 40 regarding $d(x_i, S)$, and dark green curves are proposed quadratic polynomial regressor. (b) Optimized structure frontiers after iterations.

that the prediction could be extrapolated, leading to unreliable results. We approximate prediction confidence by fitting σ-curve of hidden-state distance during model validation.

For each validation sample x_i, the minimum distance of its hidden states toward training dataset S as $d(x_i, S) = min\{\|x_i - s_j\|\}$ and its associated prediction error are measured. As shown in Fig. 6(a), the validation error along with different distances is illustrated, where x-axis is $d(x_i, S)$. The blue dots (y-axis) represent validation errors of IR-drop percentage, V_{ir}/V_{ideal} where V_{ideal} is supply voltage and V_{ir} is the drop value. To capture proper confidence penalty, the corresponding rolling mean and standard deviation σ are examined. The blue curve denotes corresponding rolling mean μ and light green curves are $\mu \pm 2\sigma$ from validation set. By observing $\mu \pm 2\sigma$ curves, we adopt quadratic regression to determine the parameters as confidence cost function.

As observed in the figure, the 2-σ quadratic regression as confidence evaluation is positively correlated with both distance and original $\mu \pm 2\sigma$ distribution with 95% sample coverage, reaching correlation coefficient 0.82 and R-squared value 0.92, respectively. To address the confidence directly into predicted IR toward a defined drop threshold D_{th}, we define the IR-drop objective in our structure optimizer as

$$c'_{ir} = |c_{ir} - D_{th}| + r_\sigma(d(x_i, S)), \tag{8}$$

where r_σ is 2σ quadratic regressor of minimum state distance.

With c_{res} and c'_{ir}, we employ modified NSGA-II as multi-objective optimizer. NSGA-II works by generating a population of candidate solutions and evolving population over generations. The architecture sequence is used to form chromosomes, and corresponding pillar templates provide

good crossover points. The crossover points offer strategic perturbation, potentially combining both parent strengths.

Fig. 7 illustrates the configuration evolution process. The pairs of template stacking with equal length from each configuration pair are collected as crossover candidates. One of the pairs is randomly selected to produce new configurations. After architecture crossover, the valid pitches x and y are examined based on the preferred direction of template stripe layers, as described in bold blue in the example. In addition, the anchor pitches of two child configurations are changed with mutation probability n_{AT}^{-1}, where n_{AT} is total template number of parent configurations. With aforementioned operations, structure configurations are gradually optimized.

After the optimization converges, we determine a set of "non-dominance" candidates with Pareto frontiers. In the context of multi-objective optimization, these frontiers represent the set of all Pareto optimal solutions. Considering c_{res} and c'_{ir} as our objectives, a structure x^* is considered Pareto optimal if there does not exist another solution x such that $c_{res}(x) \leq c_{res}(x^*)$ and $c'_{ir}(x) \leq c'_{ir}(x^*)$ for both objectives and $(c_{res}(x^*), c'_{ir}(x^*))$ is strictly better than at least one objective than other structures.

As depicted in Fig. 6(b) with two axes c_{res} and c'_{ir}, scattering points represent gradual converging structure candidates toward D_{th}, and iterations are illustrated in white toward black dots. Among these candidates, the frontiers are identified in green lines to provide opportunities to best fit different design characteristics.

IV. EXPERIMENTAL RESULTS

The prediction accuracy of PGTransformer is examined compared with several prominent models, and then optimization results empowered by the model sustaining different power densities are discussed.

A. Model Accuracy Comparison

To validate flexibility of the proposed framework, we prepared five sets of data in different cell heights, top-metal mesh designs, and metal schemes in TSMC N3E and N2 process nodes. The designs are implemented in flip-chip package with $155um$ bump pitch and supply voltage is set to $0.75V$. Separate models are trained for each of these two nodes.

Proposed structure generator randomly generates 12000 structure samples, and 3600 samples are selected by MLHS at each set where ground truths are generated by sign-off tool Cadence *Voltus*. For one set, the pool generation and sampling are done in 10 minutes from efficient string manipulation depicted in Sec. III-A, and ground truth collection takes 118 hours with distributed 2500 machine CPUs. The dataset uses 3:1 to partition into training and validation sets, respectively.

The model is implemented in PyTorch and trained on NVIDIA RTX 3090 with batch size of 16. We employ Lion [3] as the optimizer and set the weight decay to $1e^{-2}$. To train PGTransformer, we adopt an initial learning rate of 0.0001 with a cyclic learning rate schedule [13] and training epoch is set to 2500. For model comparison, three model architectures in related works, U-Net, XGBoost, and LSTM are also implemented.

To properly utilize U-Net, PG patterns and target PD are converted to tile-based map as [5], and we employ a bi-directional LSTM to align with the two-layer encoder in PGTransformer. For XGBoost, we use linear booster, max depth 10, subsample 1, eta 0.1, and number of boost round 100 with same learning rate. The structure generator and Pareto frontier are implemented in TCL and Python with 24-core Intel Xeon CPUs at 2.7GHz, respectively.

Table. II shows the validation error comparison of predicted IR-drop percentages. Column "M_{top}" describes the top-mesh PG in either mesh or mixed with signal routes. Five metrics are used to measure the quality, mean absolute error (MAE), root mean square error (RMSE), mean absolute percentage error (MAPE), and Pearson correlation coefficient (CC) and passing rate (PR). The PR is defined as the percentage among entire validation set where the gap between predicted drop percentage and ground truth lies in defined constraint (0.1%, 0.05%, 0.03% over ideal supply voltage). Column "IT" describes model inference time on one structure.

It is clear that PGTransformer achieves smallest errors among different data scenarios. Through the sequence formulation, we further strengthen PGTransformer capturing temporal dependencies in variable-length layer features. This trait is particularly useful to understand inter-layer IR impacts with subtle pattern changes over XGBoost and U-Net, and LSTM with potential vanishing gradient problem.

In addition to the smallest loss compared with other models, Fig. 8 also shows better convergence during validation. As observed, PGTransformer consistently reaches converged and smallest loss after 500 epoch; however, XGBoost and LSTM even have worse loss before 1000 (500) epoch than U-Net in N2 (N3E).

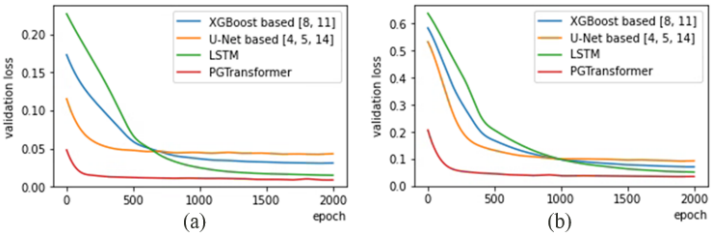

Fig. 8: Comparison of validation loss convergence between PGTransformer and prominent models in, (a) N3E 143H under 14M mixed M_{top}, and (b) N2 H130 under 16M mesh M_{top}.

B. Comparison with Well-Optimized Manual PG

To examine the effectiveness of structure optimization, the optimization framework is adopted on industrial designs compared with well-optimized manual works used in a N3E production and N2 test chip. The design statistics and target power density are summarized at left-hand side of Table III including high-speed CPU and power-efficient SoC IPs. Column "Period (ns)" denotes the target clock period, "CH" denotes adopted cell height, "PD" denotes target power density (mW/mm^2), "UR (%)" denotes initial floorplan utilization setup, "#Gates (10^6)" and "#Nets (10^6)" are total instance and net counts respectively.

We set base N3E IR threshold to 1.9% with PD 6000 and N2 1.7% over ideal supply voltage to align the objective of manual PG, and corresponding IR thresholds of other densities are scaled following Eqn. 1. Physical implementation with PGs are initiated with commercial tool Cadence *Innovus* in identical flow setup and adopt Synopsys *PrimeTime PX* to report power.

The right-hand side of Table III illustrates the circuit performance (QoR for short) comparison between manual PG and the optimized one achieving smallest WNS from Pareto frontiers. Column "$V_{ir}(\%)$" denotes reported drop percentage from *Voltus*, "$D_{mx}(\%)$ (D_{my})" denotes total PG metal density lower (above) `M5`, "Area (um^2)" denotes post-route cell area, DRC is routing violation count, and "Opt time (min)" depicts the time reaching an optimized PG. As shown in the table, after the optimization, a new structure is created with comparable IR-drop margin while releasing more routing resource and better timing. The framework also offers great efficiency improvement to facilitate global PG designs, where the Pareto optimization with presented sequence manipulation takes average 65 minutes to converge over 2–3 week manual efforts.

Through our optimization empowered by PGTransformer, the sign-off IR quality is closer toward the defined threshold for better trade-off between threshold constraint and resource utilization. For `design 5`, we even identify a solution satisfying the threshold than manual one. The generated structures with averagely comparable IR-drop margins use less PG resources of lower layers by 10% and upper layers by 21%, leading to better pin access and timing optimization. With more released routing

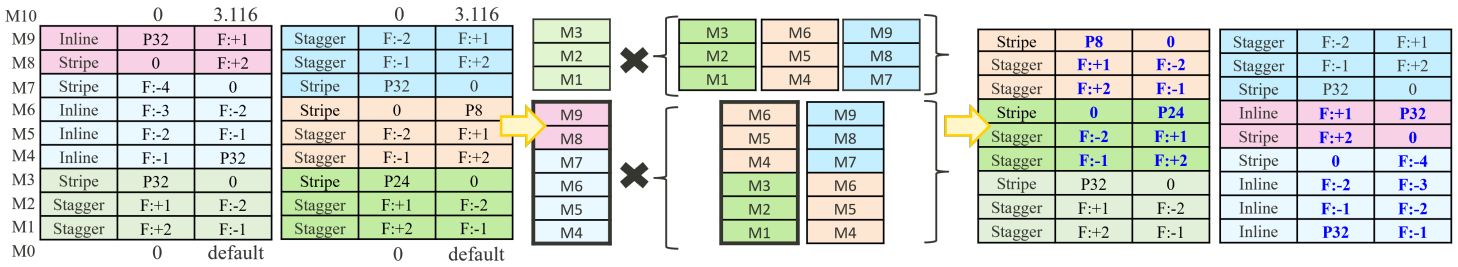

Fig. 7: Key structure crossover procedures used in modified NSGA-II to produce next generation.

TABLE II: Prediction accuracy comparison between PGTransformer and state-of-the-art models, showing PGTransformer better captures subtle structure changes. Note that it is inapplicable to compare exact models in previous works because the needed feature set and assumption (e.g., features only exist in dynamic IR analysis) are different. For fair comparison, key model architectures in related works are implemented with identical feature source.

resources, cell proximity has better chances to be closer and thus enables *Innovus* to conduct easier timing-slack improvement by 34%. In addition, the resource advantage further reduces usages of large driving cells with 0.5% smaller cell area.

V. Conclusions

We have proposed a unified framework to predict SIR drop and optimize global PG structures, with novel sequence-based structure representation. Through MLHS and direct pattern modeling into PGTransformer, the prediction well captures multi-layer interactions. In industrial designs, our model outperforms state-of-the-art models by average 51% MAE reduction and 29% error improvement under small tolerance. In addition, generated structures from Pareto-frontier optimization achieves 15% smaller PG utilization and 34% timing-slack improvement on average under defined drop threshold.

***Abstract*—The increasing complexity of integrated circuit design requires customizing Power, Performance, and Area (PPA) metrics according to different application demands. However, most engineers cannot anticipate requirements early in the design process, often discovering mismatches only after synthesis, necessitating iterative optimization or redesign. Some works have shown the promising capabilities of large language models (LLMs) in hardware design generation tasks, but they fail to tackle the PPA trade-off problem. In this work, we propose an LLM-based reinforcement learning framework, PPA-RTL, aiming to introduce LLMs as a cutting-edge automation tool by directly incorporating post-synthesis metrics PPA into the hardware design generation phase. We design PPA metrics as reward feedback to guide the model in producing designs aligned with specific optimization objectives across various scenarios. The experimental results demonstrate that PPA-RTL models, optimized for Power, Performance, Area, or their various combinations, significantly improve in achieving the desired trade-offs, making PPA-RTL applicable to a variety of application scenarios and project constraints.**

***Index Terms*—Hardware generation, PPA, Reinforcement learning.**

I. Introduction

With the broader application of Integrated circuits (ICs) in various scenarios, IC design requirements have become increasingly diverse [1]. Different applications demand tailored Power, Performance, and Area (PPA) metrics, often resulting in designs that fulfill similar functions but with vastly different optimization priorities. For instance, high-performance computing prioritizes performance over power efficiency, while IoT devices are susceptible to power consumption.

The diversity of design requirements presents challenges for hardware engineers. Hardware designs are described at the behavioral or Register Transfer Level (RTL), focusing on functional logic, while customized PPA optimization requires physical implementation with precise layout, routing, and cell library. Engineers begin with high-level hardware designs and then leverage Electronic Design Automation (EDA) tools for logic synthesis [2], verification [3], layout and routing [4], and timing analysis [5]. By defining appropriate constraints, fine-tuning tool settings, and adjusting outputs, they strive to meet the stringent power, performance, and area demands of modern ICs. However, these EDA tools are expertise-driven, raising the entry barriers for circuit design. Most engineers cannot anticipate requirements early in the design process, often discovering mismatches only after synthesis, necessitating iterative optimization or redesign. Thus, creating a PPA-oriented hardware design generation tool can greatly improve development efficiency.

With the advent of ChatGPT, its powerful natural language processing capabilities have brought new perspectives to many fields [6], making large language models (LLMs) a highly promising automation tool. In the field of hardware design generation, several studies [7]–[10] have shown that LLMs can autonomously produce hardware designs that are both syntactically and functionally accurate, offering convenience to hardware engineers. However, these models fail to consider the practical applicability of designs across different scenarios. To integrate post-synthesis metrics with the generation model, we aim to construct a hardware generation LLM with high flexibility.

LLM research technologies include prompting engineering, supervised fine-tuning (SFT), and Reinforcement Learning from Human Feedback (RLHF). Prompting methods rely on commercial general-purpose LLMs, struggling with the hallucination problem in general LLMs [11]. SFT typically enhances an LLM's performance by training the model to mimic behaviors on domain-specific datasets, but it falls short of meeting specific needs in specialized scenarios, such as generating hardware designs that align with PPA preferences tailored to specific application requirements. Moreover, SFT is highly data-intensive [12], requiring datasets of over $10,000$ examples to induce noticeable shifts in model behavior. Constructing such large-scale datasets for a specific scenario is nearly impossible, making it challenging to achieve tailored optimization using SFT alone. RLHF optimizes model behavior by incorporating human feedback and reinforcement learning (RL), which helps mitigate hallucinations [13] and reduces the need for large-scale datasets, typically requiring only a few thousand samples focused on quality rather than quantity.

In this work, we leverage RLHF-based LLM technology to generate hardware designs that better suit the diverse needs of real-world applications. We design PPA metrics as rewards, enabling the model to iteratively adjust its parameters based on feedback. Through continuous updates to its policy, the model progressively optimizes outputs to align with specific PPA preferences. However, this process faces two challenges: **(C1)** The complex trade-off between power, performance, and area typically demands sophisticated strategies and human intervention, while RL needs to formally represent these trade-offs in the reward feedback to meet different PPA objectives. **(C2)** Performing PPA calculations in every iteration would significantly slow down the model training process, as generating PPA evaluation feedback requires logic synthesis and simulation, which are computationally intensive steps that consume significant time and resources. One solution is to use machine learning (ML)–based models to approximate PPA metrics, which address real-time concerns but may lack precision. Another approach separates PPA calculations from model training by creating an offline PPA metric dataset, which balances computational demands with real-time requirements.

To overcome these challenges, we propose the PPA-RTL framework, which constructs an offline dataset of *Function Description*⇔*Reference Code* pairs with PPA metrics and introduces a PPA weighted formula to represent optimization rewards across diverse scenarios. Integrating PPA into the hardware generation process through RL allows models to more effectively navigate the complex trade-offs in hardware design, such as balancing chip performance and power consumption or optimizing the layout to reduce area without compromising functionality.

The main contributions are outlined as follows:

1) For the first time, we optimize key post-synthesis metrics, PPA, in

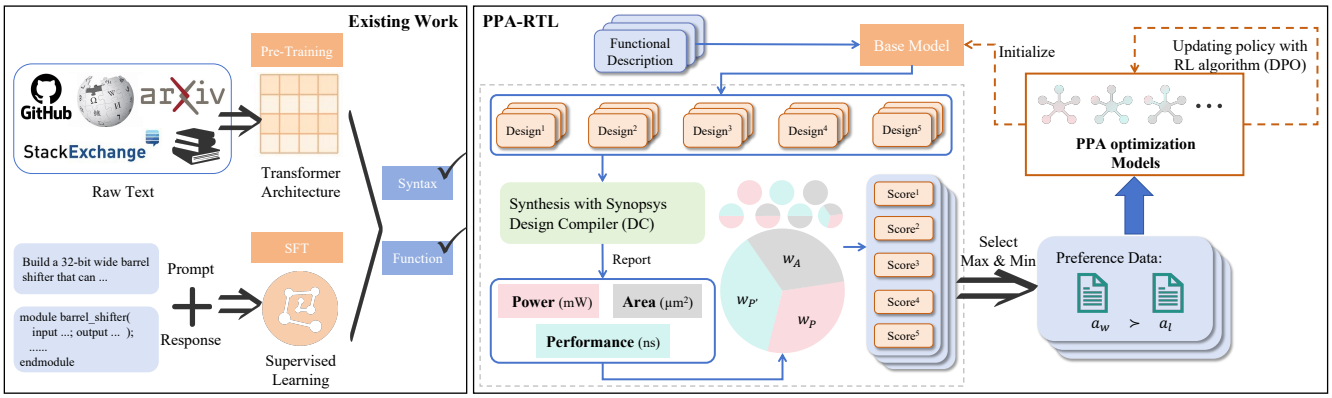

Fig. 1: PPA-RTL Framework. Existing hardware code generation LLMs primarily focus on two training methods (Pre-Training and SFT) to acquire syntactic and functional correct output. The PPA-RTL framework focuses on post-synthesis PPA metrics to enhance hardware generation quality. It first extracts PPA values from the Power, Performance, and Area synthesis report generated by RTL synthesis tools for each design. Adjusting the weights of PPA generates various preference datasets that adapt to different PPA preferences, thereby obtaining hardware code generation LLMs guided by different PPA preferences.

the context of hardware code generation using LLMs. We develop an RL-based hardware generation framework, named **PPA-RTL**, that directly integrates PPA considerations into the design process, allowing users to prioritize one or more of these metrics based on specific project requirements.

2) We configure various optimization objectives to reflect the common trade-offs in real-world hardware designs, such as Power-only, Performance-only, Area-only, and their combinations (e.g., Power & Performance, Power & Area, Performance & Area, and Power & Performance & Area). The experimental results demonstrate that PPA-RTL models significantly enhance the ability to achieve desired trade-offs, making PPA-RTL adaptable to a range of application scenarios and project constraints. Compared to the SFT-only model, the SFT-RL-PPA model improves Power by an average of 20.97%, Performance by 14.68%, and Area by 29.05%.

II. Background and Related Work

A. LLMs for Hardware Code Generation

As early as 2020, the hardware field began experimenting with fine-tuned GPT-2 models for generating hardware designs from natural language. DAVE [14] demonstrated the potential of language models in automated hardware design. However, DAVE has notable limitations: difficulties with complex, multi-task instructions, limited generalization to tasks outside its training templates, and a restriction on output length (1024 tokens).

After OpenAI released ChatGPT in 2022, it quickly attracted many researchers, sparking studies on the hardware domain, primarily focusing on two research methods: Prompt-based and SFT. Prompt-based methods [10], [15]–[17] guide advanced general-purpose LLMs to perform tasks within the hardware domain by providing domain-specific knowledge as prompts, relying on powerful commercial models like GPT-4 [6] and Claude [18]. However, the inability to modify these closed-source commercial models makes it difficult to address hallucination issues, particularly in the hardware domain [19]. SFT methods [8], [9], [20]–[22] train LLMs on hardware-specific datasets consisting of functional descriptions and corresponding hardware code to achieve higher syntactic and functional accuracy. However, generating codes is only the first step in the IC design process, which must also undergo logical synthesis, layout and routing, timing analysis, and physical verification. In these stages, the post-synthesis metrics PPA directly impact the chip's efficiency, speed, and cost. While SFT-based models can generate syntactically correct hardware designs, they do not account for post-synthesis metrics, limiting their practical applicability.

B. Reinforcement Learning from Human Feedback

In standard RLHF workflow, an LLM is modeled as a policy π, which takes a prompt $x \in \mathcal{X}$ and generates a response $a \in \mathcal{A}$ from the distribution $\pi(\cdot|x)$. The initial model, π_0, is typically fine-tuned on instruction-following data after pre-training [23]. The central idea of RLHF is to train the model using *relative feedback*, rather than relying on an absolute reward signal commonly used in traditional RL. It addresses the challenge that human evaluators often struggle to provide consistent absolute ratings but tend to be more reliable when tasked with comparing two responses and selecting the preferred one [24]. To formalize preference feedback, we introduce the concept of *Preference Oracle*.

Definition 1 (Preference Oracle). A preference oracle $\mathbb{P} : \mathcal{X} \times \mathcal{A} \times \mathcal{A} \to [0, 1]$ is a function that, when queried with a prompt x and two candidate responses a^1 and a^2, returns a preference signal. Specifically, we can sample a binary outcome y from the Bernoulli distribution $\text{Ber}(t)$: $y \sim \text{Ber}\left(\mathbb{P}\left(a^1 \succ a^2 | x, a^1, a^2\right)\right)$, if $y = 1$, it indicates that a^1 is preferred over a^2; if $y = 0$, it indicates that a^2 is preferred.

To simplify the learning process, it is often assumed that human preferences can be modeled using the Bradley-Terry (BT) model, a widely-used framework in preference learning [25].

Definition 2 (Bradley-Terry Model). Assume the existence of a ground-truth reward function r^*. Given two options a^1 and a^2, the preference probability is calculated using a sigmoid function, which reflects the difference in reward values between the two options. Specifically, the probability of preferring a^1 over a^2 given prompt x is modeled as: $\mathbb{P}(a^1 \succ a^2 | x, a^1, a^2) = \sigma(r^*(x, a^1) - r^*(x, a^2))$, where $\sigma(z) = \frac{1}{1+\exp(-z)}$ is the sigmoid function, which maps the difference in reward values to a preference probability.

Although the BT model may not fully capture the complex human preference, it provides a reasonable approximation and has proven to play a critical role in the development of ChatGPT [6] and Claude [18] by combining RLHF with reward maximization.

III. Methodology

We propose the **PPA-RTL** framework, which leverages RL to incorporate feedback from post-synthesis PPA metrics, enabling LLMs to generate hardware designs adaptable to various optimization objectives. PPA-RTL addresses the limitations of existing hardware code generation LLMs, which primarily focus on syntactic and functional correctness. It aims to improve the quality of hardware generation and ensure that the generated designs meet specific physical scenarios.

A. Motivation

LLMs are initially pre-trained on extensive universal datasets, equipping them with understanding ability. Then, the pre-trained LLM was fine-tuned on a specific task, which is IC design here, to become a domain expert. However, achieving optimal performance in real-world IC design involves navigating complex trade-offs among PPA. Decisions, such as prioritizing power efficiency over performance or balancing area constraints with power demands, require sophisticated decision-making, which labeled data cannot fully address. Therefore, SFT, which relies on labeled data, can not handle the flexible optimization to achieve PPA requirements. This leads to our first challenge: **(C1)** *How can we design a flexible framework that accommodates different PPA requirements?*

A straightforward approach for guiding LLMs in meeting diverse PPA requirements is to align models with preference via RL. Unfortunately, real-time PPA computing contradicts the overhead of LLM training, which raises our second challenge: **(C2)** *How can we avoid real-time evaluation to reduce the time delay during LLM training?*

B. PPA-RTL Framework

To construct PPA-oriented flexible hardware generation LLMs, we propose the PPA-RTL framework, which incorporates PPA metrics into the hardware code generation stage to target different application optimization objectives, as shown in Fig. 1. We address two challenges as follows.

Challenges 1 (C1) Different applications require tailored optimization strategies to balance power, performance, and area, while a single optimization strategy cannot meet the requirements of various applications. PPA-RTL needs to formally represent these trade-offs in the reward feedback to effectively guide model parameter updates.

To address **(C1)**, PPA-RTL formulates the hardware design generation as an RLHF workflow, denoted by $\langle \pi, \mathcal{X}, \mathcal{A}, \mathbb{P} \rangle$. **Policy** π represents a hardware design generation model, with the base model denoted as π_{ref}. **Prompt set** $\mathcal{X}$**:** Each prompt $x \in \mathcal{X}$ represents a functional description. **Response set** $\mathcal{A}$**:** The response $a \in \mathcal{A}$ is generated design from the distribution $\pi(\cdot|x)$. **Preference model** $\mathbb{P}\left(a^1 \succ a^2 | x, a^1, a^2\right)$ provides a relative preference signal for multiple generated designs under a specified PPA optimization strategy. In PPA-RTL, we sample k designs from the base model for each functional description x in the set $\mathcal{X}$. RTL synthesis tool then performs logic synthesis and simulation, resulting in reports about power, timing, and area. By specifying an optimization strategy, comparing PPA values, and selecting better & worse designs, the model's policy is updated using an RL algorithm to align outputs more closely with the desired PPA strategy.

To accommodate various applications, we implement a flexible approach that adjusts the weights $w_P, w_{P'}$, and w_A for each objective to simulate the priority of PPA metrics across different applications. The preference dataset is then created by selecting better or worse designs based on the scoring function $s(x, a)$.

$$s(x,a) = -\left(w_P \times v'_P + w_{P'} \times v'_{P'} + w_A \times v'_A\right)$$

where v'_P (resp. $v'_{P'}$, v'_A) represents the normalized value of power (resp. performance, area) extracted from the post-synthesis reports. The non-negative hyperparameters $w_P, w_{P'}$, and w_A can be adjusted to satisfy different PPA requirements. The negative sign indicates that the objective is to minimize these metrics: lower power consumption, higher frequency (lower critical path delay), and smaller area.

Challenge 2 (C2) Acquiring PPA values of design requires using time-consuming and computationally intensive EDA tools for synthesis, simulation, and analysis. Each update requires performing these steps, resulting in the inability to obtain real-time feedback during model training. To bridge hardware design synthesis and model training, approximate evaluation and pre-generated offline PPA datasets provide promising methods. For the approximate method, training an ML-based approximation model to predict PPA values can quickly provide PPA estimates, but it has limitations in accuracy and reliability. The cumulative error of the approximate model combined with the randomness in LLM generation creates a dual source of error, which may cause the model to gradually deviate from the optimal solution during training, leading to designs that do not meet expectations. For offline PPA datasets, using pre-generated data directly during training eliminates the intermediate steps of generating PPA values each time, simplifying the training process. The offline approach also allows for more accurate model optimization, as the dataset is already precisely calculated through EDA tools, avoiding the prediction errors associated with approximate models.

To address **(C2)**, we construct an offline dataset with PPA values for the training process by employing an EDA tool to map hardware designs into gate-level netlists. The synthesis process generates three key reports—power, timing, and area—which collectively capture the physical and performance characteristics of the design.

1) ***Power Estimation****:* Power estimation includes dynamic power from switching activity and static power dissipated by transistors without activity, providing an essential view into the design's energy efficiency, expressed in milliwatts (mW).

2) ***Performance Estimation****:* Performance is measured by the number of operations executed per unit of time. Increasing the frequency reduces the clock period, allowing the design to perform more operations within the same time frame, thereby improving overall system performance. The maximum frequency (f_{max}) is inversely related to the critical path delay, as expressed by the formula: $f_{\text{max}} = 1/critical_path_delay$. Therefore, performance can be quantified by the critical path delay (measured in nanoseconds, ns): the smaller the critical path delay, the higher the frequency, and thus, the better the overall performance.

3) ***Area Estimation****:* The total cell area is the physical area required by the synthesized design, including contributions from combinational logic, sequential elements, buffers/inverters, and other components. It reflects the cumulative area of all logic cells mapped from the technology library, measured in square micrometers (μm^2), ensuring the design fits within layout constraints.

C. PPA-RTL Training

In Algorithm 1, training the PPA-RTL model begins with the preference dataset generation, followed by the training phase. We leverages the Direct Preference Optimization (DPO) [26] to update the policy π_θ.

In the preference dataset generation stage (lines 2-13), for each functional description $x \in \mathcal{X}$, the reference model π_{ref} generates k candidate code samples. The samples that pass the synthesis check are collected in the candidate code set A. From set A, the best and worst samples, denoted as a_w and a_l respectively, are identified based

TABLE I: **Optimization objectives setting:** seven common trade-offs in real-world hardware design. **Preference dataset generation:** the valid subsets generated by $3,000$ function descriptions on the base model, excluding unsynthesizable and non-differentiated outputs. **Model training:** loss and accuracy metrics during model training based on different training strategies (RL-only and SFT-RL).

Optimization objectives	Weights			Preference dataset size ($\|\mathcal{D}\|$)	RL-only		SFT-RL	
	w_P	$w_{P'}$	w_A		Accuracy	Loss	Accuracy	Loss
Power-Only (Power)	1	0	0	1966	0.8375	0.5352	1.0	0.0322
Performance-Only (Perf)	0	1	0	1827	0.8375	0.5356	1.0	0.0540
Area-Only (Area)	0	0	1	1936	0.8250	0.6148	0.9875	0.0408
Power and Performance (PP)	1/2	1/2	0	1808	0.7625	0.5595	1.0	0.0610
Power and Area (PowerA)	1/2	0	1/2	1927	0.8625	0.5454	1.0	0.0410
Performance and Area (PerfA)	0	1/2	1/2	1813	0.7875	0.5750	1.0	0.0683

16: $\mathcal{L}_t(\pi_\theta) \leftarrow -\log \sigma \left(\beta \log \frac{\pi_\theta(a_w|x)}{\pi_{\text{ref}}(a_w|x)} - \beta \log \frac{\pi_\theta(a_l|x)}{\pi_{\text{ref}}(a_l|x)}\right)$
17: Update π_θ via gradient descent on $\mathcal{L}_t(\pi_\theta)$
18: $\pi^*_\theta \leftarrow \pi_\theta$
19: **return** π^*_θ

on the scoring function $s(x, a_i)$ and stored in the preference dataset $\mathcal{D}$ in the form of preference tuples (x, a_w, a_l).

In the training phase (lines 14-17), the model π_θ undergoes T iterations of optimization. The implicit reward function $r^*_\theta(x, a) = \beta \log \frac{\pi_\theta(a|x)}{\pi_{\text{ref}}(a|x)}$ represents the preference of the current model relative to the reference model for a given prompt-response pair. In each iteration, the loss function $\mathcal{L}_t(\pi_\theta)$ optimizes the model by maximizing the likelihood of preferred data a_w and minimizing the likelihood of non-preferred data a_l through the difference $r^*(x, a_w) - r^*(x, a_l)$ Gradient descent is used to update the model parameters iteratively. The resulting model π^*_θ can generate optimized hardware designs that align with learned preferences.

IV. Experiments

In this section, we validate the integration of RL with PPA metrics to enhance the capability of hardware code generation LLMs in meeting diverse real-world application physical demands.

A. Experimental Setup

PPA-RTL is implemented on a Linux machine with eight A100 80GB GPUs. We consider two code generation models as baselines, Deepseek-coder [27] and RTLCoder [21]. Deepseek-coder is an open-source code generation model closest to GPT-4-Turbo. RTLCoder is an open-source hardware code LLM based on Deepseek-coder with supervised fine-tuning. We use two versions of these models, Deepseek-coder-6.7b (Original) and RTLCoder-DeepSeek-6.7b (SFT-only), thereby exploring two distinct training strategies: 1) **RL-only**: Direct reinforcement training using the Deepseek-coder-6.7b model (Original). 2) **SFT-RL**: Reinforcement training based on supervised fine-tuning RTLCoder of the original model. Additionally, to demonstrate the applicability of our PPA-based RL approach to various PPA scenarios, Table I designs seven optimization objectives that reflect the common trade-offs of real-world hardware design.

B. Dataset Generation

To acquire PPA-oriented preference datasets, we leverage Synopsys Design Compiler (DC) [28] with the TSMC 90nm CMOS technology library to synthesize designs and adjust the weights of PPA based on different optimization objectives in Table I. Specifically, we sampled $3,000$ (*Function Description⇔Reference Code*) pairs from the RTLCoder dataset [29]. Function descriptions were inputs for two base models, Deepseek and RTLCoder, to generate multiple hardware designs. For each function description, we construct five hardware designs, including generated and reference code, and synthesize these designs. Samples that failed to generate synthesizable designs were filtered out. By analyzing the resulting Power, Timing, and Area reports, we extracted power (mW), critical path delay (ns), and area (μm^2). Based on different optimization objectives, calculate scores for each design, filter out samples with no score differences, and then select the maximum and minimum values to construct seven distinct chosen-rejected preference datasets.

C. Model Training

We employ DPO to train PPA-RTL hardware generation LLMs. DPO simplifies the traditional complexities of RLHF by leveraging the best and worst selected responses to directly optimize the model's predictive capabilities. Table I shows the training loss and reward accuracy for models trained with two strategies: RL-only and SFT-RL. $Loss$ quantifies the discrepancy between the model's predictions and the preferred outcomes, with lower values indicating closer alignment with preferences. $Accuracy$ shows the proportion of predictions that match the preferred outcomes, with higher values indicating better alignment with the target preferences. The SFT-RL exhibits lower loss and higher accuracy across all optimization objectives, indicating that SFT-based RL leads to more stable performance compared to RL-only.

D. Experimental Evaluation

To evaluate the effectiveness of PPA-RTL models in improving various optimization objectives, we utilize the RTLLM-v1.1 benchmark [30] to generate designs for each example using the advanced

TABLE II: PPA evaluation results. The **Original** refers to the DeepSeek-Coder-6.7B model, while the **SFT-only** is a supervised fine-tuned model based on DeepSeek-Coder-6.7B specifically for hardware code generation. **Metrics Power**, **Perf**, and **A** represent power (mW), performance (ns), and area (μm^2), respectively. Each row corresponds to a hardware design from the RTLLM benchmark. **Green** squares show better metric than the original model, while **red** squares show worse metric. The SFT-RL models are significantly better than RL-only models in PPA improvement compared to the base model.

general-purpose language model GPT-4o [31] and 14 models trained through RL-only and SFT-RL methods. These generated designs were synthesized with DC and evaluated based on power consumption, performance, and area. Table II shows evaluation results.

- **Lack of Sensitivity to PPA in Existing Models:** Compared to the original model, the current state-of-the-art model GPT-4o lacks effective optimization for these critical post-synthesis metrics, and the existing supervised fine-tuning hardware generation model SFT-only has limitations in achieving comprehensive performance improvements.
- **Trade-offs Between Metrics:** Optimizing a single metric can negatively impact others. Focusing on power metric, RL-only and SFT-RL models optimized for power (Power, PP, PowerA, and PPA) show significant improvements compared to models that prioritize only area or performance (Area, Perf, and PerfA) at the expense of power.
- **Balanced Optimization Across Metrics:** By comprehensively considering all metrics, the (SFT-)RL-PPA models demonstrate superior performance in both training strategies. The SFT-RL-PPA model improves Power by 20.97%, Performance by 14.68%, and Area by 29.05%, on average compared to the SFT-only model.
- **Design Quality Improvements with RL-based Training:** RL-based training using PPA metrics effectively improves hardware code generation quality. Moreover, the SFT-RL models show more significant performance improvements than RL-only models, with more green cells across a broader range of objectives.

Fig. 2 provides a detailed comparison of the Area and Power changes between the RL-Power model and its original model,

TABLE III: The PPA values for the calendar task based on SFT-only model and SFT-RL-PPA model. Performance is represented by the critical path delay.

Model	Power (mW)	Performance (ns)	Area (μm^2)
SFT-only	1.5884	0.29	536.9616
SFT-RL-PPA	1.4871	0.26	496.0368

Deepseek, for the designs generated on the RTLLM benchmark. The RL-Power model reduces power consumption without significantly increasing area, showcasing its ability to balance power and area trade-offs effectively.

E. Case Study

In this case study, we provide a detailed analysis of the designs generated by the PPA-RTL models before and after optimization, using the design of a `calendar` module as an example. The `calendar` module has two inputs: `CLK` (clock) and `RST` (reset). It includes three variables: `Secs`, `Mins`, and `Hours`, all initialized to zero. Each clock cycle, `Secs` increments by one. When `Secs == 59`, `Mins` increments, and `Secs` resets. When both `Secs == 59` and `Mins == 59`, `Hours` increments, and both `Secs` and `Mins` reset. This cycle continues until `Hours == 23`, `Mins == 59`, and `Secs == 59`, after which all values reset.

Table III compares the PPA values of the `calendar` designs generated by the SFT-RL-PPA model and its base model SFT-only model. Through RL targeted at Power & Performance & Area, the SFT-RL-PPA model effectively balances power, performance, and area requirements. To further analyze model differences, Table IV provides the designs generated by both models.

TABLE IV: The calendar module designs generated by SFT-only model and SFT-RL-PPA model.

SFT-only model

```
always @(posedge CLK or posedge RST)
       begin
   if (RST) begin Secs <= 6'b0; end
   else if (Secs == 6'd59) begin Secs
          <= 6'b0;end
   else begin Secs <= Secs + 1; end
end
always @(posedge CLK or posedge RST)
       begin
   if (RST) begin Mins <= 6'b0; end
   else if (Mins == 6'd59 && Secs ==
         6'd59) begin Mins <= 6'b0;
          end
   else if (Secs == 6'd59) begin Mins
          <= Mins + 1; end
end
always @(posedge CLK or posedge RST)
       begin
   if (RST) begin Hours <= 6'b0; end
   else if (Hours == 6'd23 && Mins ==
         6'd59 && Secs == 6'd59)
         begin Hours <= 6'b0; end
   else if (Mins == 6'd59 && Secs ==
         6'd59) begin Hours <= Hours
         + 1; end
end
```

SFT-RL-PPA model

```
always @(posedge CLK or posedge RST)
       begin
   if (RST) begin Secs <= 0; Mins <=
         0; Hours <= 0; end
   else begin
      if (Secs == 59) begin
      Secs <= 0;
         if (Mins == 59) begin
            Mins <= 0;
            if (Hours == 23) begin
                  Hours <= 0; end
            else begin Hours <= Hours
                  + 1; end end
         else begin Mins <= Mins + 1;
               end
      end else begin Secs <= Secs +
            1; end
   end
end
```

The SFT-only model uses three separate `always` blocks to manage updates for seconds, minutes, and hours, respectively. The processing logic for different time units is separated, enabling the logic clearer and the code easier to manage and expand. However, since the time units are scattered in different `always` blocks, potential race conditions may arise due to execution order. For example, updating `Secs` to zero might occur slightly before updating `Mins`. This brief delay could result in the minute and hour logic not detecting `Secs` as 59 in a given instant, preventing the intended increment. During logical synthesis, we observe this change that `Hours[0]` and `Mins[0]` are at $0.29ns$ on critical path delay, while `Secs[0]` is at $0.28ns$. The SFT-RL-PPA model updates of `Secs`, `Mins`, and `Hours` are completed in the same logical condition, and their updates are synchronized with each other. When `Secs` reaches 59 and resets to 0, `Mins` and `Hours` are updated within the same clock cycle. Concentrating the update logic within a single block reduces potential jitter caused by signal propagation between different `always` blocks, ensuring the atomicity of the update operations and avoiding potential race conditions.

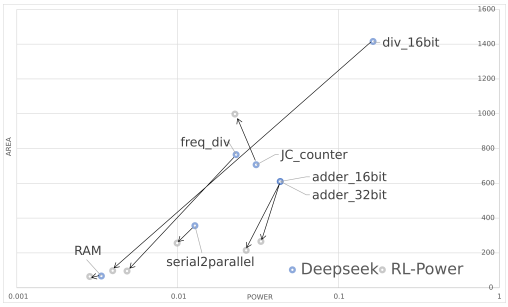

Fig. 2: The comparison of power and area between **Deepseek** (original model) and **RL-Power** (RL model based on Deepseek, optimized for Power) in RTLLM benchmark. The **x-axis** represents power consumption, and the **y-axis** represents area. Arrows indicate the performance shift from the original model (blue) to the RL-Power optimized model (gray) for the same design.

TABLE V: The Syntax and Function accuracy on the RTLLM-v1.1 (pass@5) between the SFT-only model and SFT-RL models.

		SFT-only	SFT-RL					
			Power	Perf	Area	PP	PowerA	PerfA	PPA
RTLLM-v1.1	Syn.(%)	93.1	93.1	96.6	89.6	93.1	86.2	96.6	93.1
pass@5	Func.(%)	48.3	48.3	44.8	41.4	44.8	44.8	48.3	41.4

V. Discussion

Although the PPA-RTL framework effectively achieves optimization goals tailored to different application scenarios, it is essential to evaluate whether integrating PPA into the hardware generation model affects the original model's code generation accuracy. We assess the syntactic and functional accuracy of the SFT-RL-based models on the RTLLM benchmark. Table V compares the SFT-RL models with its base model SFT-only. For syntactic accuracy, the SFT-RL models maintain the same or higher accuracy across five optimization objectives, as syntactically incorrect designs were filtered when selecting preference data based on PPA values, which benefits syntactic correctness. Two models retain their original accuracy levels for functional accuracy, while the other five models show a slight decrease of less than 7%. Overall, PPA-RTL can maintain the original model's accuracy within a limited error.

VI. Conclusion

In this paper, we propose PPA-RTL, a novel approach to align hardware code generation LLMs with variable power, performance, and area requirements. In experimental evaluation, PPA-RTL demonstrates significant improvements compared to traditional LLM-based hardware design, providing a flexible framework for balancing performance, efficiency, and resource usage. Our work paves the way for more adaptive, efficient, cost-effective IC design automated processes.

BS-PDN-Last: Towards Optimal Power Delivery Network Design With Multifunctional Backside Metal Layers

Min Gyu Park, Amaan Rahman, Sung Kyu Lim
School of ECE, Georgia Institute of Technology, Atlanta, GA
mgpark@gatech.edu

***Abstract*—The increasing demand to maximize PPA gains with backside metal layers has driven their function beyond power delivery. This study introduces a novel BS-PDN-last flow, crucial for leveraging multifunctional backside, by deferring power routing to the post-signal routing stage. This approach addresses the IR-drop and performance trade-offs inherent in conventional PDN-first flows. Experimental results show that the BS-PDN-last flow achieves a 90% reduction in Total Negative Slack and a 12% performance gain with BS-CDN. Additionally, our work presents the first comprehensive comparison of FS-PDN, BS-PDN, and multifunctional backside designs, evaluated on both physical design and workload metrics leveraging accurate vector-based analysis.**

I. Introduction

As CMOS technology scales down, increasing resistance in the frontside metal layers has led to a substantial IR-drop. The Backside Power Delivery Network (BS-PDN) has emerged as a promising solution, incorporating thicker and less resistive backside metals beneath the silicon substrate. Furthermore, backside power delivery is motivated to decouple the PDN from frontside signal and clock routes, improving power integrity and system performance due to improved frontside routability.

However, backside process incurs additional costs due to advanced processing such as wafer thinning and nano-Through Silicon Vias (nTSVs) formation [4]. To offset these costs, there is an increasing demand to leverage backside metal resources for maximizing Power, Performance, and Area (PPA) gains. For instance, recent research efforts push towards the integration of Backside Clock Delivery Network (BS-CDN) [2] and Backside Signal Routing (BSS) [5]. These studies focus on maximizing the potential of backside metals by extending their function beyond power delivery. However, they adhere to the conventional PDN-first flow, wherein BS-PDN is implemented initially, leaving BS-CDN and BSS to be deployed in the remaining regions. This approach induces substantial disruption of cell placement due to design rule violations encountered during the conversion of frontside cells to the backside, shown in Fig. 1-(a).

For the first time, we investigate the optimal sequence of design steps to maximize the benefit of multifunctional use of backside metal layers. We introduce a novel BS-PDN-last flow, which postpones P/G routing after the completion of frontside clock and signal routing as well as backside clock routing. By positioning P/G routing in the later stages, the BS-PDN-last breaks down the inherent trade-off between IR-drop and performance gain on the conventional PDN-first flow, demonstrating up to an 88% reduction in Total Negative Slack. Furthermore, we offer a comprehensive comparison of frontside only, backside with PDN only, and multifunctional backside designs, assessed through both physical design and workload metrics using precise vector-based analysis. The BS-PDN-last flow with BS-CDN achieves a 16.1% improvement in performance and an 18.9% increase in energy efficiency on the ResNet-50 workload compared to the frontside-only design.

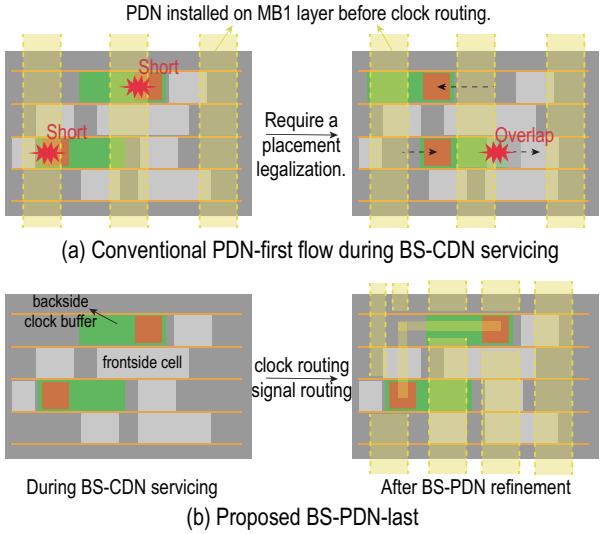

Fig. 1: Comparison between PDN-first and BS-PDN-last flows: The conventional PDN-first flow triggers substantial placement legalization to resolve short between PDN and nTSVs as well as cell overlap. However, BS-PDN-last maintains optimal cell positions with maximization of PDN.

II. Related Work and Shortcoming

Backside Clock Delivery Network was initially presented in [2], [8]. The approach involves building the clock tree on the frontside first, then converting selected clock buffers into backside buffers. This method employs a paired-buffer strategy, as illustrated in Fig. 2-(a): backside-out buffers transfer the clock signal from the frontside to the backside, while backside-in buffers route the clock from the backside to the frontside. To achieve this, nano-TSVs are employed on the output and input pins, respectively, within each cell. They revealed that combining BS-CDN with BS-PDN provides performance improvements of 8.7% in one benchmark. However, the performance gains were marginal in other benchmarks, achieving only 1.3% and 2.8% improvements, respectively. This failed to deliver improvements compelling enough to offset the increased costs of backside integration, raising concerns about whether successful improvements can be achieved in industrial-scale designs. We also face similar challenges when using the PDN-first flow with BS-CDN as shown in Table II.

III. Problem Formulation and Benchmark

A. Problem Formulation

The conventional PDN-first flow employed in prior work [2] follows the sequence of backside power routing, frontside clock construction, backside clock servicing, clock routing, and frontside

signal routing. In scenarios where backside metal layers are utilized for multiple purposes, our goal is to determine the optimal sequence of each step to maximize the benefits of backside integration for both performance and IR drop.

B. Benchmark Architectures

We evaluate the impact of BS-PDN-last flows using the Rocket Chip, an open-source processor, and the Gemmini SoC, a DNN accelerator system, along with a simple pure logic AES benchmark.

The Rocket Chip [1], a RISC-V CPU generator, provides a complete SoC RTL with support for CPU cores, a memory system interfacing with L2 cache, MMIO peripherals, and a DMA device. The specific configuration used in this study includes a dual-core setup, with each Rocket Core featuring a 5-stage in-order scalar processor, along with 16kB L1 data cache and 16kB L1 instruction cache.

The Gemmini project [3] offers a reconfigurable full-stack platform that integrates the DNN accelerator Gemmini, a CPU, and a L2 cache, enabling comprehensive system-level analysis. This platform not only generates hardware RTL for given configurations but also enables workload simulation, providing instance-level toggle rates and total cycle counts. For this study, we utilized a Gemmini accelerator configured with a 16x16 systolic array comprising a 4x4 tile and 4x4 mesh, a 4-bank 128kB scratchpad, a 2-bank 64kB accumulator, a Rocket single core with 16kB L1 data cache and 16kB L1 instruction cache, and a 128kB L2 cache.

IV. Backside PDN-last Flow

A. Motivation

With the conventional PDN-first flow, the conversion of frontside buffers to backside requires careful consideration of Power/Ground (P/G) straps on Backside Metal layer 1 (MB1), as shown in Fig. 2-(b). They can cause a P/G-to-clock short if any overlap happens between MB1 P/G straps and nano-TSV in the backside buffer. Additionally, backside buffers have a longer width than frontside buffers due to the presence of the nano-TSV. This can potentially lead to overlaps with adjacent cells if the back buffer is placed in its original front buffer position, as illustrated in Fig. 2-(c). To address potential design rule check (DRC) violations within a PDN-first flow, Algorithm 1 legalizes cell placement with minimal displacement. Recognizing that relocating adjacent cells facilitates DRC resolution, the algorithm allows the movement of both BS cells and surrounding cells. This is achieved by employing an advanced legalizer option with the *place* status set for all cells, excluding those on timing-critical paths.

However, such an approach can significantly disrupt the original clock tree structure. The impact becomes more pronounced with higher BS-PDN utilization, as shown in Table I: with a 70% BS-PDN utilization in a PDN-first flow, backside clock buffer displacement reaches up to 4.13 μm, equivalent to a vertical shift of approximately 35 rows. Such substantial alterations to the clock tree structure degrades the performance compared to the design without BS-CDN. Furthermore, even with 50% PDN utilization, the effectiveness of backside clock routing is reduced compared to a BS-CDN implementation without PDN. This result reveals the following insights: (1) The PDN-first flow obstructs backside buffer conversion, potentially leading to suboptimal performance or performance degradation. (2) The PDN-first flow introduces a trade-off between IR-drop reduction and performance gain, depending on PDN utilization. This trade-off arises because higher PDN utilization increases interference but reduces IR-drop.

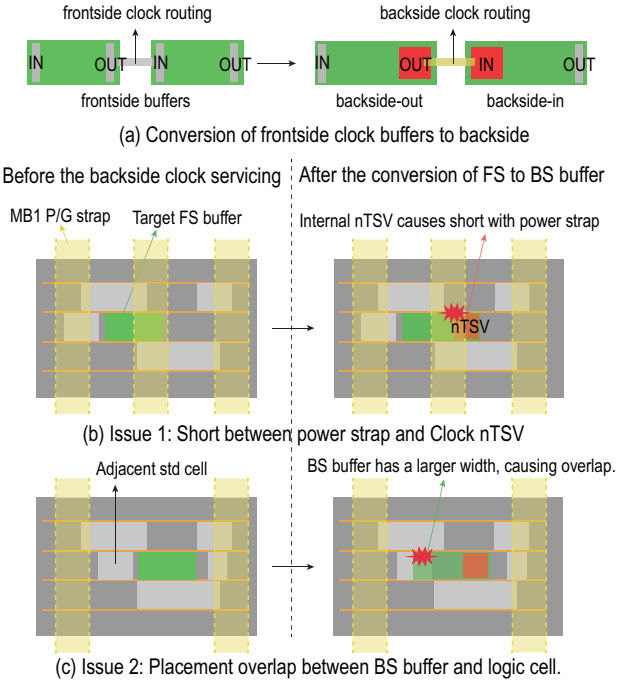

Fig. 2: Backside clock buffer overlap issues in [2]. (b) between a nTSV and a backside wire, (c) between a BS buffer and a frontside logic cell.

TABLE I: Quantification of the overlap issues with PDN-first flow described in Fig. 2. In this experiment, Gemmini SoC services 218 backside clock buffers for BS-CDN.

BS-CDN	disabled	enabled		
PDN util.	90%	None	50%	70%
Displacement of clock buf. (μm)	- -	- -	Mean: 0.27 Max: 0.49	Mean: 0.39 Max: 4.13
WNS (ps)	192.6	114.1 (-40.8%)	177.3 (-7.96%)	206.6 (+7.27%)
D. IR-drop (mV)	54.6	-	89.9	79.3

B. Overview of the Approach

To break down the inherent trade-off in the PDN-first flow, we proposed the BS-PDN-last flow, shown in Fig. 3. It is designed to fully leverage backside metal layers, supporting BS-CDN to maximize the performance gain. This methodology postpones PDN routing to the final stage of physical design, introducing an initial routing blockage on backside metal layers to pre-allocate essential regions. It accommodates various process constraints, including metal density limits, regular P/G pad placement rules, and spacing requirements between backside power and clock routing for signal integrity, through parameter adjustments in the Algorithm 2. Additionally, if the design fails to meet IR-drop targets, the BS-PDN-last flow can re-build PDN with minimal impact on overall physical design time.

C. Step 1: BS-PDN Planning

To defer PDN routing after the signal routing stage, it is crucial to ensure that BS-CDN does not obstruct power delivery to each cell and macro. Therefore, the BS-PDN planning step is implemented before utilizing backside resources for other purposes. This step pre-allocates routing blockages in critical regions to ensure proper P/G routing in subsequent steps.

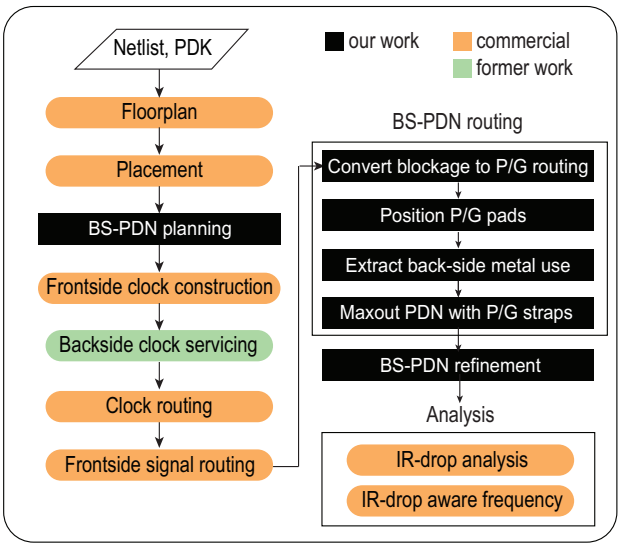

Fig. 3: Proposed BS-PDN-last flow: It preserves optimal backside clock buffer placement while maximizing PDN utilization to mitigate IR-drop.

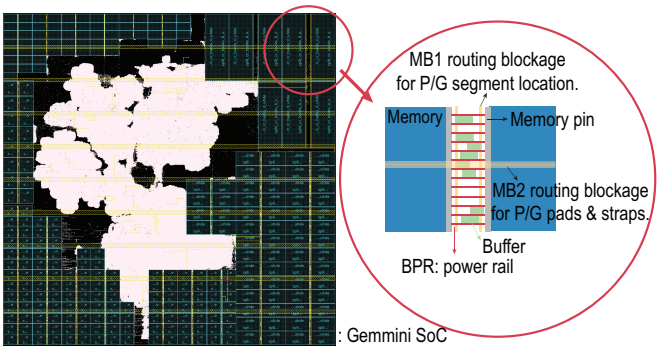

Fig. 4: BS-PDN planning: Routing blockages are added on MB1 and MB2 layers to ensure power delivery to every component.

In detail, for the design with memory macros, EDA tools often place buffers within the narrow spaces between memory macros to meet the timing. During multifunctional backside servicing, backside buffers can limit available space for power routing in these regions. To prevent such issues, Fig. 4 illustrates the placement of routing blockages on the vertical MB1 layer to reserve future P/G segment areas. Moreover, when the P/G pads need to follow a regular arrangement, routing blockages are established on the horizontal MB2 layer to facilitate subsequent assignment of MB2 P/G straps. These MB2 P/G straps will be aligned directly above the regular P/G pads. With these two strategies, essential power routing regions can be pre-allocated, facilitating seamless integration with BS-CDN while maintaining robust power delivery across all cell instances.

D. Step 2: BS-PDN-aware Backside Clock Servicing

Algorithm 1 is employed to identify candidates within the frontside clock tree and switch to backside buffers in both PDN-first and BS-PDN-last flows. Candidates are selected from buffers located on the path between the clock pin and the launch DFF of timing-critical paths. This effectively minimizes Worst Negative Slack (WNS) by reducing the delay from the clock pin to the launch DFF and providing additional timing margin for signal routing between the launch and capture DFFs. To ensure the paired scheme of backside

Algorithm 1 BS-PDN-aware Backside Clock Servicing

Input: $\mathbf{G_{clock}}$: Clock tree graph using only frontside buffers.
$\mathbf{Path_{crit}}$: List of timing critical paths in order of worst case.
$\mathbf{N}$: Target percentage.
Output: $\mathbf{G^*_{clock}}$: Clock tree graph with backside buffers.

```
Lock the location of logic cells (non-clock cells) on critical paths.
for path in {top N% of Path_crit} do
    ctp ← clock tree path from clock pin to launch DFF on path
    for buf in {reverse order of ctp} do
        if dests of buf are all frontside buffers then
            Convert buf to BS-OUT and dests to BS-IN.
            Legalize placement with minimum displacement.
```

buffers, the algorithm verifies that all destinations are frontside buffers, enabling their conversion to backside-in buffers. Furthermore, logic cells on timing-critical paths are fixed during legalization, ensuring no disruption to the placement quality. For the BS-PDN-last flow, as PDN is not installed in the initial phase, only a small amount of MB1 routing blockage and cell placement overlap causes legalization.

E. Step 3: BS-PDN Routing

Once the physical design is done alongside routing blockages on MB1 and MB2 layers, these blockages are converted into P/G routing, and P/G pads are positioned according to a specified pitch. Furthermore, backside metal regions used by BS-CDN and pre-installed BS-PDN are identified to ensure P/G routing compatibility in subsequent steps. For the MB1 layer, regions with existing MB1 metal usage, nano-TSV locations within backside clock buffers, and VB1 (via between MB1 and MB2) locations are extracted. On the other hand, for the MB2 layer, areas with existing MB2 metal usage and VB1 locations are extracted.

Unlike the conventional FS-PDN, which must balance routing resource allocation and IR-drop mitigation due to interference with frontside routing, BS-PDN focuses on maximizing the remaining backside metal resources. This strategy not only minimizes IR-drop but also enhances lateral thermal conduction [6]. By implementing the BS-PDN after BS-CDN servicing, it is possible to fully maximize PDN deployment without concerns of interference with BS-CDN.

Accordingly, first step of Algorithm 2 positions P/G straps between existing backside metal usage while avoiding overlap and spacing rule violations. For the maxout process with P/G straps, we can adjust the width and pitch of P/G straps to achieve the target PDN utilization, while also varying spacing to control the impact of P/G straps on backside clock routing. These adjustments help to manage key factors, including IR-drop, thermal conduction, coupling capacitance, and signal integrity.

F. Step 4: BS-PDN Refinement

In conventional power routing, P/G straps are used in a form that connects both ends of the core to ensure connectivity between different metal layers regardless of strap locations. However, when a sufficient number of P/G straps are installed, short P/G segments can also maintain reliable inter-layer connections. Additionally, as illustrated in Fig. 5-(a), in cases where backside clock routing is densely packed, broad areas without P/G straps happen, leading to significant IR-drop. Therefore, Algorithm 2 positions shorter P/G segments between existing P/G straps in step 2, avoiding any overlap with previously installed backside routing. By incorporating

Algorithm 2 BS-PDN Routing & Refinement.

Input: $\mathbf{GDSII_{in}}$: Layout with P/G planning and backside clock.
$\mathbf{MB1_x}, \mathbf{MB2_y}$: Lists of [*start*, *end*] intervals indicating regions where the respective metal layers are occupied.
$\mathbf{MB1_y}, \mathbf{MB2_x}$: Intervals in the y and x-direction representing the occupied ranges for each interval in $\mathbf{MB1_x}$ and $\mathbf{MB2_y}$.
$\mathbf{w1}, \mathbf{w2}, \mathbf{w3}, \mathbf{w4}$: Target widths of P/G.
$\mathbf{p1}, \mathbf{p2}, \mathbf{p3}, \mathbf{p4}$: Target pitch values.
$\mathbf{spacing}$: P/G spacing from backside clock routing.
Output: $\mathbf{GDSII_{out}}$: Layout with maximized P/G utilization.

Step 1: Maxout BS-PDN with P/G straps.
for i in $\{1, 2\}$ **do** ▷ loop over MB1 and MB2.
  $unit \leftarrow \mathbf{w}i + \mathbf{p}i$
  for j in $\{0, \ldots, \text{len}(\mathbf{MB}i_{\mathbf{x}|\mathbf{y}})\}$ **do**
    ▷ Insert P/G straps between consecutive occupied regions.
    $interval \leftarrow start_j - end_{j-1}$
    if $interval - 2 \times \mathbf{spacing} > unit$ **then**
      $N \leftarrow \text{CEIL}((interval - 2 \times \mathbf{spacing})/unit)$
      Integrates N P/G straps between end_{j-1} and $start_j$.
Step 2: Add P/G Segments
$unit \leftarrow \mathbf{w}(i+2) + \mathbf{p}(i+2)$ ▷ loop over MB1, MB2. ($i \in \{1, 2\}$)
for j in $\{0, \ldots, \text{len}(\mathbf{MB}i_{\mathbf{x}|\mathbf{y}})\}$ **do**
  $width \leftarrow end_j - start_j$
  if $width > unit$ **then**
    $M \leftarrow \text{CEIL}(width/unit)$
    for k in $\{0, \ldots, \text{len}(\mathbf{MB}i_{\mathbf{y}|\mathbf{x}}[\mathbf{j}])\}$ **do**
      $H \leftarrow start_k - end_{k-1}$
      Inserts M P/G segments of $\mathbf{w}i$ width and H height.

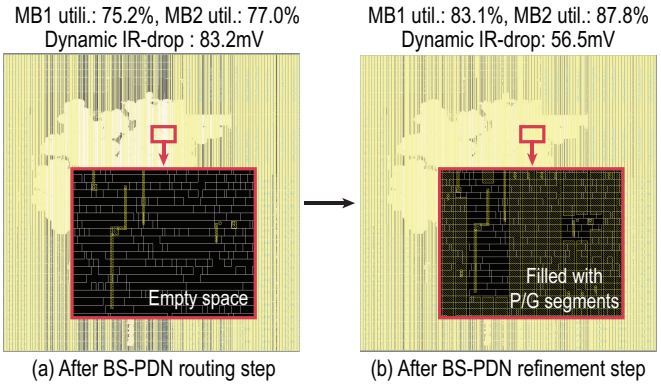

Fig. 5: Maximizing PDN utilization through the addition of P/G wire segments during the BS-PDN refinement step.

supplementary P/G segments, BS-PDN utilization is fully maximized, achieving reduced IR-drop, as demonstrated in Fig. 5-(b).

V. Results and Discussion

A. Experimental Setup

For the Gemmini SoC benchmark, we incorporate waveform-based analysis with the instance-wise switching activity throughout workload execution, whereas other benchmarks use common methods that assume uniform switching across all DFFs. Designs with backside integration leverage six frontside metal layers and two backside metal layers, along with buried power rails, across all three benchmarks.

The detailed methodology of waveform-based analysis is presented in Fig. 6. First, workload simulation using Synopsys VCS provides

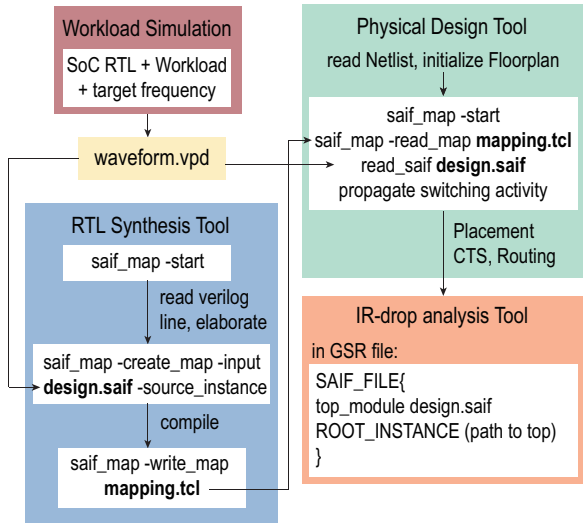

Fig. 6: Waveform-based analysis used in this study for Gemmini SoC benchmark. It enables a comprehensive evaluation of PDN-first and BS-PDN-last flows in real-world applications.

output in the Value Change Dump Plus (VPD) format, detailing value changes across each RTL component. However, component-wise VPD files can be extremely large; for instance, a 16x16 Gemmini SoC running ResNet-50 generates approximately 1TB of waveform data. To streamline power analysis, the waveform is converted into a Switching Activity Interchange Format (SAIF) file, summarizing average toggle counts across the duration of the workload.

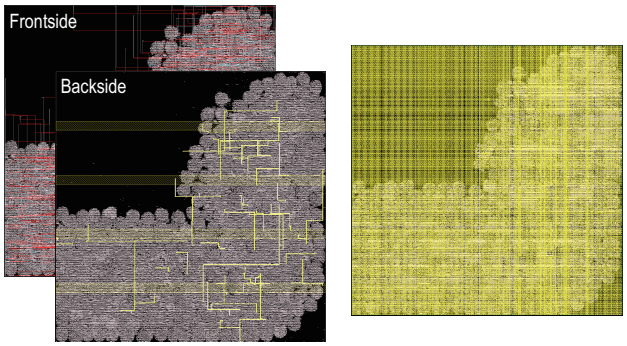
Using the GTCAD 3nm PDK [9] at a supply voltage of 0.7V, Synopsys Design Compiler facilitates mapping between RTL instances in the SAIF file and gate-level cells in the synthesized netlist file by creating a naming correlation file. Using Synopsys ICC2, toggle counts from the SAIF file are then mapped into the corresponding cells, enabling precise vector-based power consumption estimates under workload conditions.

For IR-drop analysis, Ansys Redhawk incorporates SAIF files to yield a realistic IR-drop profile. This IR-drop information is then integrated into performance analysis through Synopsys Primetime, leveraging gate-level cell-specific voltage drops to improve the accuracy of timing assessments.

Using these comprehensive methodologies, workload runtime, energy consumption, and energy efficiency are calculated as shown below. Total cycles can be obtained from workload simulation. In this study, we use the inference of ResNet-50 workload with a batch size of 4 to analyze the impact of PDN-last flow on workload metrics.

$$\text{Runtime (ms)} = \frac{\text{Total Cycles}}{\text{Performance (GHz)} \times 10^6}$$

$$\text{Energy (mJ)} = \frac{\text{Vector-based Power (mW)} \times \text{Runtime (ms)}}{10^3}$$



$$\text{Energy Eff. (TOPS/W)} = \frac{\text{Trillion Operations (TOP)}}{\text{Runtime (ms)} \times \text{V.-Power (mW)} \times 10^6}$$

B. Comparison between PDN-first and PDN-last Flow

Given the trade-off between IR-drop and performance in the PDN-first flow, it is important to select the PDN specifications carefully to enable a fair comparison between the PDN-first and PDN-last flows. In this work, we apply the same PDN utilization achieved from the PDN-last flow to ensure comparable IR-drop levels while demonstrating the performance advantages.

TABLE II: Iso-performance comparison between BS-PDN-first vs. PDN-last flow. BS-CDN is added in both cases (baseline: BS-PDN only.)

	AES (#cell=163K, 7.5GHz)			Rocket Chip (#cell=388K, 2.6GHz)			Gemmini SoC (#cell=1.17M, 1.5GHz)

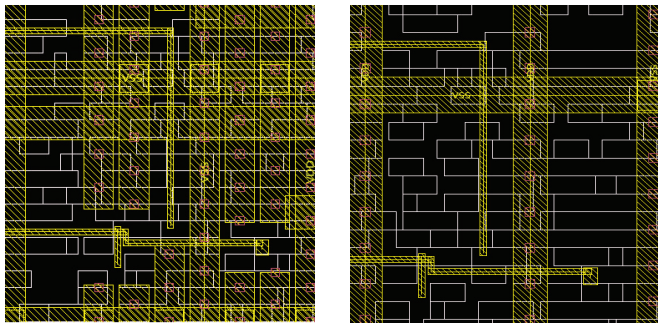
Fig. 8: Impact of backside metal layer 1 (= MB1) P/G width & pitch on Rocket Chip.

Table II shows an iso-performance comparison across three configurations: BS-PDN only, BS-CDN with PDN-first flow, and BS-CDN with BS-PDN-last flow for each benchmark. As the BS-PDN-last flow defers PDN installation with minimal routing blockages, cell displacement during backside clock buffer conversion is significantly reduced compared to the PDN-first flow. Therefore, the BS-PDN-last flow successfully preserves the optimal logic cell and clock buffer positions, addressing the limitations of the PDN-first flow and achieving significant performance gains.

The results also indicate, as design size increases, legalizing placement for backside buffers within a PDN-first flow becomes significantly more challenging, leading to greater maximum displacements. This is because larger designs require stronger drive-strength buffers to meet clock specifications; however, these wider (=stronger) backside buffers are more difficult to legalize under a PDN-first approach. Consequently, the performance benefits gained from backside clock routing are further diminished. Given that the Gemmini SoC used in this study comprises 1.17 million cells—and recognizing that typical industrial designs are substantially larger—these observations highlight the critical importance of adopting a BS-PDN-last flow.

C. Impact of Backside Metal Width & Pitch

For a given PDN utilization, adjustments to P/G width and pitch are possible. For instance, a 90% target utilization can be maintained regardless of the absolute width and spacing values, as long as the width-to-spacing ratio remains 9:1. In this section, we examine the impact of varying the MB1 P/G spacing from 1x to 6x Contacted Poly Pitch (CPP) while maintaining a consistent 90% target utilization. Although Fig. 8-(a) illustrates a simplified layout with a regular BS-PDN arrangement, the actual design contains irregular pattern of P/G straps and segments similar to Fig. 7-(b). Under the current setting, MB1 utilization remained relatively stable, ranging from 79% to 81%, ensuring an equitable comparison across different spacing options.



As shown in Fig. 8-(b), larger spacing increases the length of the high-resistance BPR paths, resulting in a larger dynamic IR-drop. As a result, timing metrics are negatively impacted, increasing the number of timing failure points from 428 to 480 and raising Total Negative Slack (TNS) from 1.7ns to 1.9ns. On the other hand, reducing the width and spacing of MB1 P/G straps increases the number of power nano-TSVs for MB1-BPR connection. Consequently, it improves lateral thermal conduction [6]; however, manufacturing costs increase. In summary, the MB1 width and pitch settings have a direct impact on the number of nano-TSVs and the power delivery path, creating a trade-off between IR-drop, TNS, thermal conduction, and cost.

D. Impact of Spacing between Backside Power and Clock Wires

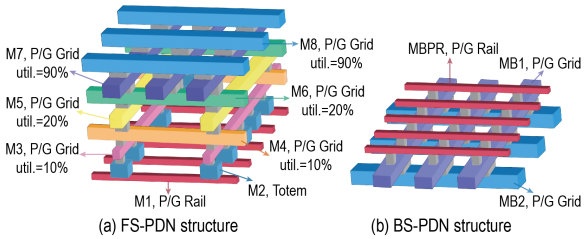
The application of BS-CDN necessitates the PDN to share metal layers with clock routing, which introduces potential signal integrity issues due to coupling capacitance. To evaluate this, we compute the coupling capacitance by comparing the total capacitance of the backside net before and after PDN implementation. The spacing between P/G lines and clock/signal routing are varied from 1x-20x and 40x of the minimum pitch, respectively. According to Table III, increasing the spacing reduces total coupling capacitance by 2.9% and 3.1%, respectively. However, with increased spacing, as illustrated in Figure 9, the length and number of P/G straps decreased. Therefore, substantial spacing can hinder the installation of P/G straps, which

TABLE III: Effect of spacing between backside P/G and backside clock routing. The spacing in the x and y directions is set as a multiple of the minimum pitch for the MB1 and MB2 layers, respectively.

Spacing	1x	20x	40x
Total coupling cap. (fF)	49.4	47.9 (-2.9%)	47.8 (-3.1%)
Average PDN util. (%)	83.4	83.1	82.9
Dynamic IR-drop (mV)	37.3	38.2 (+2.4%)	39.9 (+7.0%)

(a) spacing = 1x min_pitch (b) spacing = 40x min_pitch

Fig. 9: Different spacing between power and clock net on Rocket Chip.



exacerbates IR-drop. Moreover, increasing P/G strap spacing beyond a specific threshold incurs minimal impact on coupling capacitance. Thus, determining an optimal spacing level is crucial to balance coupling capacitance minimization and efficient P/G planning.

E. Workload Simulation Results

This section presents a comparative analysis of FS-PDN, BS-PDN, and BS-CDN + BS-PDN-last flow on the Gemmini SoC, evaluating both physical design-related and workload-related metrics. Designs utilizing backside metal layers implement power grids on MB1 and MB2 with buried power rails, whereas FS-PDN designs construct power grids from M3 to M8 with distinct utilization, with power rails located on M1 as shown in Fig. 10-(a). The FS-PDN specification was configured to approach a worst-case dynamic IR-drop as close to 10% of the supply voltage as possible, while avoiding significant interference with frontside routing.

The GTCAD 3nm PDK [9] used in this study provides cells with consistent height across both BPR-enabled and BPR-free configurations, resulting in an equivalent footprint for all designs. Rather than achieving footprint savings as seen in conventional FS-PDN vs. BS-PDN analysis [7], our BS-PDN designs achieve power benefits due to reduced parasitic capacitance at cell pins as well as smaller load capacitance from better frontside routability.

As shown in Table IV, the design integrating BS-CDN with the BS-PDN-last flow achieves a 16.1% enhancement in performance, along with a 13.7% reduction in ResNet-50 runtime, a 17.4% improvement in energy consumption, and an 18.9% increase in energy efficiency. Additionally, BS-CDN with BS-PDN-last flow demonstrates substantial gains over the design with BS-PDN alone, especially in terms of performance and runtime, by 7.8% and 7.3% respectively. Given the relatively low cost of extending existing backside metal layers from single-function BS-PDN to multi-functional BS-PDN + CDN designs—compared to the higher cost of converting a frontside-only design to a backside-integrated —the importance of leveraging backside metal layers for diverse functionalities becomes evident.

(a) FS-PDN structure (b) BS-PDN structure

Fig. 10: PDN structure used in this work: the baseline FS-PDN uses P/G rails on M1 and grids on M3–M8, while the BS-PDN is implemented on the BPR and backside.

TABLE IV: Comparison between FS-PDN, BS-PDN, BS-CDN + PDN-last with 3nm PDK (supply voltage=0.7V). Workload metrics (runtime, energy, E-eff) are based on ResNet-50 with a batch size of 4.

Gemmini SoC	FS-PDN	BS-PDN	BS-PDN + CDN

Vector-based Power (mW)	690.4 -	642.0 (-7.0%)	670.8 (-2.8%)
Perf. (GHz)	1.08	1.16 (+7.7%)	1.25 (+16.1%)
D. IR-drop (mV)	89.8	54.6	56.5
Runtime (ms)	115.5	107.5 (-6.9%)	99.7 (-13.7%)
Energy (mJ)	79.7	69.0 (-13.4%)	65.8 (-17.4%)
Energy-eff. (TOPS/W)	0.185 -	0.214 (+15.7%)	0.220 (+18.9%)

VI. Conclusion and Future Work

We present a BS-PDN-last flow that enhances performance and energy efficiency while maintaining IR-drop levels in multifunctional backside metal layer applications. By deferring PDN routing to the final design phase, this approach achieves up to a 90% reduction in Total Negative Slack and up to a 12% increase in performance when integrated with BS-CDN, effectively eliminating the trade-off between IR-drop and performance gain inherent to PDN-first flows. Notably, the benefits of the BS-PDN-last flow scale significantly with increasing design complexity, highlighting its relevance for industrial-scale chip implementations.

While our current focus is on backside clock and power routing, the proposed approach is readily extendable to backside signal routing (BSS). Since BSS involves relocating critical frontside signal nets to the backside, it necessitates the use of nano-TSVs and the MB1 layer, resulting in a competitive allocation with the BS-PDN—similar to the conflict observed with BS-CDN. Especially, the MB1 routing blockages introduced during our BS-PDN planning stage are effective in mitigating issues associated with memory-to-register frontside net conversions to backside.

***Abstract*—Today, DNN inference is widely adopted, with numerous inference services being spawned from scratch across instances in scenarios such as spot serving, serverless scaling and edge computing, where frequent start-stops are required. In this work, we first delve into the inference workflow and uncover the origins of cold start when invoking a DNN model. Specifically, DNN execution is blocked by the kernel loading process to prepare the code object executing on GPU at the DL primitive library (e.g., cuDNN and MIOpen). To tackle this, we propose PASK, a kernel loading and reusing middleware to mitigate the widespread cold start issue. Unlike the reactive kernel scheduling policy used by existing frameworks, PASK adopts a proactive strategy to interleave code loading, kernel issuing and GPU computation to achieve higher hardware utilization. To further reduce the loading overhead, PASK recycles existing loaded kernels to accomplish the DNN operator, rather than introducing new kernels for every layer. Meanwhile, PASK categorically organizes the cached kernels to efficiently find the applicable kernel for reuse and thus minimize incurred runtime overhead. We implement and evaluate PASK atop of open source DNN inference engine and primitive library on off-the-shelf GPUs. Experiments demonstrate PASK is capable of alleviating the cold start overhead of popular DNN models with $5.62\times$ speedup on average.**

***Index Terms*—Cold Start, GPU, DNN, Inference**

I. Introduction

The last decade has witnessed the unprecedented prosperity of deep learning and its widespread application in many aspects like computer vision [1]–[9], recommendation [10], and natural language processing [11]. Serving model inference has become the dominating workload in modern data centers, which accounts for more than 90% infrastructure costs in AWS [12] and 200 trillion daily invocations in Meta [13].

This trend also sparks the research efforts devoted into the ML inference infrastructures like request batching [14]–[17], model selection [18], [19], memory optimizations [20], tensor pre-fetching [21] and resource sharing [22], [23]. As underlying support, the accelerators like GPUs are trending to be much more powerful and the DNN operators are continuously optimized by experts for efficient computation [24]–[27]. As a result, DNN inference tends to be more hindered by the non-computation aspects, with a significant portion being spent on the models' cold starting process [28]. Fig. 1(a) compares the cold and hot execution times (ratios between the first and successive iterations) of representative DL models on both data center and consumer-grade GPUs from different vendors, where significant cold start slowdowns are commonly observed on respect platforms ($23.7\times$, $19.5\times$ and $31.3\times$ for MI100, A100 and 6900XT, respectively). Fig. 1(b) further demonstrates the breakdowns of the cold start overhead, which is classified into four parts by their execution ordering phases. Before launching a kernel onto the GPU, the host runtime (i.e., CUDA or HIP) is responsible for checking whether the kernel code object (e.g., compiled SASS instructions binary stream) is present in the managed host memory. If not, the runtime will load it from either the shared library or compiled ELF executables, then set memory permissions and look up the target symbol positions. It can be captured from Fig. 1(b) that the majority (65.8%) of cold start overhead is attributed to loading absent kernel code objects (`code loading`) while the computation (`GPU execution`) constitutes only a small proportion (8.4%). Therefore, the code loading should be considered alongside data pre-fetching [21], keep alive [29] and pre-warming [30] techniques to mitigate DNN cold start overhead.

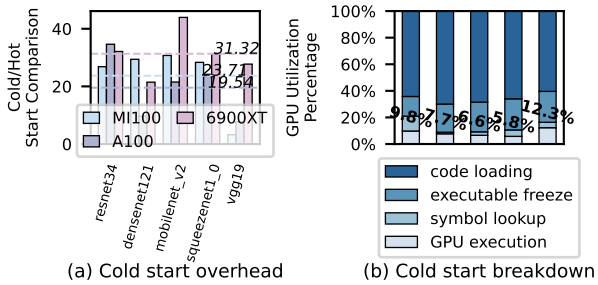

Fig. 1. DNN model cold start (a) overhead and (b) breakdown of typical models. The dashed lines in (a) represents averaged slowdowns and percentage numbers in (b) mark the GPU execution portion.

The cold start overhead originated from code loading is inevitable in scenarios like preemptive serving [31]–[36], serverless scaling [17], [20], [29], [37] or edge computing [30], [38], [39]. For example, the inference service has to be migrated across preemptive instances, or deployed in new instances to cope with request spikes. In edge or mobile devices, the inference service is forced to be suspended or swapped out due to limited hardware resources (e.g., memory capacity), and restarts later. Under these circumstances, code loading is unavoidable when starting a DNN model as there are no available loaded kernels in the system.

There are multiple proposed approaches to mitigate the non-computation overhead of DNN models [25]–[27], [40]. TASO [25], Rammer [26], Cocktailer [27] and MonoNN [40] apply some operator-level transformations on the models' computation graph for higher execution efficiency. Nevertheless, these methods focus on the *static* optimizations to produce a series of fast kernels running on GPUs, failing to consider the crucial runtime overhead of loading these kernels. There also exist designs sharing container [29], [41], runtime [30], [42] or tensor [20] to warm up the cold models, but

§ Xianwei is the corresponding author.

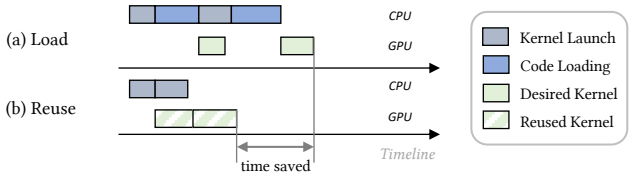

Fig. 2. Instead of waiting for the fresh loading (a), PASK reuses existing loaded kernels (b) to implement the DNN layers.

the sharing granularity is generally too coarse as DNN models are monolithic and cannot be efficiently transformed via dependency analysis for traditional services [43]. As such, extra steps are needed to transform the shared resources for accommodating with the cold start model. NNV12 [38] optimizes the DNN cold start process via selecting different kernels to implement the NN operator to reduce the tensor layout interchange overhead before execution. Nonetheless, the above existing methods ignore the kernel code object loading procedure, which actually constitutes the most significant portion of the cold start overhead for DNN models (Fig. 1).

In this work, we propose PASK, a kernel loading and reusing approach to mitigate the cold start latency of DNN inference. We first analyze the DNN inference serving procedure and attribute the cold start overhead to the mismatch between static model materialization and runtime kernel loading: inference framework determines the finalized kernel sequences from abstract model computation graph without considering the incurred loading overhead at runtime. To cope with this, PASK seeks the opportunities to *reuse* existing potentially less performant but already loaded kernels to materialize NN operator, thereby skipping the more substantial kernel loading procedure, as depicted in Fig. 2.

However, it's non-trivial to efficiently select the substitute from all cached kernels as checking whether the kernel is applicable for current problem can be pretty time-consuming. To this end, we design a categorical cache which stores the cached kernels based on their patterns to minimize the applicable checking overhead. We integrate PASK into the open source inference stack with AMD GPUs [1], and conduct evaluations on various DNN models which show remarkable performance improvements.

To summarize, this work makes the following contributions:

- We investigate the origins of DNN model cold start overhead, and uncover it is primarily due to the mismatch between static model materialization and runtime kernel loading.
- With the insights, we propose PASK, a kernel loading and reusing approach leveraging the already loaded kernels to finalize the NN operator, thus circumventing the substantial kernel loading process. Equipped with interleaved execution and categorical cache, PASK achieves higher GPU utilization meanwhile minimizing the incurred runtime overhead.
- We implement PASK atop of open source inference software stack, and evaluate using representative DNN models to demonstrate its ability to mitigate the cold start overhead.

II. Background and Motivation

A. DNN Model Serving with GPU

GPU has become the *de-facto* accelerator to speed up DNN execution. A DNN model is composed of multiple layers with each defining a specific operation like convolution or pooling. To harness the hardware resources, DNN operators are offloaded onto GPUs for faster execution through various frameworks like TensorRT [44] for NVIDIA and MIGraphX [45] for AMD GPUs. These frameworks *materialize* the DNN layers with the computation graph optimizations [46]–[48] and tuned kernels [24], [49] for efficient execution.

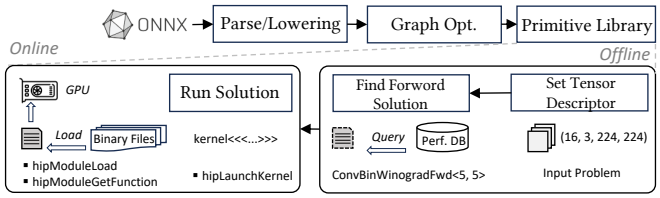

Fig. 3. DNN inference serving workflow. The serving framework firstly lowers the model and applies multiple optimizations on the requested model, then invokes operators from the primitive library to materialize the model.

Offline preparation. Fig. 3 depicts a typical workflow of DNN serving with GPU, where the requested model is submitted in the ONNX format containing multiple canonical operators [50] for the ease of model description and exchange. After receiving the model, the serving framework first converts the ONNX structure into lower descriptions with regard to the backend hardware, including GPU context creation, host-device synchronization setup, and tensor memory layout generation. Then the serving framework applies a series of hardware-independent graph-level optimization passes like *dead code elimination* and *common subexpression elimination* [45], [51] to reduce unnecessary computations. Finally, the serving framework exploits the highly-optimized kernels from vendor-provided primitive libraries (e.g., MIOpen and cuDNN) to accomplish the operators defined in the computation graph.

For each DNN layer (e.g., convolution), the serving framework sets the tensor descriptors needed by the primitive library with input *problem* (image and filter sizes, number of filters, data types etc.). Then the library finds the optimal *solution* [2] for the given problem from all applicable ones by querying an integrated database [52] which records the anticipated performance of each solution on current problem. After this, the lower operations and the determined optimal solutions for each layer are saved in framework-specific formats (e.g., `.trt` files for TensorRT and `.mgx` files for MIGraphX) for online inference request serving. The framework usually maintains a model registry [53] to store the lowered model and directly loads them when the request comes to avoid redundant lowering.

Online inference serving. When the inference request arrives, the framework invokes the corresponding optimized model and runs the determined solutions sequentially by launching the underlying kernels onto the GPU. Nevertheless, there are often cases where the code object of the desired kernel is absent due to the lazy loading behavior [54] which delays the loading until launch. Therefore, the primitive library has to *load* the code objects for the missing kernels from compiled binary files (e.g., dynamic linked ELF), resulting in unbearable cold start latency for model inference. Only after the code objects are loaded into memory will the kernels be issued to the GPU for computation. Such a reactive launch and lazy loading behavior leads to substantial latency at model cold start. Note that the loading delay comes from the mismatch between the offline operator lowering and the runtime solution loading: the primitive library determines solutions from the GPU performance perspective, meanwhile introducing extra loading overhead when launching missing kernels. In

[1]This can be implemented on NVIDIA platforms as well if more flexible interfaces are accessible.

[2]One solution may contain multiple kernels to transform input/output tensor layout/precision, conduct primary computation and epilogue reduction.

principle, the gap can be effectively bridged if one can proactively interleave the code loading and kernel launch executions, and reuse already loaded kernels to accomplish the computation rather than loading missing kernels from scratch each time.

B. Generalized Solution for Wider Applicability

Fig. 4. Generality-performance trade-offs for *Winograd* solutions. Specialized solutions are more performant but applicable for specific problems, while generic solutions can be applied to more problems but are less efficient.

Solution specialization. Fig. 4 demonstrates some exemplified convolution solutions embedded in MIOpen. The solution usually follows certain *patterns* to conduct the computation. For example, solutions using *Winograd* [55] accomplish the convolution via matrix multiplication, and apply some transformations on both the input image and filters to lessen the number of multiply-and-add instructions. Other commonly used patterns include *GEMM*, *DirectConv* and *ImplicitGEMM*. Solutions with the same pattern typically follow similar workflows to accomplish the computation. Besides, there are further optimization spaces to exploit if certain problem fields are deterministic before the model starts (i.e., compile time). In Fig. 4, instead of taking the `ConvWinogradNaiveFwd` solution which accepts inputs with any dimension, one can alter to invoke `ConvBinWinogradRxSFwd` if the input is deemed to be a 2D image. By avoiding unnecessary loops and boundary checks, the latter hence brings in higher GPU performance, but at the expense of generality. Furthermore, the library opts for leveraging more specialized solution `ConvBinWinogradFwd<5,5>` if the filter size is also a specific value (5×5), which helps organize the shared memory layout and better overlap the memory access and computation within the kernel. The highly specialized solutions produce better GPU performance tailored for the specific problem, but they are not applicable to other problems as there are more constraints. Currently, the primitive libraries (cuDNN, MIOpen) tend to harness the specialized solutions from the performance perspective, and fallback to the more general solutions only if no specialized solution is located. Inevitably, this leads to more solution loads at the model cold start, as the library may select an uniquely specialized solution for each individual layer with varying problem description.
Solution applicability. To ensure successful executions and correct results of DNN inference, the primitive library should only return *applicable* solutions for a given problem. The applicability checking process is time-consuming as it includes complicated logic such as workspace size checking, input format match, environment variable and hardware capability validation. In MIOpen, each solution implements the `IsApplicable` interface for the library to check whether it can be used to accomplish the computation for a given problem without any constraint violations (e.g., data type mismatch, out-of-bound memory access). Apparently, the incurred runtime overhead can be significantly alleviated if the applicable checks can be reduced to quickly identify a valid substitutive solution.

III. Design

In this section, we present the components and workflow of PASK. Fig. 5 illustrates the overview of our design, where PASK receives the lowered model as its input. During model parsing, PASK chooses to proactively load the solutions once they are parsed and starts the execution immediately once they are loaded (section III-A). For an absent solution, PASK checks the applicability of loaded solutions to seek the opportunities of reusing existing solution to accomplish the computation, thereby skipping to load the missing one (section III-B). Upon reusing, PASK integrates a categorical solution cache (section III-C) to organize existing loaded solutions and provides an interface to efficiently select an applicable solution for the given problem. Finally, we elaborate the implementation of PASK atop of open source inference engine and DL primitive library (section III-D).

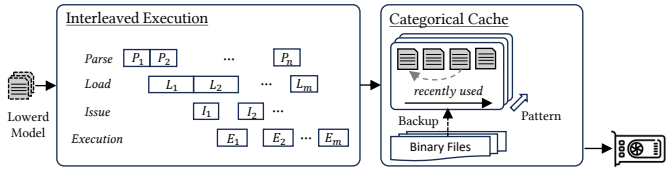

Fig. 5. Design overview. PASK receives the lowered model (a sequence of n solutions) as input, and then proactively parses, loads, issues the DNN layer to improve the GPU utilization via interleaved execution. Upon absent solution, PASK seeks the opportunities to reuse the loaded solutions and organizes them based on their patterns for efficient applicability checking.

A. Proactively Interleaved Execution

We introduce the interleaved execution to cope with the the inefficient execution hindered by the reactive launch and lazy loading pattern mentioned in section II-A. During parsing layers in DNN computation graph, PASK spawns two extra host threads to handle code loading and kernel issuing, respectively (Fig. 5). For a layer i, once it gets parsed (P_i, de-serialize the framework-specific model file to obtain the determined solution), the loading thread immediately starts to load the code objects of the desired solution (L_i). Once finish, the loading thread notifies the issuing thread to issue the kernels of the loaded solution (I_i) and execute them on GPU (E_i). This proactive design loads the necessary code objects in advance (once the parse finishes), therefore launches of the corresponding kernels incur no loading overhead. Besides, PASK starts the kernels at the earliest feasible time right after the loading. For comparison, current reactive serving frameworks start to launch the solutions only after all layers are parsed, and load the absent code objects on demand during launch. PASK mitigates the inefficiency with proactive interleaved execution, thereby achieving higher GPU utilization than traditional reactive inference engines.

As the DNN layer parsing is much faster than the code loading and execution, there will be a layer m where all the n layers are parsed and all preceding layers, including m, have finished their executions on GPUs (Fig. 5). We denote layer m as the *milestone* where PASK unconditionally loads the missing solutions into cache set $\mathcal{S}_m$ before m and selectively reuses the cached solutions after m. Note the minimal duration of a model execution is no less than the parsing process, hence there are free time slots for PASK to load before m solutions, which act as cached alternatives for the selective reuse in subsequent layers.

B. Selective Solution Reuse

After the milestone layer m, PASK quickens the execution of the remaining layers by avoiding unnecessary solution loads with selective adoption of cached solution. *Algorithm* 1 lists the solution reusing procedure where the ExecutionPlan function describes the layer-wise reuse decision procedure. When the target solution s_i^* ($i > m$) in layer i is parsed, PASK checks whether the corresponding

code object has been already loaded. If so, s_i^* will be directly used to complete the computation defined in layer i without incurring any loading overhead. Otherwise, PASK firstly attempts to acquire the applicable alternative solution by querying the cached solution set $\mathcal{S}_m$ (section III-C). Once a valid substitutive solution $\hat{s_i}$ exists, PASK will reuse it to accomplish the computation in layer i rather than loading the original absent solution s_i^* from scratch.

If, unfortunately, no valid solution can be found in the cached set $\mathcal{S}_m$, PASK has no choice but to load the desired solution s_i^*.

Algorithm 1 DNN execution with solution reuse

Input:
n: number of layers in the DNN model
m: the milestone layer (section III-A)
$\mathcal{S}_m$: solution cache set at layer m
p_i: problem to be solved in layer i
s_i^*: statically optimal solution in layer i

function EXECUTIONPLAN($\mathcal{S}, L, i$)
  for layer i from $m+1$ to n **do**
    if $s_i^* \in \mathcal{S}_m$ **then** ▷ s_i^* already loaded
      compute layer i with s_i^*
    else
      $\hat{s_i} \leftarrow$ GETSUBSOLUTION($\mathcal{S}, s_i^*, p_i$)
      if $\hat{s_i} \neq null$ **then** ▷ reusable solution found
        run layer i with substitutive solution $\hat{s_i}$
      else ▷ no applicable solution
        wait for s_i^* loading
        add s_i^* to $\mathcal{S}_m$
function GETSUBSOLUTION($\mathcal{S}, s^*, p$)
  list $\leftarrow \mathcal{S}[s^*.\text{pattern}]$
  for $s \in$ list's most recently used solution **do**
    if s.IsApplicable(p) **then**
      lru.update(s)
      return s
  return $null$

C. Categorical Solution Cache

In *Algorithm* 1, PASK queries the solution cache for a loaded solution to be reused for implementing the operator. As discussed in section II-B, it is expensive to lookup the applicability with current problem for every loaded solution in the cache. PASK thus adopts a categorical solution cache design to effectively find an applicable solution from all existing loaded ones.

In PASK, the loaded solutions are categorically organized in separated lists based on their *patterns* (section II-B). When a solution is loaded/invoked, it will be inserted/moved to the head of list. The GETSUBSOLUTION function in *Algorithm* 1 details how PASK handles the query for a substitutive solution given the desired solution s^* and problem p. It seeks for $\hat{s}$ from the list with the same pattern as s^* in the the most recently accessed (load or lookup) order. If one applicable solution is found in the categorical list, it is returned and moved to the list head (Fig. 5). Otherwise, the cache returns $null$, indicating there are no applicable solutions for current problem.

PASK adopts this categorical design to minimize the number of lookups (i.e., solution applicability checking for a problem) when searching for $\hat{s}$. When a specialized solution for problem p is missing, it is more likely to find a more general one with the same pattern to solve p (Fig. 4). If there are no applicable solution in one categorical list, PASK regards the query failed and returns $null$ directly to skip more lookups for other categories. We search the solutions in the recent access order similar to the LRU cache, as the neighboring layers in DNN models usually possess similar problem descriptions. Therefore, recently used solutions are more likely to be applicable to current problem.

D. Implementation

We implement PASK on the basis of the open source inference engine MIGraphX [45] and DL primitive library MIOpen [56] for AMD GPUs. PASK acts as a transparent middleware for end users.

We enhance MIGraphX to support the interleaved execution (section III-A). MIGraphX abstracts the computation graph by a list of instructions, which define the DNN operators and their corresponding input/output tensors. For interleaved execution, PASK spawns 3 host threads responsible for parsing, loading and issuing kernels, respectively (Fig. 5). We leverage single-producer-single-consumer (SPSC) channels to coordinate the interactions among host threads in MIGraphX. Instructions are fed to the loading thread when finishing the parse and leaves for the interleaved execution in the FIFO order. For each callee kernel of the solution, PASK invokes `hipModuleLoad` and `hipModuleGetFunction` (Fig. 3) to proactively load the target ELF sections from the binary files and determine location of the desired symbol by the kernel name.

We further augment MIOpen to support the solution reuse and loading skip in PASK. When the inference framework invokes `miopenRunSolution`, PASK follows *Algorithm* 1 to reuse the potentially applicable loaded solution for the computation in current layer. PASK implements the reuse logic for the common convolution, pooling and activation primitives in MIOpen.

IV. EXPERIMENT SETUP

Testbed. We evaluate PASK in a sever equipped with AMD EPYC 7773X CPU and AMD Instinct MI100 GPU, which possesses 32 GB VRAM and 120 Compute Units. The DNN inference server is implemented atop of MIGraphX and MIOpen as the graph optimization engine and DL primitive library backended by ROCm 6.0.2.

Workloads. We collect representative DNN workloads (Table I) from multiple fields (e.g., image recognition, object detection, semantic segmentation and vision transformer) implemented the PyTorch model zoo as served models in inference requests, where the vision transformer models are also used to emulate the transformer-based language models. Models are exported as ONNX format from PyTorch under the default configuration and then fed into MIGraphX for compute graph optimizations, and finally lowered to the corresponding GPU operations. The number of MIGraphX layers for each model is also listed in Table I. We follow the common image settings used in the ImageNet [57] dataset.

Evaluated schemes. To faithfully validate the effectiveness of PASK, we evaluate the above models under the following schemes:

- *Baseline*: the default inference workflow used by MIGraphX inference framework which loads every absent solutions.
- *NNV12*: the cold start mitigation design in NNV12 [38] to avoid input/output tensor layout transform.
- *Ideal*: hot execution of the DNN model, with all the desired solutions already resident.
- *PaSK*: full design of PASK, including interleaved execution and categorical solution cache.
- *PaSK-I*: PASK with only interleaved execution module being enabled, no solution reuse mechanism is enabled.

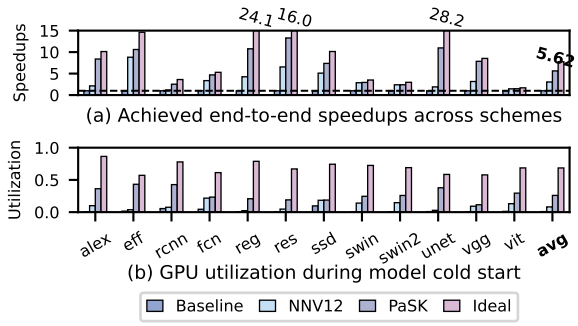

Fig. 6. (a) End-to-end cold start speedups for evaluated models under different schemes; (b) GPU utilization (fraction of time when GPU is active for computing) during model cold start.

- *PaSK-R*: PASK with solution reusing only, which exhaustively checks the applicability of every cached solution.

V. Results and Analysis

A. Cold Start Mitigation

We first investigate the achieved cold start mitigation effect under different schemes. Fig. 6(a) compares the end-to-end cold start speedups under *Baseline*, *NNV12*, *PaSK* and *Ideal* schemes, where *PaSK* achieves 5.62× speedups over *Baseline*. Compared to *Baseline*, *NNV12* possesses only moderate speedups (3.04×). *NNV12* mitigates the cold start by avoiding tensor layout transforms (e.g., NCHW → NHWC) between layers, limiting the optimize opportunities on specific layers. Furthermore, we can observe that *PaSK* performs better on models with more primitive layers (`eff`, `unet`, `reg` and `ssd`), as there are more opportunities for PASK to reuse the existing substitutive solution to replace the absent one to accomplish the computation. On the other hand, transformer models (`vit`, `swin` and `swin2`) perceive less end-to-end cold start latency improvement compared to other convolution-based models. As transformer models primarily comprise of GEMM operators from the BLAS library, there is only one primitive layer provided by MIOpen (Table I). Hence, there are less reuse chances as PASK could be invoked only when the primitive routine is called.

TABLE II
COLD START SPEEDUP WITH VARYING INFERENCE BATCH SIZES.

Batch Size	1	4	16	64	128
NNV12	3.04×	2.82×	2.49×	1.91×	1.74×
PaSK	5.62×	5.24×	4.55×	3.91×	3.10×
Ideal	7.75×	7.23×	6.94×	6.78×	6.41×

We further demonstrate the cold start improvements with varying batch size for each inference request in Table II. With enlarged batch size, GPU is better utilized and the proportion of duration consumed on code loading is thereby lower. Besides, hot execution is still far more efficient compared to cold start, while *PaSK* still outperforms *NNV12* with a large margin (210%).

B. Utilization and Breakdown

To understand the effectiveness of PASK, we adopt the hardware utilization (the proportion of time when GPU is active relative to the entire inference duration) as the metric to explain how PASK boosts the cold start performance of DNN models on GPU. Fig. 6(b) illustrates the achieved utilization under the various schemes, where we can capture that the GPU active time accounts for only a few portion (8.2%) of model execution for *NNV12*. As the majority of time is spent on kernel code loading, the cold start latency is several times higher than the one in hot start. *PaSK* avoids this substantial overhead by reusing the applicable solutions from rather than always loading the missing one, and effectively elevates the utilization to 25.9% on average. For *Ideal*, since all solutions are already cached, there is no loading overhead when launching the desired kernels onto the GPU thus the accomplished utilization is up-to 68.5% on average.

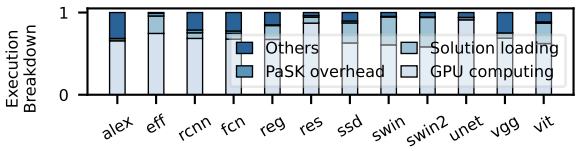

Fig. 7. Model cold start breakdown for *PaSK*.

Figure 7 further depicts the breakdowns of times consumed on different stages during model execution. We compare the ratios of times spent on GPU computing, solution loading, PASK overhead and others (e.g., host-device synchronization, model parse). The portion of time consumed on solution loading (11.2% on average) is acceptable compared to the cold start execution without dedicated management (Fig. 1). For transformer models (`vit`, `swin`, `swin2`), the solution loading proportion is relatively larger than other models, as the major operations are GEMMs. Moreover, the extra time incurred by PASK takes only 1.3% of the entire execution on average, indicating that PASK can efficiently retrieve the applicable alternative solution with negligible overhead.

C. Ablation Studies and Cache Statistics

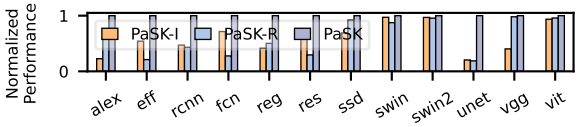

Fig. 8. Normalized performance of variants compared to *PaSK*.

In this section, we compare *PaSK* with its variants *PaSK-I* and *PaSK-R* to validate the effectiveness of solution reusing and categorical cache. For *PaSK-I*, the cold start latency reduction comes from the interleaved execution. Regarding *PaSK-R*, it adopts the naive cache which exhaustively searches all cached solution to find the optimal one, suffering from spending too much time in the applicability checking which is time-costly (section II-B). Fig. 8 illustrates the achieved proportional performance normalized to *PaSK*. For models perform worse in *PaSK-I* (`alex`, `vgg`, `unet`), we find the GPU execution durations before the milestone layer are short, thus there are less opportunities for *PaSK-I* to overlap the loading and execution process in these models. And we can only observe nuances of performance for transformer models, as they contain only one DL primitive operator (Table I) thereby possess few reuse opportunities.

To further investigate the impact of categorical cache, we collect the cache statistics during cold start. The cache hit rate describes the averaged possibility of successfully finding a applicable solution following the GETSUBSOLUTION routine in *Algorithm* 1. Fig. 9(a) shows the hit rate of categorical cache in PASK across models (69.7% on average) where transformer models are omitted as they contain only one primitive operator. We can capture that models comprising of more operators possess higher hit rates, as there are more chances for PASK to load the desired solution into the categorical cache following *Algorithm* 1. For subsequent queries, it is more likely to find a applicable solution in a cache with more entries.

Fig. 9(b) presents the averaged number of lookups per query (i.e., number of solutions whose applicability are checked), where the

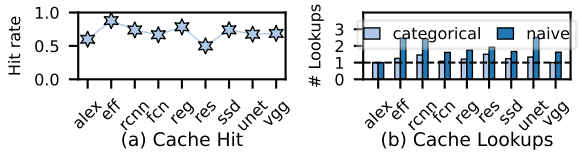

Fig. 9. Cache hit rate and averaged number of solution lookups for each hit.

categorical organization only uses 1.22 lookups per query while the naive searching requires 1.89 on average. As introduced in section II-B, checking the solution's applicability for a given problem is time-costly. Therefore, the naive solution searching strategy may result in severe performance downgrade due to enormous applicable checking overhead. It can be drawn from Fig. 9(b) that models with more lookups in the naive cache (`eff`, `unet`, `res`, `rcnn`) suffer from more pronounced performance downgrade in *PaSK-R* in Fig. 8. And the categorical organization in PASK can effectively reduce the number of required lookups per query, thus further boost the achieved performance.

VI. Discussions

Library supporting. As discussed earlier, the vision transformer models (`vit`, `swin`, `swin2`) possess less performance boosts from PASK because the major computation is matrix multiplication in the attention module [61]. Currently PASK is implemented atop of MIOpen, which contains the primitive operations used in DNN models (e.g., convolution, pooling), while the GEMM kernels are provided by the BLAS library (e.g., hipBLAS). Therefore, PASK can only identify and reuse a small portion of layers in the transformer models and offers limited cold start latency reduction for them. Note that it is trivial to extend PASK to support GEMM operators and accommodate with transformer models if more engineering efforts can be devoted to apply the similar modifications to hipBLAS. As hipBLAS and other vendor libraries (e.g. hipSPARSE [62] for sparse operators in GPU) following the same find-execution pattern (Fig. 3).

More factors for kernel specialization. Furthermore, PASK could be combined with other mechanisms by considering more factors. For instance, recent researches [63], [64] leverage the mix-precision components integrated in accelerators [65] to speedup the inference since DNN models usually have better tolerance on significance loss and numeric error. As the DNN operators are also specialized for tensor data types (`fp16`, `int8`), one may choose to still use high-precision data types if the corresponding kernels are already loaded while the low-precision ones are not. This offers the opportunities to accelerate the inference with high-precision computation by avoiding the overhead to load the absent kernels tailored for low-precision data types, even though the latter provide better performance on GPU. PASK can be generalized and applied to scenarios where the GPU kernels are specialized for some factors like input/output layout, data type, tensor tile size.

Loading desired solutions. Although PASK selectively skips the originally desired solutions to avoid the loading overhead, one can still load the skipped solutions during the intervals between two consecutive inference requests. Based on cloud workload traces [66], there are several seconds on average between the interval of two requests scheduled into the same inference instance. The interval duration is sufficient for PASK to proactively load the previously skipped solutions into the managed cache. Synergistically, they can act the candidates for reuse, or the desired solution which are already loaded for subsequent requests.

VII. Related Works

A. Cold Start Mitigation of DNN Models

Mitigating the cold start of DNN model has become the research appetite in recent years. Optimus [29] tackles the ML serverless container cold start problem by proposing the inter-function model transform approach which reuses operators from models of idle containers to compose the target model. Tetris [20] improves the serverless DNN inference latency and system container density via reusing duplicated tensors across instances. Pagurus [41] designs the algorithm to calculate the software dependency similarities between containers and then harness the idle container to build the intermediate image ready for helping to start the container rather than building from scratch. NNV12 [38] selectively loads the transformed weights in advance to avoid the tensor layout interchange overhead, and distributes the load and computation to different hardware units on edge/mobile devices.

These existing works share the container [29], [37], [41], service runtime [30], or model weights [20] among models. However, DNN models monolithic and cannot be transformed separately. Hence, some extra steps are needed to transform the shared resources to accommodate with the target model (e.g., modify the structure of warm models [29]). There are also general cold start mitigation approaches designed for cold microservice or serverless environments [37], [41], [67]–[70], but they fail to investigate the inference workflow and propose dedicated optimizations for DNN model invocations.

B. DNN Inference Optimizations

As the new computing paradigms thrive in recent years, cold start mitigation approaches have been proposed for preemptive spot [31], [33], [35], [41] computing and serverless computing [37]. For DNN model inference services under these two circumstances, the cold start process is inevitable as the serving instance has to be migrated across instances, or spawned in a new environment to satisfy the resource demands. PASK can be further integrated into the spot serving and serverless frameworks to mitigate the cold start issues with dedicated kernel loading management.

To harness the GPU capability for accelerating DNN computation, performance experts attempt to optimize operator graphs and model workflows to alleviate the memory bandwidth bottlenecks. TASO [25], Rammer [26], Cocktailer [27] and MonoNN [40] are graph transformation methods applying the intra- and inter-operator optimizations for the better hardware utilization. However, these approaches solely consider the kernel efficiency on GPU, and ignore the overhead of loading the multifarious generated kernels. PASK can be used to enhance these methods by assisting with some runtime information (e.g., the loaded kernels) to generate a more efficient execution plan for cold models.

VIII. Conclusion

In this work, we investigate the DNN model inference procedure and attribute cold start latency to the reactive scheduling strategy and kernel loading overhead. In order to mitigate the cold start latency, we propose PASK, a transparent middleware to schedule model kernels in a proactive strategy, and seek the opportunities to reuse existing loaded solutions organized categorically. We implement PASK on basis of the open source inference framework and primitive library and evaluate PASK with several popular DNN models. Detailed experiments demonstrate that PASK can effectively alleviate the cold start overhead for DNN model inference with 5.62× speedups compared to the default workflow used by the inference frameworks.

***Abstract*—We study the vulnerability of Cyber-physical systems (CPS) under stealthy sensor attacks in black-box scenarios. "Black-box" refers to scenarios where the attacker has minimal knowledge of the target system. Designing a stealthy sensor attack sequence under this scenario has two main challenges. The first one lies in ensuring the stealthiness of the sensor attack, meaning does not trigger an alert when applying the generated sensor attack sequence to the CPS. The second one is maintaining stealthiness throughout the attack generation process, indicating the limitation on the alarm frequency when generating the attack sequence. To address the above challenges, we develop a query-based black-box stealthy attack framework to violate the safety of the CPS. To maintain stealthiness during training, an active learning method has been introduced to extract the detector's information to a time series model. The stealthy attack sequence is then generated from that model. Experiments on four numerical simulations and a high-fidelity simulator demonstrate the effectiveness of the proposed framework.**

I. Introduction

Cyber-physical systems (CPS) integrate computing, networking, and physical systems via sensors and actuators. Widely used in applications like autonomous vehicles, drones, and power grids, CPS face significant security and safety challenges due to their complex environments, high connectivity, and long working periods. Sensor attacks are particularly severe, allowing attackers to manipulate sensor data and mislead controllers into issuing dangerous commands, such as manipulating the LiDAR sensor to steer a vehicle into obstacles [1] or crushing a drone by corrupting the values of an altitude sensor [2]. These emerging threats have spurred innovative research into sensor attack detectors [3]–[5]. The detectors trigger an alert by analyzing the difference between the predicted system states and system states from sensor readings.

Despite the presence of these detectors, some well-designed stealthy sensor attack methods can still achieve their objectives without triggering alarms. A stealthy sensor attack refers to the successful steering of a system into an unsafe zone while simultaneously avoiding the activation of detector alarms. These methods [6]–[8] often require significant knowledge of the system, such as system dynamics. However, having a thorough knowledge of the system is often unrealistic in practical applications. For example, attackers may find it hard to know the system model of a specific chemical plant. To fill this gap, we introduce the query-based method outlined in this paper for generating effective stealthy sensor attack sequences aimed at black-box CPS. In this context, "black-box" refers to scenarios where the attacker has minimal knowledge of the target system.

Designing a successful black-box stealthy sensor attack is promising yet challenging. The first challenge lies in ensuring the stealthiness of the sensor attack. Maintaining stealthiness of attack resides in devising an entire attack sequence that avoids triggering any alerts. Due to security and privacy considerations, CPS applications often obscure domain knowledge, including system dynamics and detector design, from external entities. Consequently, existing stealthy attack approaches that assume access to such knowledge are not applicable in this black-box scenario.

The second challenge is maintaining stealthiness throughout the attack generation process. This challenge implies that the process of obtaining the attack generator should not excessively trigger alarms, as system administrators may notice these additional alarms and modify the system or detector parameters, rendering the attack ineffective or exposing the attacker. Query is a widely used technique in black-box vulnerability analysis and attack synthesis. However, generating the attack through queries will inevitably trigger alarms. Reducing the number of alarms during the query process to ensure stealthiness during training poses a significant challenge.

To address these challenges, we propose a query-based black-box stealthy sensor attack framework to generate an efficient stealthy attack sequence while adhering to these constraints. We employ an active learning approach to generate attack sequences offline and utilize online queries to collect data. This enables the training of a neural network to replicate the system's detector, ultimately producing effective and stealthy attack sequences.

Our contributions are as follows. 1) We develop a framework to train a time series model that mimics a black-box system's detector behavior, capable of creating stealthy sensor attacks that significantly alter the system state. 2) Our method, based on active learning, efficiently gathers training data without triggering frequent alerts, maintaining training stealth. 3) We implement and evaluate our framework on various numerical and high-fidelity simulators, demonstrating its efficiency and effectiveness compared to existing methods.

II. Background and Related Works

In this section, we introduce some existing works on stealthy sensor attacks. The first group is conventional model-based approaches. The replay attack [9], a basic stealthy sensor attack, replaces real-time sensor data with previously recorded data. It simulates disturbance factors such as environmental noise, achieving a stealthy effect. However, it fails to effectively guide the system into the unsafe region. Covert attack [6], zero dynamic attack [7], and false data injection attacks [8] are all capable of performing stealthy sensor attacks. These methods typically generate a stealthy attack sequence offline, relying on complete knowledge of the system dynamics. However, such approaches necessitate an in-depth understanding of the system model, which significantly limits their applicability in real-world scenarios.

The second group uses data-driven methods to attack CPS. Studies like [10] and [11] target linear time-invariant (LTI) systems by learning the open-loop gain from control inputs, systems states, and

* denotes equal contribution.

some other information to generate attacks. Khazraei et al. [12] go further by designing a neural network-based attack generator to produce effective and covert sensor attacks. This is achieved by incorporating the detector's residuals and system deviation values as loss functions.

Although these learning-based methods can generate effective stealthy sensor attacks, they are ineffective in black-box scenarios, as they require access to internal system information such as control inputs and detector residuals. In contrast, our approach is designed for black-box settings, relying solely on sensor measurements and detector alarm status. These can be obtained through external observation: for sensor measurements, attackers can leverage their own additional sensors; for detector alarm status, the system's abnormal responses, such as recovery or reboot, often indicate an alarm has been triggered.

III. Preliminaries

A. System Model

The CPS model considered in the paper is a physical process governed by a discrete-time feedback controller. The controller operates at every time step. At the beginning of the time step t, the controller reads the state estimation $\hat{x}_{t|t-1}$ from the state estimator and uses a control algorithm to calculate a control input u_t. The control input u_t is then sent to the plant and drives the plant's evolution. Then the state estimator reads the sensor measurement y_{t+1} and gives the new state estimation $\hat{x}_{t+1|t}$. The system can be modeled as below:

$$\begin{aligned} x_{t+1} &= f(x_t, u_t) + w_t \\ u_t &= \Omega(\hat{x}_{t|t-1}),\ y_t = h(x_t) + v_t \end{aligned}$$

where $x_i \in \mathbb{R}^n$, $u_t \in \mathbb{R}^m$ and $y_t \in \mathbb{R}^p$ are the real system state, control input, and sensor measurements. n, m and p denote the corresponding dimensions. $f : \mathbb{R}^m \to \mathbb{R}^n$ is the system dynamics, $\Omega : \mathbb{R}^n \to \mathbb{R}^m$ is the control algorithm, and $h : \mathbb{R}^n \to \mathbb{R}^p$ is the observation function.

B. Threat Model

We investigate the scenario of a black-box sensor attack, where an attacker can only access the sensor measurement and the alarm notifications. This assumption is valid, as attackers can measure accurate sensor values externally. Additionally, many systems visibly respond to detected attacks, such as by initiating recovery [13] or restarting [14].

In real-world scenarios, attacking multiple sensors simultaneously increases complexity and detection risk, especially in the black-box context of this paper. Thus, our approach assumes the attacker targets only one sensor at a time. Shown in the equation: $supp(a_t) = \{i \,|a_{ti} \neq 0\} \subseteq \{0, 1, ..., p\}$, where the support of attack vector $a_t \in \mathbb{R}^p$ at time step t is equal to 1, meaning only one sensor is under attack.

Under these sensor attacks, the state estimator will receive y_t^c as the sensor reading instead, as shown below:

$$y_t^c = y_t + a_t = h(x_t) + v_t + a_t$$

where a_t indicates the sensor attack at time step t. As a result, the estimated system state $\hat{x}_{t|t-1}$ may significantly deviate from the actual state x_t, leading to $\hat{x}_{t|t-1} \neq x_t$. Such discrepancies can prevent the controller from generating accurate control inputs, expressed as $\Omega(\hat{x}_{t|t-1}) \neq \Omega(x_t)$. Consequently, this may lead to the system state deviating to the unsafe area.

C. Ordinary Detector

We assume that the system is equipped with a residual-based detector, such as window-based [3], cumulative sum (CUSUM) [5], and χ^2 [4], which are three most commonly used detectors.

Regardless of the type of state estimator used in the system, the residual r_t, as shown in Equation (1), is calculated by subtracting the real sensor readings from the inferred sensor readings calculated by the state estimator.

$$r_t = \| \ y_t - h(\hat{x}_{t|t-1}) \ \| \tag{1}$$

1) Window-based detector: It is a short-memory detector that focuses on accumulating residuals within an observation window time. If the accumulated residuals r_t^{sum} exceed a predefined threshold τ, meaning $r_t^{sum} > \tau$, an alarm is triggered.

2) Cumulative sum (CUSUM): This approach enhances long-term memory for a window-based detector. It is predicated on the observation that the residual value, typically a small quantity associated with noise, remains low in the absence of an attack on the system. Unlike window-based detector, CUSUM lacks a fixed observation window w and updates s_t using the equation: $s_{t+1} = (s_t + |r_t| - b)^+$, where r_t is the current residual, drift b counters noise to prevent s_t from growing infinitely in the absence of attacks. An alert is triggered when $s_t > \tau$.

3) χ^2: This detector is also a long memory detector. χ^2 is based on the distribution of cardinality. It is depicted in equation: $g_t = r_t^T S_t^{-1} r_t$, where S_t is the covariance matrix of r, thus g_t is the weighted norm of r_t, with χ^2 distribution. The detector will raise an alert if g_t exceeds the threshold τ, indicating that the residuals' distribution has altered, possibly as a result of attacks.

D. Problem Statement

The attacker aims to perform effective and stealthy sensor attacks in black-box scenarios. Specifically, the goal is to generate an attack sequence targeting one sensor over a duration T, causing significant system deviation from reference values while avoiding detection and alarm triggers.

1) Effectiveness: The attacker seeks to generate an attack sequence that maximizes the impact on the target sensor, measured by state estimation errors, defined as:

$$\Delta x_t = x_t - \hat{x}_{t|t-1} \tag{2}$$

Before the sensor attack starts, the value of Δx_t is constrained by noise, and the real system state x_t is close to the reference value. Sensor attacks corrupt the data received by the estimator, causing significant deviations from the system's actual state and resulting in estimation errors. Furthermore, this leads the system to deviate from the reference.

2) Stealthiness: Regarding stealthiness, we require not only that the final attack sequence generated avoids triggering system alarms, but also that the process of creating the attack sequence through the algorithm minimizes excessive or frequent alarm triggers.

Specifically, the problem can be formulated as the following: Consider a CPS where the attacker has access only to sensor measurements and the detector's alarm status. The attacker generates an attack sequence targeting a single sensor. During the attack generation process, the attacker ensures that the detector alarm is not triggered frequently. Once the attack is initiated, the goal is to maximize state estimation errors while avoiding triggering the detector's alarm.

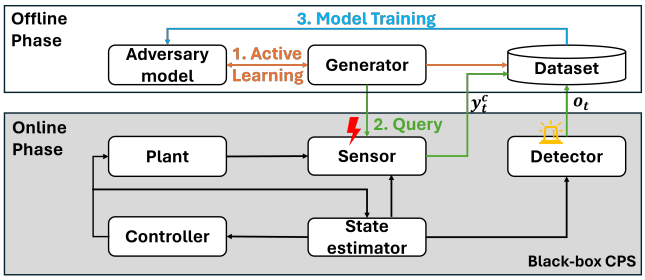

Fig. 1: The overview of the framework.

IV. Overview of the Framework

This section provides an overview of our query-based black-box stealth sensor attack framework, as shown in Fig. 1.

The grey box at the bottom represents the black-box CPS, whose internal information is inaccessible to us. We can only obtain sensor data y_t^c and the detector's result o_t. The white box at the top illustrates our query-based black-box stealth sensor attack framework. The adversary model is a time series model. It takes the sensor measurement y_t^c as the input and output alert or not o_t, allowing it to simulate the behavior of the detector. The generator is responsible for creating attack sequences based on our specifically designed active learning algorithm. The dataset is tasked with collecting data that is used to train the adversary model.

The orange, green, and blue arrows represent the three phases: active learning, querying, and model training. These phases are executed sequentially in a loop until a stealthy attack sequence meeting the requirements is generated. Active learning and model training occur offline, while the querying phase involves interaction with the CPS and operates online.

The process begins with the active learning phase, where the generator creates an initial attack sequence $a = \{a_0, a_1, ..., a_T\}$ of length T by interacting with the adversary model. In the query phase, this sequence is applied to the target system, producing sensor measurements y^c and detector alarm information o, which are collected into the dataset. A "one-step query" stops when the detector triggers an alarm, discontinuing any further attacks in the sequence. In the model training phase, the updated dataset, containing each attack sequence and corresponding alarm responses, is used to train the time-series model. The process then cycles back to active learning to generate a new attack sequence. This loop continues until a sequence of length T is produced that avoids triggering any alarms, resulting in the final stealthy attack sequence.

V. Query-based black-box stealthy sensor attack

This section outlines the process for generating a stealthy attack sequence targeting a black-box CPS. The first step is selecting a victim sensor, as the attacker in our threat model targets only one sensor at a time. The sensor with the highest potential to deviate the system from its reference should be chosen. A simple method is selecting the sensor most closely tied to the attack objective, such as targeting the distance sensor in a vehicular platooning system to cause collisions. Alternatively, a more refined approach involves testing the query-based attack method on each sensor and selecting the most effective one. For simplicity, we assume the appropriate sensor is pre-selected as the target.

A. Query

In this phase, a sensor attack sequence is applied to a stable system. The detector then identifies whether the sensors are maliciously perpetuated based on the ordinary detectors. The attacker collects the post-attack sensor measurements $y_t^c = y_i + a_i$ and alarm information o and compiles them into a set of training data.

When an alarm is triggered, the attacker halts the current attack and ends the one-step query. The query process concludes either when the detector raises an alarm or when the attack sequence reaches its end at T. For instance, if the query stops at step k, the training data includes $y^c = \{y_0^c, y_1^c, ..., y_k^c\}$, $y \in \mathbb{R}^{k*p}$ and the labels are $o = \{0, 0, ..., 1\}$, $o \in \mathbb{R}^k$. The attack sequence is then refined using an active learning algorithm, which is detailed later, and the refined sequence becomes the input for the next one-step query.

To maintain system stability, the next query is only initiated after the system returns to a stable state, allowing the attacker to control the interval between alarms and reduce detection risks. This flexibility improves stealth by spacing alarms and is especially useful during early training when initial attack sequences are more likely to trigger alerts.

B. Model Training

In this phase, we train the time series model to mimic the detector using the updated dataset.

Existing studies [10], [12] demonstrate that attackers can design stealthy attack sequences when they have access to the system model, detector parameters, and control signals. To reduce alarm triggers and minimize queries, having an approximate replica of the detector is crucial, as it allows for evaluating the likelihood of an alarm before launching a query.

The detector evaluates sensor readings across multiple time steps, forming correlated time series data, to decide whether to trigger an alarm. To replicate this behavior, we use a time series model, specifically a Long Short-Term Memory (LSTM) network in this paper. The LSTM model takes the attacked sensor readings y_t^c at time t as input and outputs the likelihood of the detector raising the alarm, shown in the equation below:

$$h_t = W_\theta(h_{t-1}, y_t^c), \ \hat{o}_t = \sigma(h_t)$$

where h_t denotes the hidden state calculated in the LSTM model at time t. The function σ is a mapping from h_t to $\hat{o}_t$, which is the alarm signal predicted by the current model.

Using the updated training dataset, the LSTM model learns the detector's behavior under various outputs and attack sequences. Since this is a binary classification task, the binary cross-entropy loss (BCEloss) [15] is used to calculate the loss.

At each training step, the LSTM model is trained on the previously collected dataset until it converges, ensuring $\hat{o}_t > 0.5$ if $o_t = 1$ and vice versa. This alignment ensures the model accurately reflects the detector's behavior in the real system. Consequently, the attack sequences generated using the LSTM model remain stealthy while achieving the maximum possible attack amplitude. Moreover, this approach enhances data utilization, which is especially valuable given the limited data available in this scenario.

C. Active Learning

In this phase, the generator generates the new attack sequence based on the LSTM model.

Attacking a system repeatedly to gather large amounts of data for training can significantly improve the LSTM model's performance. However, this is impractical under constraints on the number of alarms during training. To address this, we propose a generator based on an active learning algorithm to create new attack sequences using the trained LSTM model. By analyzing confidence scores, we identify

regions where the LSTM model is uncertain, guiding us to explore these areas to better simulate the detector's behavior. The details of

Algorithm 1 Active Learning

Input: y, a, β, k, a_{min}, a_{max}
Output: a_k
1: **while** $\beta > 0$ **do**
2: **for** $t = 0 : k$ **do**
3: $h_t = W_\theta(h_{t-1}, y_t^c)$
4: $\hat{o}_k = \sigma(h_k)$
5: **if** $ground(\hat{o}_k) == 0$ **then**
6: $a_{min} \leftarrow a_k$
7: **else**
8: $a_{max} \leftarrow a_k$
9: $a_k \leftarrow (a_{min} + a_{max})/2$
10: $\beta \leftarrow \beta - 1$

the active learning are summarized in Algorithm 1, which takes as inputs the time step k where the detector triggers an alert, sensor measurements, the partial attack sequence from step 0 to k, and the attacker-defined parameter a_{min}, a_{max}. The algorithm operates as follows: 1) Lines 2-4 are the LSTM inference process to get the output $\hat{o}_k$, the likelihood of an alert at step k. 2) Lines 5-9 update the a_k based on the output similar to binary search. If $\hat{o}_k < 0.5$, we change the a_{min} to a_k; If $\hat{o}_k > 0.5$, we set a_{max} to a_k. Then the new a_k is calculated from $(a_{min} + a_{max})/2$. 3) After β iterations, the updated a_k converges to a value near the boundary of the LSTM model's classification. This boundary value is used for subsequent queries as it represents data points where the model is most uncertain, making it highly valuable for refining the model.

The refined attack sequence a_t is generated based on the current LSTM model, minimizing the risk of triggering the detector during real-system queries. The active learning method further enables exploration near the LSTM model's decision boundary. Since the LSTM model is trained to approximate the system detector, the attack sequence performs similarly on both, ensuring stealthiness by avoiding alerts on the LSTM model. Additionally, the attack sequence is crafted using values near the detector's threshold at each time step, potentially maximizing Δx_t under the trained LSTM model, as per Equation (2). This aligns with our objective of pushing the system to deviate significantly without triggering alarms.

Although this method does not guarantee optimal attack performance, it achieves strong results in black-box scenarios, as the well-trained LSTM model closely mimics the real system detector. The active learning approach reduces the dataset size needed for LSTM model training, thereby minimizing alarm occurrences during data collection, and enhancing both the efficiency and stealth of the generator.

To summarise, the whole method is illustrated as algorithm 2. We first initialize a sequence of relatively large a and the LSTM model parameter θ. The T is the total length of the attack sequence which is defined by the attacker. The method works as follows: 1) Line 3-4: The attacker queries the system with the current attack sequence a; 2) Lines 5-8: Collect the data from time step 0 to k if the detector alerts at time step k; 3) Lines 9-10: Train the LSTM model until convergence and update the a_k using Algorithm 1; 4) Lines 11-13: Reset k to 0 if alarms, continue if not; 5) repeat the process after the attacker obtains a length of T attack sequence. By updating the attack duration steps, our LSTM model can effectively simulate the behavior of the detector in the actual system. The attack sequence

Algorithm 2 Query-based black-box stealthy attack algorithm

1: $Initialize\ \theta, T, a, \beta, a_{min}, a_{max}$
2: **for** $t = 0 : T$ **do**
3: **while** $k \leq t$ **do**
4: $a \rightarrow System$
5: **if** $alarm$ **then**
6: $y = \{y_0, y_1, ..., y_k\} \in \mathbb{R}^{p*k}$
7: $y^c = \{y_0 + a_0, y_1 + a_1, ..., y_k + a_k\} \in \mathbb{R}^{p*k}$
8: $o = \{o_0, o_1, ..., o_k\} \in \mathbb{R}^k$
9: $\theta \leftarrow LSTM\ update(\theta, y^c, o)$
10: $a_k \leftarrow Active\ Learn(y, a, \beta, k, a_{min}, a_{max})$
11: $k \leftarrow 0$
12: **else**
13: $k \leftarrow k + 1$

updated through this process can be utilized as a stealthy attack, causing the system to deviate from the reference without triggering an alert.

VI. Evaluation

We now compare the performance of our proposed stealthy attack strategy with two baselines. We test them on four numerical simulators and a high-fidelity simulator.

A. Numerical Simulation

To evaluate our algorithm and compare it with the baseline method, we consider several numerical CPS simulations: vehicle platoon, quadruple tank, DC motor speed, and aircraft pitch. We set $\beta = 25$ in all four benchmarks.

1) Simulator setting: **Vehicle platoon.** This system consists of four vehicles maintaining a stable 1-meter gap, forming a platoon, modeled after [16]. Each vehicle uses a lidar to measure the gap from the vehicle ahead. It also monitors the velocities of all vehicles. An attacker aims to reduce the gap between the front two vehicles and can only manipulate the distance sensor readings between them.

Quadrotor. The system model for controlling a four-rotor quadrotor is described in [17]. The input of the system is the total vertical thrust of the quadrotor, along with the three angular motions, The output of the system consists of six variables: The first three represent the relative position, while the last three correspond to the angles of pitch, yaw, and roll, respectively. In our scenario, we assume that the quadrotor is maintaining its altitude at 5 meters. An attacker manipulates the sensor measuring the altitude, causing it to drop.

DC Motor speed. The DC motor is an actuator to provide rotary motion and is usually coupled with wheels, drums and cables. The input of the system is the voltage source applied to the motor's armature, while the output is the rotational speed of the shaft. An attacker can manipulate the rotational speed sensor and the goal is to decrease the speed of the shaft.

Aircraft pitch. The aircraft pitch system [18] is an autopilot controlling the pitch angle of an aircraft. The system takes the elevator deflection angle as input and outputs the pitch angle. Assuming the yaw angle remains at 0 radians, the attacker aims to disrupt this stability by manipulating the pitch angle to deviate from its original value of zero.

2) Detector setting: For each benchmark, we employ both the CUSUM and χ^2 detectors. Process noise is modeled as zero-mean white noise. We tune the detectors to maintain a false alarm rate below 0.01 in the absence of attacks.

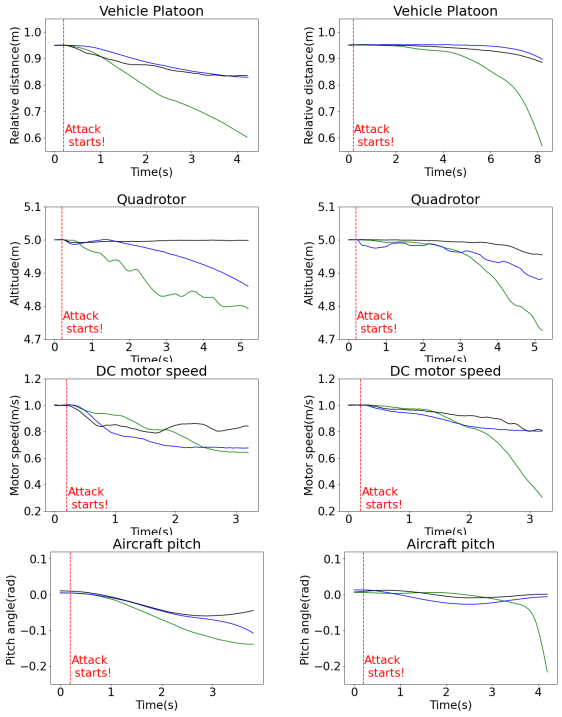

Fig. 2: Attack on each benchmark with CUSUM (left column) and χ^2 (right column) detector. The x-axis represents the time steps, while the y-axis represents the target system states. Green, blue, and black denote our query-based methods, the learning method, and random search methods, respectively.

3) Baseline setting: **Learning method.** We use the learning-based method [12] as a baseline. This method generates attack sequences using sensor measurements y_t and the detection function g_t during training. It also relies on N offline copies of the system, which is impractical in real-world scenarios. To adapt the baseline to our case, we set $N = 1$. **Random search method.** We introduce a second baseline method that uses a modified random search strategy to select the next attack sequence, as a purely random search is too inefficient. This method begins with the same initial value as our query-based approach and updates the attack sequence if it triggers an alarm, using the equation $a_t = random(a_t * 0.8, a_t)$, where the random function selects a value between $a_t * 0.8$ and a_t.

4) Attack effect analysis: We evaluated our query-based attack method against the two baseline methods in terms of attack effectiveness without imposing time constraints on the attacker. As shown in Fig. 2, our method drives all four benchmark systems away from their stable states more quickly and significantly than the baselines, demonstrating superior effectiveness. The results also reveal that with χ^2 detectors, the learning-based method often fails to consistently destabilize the system. Meanwhile, the random search method can generate attack sequences but performs the worst, as it lacks the capability to maximize the attack's impact. In contrast, our query-based black-box stealthy attack method significantly enhances the attack's impact compared to baselines.

5) Stealthiness analysis: In the experiments, all methods generate stealthy final attack sequences, making a comparison of final stealthiness irrelevant. Instead, we analyze stealthiness during the training process, focusing on two key aspects: 1) the number of queries and 2) the number of alarms triggered during training. Notably, the learning-based method leverages knowledge of the detector's residual, enabling it to avoid many alarm triggers during training. As a result, this method is excluded from the comparison in this subsection.

For the first aspect, we analyze how the number of queries varies with the length of the attack sequence. As shown in Table I, our method substantially reduces the number of queries compared to the random search method. This reduction highlights the effectiveness of the trained LSTM model in capturing the dynamic changes in the system's sensor values, enabling fewer queries and faster generation of the attack sequence within a shorter training period.

No. of queries: Query / Search	Detector	T = 50	T = 100	T = 150
Vehicle platoon	CUSUM	70 / 291	102 / 514	154 / 916
	Chi-square	111 / 533	190 / 988	293 / 1424
Quadrotor	CUSUM	95 / 373	298 / 671	526 / 998
	Chi-square	172 / 486	323 / 858	410 / 1257
DC motor speed	CUSUM	61 / 251	113 / 488	165 / 716
	Chi-square	103 / 356	262 / 581	489 / 752
Aircraft pitch	CUSUM	122 / 255	235 / 542	368 / 780
	Chi-square	116 / 405	216 / 865	269 / 1286

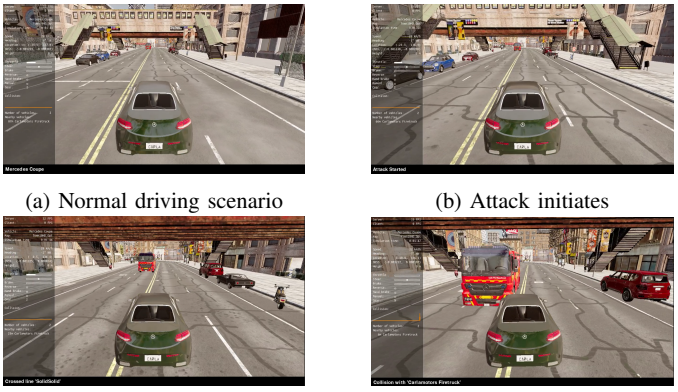
TABLE I: The number of queries to generate a certain length of attack sequence under different benchmarks and detectors using our query-based method and random search method.

For the second aspect, we ensure the system manager remains unaware of the attack by pausing the attack and loop processes when an alarm triggers during attack generation. The overall alarm rates for our method are shown in Table II. As can be observed, the attack remains highly stealthy during the training process.

B. CARLA

We implement the lane-keeping autonomous driving system [1] and on the high-fidelity simulator CARLA [19]. An attacker can manipulate GPS sensor readings, deviating the vehicle from its path and potentially crashing into other vehicles or obstacles. System variable e_d is used to measure the distance by which the vehicle deviates from the reference.

The results are shown in Fig. 3. The attacker generates an attack sequence for a duration of T=300 control steps. Prior to the start of the attack, the vehicle remains centered within the lane, with $e_d = 0$, and the residual is minimal. Once the attack commences, the vehicle progressively veers away from the lane without triggering any alarms. Ultimately, the vehicle collides with an off-road firetruck, but even then, the residual value fails to activate an alarm. This stealthy behavior indicates the success of the attack. Fig. 4 illustrates the process by which the attack impacts the vehicle. Note that the residual changes once the attack starts, this is inevitable because the χ^2 detector is sensitive to the noise changes. However, our attack does not trigger an alarm during the implementation phase.



C. Discussion

One possible solution to defend against our proposed attacks is to block malicious users from gaining information about the detector by the query. As we mentioned before, the query process will inevitably generate alarms by the detector to get meaningful information. Defenders can utilize more sophisticated detectors, such as adaptive detector [20] and stealth attack detector [21].

The other direction to defend is protecting the system from being steered to non-secure areas under our proposed sensor attack

	Vehicle platoon	Quadrotor	DC motor speed	Aircraft pitch
Alarm rate	0.0036	0.0034	0.0035	0.0036

sequence. The simplest way to block sensor attacks is to leverage sensor redundancy. For example, in aircraft, there is usually more than one pitot tube to obtain airspeed. Some other methods, such as sensor fusion [22], well-designed state estimation [23], [24] can also be helpful.

VII. Conclusion

We propose a query-based black-box sensor attack method for CPS with a residual-based detector. Our approach ensures stealthiness both during the training process and throughout the attack execution. Extensive experiments have demonstrated the effectiveness of the proposed method.

***Abstract*—The emergence of new applications in high-performance computing is driving the need for more efficient computing machines. As supercomputer architectures become increasingly complex, the combinatorial explosion of design spaces and the time-consuming nature of design simulations lead to challenging design space exploration problems. This work introduces an automated search framework to achieve power-performance-area efficient Arm Neoverse V1 processor designs. Based on multi-objective Bayesian optimization, we propose a new exploration algorithm named SEBO by enhancing the three main stages of the optimization. Experimental results show that SEBO can not only compete with the top state-of-the-art baseline algorithms, but also outperforms them in terms of the quality and diversity of the returned Pareto-optimal designs.**

***Index Terms*—High-performance computing, design space exploration, Bayesian optimization, ensemble learning**

I. Introduction

High-Performance Computing (HPC) is at the heart of recent advances in large-scale processing and modeling problems. From weather forecasting and physics simulations to machine learning and data analysis, these applications are becoming more and more computational intensive, leading to a sophistication of supercomputer architectures within the Multi-Processor System-on-Chip (MPSoC) design paradigm.

To ensure their efficiency before chip manufacturing, heavy simulation-based design is the state-of-the-art approach [5]. By running target applications on virtual prototypes, it gives designers access to key performance indicators (latency, power, etc.) of simulated architectures. The challenge is to figure out efficient architectural configurations by tuning through simulations, various hardware parameters such as core count, cache size, Network-on-Chip (NoC) topology, etc. However, due to the combinatorial explosion of design spaces and the time-consuming nature of design simulations, engineers must adopt a co-design approach by carefully selecting which architectural configurations to prioritize and for which target applications. Analytical formulations [32], [34] have been proposed as a simulation-substitute method for calculating performance metrics, but it requires confidential data from industry to correctly parameterize formulas and their coefficients. As a result, the choice of the final architectural configuration often relies on expert knowledge gained from engineering experience.

On the other hand, Design Space Exploration (DSE) [27] methodologies have shown impressive results for reaching more efficient designs [1], [22] than expert-made ones. Machine learning and operations research techniques provide powerful exploration algorithms to overcome high-dimensional multi-objective optimization difficulties. In this work, an automated design space exploration framework is proposed based on an advanced state-of-the-art Bayesian optimization algorithm for efficient 7nm Arm Neoverse V1 processor designs. Our contributions are as follows:

- The automated design space exploration framework uses VPSim [7], a SystemC transaction-level modeling (TLM) simulator, and a 7nm-supported McPAT [21], [38] modeler to compute Power-Performance-Area (PPA) estimations with a good simulation speed-accuracy trade-off.
- We propose a new exploration algorithm named SEBO, for Stage-Enhanced Bayesian Optimization, featuring a two-step Hammersley-transductive experimental design [37] model initialization, a trust region-based [12] ensemble surrogate modeling, and a batch acquisition function with parallel simulations. Each stage of the optimization is optimized to unveil an end-to-end efficient framework.
- The experimental results were validated for various standard HPC applications on large Arm Neoverse V1 architectural configurations with up to 128 cores. SEBO has been compared with the top state-of-the-art DSE baselines [1], [4], [25] and shows excellent performance in terms of the quality and diversity of the returned Pareto-optimal designs for a reasonable running time.

The paper is structured as follows. Section II discusses the state of the art of exploration algorithms. Section III depicts our proposed framework, followed by experimental results and observations in Section IV. Finally, Section V ends with conclusion and perspectives.

II. Related work

A. Model-free and model-based approaches

Exploration algorithms can be divided into two main classes: model-free and model-based approaches [27]. Understanding these is key to strengthening exploration by selecting the most adapted one to each workflow's specificities.

Early works focused on model-free approaches with algorithmic improvements. Platune [19], a platform-tuning environment, used Pareto local search with parameter clustering for efficient MIPS R3000 processor SoC design. By building a parameter dependency model, Platune enables exploration at

scale through design space reduction. The high-level synthesis DSE tool Cwbexplorer [29] has also adopted a clustering approach with simulated annealing. Despite the benefits of clustering, Palesi and Givargis [26] found that it may be insufficient to significantly reduce the design space and further improved Platune's scalability using the genetic algorithm SPEA2. However, since the model-free algorithms mentioned above heavily rely on heuristic functions, the exploration outcomes may be driven by some degree of intrinsic randomness. That means model-free algorithms are only efficient for high evaluation budgets. The greater the number of evaluations, the more quantitative information the randomness provides.

While evaluating a single configuration in Platune takes on average 1.5s, other frameworks like the VLSI flow of RISC-V Berkeley Out-of-Order Machine (BOOM) [1] can require 6 to 14 hours. In such cases, the randomness of model-free algorithms becomes undesirable, making sample-efficiency a critical feature to consider. In contrast, model-based approaches leverage machine learning models to capture the relationship between design parameters and objective functions. A typical example of that is reinforcement learning. Beltrame *et al.* [3] for instance, translated the domain knowledge of an MPSoC into a discrete-space Markov decision process and found the optimal exploration policy with value iteration. Lin *et al.* [22] went further using Monte-Carlo tree search to learn a deep policy network for efficient routerless NoC design. However, deriving optimal policies through reinforcement learning techniques is naturally sample-expensive, leading them to be more suitable for learning optimal control in applications like robotics or autonomous agents rather than for expensive simulation-based objective optimization.

B. Bayesian optimization: a sample-efficient methodology

As a similar learning-based alternative, Bayesian optimization [18] offers a more sample-efficient strategy. It sequentially employs two key components: the surrogate model and the acquisition function. After each design evaluation, the results are fed into the surrogate model to improve the objective function approximation. The acquisition function then leverages the surrogate model as a fully information-aware decision making tool to optimally suggest the next design to evaluate and so on. The sample-efficiency is therefore guaranteed by the surrogate model's ability to approximate the objective function precisely.

Among Bayesian optimization-based DSE frameworks, HyperMapper [25] proposed a random forest surrogate model for each objective function and combined with the expected improvement acquisition function using a randomized Chebyshev aggregation. Although random forests offer strong non-linear regression for discrete design spaces, their ability to model uncertainty as accurately as Gaussian processes, commonly used in Bayesian optimization, is debatable. In contrast, BOOM-Explorer [1] takes advantage of the latter and increases their modeling power through deep kernel learning. Moreover, since surrogate models need to be initialized, Bai *et al.* also implemented a clusterized transductive experimental design [37] as initial sampling for an informative warm start.

Despite the promising results of Bayesian optimization in DSE problems, most advanced Bayesian optimization techniques have been studied beyond hardware design. In the NeurIPS 2020 black-box optimization challenge [31], participants were asked to implement an efficient algorithm that outperforms the strongest baseline TuRBO [16], a new state-of-the-art Bayesian optimization algorithm, for various machine learning hyperparameter tuning tasks. The main conclusions of the challenge suggest that, first, Bayesian optimization was consistently effective. Not only did less-efficient Bayesian optimization-based baselines outperform genetic algorithms, but also all of the top proposed methods were Bayesian optimization techniques. Secondly, to outperform TuRBO, top participants naturally employed its main feature: using trust regions for local Bayesian optimization and incremented, on top of that, multiple surrogate and acquisition models as ensemble learning. Considering the no free lunch theorems [35], leveraging multiple surrogate models can further improve the approximation of objective functions.

To illustrate how the fit of surrogate models impacts exploration, Dreczkowski *et al.* [15] conducted a comparative study on discrete kernel-based Gaussian processes for combinatorial Bayesian optimization. They found that some kernels, such as the string subsequence [20], the overlap, and the Hamming embedding via dictionary [13], provide better model fitting than others across various benchmarking tasks. Furthermore, they also observed that trust region-based methods consistently outperform the non-trust region ones, confirming the efficiency of local modeling for any problem instances.

Assuming hardware design optimization deals with discrete parameters, leveraging trust regions and ensemble learning with efficient discrete space-tailored surrogate models is key to achieving a state-of-the-art Bayesian optimization-based DSE.

III. Automated Exploration framework

Fig. 1 shows our proposed framework and provides an overview of how an automated model-based DSE works. By alternating between design suggestions and simulation feedback, the exploration model progressively accumulates relevant information, which further enhances this alternating mechanism, driving the convergence toward efficient designs. Known as active learning, the way in which the model makes suggestions and updates itself with new information is central to exploration performance.

A. Multi-objective optimization problem

In hardware design, the quality of an architecture is measured through different key performance indicators, such as energy consumption, latency, and area. Since the latter are negatively correlated, the ideal design, which is the one that would have the best value for each metric at the same time, is in reality, not feasible. Trying to optimize one objective comes at the cost of degrading another. While in single-objective optimization, the optimality is trivially deduced from the total order of real numbers, searching optimal design in multi-

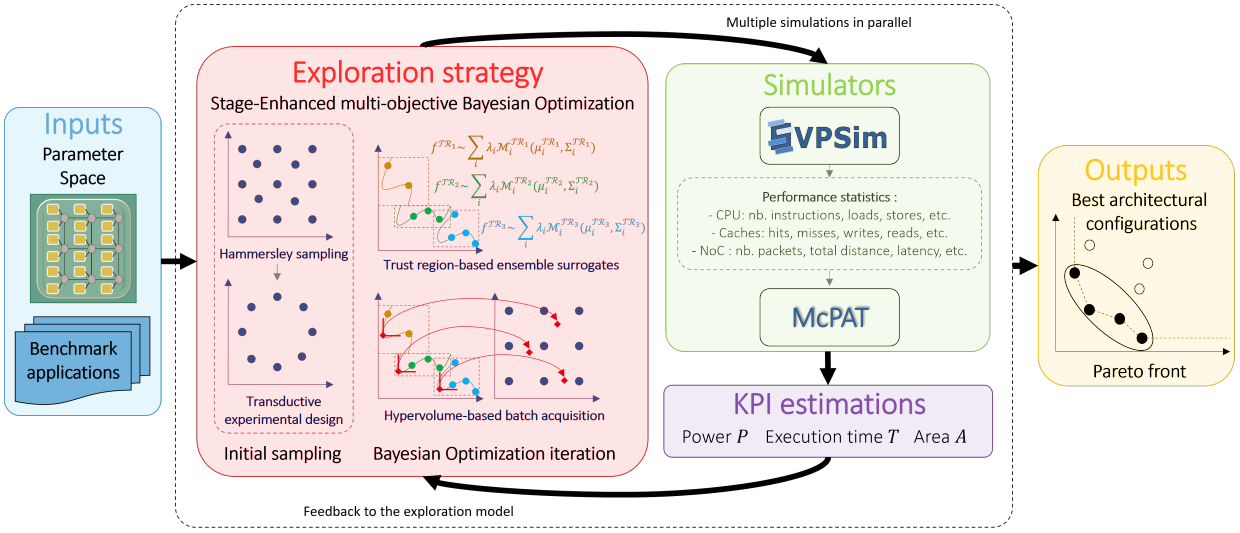

Fig. 1: Overview of proposed automated design space exploration framework

objective optimization comes down to making objective trade-offs defined by the Pareto optimality.

Definition 1 (Pareto optimality)**.** *Let $\mathcal{X}$ be the design space and $M \geq 2$. Given a M-dimensional multi-objective function $F(\mathbf{x}) = [f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_M(\mathbf{x})]^\top$, a solution $\mathbf{x} \in \mathcal{X}$ is said to be dominated by $\mathbf{y} \in \mathcal{X}$, denoted as $\mathbf{x} \preceq \mathbf{y}$, in minimization (resp. maximization) problem if and only if:*

$$\begin{aligned} &\forall\, p \in [\![1, M]\!], \quad f_p(\mathbf{y}) \leq f_p(\mathbf{x}) \quad (\textit{resp. } f_p(\mathbf{y}) \geq f_p(\mathbf{x})) \\ &\exists\, q \in [\![1, M]\!], \quad f_q(\mathbf{y}) < f_q(\mathbf{x}) \quad (\textit{resp. } f_q(\mathbf{y}) > f_q(\mathbf{x})) \end{aligned} \tag{1}$$

A solution $\mathbf{x}$ is Pareto-optimal if and only if no other solution dominates it (i.e. $\nexists\, \mathbf{y} \in \mathcal{X}, \mathbf{x} \preceq \mathbf{y}$).

Since different objective trade-offs are possible (*e.g.*, a design can be more latency efficient at the cost of higher energy consumption, or *vice versa*), the goal of multi-objective optimization is to return all feasible Pareto-optimal solutions.

Therefore, achieving PPA-efficient hardware designs involves multi-objective optimization. Given a design space $\mathcal{X}$, we want to retrieve the Pareto set $\mathcal{X}_P$ by simultaneously minimizing the energy consumption e, the execution time t and the area a given a target application γ:

$$\min_{\mathbf{x} \in \mathcal{X}} F(\mathbf{x}) = [e(\mathbf{x}, \gamma), t(\mathbf{x}, \gamma), a(\mathbf{x})]^\top \tag{2}$$

$$\mathcal{X}_P = \{\mathbf{x} \in \mathcal{X} \mid \nexists\, \mathbf{y} \in \mathcal{X}, \mathbf{x} \preceq \mathbf{y}\} \tag{3}$$

In our problem instance, a design $\mathbf{x}$ is in the design space $\mathcal{X}$ if its architectural parameters are among candidate values defined in TABLE I and satisfy hardware constraints.

As analytical formulations are not exploited here, the multi-objective values $F(\mathbf{x})$ are obtained through design simulations using various electronic design automation tools. In particular, we leverage VPSim and an enhanced version of McPAT [38] to build our simulation flow for Arm processor design.

B. VPSim simulator and McPAT modeler

VPSim [7] is a SystemC TLM-based virtual prototyping tool dedicated to hardware-software co-design. Based on the emulation platform QEMU [2] augmented with fast memory hierarchy models, VPSim enables running software applications on simulated architectures for various processor models including Arm cores. With a good balance between simulation speed and accuracy, VPSim not only estimates application execution time but also provides performance statistics such as the number of instructions, cache reads/writes, hits/misses, etc. However, since it computes only one of the objectives, we use McPAT to handle the remaining objective computations.

TABLE I: System-level design space of Arm Neoverse V1

Architectural parameters	Candidate values
Number of cores n_c	2, 4, 8, 16, 32, 64, 128
Number of cores per cluster n_q	1, 2, 4, 8, 16
L1 data/instruction cache size (KB) s_1	16, 32, 64, 128
L2 cache size (KB) s_2	256, 512, 1024, 2048
L3 cache size (KB) s_3	512, 1024, 2048, 4096, 8192
Cache block size (B) b	64, 128
L1 cache associativity a_1	2, 4
L2 cache associativity a_2	4, 8, 16
L3 cache associativity a_3	4, 8, 16, 32
Mesh NoC XY dimensions d_X, d_Y	1, 2, 4, 8, 16

McPAT [21] is a power and area modeling framework for many-core architectures. Built on top of CACTI [24], McPAT follows the same analytical approach to extend power and area evaluations for between 90nm to 22nm technology node-based MPSoC. Since McPAT needs to be combined with a performance simulator to function, the coupling of McPAT and VPSim is perfectly matched to form a complete PPA evaluation flow.

Furthermore, to support 7nm design, we draw inspiration from McPAT-Calib [38] by integrating 7nm FinFET technology [8] scaling parameters into McPAT's analytical models. Whereas McPAT-Calib leveraged on top of that, already simulated architecture data to train McPAT's models for better accuracy, we assume here to be design-agnostic, and to not use any prior simulation information before the start of DSE.

To automate DSE efficiently, we propose our own exploration algorithm named SEBO, based on improvements at

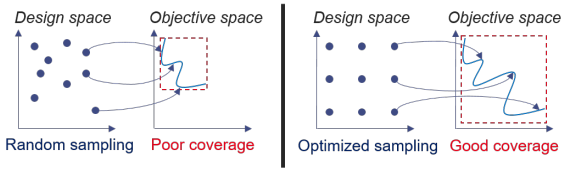

Fig. 2: Example of efficient sampling

three main stages of Bayesian optimization.

C. Stage-enhanced multi-objective Bayesian optimization

SEBO is a model-based algorithm based on Bayesian optimization principle [18] for multi-objective optimization. As SEBO employs surrogate models, they must first be initialized by training on an initial set of solutions with their corresponding labels (their objective values). In our problem, it means choosing initial architectural configurations and simulating them. This can be considered as the first stage of DSE.

A common method for selecting initial solutions is random sampling. Despite its simplicity, the stochasticity of random sampling can lead to a poor quality of initial solution set, ultimately biasing surrogate models by feeding them with undiversified information. Fig. 2 illustrates this impact.

In order to achieve an informative model initialization, we introduce the two-step Hammersley-transductive experimental design sampling as our first improvement. To understand the logic behind this, let's consider the ridge regression problem.

Definition 2 (Ridge regression)**.** *Given n training samples $X = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n]^\top$, $\mathbf{y} = [y_1, y_2, \dots, y_n]^\top$ where $(\mathbf{x}_i, y_i) \in \mathbb{R}^N \times \mathbb{R}$ for $i = 1, \dots, n$, small $\lambda > 0$ and $\|\cdot\|$ the Euclidean norm, Ridge regression consists of solving:*

$$\hat{\mathbf{w}} = \underset{\mathbf{w} \in \mathbb{R}^N}{\arg\min} \|\mathbf{y} - X\mathbf{w}\|^2 + \lambda \|\mathbf{w}\|^2 \tag{4}$$

Trivially, $\hat{\mathbf{w}} = \left(X^\top X + \lambda I\right)^{-1} X^\top \mathbf{y}$ with identity matrix I. Considering regression is not exact due to the potential influence of unseen factors, the labels $\mathbf{y}$ are commonly modeled as $y_i = \mathbf{w}^\top \mathbf{x}_i + \epsilon_i$ where $\epsilon_i \sim \mathcal{N}\left(0, \sigma^2\right)$ for $i = 1, \dots, n$. Then, the estimation error $\hat{\mathbf{w}} - \mathbf{w}$ has (with the zero vector denoted as $\mathbf{0}$ and $\boldsymbol{\epsilon} = [\epsilon_1, \epsilon_2, \dots, \epsilon_n]^\top$):

$$\begin{aligned} \mathbb{E}\left[\hat{\mathbf{w}} - \mathbf{w}\right] &= \left(X^\top X + \lambda I\right)^{-1} X^\top \mathbb{E}\left[\boldsymbol{\epsilon}\right] = \mathbf{0} \\ \mathrm{Var}\left[\hat{\mathbf{w}} - \mathbf{w}\right] &= \mathrm{Var}\left[\left(X^\top X + \lambda I\right)^{-1} X^\top \boldsymbol{\epsilon}\right] \\ &= \sigma^2 \left(X^\top X + \lambda I\right)^{-1} X^\top X \left(X^\top X + \lambda I\right)^{-1} \end{aligned} \tag{5}$$

If the regression is exact, $\mathrm{Var}\left[\hat{\mathbf{w}} - \mathbf{w}\right]$ should be equal to $\mathbf{0}$. $\mathrm{Var}\left[\hat{\mathbf{w}} - \mathbf{w}\right]$ is therefore the metric which quantifies the amount of information that regression models cannot capture. Suppose we can now select our n training samples from the design space $\mathcal{X}$. Let V be the matrix composed of all designs $\mathbf{v} \in \mathcal{X}$. Selecting the most informative samples (for linear models) is equivalent to "minimize":

$$\mathrm{Var}\left[V\hat{\mathbf{w}} - V\mathbf{w}\right] = V\,\mathrm{Var}\left[\hat{\mathbf{w}} - \mathbf{w}\right] V^\top = \sigma^2 C C^\top \tag{6}$$

where $C = VX^\top \left(XX^\top + \lambda I\right)^{-1}$ with the push-through identity. As we can notice, "minimizing" this variance doesn't require any labels $\mathbf{y}$. This means we can select the most informative design solutions for our model initialization without simulating them. The kernel trick [30] is then applied within the regression framework to handle non-linear models, hence, defining the transductive experimental design problem (note that our formulation differs from the original paper [37]).

Definition 3 (Transductive experimental design)**.** *Let $\mathcal{H}$ be a reproducing kernel Hilbert space with a kernel function $k(\mathbf{u}, \mathbf{z}) = \langle \phi(\mathbf{u}), \phi(\mathbf{z}) \rangle_{\mathcal{H}}$ where $\mathbf{u}, \mathbf{z} \in \mathbb{R}^N$ and $\phi : \mathbb{R}^N \to \mathcal{H}$ is a feature mapping. Supposing $\|\cdot\|_F$ is the Frobenius norm and $f \in \mathcal{H}$ has the form $f(\mathbf{x}) = \mathbf{w}^\top \phi(\mathbf{x})$, the optimal transductive experimental design is solution of, with matrix notation $K_{VX} = \left(k(\mathbf{v}_i, \mathbf{x}_j)\right)_{1 \le i \le s,\, 1 \le j \le n}$:*

$$\begin{aligned} &\min_X \left\| K_{VX} \left(K_{XX} + \lambda I\right)^{-1} \right\|_F^2 \\ &\textit{s.t. } \{\mathbf{x}_i\}_{i=1}^n \subseteq \{\mathbf{v}_i\}_{i=1}^s \end{aligned} \tag{7}$$

Since solving transductive experimental design over the entire design space is NP-hard due to combinatorial explosion, we leverage Hammersley sampling [9], [36] to build a low-discrepancy representative subset of the design space for V. We then solve transductive experimental design on it, using a scalable genetic algorithm. While BOOM-Explorer [1] relies on architecture-specific prior knowledge for pre-sampling its transductive experimental design, Hammersley sampling, by contrast, doesn't require any prior information about interactions between design space variables to sample, making it adapted for all DSE problem instances. Thus, our two-step Hammerlsey-transductive experimental design sampling forms the initial set of designs to be explored.

Given this first stage improvement, our second involves proposing accurate and expressive surrogate models. An efficient approach to achieve that is to employ Gaussian processes (GP) [28] for each objective. GP are non-parametric models that can be viewed as multivariate normal distributions over functions. In other words, $f \sim \mathcal{GP}(m, k)$ if for any finite collection of function values $\mathbf{f} = [f(\mathbf{x}_1), f(\mathbf{x}_2) \dots, f(\mathbf{x}_n)]^\top$:

$$\mathbf{f} \sim \mathcal{N}\left(\left[m(\mathbf{x}_1), \dots, m(\mathbf{x}_n)\right]^\top, K_{XX}\right) \tag{8}$$

where m and k are the mean and variance functions. This definition implies that any $f(\mathbf{x}_i)$ is modeled by a Gaussian distribution, where the density function represents the plausibility of $f(\mathbf{x}_i)$ to be equal to the corresponding value from the support. By setting m and k correctly, these plausibilities which characterize our beliefs about the objective space in relation to the design space, can be parametrized, enabling machine learning process. Assuming simulations may be noisy, let $m(\mathbf{x})$ be associated with its observed value y as the empirical mean and k be a kernel function with hyperparameters $\boldsymbol{\theta}$, the objective values of an unexplored design $\mathbf{x}_* \in \mathcal{X}$ can be predicted by computing the posterior probability distribution $f(\mathbf{x}_*) \,|\, \mathbf{x}_*, X, \mathbf{y}$ using Bayes' rule with the joint distribution:

$$\begin{bmatrix} f(\mathbf{x}_*) \\ \mathbf{f} \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} m(\mathbf{x}_*) \\ \mathbf{y} \end{bmatrix}, \begin{bmatrix} k_{\boldsymbol{\theta}}(\mathbf{x}_*, \mathbf{x}_*) & K_{\mathbf{x}_* X | \boldsymbol{\theta}} \\ K_{X \mathbf{x}_* | \boldsymbol{\theta}} & K_{XX|\boldsymbol{\theta}} + \sigma^2 I \end{bmatrix}\right) \tag{9}$$

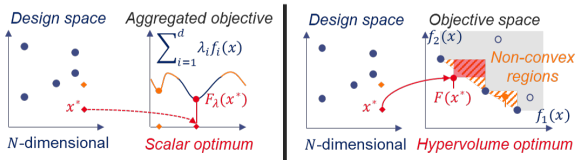

Fig. 3: Omission of non-supported Pareto-optimal solutions

where $\boldsymbol{\theta}$ is tuned by maximizing the marginal likelihood. As their expressiveness depends on the kernel function, the choice of the latter becomes critical.

To mitigate the risk of choosing an unsuitable kernel, we bring ensemble learning by selecting the most appropriate kernel from the power set of different linear combinations of discrete space-tailored kernels at each iteration of Bayesian optimization and more importantly, for each objective function. In particular, we leverage the overlap k^{O}, the transformed overlap k^{TO} [33] and the Hamming embedding via dictionary k^{HED} as our base kernels to construct our ensemble $\mathcal{K}$:

$$\mathcal{K} = \left\{ \sum_{k \in \mathcal{E}} k \;\middle|\; \mathcal{E} \in \mathcal{P}(\{k^{\text{O}}, k^{\text{TO}}, k^{\text{HED}}\}) \setminus \{\emptyset\} \right\} \tag{10}$$

$$k^{\text{O}}(\mathbf{u}, \mathbf{v}) = \frac{\sigma}{N} \sum_{i=1}^{N} \ell_i \delta(\mathbf{u}_i, \mathbf{v}_i) \quad k^{\text{TO}} = \exp\left(\frac{k^{\text{O}}}{\sigma}\right) \tag{11}$$

$$k^{\text{HED}}(\mathbf{u}, \mathbf{v}) = k_{\text{M}}^{5/2}\left(\phi_A(\mathbf{u}), \phi_A(\mathbf{v})\right) \tag{12}$$

where δ is the Kronecker delta, $k_{\text{M}}^{5/2}$ the Matérn 5/2 kernel, ϕ_A the embedding based on the dictionary A [13], ℓ_i are the lengthscales and the hyperparameters $\boldsymbol{\theta} = (\sigma, \ell_1, \ldots, \ell_N)$. Given a random test set $\mathcal{T}$ from already simulated designs and the density functions $\varphi_\cdot$, the optimal kernel $k_{\boldsymbol{\theta}} \in \mathcal{K}$ is selected by maximizing the sum of log predictive densities through leave-one-out cross validation:

$$k_{\boldsymbol{\theta}} = \underset{k \in \mathcal{K}}{\arg\max} \sum_{(\mathbf{x}_*, y_*) \in \mathcal{T}} \log\left(\varphi_{f(\mathbf{x}_*) \mid X, \mathbf{y} \setminus \{(\mathbf{x}_*, y_*)\}}(y_*)\right) \tag{13}$$

Although ensemble learning can improve model accuracy, it incurs a higher learning cost. To counter that, we leverage local Bayesian optimization by dividing the search space into trust regions [12], [16] to form several localized surrogate models trained on smaller datasets for faster multi-ensemble learning. Moreover, since each surrogate model is independent, we take advantage of training parallelization to accelerate our algorithm even further. For the trust region setup policy, we adopt the same policy from the original paper MORBO [12].

Let's now focus on our third stage improvement, which concerns sampling designs to be simulated using the acquisition function. Although there are popular ones [18] such as expected improvement and entropy search, all of them are single surrogate-based, making them unpractical for multi-objective Bayesian optimization. A common approach to break it down is to employ scalarization methods by aggregating all surrogate models into a single one. Nevertheless, optimizing an aggregated function such as a weighted linear aggregation can omit non-supported Pareto-optimal solutions in non-convex search space regions as illustrated in orange in Fig. 3.

To address this, we instead preserve the multidimensionality of multi-objective functions, and exploit hypervolume-based acquisition functions [10]. In particular, we leverage the noisy expected hypervolume improvement acquisition function [11] to even account the uncertainty in the Pareto front.

Definition 4 (Noisy expected hypervolume improvement)**.** *Given $\mathbf{r} \in \mathbb{R}^M$ a reference point, $\mathcal{D} = \{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^n$ the current set of observations, $\mathcal{Y}_P^{\mathcal{D}}$ the Pareto front of $\mathcal{D}$ in objective space, noisy expected hypervolume improvement is defined as:*

$$\alpha_{\text{NEHVI}}(\mathbf{x}) = \int \alpha_{\text{EHVI}}(\mathbf{x} | \mathcal{Y}_P^{\mathcal{D}}) p(f|\mathcal{D}) df \tag{14}$$

where α_{EHVI} is the expected hypervolume improvement [10] *and $p(f|\mathcal{D})$ the joint distribution of the Gaussian process f on $\mathcal{D}$.*

Since (14) is analytically untractable, Daulton *et al.* proposed Monte-Carlo integration to approximate it. Maximizing the acquisition function therefore provides the most promising design according to the joint surrogate model. As the acquisition function can only be computed pointwisely, we use multi-start local search to determine our next design to evaluate. We perform this for each trust region-based joint model, all in parallel, as a batch acquisition to support multi-simulations.

With all the aforementioned features, SEBO is set for efficient automated DSE and can be interfaced with any electronic design automation tools. Its algorithm is outlined below.

Algorithm 1 SEBO($\mathcal{X}$, s, n, n_{TR})

1 $V \leftarrow$ sample s Hammersley designs in $\mathcal{X}$ [36]
2 $X \leftarrow$ solve *transductiveExperimentalDesign*(V, n) *eq.* (7)
3 $Y \leftarrow$ *simulate*(X) **in parallel**
4 Initialize trust regions using procedure [12] Section 3.2
5 **while** simulation budget not exhausted **do**
6 **for** trust region $\mathcal{TR}_{i \in [\![1, n_{\text{TR}}]\!]}$ **do in parallel**
7 $\mathcal{T}_i \leftarrow$ build random test set in $\mathcal{TR}_i$
8 **for** objective $j \in [\![1, M]\!]$ **do in parallel**
9 $k_{\boldsymbol{\theta}} \leftarrow$ find best kernel with $\mathcal{T} = \mathcal{T}_i$ *eq.* (13)
10 Fit $f_j^{\mathcal{TR}_i} \sim \mathcal{GP}(m, k_{\boldsymbol{\theta}})$
11 $\mathbf{x}_i \leftarrow \arg\max_{\mathbf{x} \in \mathcal{X} \cap \mathcal{TR}_i} \alpha_{\text{NEHVI}}(\mathbf{x})$ *eq.* (14)
12 $\mathbf{y}_i \leftarrow$ *simulate*$(\mathbf{x}_i)$, $X \leftarrow X \cup \{\mathbf{x}_i\}$, $Y \leftarrow Y \cup \{\mathbf{y}_i\}$
13 Update trust regions with MORBO [12] lines **7-19**
14 **return** Pareto-optimal designs $\tilde{\mathcal{X}}_P$ and image values $\tilde{\mathcal{Y}}_P$

IV. Experimental results

To evaluate each aspect of candidate configuration efficiency, we chose `STREAM` [23], `DGEMM` [14], and `waLBerla` [17] as commonly used HPC benchmark applications. These benchmarks respectively target memory bandwidth, matrix computation, and numerical simulation performances.

We implemented SEBO, HyperMapper [25], and BOOM-Explorer [1] and interfaced them with our simulation flow to compare them on the same basis, on our benchmark applications. We also bring for the first time, a comparison with Hexaly Optimizer 13.0 (formerly known as LocalSolver) [4], a state-of-the-art commercial solver that provides simulation

*For `STREAM`, the core count is fixed to 16, since its application size depends on it.
†The parameters follow the same order as TABLE I.
§The objectives use the same units as in Fig 4.
‡The trade-off design, which considers all objectives as equally important, is obtained by minimizing the equally-weighted Chebyshev aggregation evaluated on multi-objective values.

optimization solutions based on surrogate modeling, for more significant results. Since BOOM-Explorer and Hexaly do not support parallel exploration, the total simulation budget is set to 1000 for all algorithms, including the model initialization budget of $n = 64$ to ensure a fair comparison. For others, we allow $n_{\text{TR}} = 4$ parallel simulations (which is also the number of trust regions) at the same time during exploration. Assuming the core count is the most influential design parameter here, we also modify BOOM-Explorer's clustering parameter by the latter to enable it to be applied to our problem instances.

To compare exploration algorithms quantitatively, we propose three performance metrics: the hypervolume indicator, computed as the Lebesgue measure between the Pareto front and the nadir point of all Pareto fronts combined, the diversity indicator from Cai *et al.* [6] which evaluates the spreading and distribution of the front, and the normalized running time. In particular, the higher hypervolume, the better, and the lower diversity indicator and normalized running time, the better.

Fig. 4 provides an overview of the obtained Pareto fronts from SEBO and the baselines. The experimental results show that SEBO outperforms other baselines by around 1-7% in terms of hypervolume, indicating a higher overall quality of its Pareto front. Although the chosen baselines are top-performing DSE algorithms, SEBO still competes with them and demonstrates other strengths. For nearly the same hypervolume and normalized running time performances, SEBO provides a much higher diversity of its Pareto front than the commercial solution Hexaly by around 24% and than HyperMapper by 11%. Not only does SEBO return better Pareto-optimal designs related to their objectives values, but also provides a better diversification of solutions, which is essential for offering a broader range of efficient design choices to the architect. Furthermore, SEBO outscales BOOM-Explorer by running 2× faster and achieving a better Pareto front in the end. Interestingly, SEBO spent as much time as Hexaly to retrieve the Pareto front whereas the latter doesn't support parallel simulations. The increasing computational cost induced by ensemble learning is exactly counterbalanced by the use of trust regions and parallelization methods, thereby confirming the observations made in previous sections.

In TABLE II, we present some key Pareto-optimal designs that may interest designers. First, the results seems to be coherent. If we observe area-efficient designs, these are the ones that aim to minimize the values of design parameters, thus proving the consistency of the chosen simulators in correctly modeling design behavior. Secondly, we show the trade-off-efficient designs, which correspond to the best designs for architects who treats all objectives as equally important. The trade-off designs offer particular characteristics and are not necessarily the "average" of extreme designs. For instance, the trade-off design for `waLBerla` is around 2× slower than the time-efficient one, but about 4× and 11× more energy and area-efficient respectively. The gains are not proportional. Lastly, increasing the size of the architecture beyond a certain point no longer leads to faster execution times. If we observe time-efficient designs, None of them have the maximum core count. Whereas manual exploration may miss these observations, automated DSE procedures, in contrast, can capture non-trivial interactions between design configurations and performance metrics, highlighting DSE algorithms as game changers for designing efficient architectures.

V. Conclusion and Perspectives

In this work, we presented an automated framework based on our own DSE algorithm, SEBO, for efficient HPC processor design. With adapted features, SEBO returns qualitative and diversified Pareto designs with state-of-the-art performance. While we also provided key designs, selecting the optimal design according to the decision maker's preferences remains difficult and deserves to be studied as the final step of DSE.

***Abstract*—Data deduplication enhances storage efficiency through non-destructive compression but is often hindered by the chunking process, which requires scanning the entire dataset. While traditional methods leveraging conventional architectures and hardware accelerators (e.g., GPUs and FPGAs) have been developed to address this issue, they continue to face challenges related to excessive data movement and associated performance degradation. These limitations stem from the von Neumann architecture, where computation and storage are separated in a processor-centric design, necessitating multiple memory hierarchy traversals and causing inefficiencies. To overcome these challenges, we explore UPMEM's DPU, a processing-in-memory (PIM) technology that reduces data movement by performing computations directly within memory. However, designing a deduplication system for DPUs presents unique obstacles, including restricted inter-DPU data sharing, the absence of native multiplication support, and significant DPU-CPU communication overhead. In response, we propose PIMDup, a DPU-optimized deduplication system that addresses these constraints through efficient parallelization, DPU-friendly chunking techniques, and reduced data transfer volumes. Experimental results demonstrate that PIMDup improves chunking performance without compromising deduplication accuracy, achieving a 1.67× speedup over CPU-based systems while maintaining 100% result consistency.**

***Index Terms*—Deduplication system, processing-in-memory, UPMEM DPU**

I. Introduction

In recent years, we have entered the era of the information explosion. This growing disparity places significant strain on storage systems, which must manage increasingly larger volumes within constrained capacities. To address these challenges, various solutions have been proposed, including distributed storage systems [1], [2], parallel architectures [3], [4], and hybrid systems leveraging solid-state drives (SSDs) [5], [6], which offer performance advantages over traditional hard disks. However, despite these advances, the fundamental issue persists: the sheer volume of data must be reduced. As a result, techniques for lowering storage costs are becoming increasingly critical.

Compression [7] and data deduplication [8] are two primary methods for enhancing storage efficiency. Compression reduces the size of individual files by identifying and re-encoding redundancy, with the degree of reduction depending on whether the process is lossy or lossless. In contrast, data deduplication identifies and eliminates duplicate data segments by referencing existing copies, conserving write bandwidth, and improving storage utilization. In data centers, deduplication typically achieves higher compression ratios than traditional compression while preserving non-destructive characteristics, allowing full restoration of original data. The deduplication process consists of four key steps [9]: (1) files are divided into chunks, the smallest units for deduplication; (2) each chunk is assigned a unique hash value (fingerprint) using a secure hash algorithm; (3) fingerprints are compared with existing ones to identify duplicates; and (4) duplicate chunks are replaced with references, while unique chunks and their fingerprints are stored for future reconstruction. Among these steps, *chunking—segmenting data into de-duplicatable fragments—is the most time-intensive, accounting for up to 53% of deduplication runtime [10]*. Accelerating chunking through processing-in-memory (PIM) technologies offers a promising approach to improving overall deduplication performance.

Processing-in-Memory (PIM) technology addresses data-intensive challenges by enabling computation directly within memory, reducing data movement overhead [11]. The UPMEM DPU, the first commercially available PIM solution [12], has demonstrated significant potential for tackling memory-bound workloads [13]–[19]. By integrating hundreds of processors within DRAM DIMMs, UPMEM DPUs allow parallelized, on-site data processing, making them well-suited for accelerating deduplication workflows. However, two major limitations constrain UPMEM DPU's effectiveness. First, data transfer remains dependent on the host CPU, as DPUs cannot directly access storage, limiting the offloading of the entire deduplication process. Second, UPMEM DPUs lack inter-processor communication [20], [21], complicating the generation of consistent chunking results across multiple processors. Despite these challenges, UPMEM DPUs offer substantial advantages, provided that data transfer costs are carefully managed and deduplication accuracy is maintained. Motivated by these opportunities and limitations, we propose PIMDup, a deduplication system explicitly optimized for DPU archi-

tectures. PIMDup addresses the unique challenges of DPU-based deduplication through a carefully designed system that balances hardware constraints with deduplication principles. This work aims to: (1) identify and address the technical challenges of implementing chunking on DPUs, (2) design a deduplication framework tailored for DPU hardware, and (3) evaluate the system's performance and deduplication accuracy through comprehensive experiments.

II. Background

A. Data Deduplication

Deduplication operates across files by identifying and eliminating redundant data segments, ensuring only unique data is stored. By referencing duplicate data instead of storing it repeatedly, deduplication significantly reduces storage volume, delivering high compression ratios while retaining lossless, non-destructive characteristics. Due to these advantages, deduplication has become a widely adopted technique in modern storage systems, offering both bandwidth savings and improved storage efficiency.

The deduplication process typically consists of four main steps: chunking, fingerprinting, indexing, and storage, as illustrated in Figure 1. (1) Chunking: Each file is divided into chunks, either of fixed or variable size, depending on the chosen chunking strategy. (2) Fingerprinting: A secure hash algorithm, such as SHA-1, MD5, or SHA-256 [22]–[24], is used to compute a unique fingerprint (hash value) for each chunk, serving as its identifier. (3) Indexing: The generated fingerprints are compared against an index to check for duplicates. If a matching fingerprint is found, the chunk is identified as redundant; otherwise, it is considered unique. (4) Storage: Unique chunks are stored, and their fingerprints are added to the index. For duplicate chunks, the system creates references to the already stored chunks, avoiding redundant storage. When reading data in a deduplication system, the original file is reconstructed by retrieving both unique chunks and references to duplicates. Using metadata to identify the correct chunk sequence, the system reassembles the data in its original form. This ensures that deduplicated data can be seamlessly restored when needed, maintaining usability and reliability.

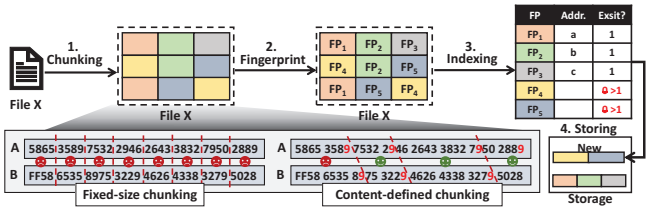

Fig. 1. The work-flow of deduplication process.

Among the four steps, chunking is particularly critical, as it determines how data is segmented into the smallest units for deduplication. An effective chunking strategy maximizes storage efficiency by accurately identifying redundant data. Conversely, a poorly designed chunking method may fail to detect similarities, resulting in suboptimal deduplication ratios and wasted computational effort. As shown in Figure 1, chunking methods are broadly classified into two categories: fixed-size chunking [25] and content-defined chunking [26]. Fixed-size chunking method has a well-known limitation, the boundary-shift problem [27], [28], which results in reduced deduplication ratios. To address this, content-defined chunking (CDC) has been developed. CDC uses specific patterns within the file's content as chunk boundary markers. Combining these markers with predefined maximum and minimum chunk sizes helps determine chunk boundaries, as seen in the example of number 9 in Figure1. The data between two chunk boundaries forms a chunk. Since the content itself determines these boundaries, CDC is capable of detecting redundant data even in files with slight variations, such as insertions or deletions. Therefore, this work adopts content-defined chunking to optimize the chunking process in deduplication systems.

B. UPMEM PIM DIMM

The UPMEM DRAM DIMM is a widely adopted commercially available Processing-in-Memory (PIM) product [12]. It integrates multiple in-DRAM processors, known as DRAM Processing Units (DPUs), directly into the memory. Unlike the traditional von Neumann architecture, which separates processing unit (CPU), memory, and storage, the UPMEM PIM DIMM enables computational capabilities at the memory tier, effectively breaking the conventional von Neumann bottleneck, i.e., data movement overheads. As shown in Figure 2, each UPMEM PIM DIMM comprises 16 PIM DRAM chips, and they are organized into two ranks of 8 chips each. Every chip contains 8 DPUs, resulting in 64 DPUs per rank. Each DPU operates as an independent processor and is equipped with a 64 MB DRAM bank, referred to as MRAM. In addition, each DPU has 64 KB of working memory (WRAM), functioning as a scratchpad, and 24 KB of instruction memory (IRAM) to store encoded instructions.

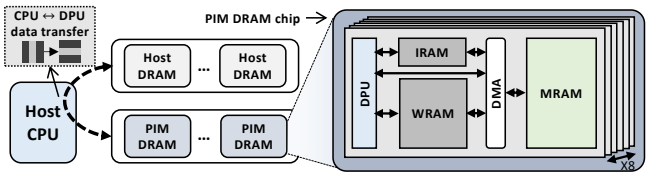

Fig. 2. The architecture of UPMEM DPU.

While DPUs enable memory-level computation and provide high external communication bandwidth via DDR slots, their architecture poses several challenges [20]. First, each DPU can only access its own MRAM, with no capability for direct data sharing or communication between DPUs, even within the same rank. Any inter-DPU communication must be mediated by the host CPU, introducing significant latency. Second, the limited capacity of WRAM necessitates careful memory management to minimize data transfers between WRAM and MRAM, as frequent transfers can negatively impact performance [15]. Third, DPUs cannot directly access data stored on disk; instead, data must first be transferred to the host CPU, which then forwards it to the DPU's MRAM. This process introduces additional overhead, such as matrix transpositions, which can further reduce system efficiency. Finally, the computational performance of DPUs is generally

lower than that of the host CPU, particularly for operations such as multiplication and division. These computational limitations can lead to increased execution latency during complex workloads, as further discussed in Section II-C.

C. Observation and Motivation

As outlined in earlier sections, DPUs cannot directly access data from storage nor share data among themselves. However, the deduplication process, particularly the indexing stage, relies on a global table for storing all fingerprints and involves storage I/O operations. Additionally, chunking—responsible for nearly half of the deduplication runtime—is a highly data-intensive task. Consequently, chunking presents a more suitable target for DPU acceleration. Based on this observation, large files can be divided into multiple segments and allocated to UPMEM PIM DIMMs for chunking within the DPUs, while the CPU handles the remaining tasks. Such a management procedure is illustrated in Figure 3: (❶) Each file segment undergoes chunking on the DPUs. (❷) The resulting chunking data is sent back to the host CPU. (❸) The host performs fingerprinting, indexing, and storage I/O while the DPUs concurrently process chunking tasks for subsequent file segments (looping back to ❶). This pipelined approach overlaps DPU and CPU operations, maximizing resource utilization.

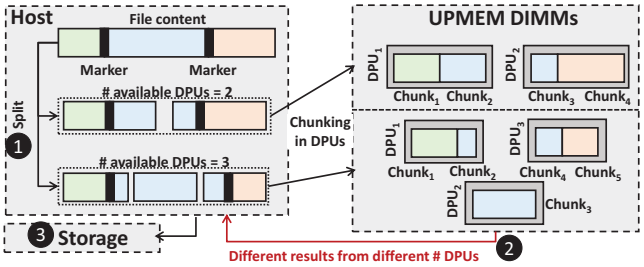

Fig. 3. A naïve design of a DPU-based deduplication.

This straightforward design encounters several critical challenges. First, the chunking process relies on a sliding window mechanism that scans each file segment, computing a hash at each position. When the hash matches a predefined value, a marker is placed to denote a potential chunk boundary. However, if a marker spans two DPUs, it cannot be accurately identified. Once markers are determined, each DPU uses them to define chunk boundaries, adhering to constraints on maximum and minimum chunk sizes. A key issue arises at the boundaries of file segments, where the DPU may fail to identify markers accurately, treating the remaining portion as a single chunk. This inconsistency leads to varying chunking results depending on the number of DPUs utilized. For instance, as illustrated in Figure 3, processing a file with 2 DPUs produces 4 chunks, whereas using 3 DPUs results in 5 chunks, undermining the stability and effectiveness of the deduplication process. Second, existing studies highlight a disparity in data transfer bandwidth between the CPU and DPUs. Specifically, the bandwidth for sending data from the host CPU to the DPUs exceeds that for returning processed results from DPUs to the CPU [20]. In the naïve design depicted in Figure 3, this imbalance results in smaller data volumes being transmitted over the faster channel (CPU to DPU), while larger processed data sets are sent over the slower channel (DPU to CPU). This inefficiency increases data transfer times and ultimately degrades overall system performance.

Moreover, the chunking process relies on hash functions to identify markers within file content. However, state-of-the-art hashing algorithms are not well-suited for execution on DPUs due to their reliance on polynomial equations that involve a significant number of multiplication operations. DPUs exhibit a substantial performance gap between addition and multiplication operations due to hardware limitations. As illustrated in Figure 4, the throughput for addition/subtraction operations on 32-bit integers reaches approximately 58.33 MOPS, whereas the throughput for multiplication operations is considerably lower. This disparity becomes even more pronounced for 64-bit integers, where addition/subtraction operations significantly outperform multiplication. These performance trends are consistent with benchmarks from prior research, which demonstrate that DPUs are poorly suited for tasks requiring extensive multiplication.

To address these challenges and the inherent hardware limitations of DPUs, we have formulated several key design objectives. First, all potential marker positions within a file must be identified accurately, even when markers span across multiple DPUs, to ensure precise chunking boundaries. Second, the chunking results must remain consistent, irrespective of the number of DPUs involved, to preserve the deduplication system's capacity for effective storage reduction. Third, considering the inefficiency of DPUs in performing multiplication-heavy operations, it is crucial to develop a chunking method tailored to the computational strengths of DPUs, thereby enhancing execution performance. Finally, the disparity in data transfer speeds between the DPUs' input and output channels must be addressed through optimized data transfer mechanisms to minimize performance bottlenecks. With these objectives in mind, this work introduces *PIMDup*, a DPU-based deduplication system specifically designed to capitalize on the in-memory processing capabilities and parallelism of DPUs. PIMDup is structured to address the outlined challenges while ensuring consistency and efficiency across a range of DPU configurations.

III. Proposed PIMDup Desing

A. Overview

Content-defined chunking is essential for efficient data deduplication but is also the most time-consuming step. To address this, we employ DPUs as parallel workers to accelerate the process. To ensure consistent chunking results across varying DPU counts, we propose an *anti-splitting file segmentation* (ASFS) method to identify all markers in the input file accurately. A *chunk boundary vector* mechanism records marker positions in DPUs, which are merged on the host CPU to define global chunk boundaries based on conditions like maximum chunk size (see Section III-B). Additionally, an *encoded boundary vector* compresses boundary data, reducing data transfer to one-eighth of the input file size (see Section III-C). To enhance performance, a *DPU-friendly chunking method* avoids inefficient computational patterns, improving speed without sacrificing accuracy (see Section III-D).

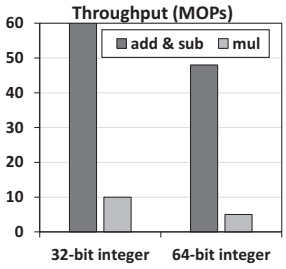

Fig. 4. A huge gap between arithmetic performances in the DPU.

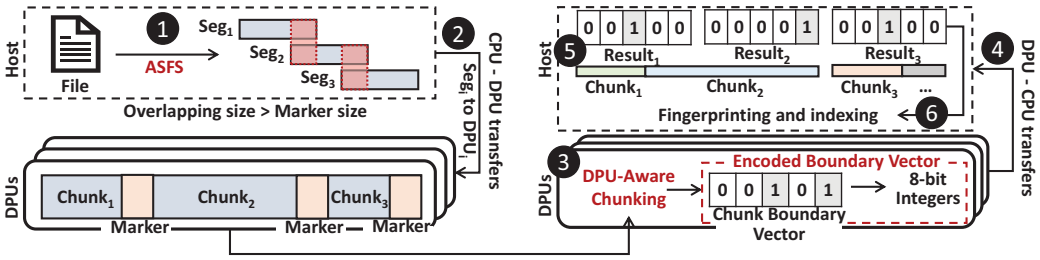

Fig. 5. Overview of proposed PIMDup.

Figure 5 outlines the workflow of the proposed *PIMDup* system. The host CPU first segments the input file using ASFS ❶ and distributes segments to the DPUs ❷. DPUs perform chunking using the DPU-friendly method, identifying markers and storing them in a chunk boundary vector ❸. These vectors are encoded into 8-bit integers and sent to the host CPU ❹, which reconstructs the vectors, aligns them with the input file, and applies constraints to finalize chunk boundaries ❺. The host CPU then completes fingerprinting and indexing ❻. While the CPU processes chunking results, the DPUs can immediately begin processing the next file segment, ensuring efficient parallelism and maximizing throughput. This pipeline reduces data transfer overhead and accelerates the deduplication process.

B. Anti-Splitting File Segmentation (ASFS)

DPUs lack a direct mechanism for sharing data among themselves. Consequently, if a file is split into mutually exclusive segments and distributed across multiple DPUs, a marker could fall on the boundary between segments, resulting in an incorrect marking of chunk boundary candidates. This error compromises the deduplication system's efficiency, reducing its bandwidth and space-saving benefits. To address this issue, we propose the anti-splitting file segmentation (ASFS) technique, which introduces overlapping regions between file segments during segmentation. The length of this overlap is set to exceed the size of the designated markers, as illustrated in Figure 5. In cases where a marker lies on the boundary between two DPUs, one of the DPUs will contain a complete copy of the marker within its overlapping segment. This ensures that the marker can be correctly identified during content-defined chunking, preventing errors in chunk boundaries. By using ASFS, we can guarantee that all markers are accurately detected, regardless of the number of active DPUs. In large-scale systems with thousands of DPUs, particularly in scenarios where the UPMEM PIM DIMM's yield varies, the number of DPUs assigned to a task may change dynamically. ASFS addresses this challenge by ensuring consistent chunking results across different DPU allocations, even when a varying number of DPUs processes the same file.

It is worth mentioning that the overlapping segment caused by applying ASFS does not incur significant memory duplicated overhead. Given that typical marker sizes are around 32 bytes, the extra memory required for overlapping segments is negligible. As these markers are often numerous and distributed randomly throughout the file, ASFS significantly enhances performance. By ensuring that each marker is contained fully within at least one segment, ASFS prevents costly chunking errors and preserves the deduplication system's bandwidth and storage efficiency. The benefits of this solution scale effectively, particularly in systems with high marker density, leading to improved overall performance with minimal trade-offs in space utilization.

C. Encoded Boundary Vector

The primary cause of inconsistency in chunking results is the inability of DPUs to communicate, which prevents them from having a "global view" when determining chunk boundaries. This limitation can result in some data segments being arbitrarily defined as chunks, even if they lack proper boundaries on both ends. To address this issue, we propose using a chunk boundary vector. As shown in Figure 5, after each DPU completes its chunking process, it generates a chunk boundary vector that records the positions of special markers, which are potential candidates for chunk boundaries. At this stage, these segments are not yet defined as chunks. Instead, each DPU transmits its chunk boundary vector to the host CPU. The host CPU then aggregates these individual vectors to create a "global vector" that corresponds to the entire file, capturing all potential chunk boundaries. Based on this global vector and predefined parameters, such as maximum and minimum chunk sizes, the host CPU determines the final chunk boundaries. Compared to the naïve design in Figure 3, where each DPU independently defines chunk boundaries, this approach allows the host CPU to make boundary decisions with a comprehensive, file-wide perspective, thereby ensuring consistency in the chunking results. Thus, it can eliminate the problem shown in Figure 3, that is, the inconsistent chunking outcomes for the same file when it is distributed across varying numbers of DPUs.

As discussed in Section II-C, the data transfer channels between the CPU and DPUs have differing speeds, with the output channel (DPU-to-CPU) being slower than the input channel (CPU-to-DPU). This difference makes it crucial to minimize the amount of data sent through the slower output channel. As shown in ❸ of Figure 5, to optimize data transfer efficiency, we encode the chunk boundary vector as a binary array, where each '1' represents the presence of a marker. By grouping every 8 bits of this array into a single binary integer, we can represent the chunk boundary information

much more compactly. Each element in the chunk boundary vector corresponds to the outcome of the sliding window hash operation, indicating whether the calculated hash value at each byte matches the designated marker. This setup enables the chunking results for every 8 bytes of the file to be encoded as a single 8-bit integer, which is then transferred from the DPUs back to the main memory. Compared to a non-encoded chunk boundary vector, where each byte in the vector represents whether a corresponding byte in the input file contains a marker, this binary encoding is much more efficient. By encoding each marker presence as a single bit, we reduce the data size that needs to be transferred. This approach ultimately reduces the transfer data size to one-eighth of the original, as it efficiently captures marker information within each byte.

D. DPU-Friendly Chunking Method

As illustrated in Figure 4, DPU performance is critical for determining processing speed. However, conventional chunking algorithms often rely on hashing with polynomial functions, which significantly hinder DPU execution efficiency. A straightforward solution might involve using a pre-defined table within each DPU to store all possible string values. However, this approach is impractical due to the limited 64 MB of MRAM available per DPU, which must simultaneously accommodate data storage and results for transfer back to the host, leaving insufficient memory for such a table.

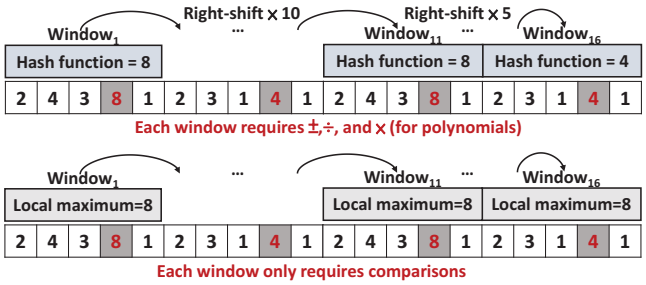

Fig. 6. Chunking by Rabin-based hashing v.s DPU-friendly chunking method

To overcome this limitation, we propose a non-hashing, DPU-friendly chunking method based on local-maximum-byte chunking [29]. This method employs a sliding window of predefined size to scan the data. As the window moves, the middle byte is checked to determine if it is the maximum within the window. If it is not, the window advances. If it is, the boundary between the middle byte and the preceding one is marked as a candidate chunk boundary. These boundary positions are then recorded using the encoded boundary vector method, ensuring efficient transfer back to the host. To align with the granularity of the encoded boundary vector, the proposed method uses a 32-byte sliding window to process the file. Unlike hashing-based approaches that rely on polynomial calculations and require multiplication and division operations, the local-maximum-byte chunking method only involves comparing byte values within the window. This comparison-based approach eliminates the computational overhead associated with polynomial functions. As shown in Figure 6, Rabin-based hashing methods involve numerous multiplications for polynomial functions, whereas the DPU-friendly chunking method relies solely on comparisons. These comparisons, implemented using subtraction, are highly efficient for DPUs due to their hardware design, further enhancing overall processing performance.

IV. Experiemt

A. Experiemtal Setup

In this section, we evaluate the performance of the proposed PIMDup design from multiple perspectives. The analysis of the experimental results is conducted based on the following metrics: (1) Internal DPU Performance: This metric assesses the benefits derived from the DPU-Friendly Chunking Method. (2)Data Transfer Bandwidth: To evaluate the effectiveness of the Encoded Boundary Vector, we measure the data transfer bandwidth between the CPU and DPUs. (3) Result Consistency: We verify that different numbers of DPUs performing chunking do not lead to inconsistent results. (4) Overall System Performance: We compare the performance of PIMDup against a traditional CPU-based deduplication system.

To demonstrate the feasibility of the PIMDup design, experiments were conducted on a real system equipped with UPMEM DPUs. Specifically, we utilized a UPMEM server with the following configuration: an Intel(R) Xeon(R) Silver 4110 CPU, 128 GB of host main memory, and 20 dual-rank PIM DIMMs, providing a total of 40 ranks and 2560 DPUs operating at @ 350 MHz. . The PIMDup system was implemented in C/C++ using the UPMEM SDK[1], and DPU-side chunking logic was programmed using the LLVM-based compiler provided by the SDK. This setup enabled direct performance comparison between PIMDup and traditional CPU-based deduplication systems.

The dataset used to evaluate PIMDup comprises 30 different release versions of virtual machine image files [9], [30]. The dataset includes 6 CentOS, 5 Fedora, and 19 Debian image files, collectively amounting to approximately 30 GB. These files exhibit deduplication ratios ranging from 38% to 55%, providing a comprehensive and diverse testbed for performance evaluation. The mixture of distributions and versions allows for a robust assessment of PIMDup's performance and consistency across various data types, thereby validating its effectiveness and reliability in real-world scenarios.

B. Experiemtal Result

To comprehensively evaluate the scalability of the proposed PIMDup design, we incrementally increased the number of DPU ranks from 4 to 36 (with each rank consisting of 64 DPUs) and measured the total execution time required for deduplication.

Figure 7 illustrates the results, detailing the time required for chunking, fingerprinting, and indexing across varying numbers of DPU ranks. The experimental results reveal a significant reduction in the total deduplication time as the number of DPU ranks increases. Notably, chunking remains the largest contributor to the overall deduplication time, though it decreases substantially with the addition of more DPU ranks. This improvement is attributable to the parallel processing

[1]https://sdk.upmem.com

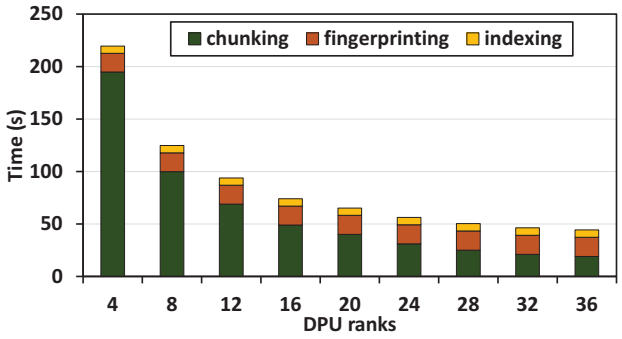

Fig. 7. The breakdown analysis for chunking, fingerprinting, and indexing time of PIMDup.

capabilities of the DPUs, which allow for more efficient handling of data chunks. In contrast, fingerprinting and indexing times show little to no improvement as the number of DPU ranks increases. This is because these tasks are executed by the CPU in PIMDup and are therefore unaffected by the scaling of DPUs. Despite this, the proposed PIMDup design ensures that the host CPU does not experience significant overhead during the integration of processed data. This demonstrates the scalability and efficiency of PIMDup in leveraging parallelism within DPUs while maintaining minimal impact on host-side operations.

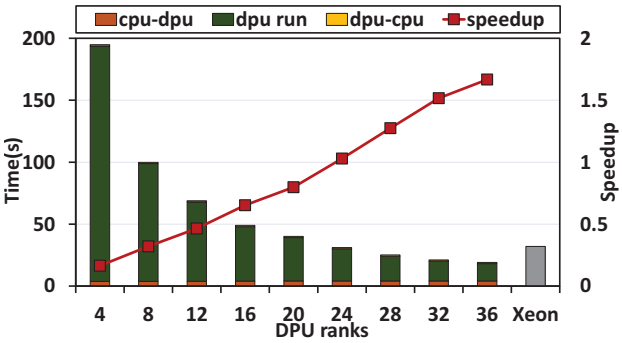

Fig. 8. The overall performance analysis and comparison for PIMDup.

Figure 8 provides several important insights into the performance of PIMDup. As the number of DPU ranks increases, the deduplication time decreases significantly, showcasing the scalability of the DPU-based implementation. Specifically, the processing time drops dramatically—from nearly 200 seconds with 4 DPU ranks to approximately 20 seconds with 36 DPU ranks. When compared to CPU-based deduplication (e.g., using Xeon processor), the advantages of our proposed PIMDup become even more apparent. At the maximum number of DPU ranks, PIMDup achieves a 1.67× reduction in processing time relative to the Xeon-based system. This improvement highlights how the DPU architecture excels in managing memory-bound workloads more efficiently than traditional CPU-based systems. Moreover, the data transfer overhead between the CPU and DPUs remains minimal, thanks to the adoption of the Encoded Boundary Vector design. This mechanism allows DPUs to efficiently notify the host of chunking results using a compact representation, reducing the volume of data that must be transferred. Consequently, the host is able to seamlessly integrate the chunking information while minimizing data transfer overhead, further enhancing the overall system efficiency.

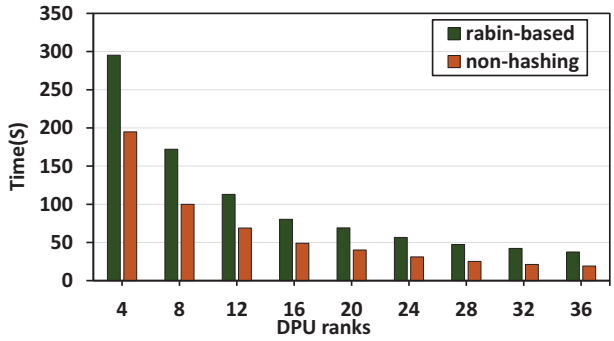

Fig. 9. The time required for rabin-DPU and non-hashing-DPU using different numbers of DPU ranks.

Figure 9 demonstrates that the DPU-friendly chunking method consistently outperforms the Rabin-based chunking method across all tested DPU configurations, regardless of the number of ranks employed. Notably, the DPU-friendly chunking method achieves an approximately 50% reduction in processing time compared to the Rabin-based approach. This substantial performance improvement stems from the inherent hardware constraints of the DPUs. As highlighted in our preliminary analysis, DPUs exhibit significantly higher throughput for addition and subtraction operations than for multiplication and division. The Rabin-based algorithm, which relies on polynomial multiplication to compute hash values, is computationally intensive and less suited to the architecture of the DPUs. In contrast, the DPU-friendly chunking method aligns better with the DPUs' operational strengths, enabling more efficient processing.

V. Conclusion

In this work, we present PIMDup, a deduplication system specifically optimized for DPUs, addressing critical challenges such as limited inter-DPU data sharing, the absence of native multiplication support, and the overhead associated with DPU-CPU data transfers. To overcome these issues, PIMDup introduces three key innovations: Anti-Splitting File Segmentation (ASFS) for efficient data allocation, an Encoded Boundary Vector to streamline data transfers between DPUs and the CPU, and a DPU-Friendly Chunking Method to enable high-performance execution on DPUs. Our experimental evaluation demonstrates that PIMDup achieves a 1.67× speedup compared to a CPU-based deduplication system while ensuring 100% result consistency. This highlights the effectiveness and reliability of our proposed design.

Quorum: Zero-Training Unsupervised Anomaly Detection using Quantum Autoencoders

Jason Zev Ludmir*, Sophia Rebello*, Jacob Ruiz†, Tirthak Patel*
Rice University, Stanford University†*

***Abstract*—Detecting mission-critical anomalous events and data is a crucial challenge across various industries, including finance, healthcare, and energy. Quantum computing has recently emerged as a powerful tool for tackling several machine learning tasks, but training quantum machine learning models remains challenging, particularly due to the difficulty of gradient calculation. The challenge is even greater for anomaly detection, where unsupervised learning methods are essential to ensure practical applicability. To address these issues, we propose Quorum, the first quantum anomaly detection framework designed for unsupervised learning that operates without requiring any training.**

I. Introduction

Anomaly detection plays an essential role in various industries, from identifying fraudulent transactions in finance to detecting irregularities in power grids [26], [8], [25], [36] As datasets grow in complexity, traditional machine learning (ML) methods struggle with scalability and accuracy. Quantum computing offers a promising new approach, with its potential to accelerate computations and detect subtle patterns and correlations in data. Leveraging quantum algorithms for ML tasks, particularly for anomaly detection, could transform how we tackle these challenges [28], [27], [33].

The Challenge. Applying quantum computing to anomaly detection presents significant hurdles. Quantum machine learning (QML) models typically rely on parameterized circuits that require training, which is challenging due to the complexity of computing gradients in quantum systems [16], [31]. Quantum systems require gradient calculations from first principles using the parameter shift rule, and these gradients are prone to exponential vanishing in "barren plateau" regions [13]. Moreover, anomaly detection, by nature, is unsupervised, adding another layer of difficulty since no labeled data is available to guide the training [29], [15]. These two factors – quantum training complexity and unsupervised learning requirements – create a considerable challenge for developing efficient quantum anomaly detection methods [29], [14].

The Gap. *Current quantum-based approaches for anomaly detection fall short because they still require training and often rely on supervised or semi-supervised learning.* These methods involve optimizing quantum circuits with labeled data, which limits their applicability in real-world scenarios where such data is scarce. This dependency on training creates both computational overheads and reduces the flexibility needed for fully unsupervised tasks [16], [13], [21], [12], [29], [14], [1].

Our Solution. To address this, we propose Quorum, the first quantum anomaly detection framework that requires zero training and is designed for unsupervised learning. Quorum leverages quantum principles such as amplitude encoding, random quantum transformations, and SWAP tests to identify anomalies without needing any parameter optimization [16], [13]. By utilizing quantum correlations and random projections, Quorum detects anomalies based on deviations from the statistical norms of quantum transformations [17], [21], [13].

First, Quorum's open-source technique carefully distributes the data into buckets based on the likelihood of anomalous events in the dataset before embedding it into quantum states using amplitude encoding [12], [2]. Then, Quorum applies random quantum transformations to this data and uses a SWAP test to measure similarly between quantum states [13], [16]. Quorum constructs an "embarrassingly parallelizable" ensemble of such random transformations and leverages statistical measures to identify anomalies. This approach is scalable and flexible, allowing for efficient anomaly detection without the computing cost of gradient calculation and training [29], [21].

Quorum's Evaluation. We evaluate Quorum through extensive experiments on various datasets, including medical, industrial, and lexical data. We compare its performance to a state-of-the-art method that uses a quantum neural network (QNN) which relies on training and supervised labels. Our results show that Quorum has a 23% higher average F1 score over the QNN across evaluated datasets. We also provide an ablation study of how Quorum performs with different-sized subsamples (buckets). *Quorum consistently identifies subtle anomalies that the state-of-the-art method may overlook, proving to be an effective zero-training quantum solution for unsupervised anomaly detection [29], [21].*

II. Background

Before we present the design of Quorum, we first provide some brief but necessary background.

A. Quantum Computing

The fundamental unit of quantum computation is the qubit, which exists in a superposition of binary states, represented as $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$, where α and β are complex numbers that correspond to the amplitudes of the basis states $|0\rangle$ and $|1\rangle$. The probabilities of measuring the qubit in the $|0\rangle$ or $|1\rangle$ state are $|\alpha|^2$ and $|\beta|^2$, respectively, and these probabilities must sum to 1: $\|\alpha\|^2 + \|\beta\|^2 = 1$. Qubits can also be entangled, meaning their quantum states are correlated in such a way that they cannot be described independently of one another, which

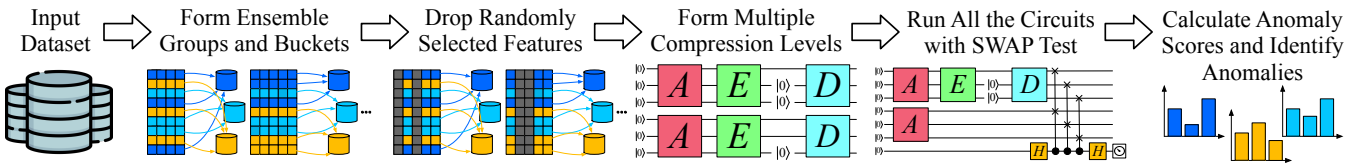

Fig. 1: Visual representation of the steps taken by Quorum to detect the anomalies in a given dataset using quantum computing.

is a key property leveraged in quantum computing applications and algorithms to achieve a quantum advantage [4].

Quantum gates, represented as unitary matrices, are the basic operations applied to qubits. Common single-qubit gates include the parameterized rotation gates, such as the RX, RY, and RZ gates, which rotate a qubit around the x, y, and z axes, respectively. Two-qubit gates, such as the controlled-X (CX) gate, are used to create entanglement between qubits. These single- and two-qubit gates are defined as:

$$RX(\theta) = \begin{pmatrix} \cos\frac{\theta}{2} & -i\sin\frac{\theta}{2} \\ -i\sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{pmatrix}, \quad RY(\theta) = \begin{pmatrix} \cos\frac{\theta}{2} & -\sin\frac{\theta}{2} \\ \sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{pmatrix},$$

$$RZ(\theta) = \begin{pmatrix} e^{-i\theta/2} & 0 \\ 0 & e^{i\theta/2} \end{pmatrix}, \quad CX = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

Quantum circuits are constructed by applying sequences of these gates to qubits, followed by measurements. Due to the probabilistic nature of quantum measurements, a circuit's execution yields a probability distribution of possible outcomes, which often requires many repetitions (or shots) to obtain statistically significant results [11], [6]

B. Quantum Encoding and SWAP Test

In quantum computing, classical data must be encoded into quantum states. One common method is *Amplitude Encoding*, [35] which maps classical data points $x_0, \ldots, x_{n-1}$ to the quantum state: $|\psi\rangle = \sum_{j=0}^{n-1} x_j |j\rangle$. This method allows n classical data points to be encoded into $\log_2 n$ qubits, enabling efficient representation of high-dimensional data.

The *SWAP Test* is a quantum algorithm used to determine how similar two quantum states are [7], [22]. It computes the inner product $\langle\phi|\psi\rangle$ between two states $|\phi\rangle$ and $|\psi\rangle$. If the states are identical, the test returns a high overlap; otherwise, a lower overlap indicates dissimilarity. This is a key tool in quantum anomaly detection, where dissimilarity between two states may indicate an anomalous data point [22].

C. Anomaly Detection

Anomaly detection involves identifying data points that deviate significantly from the norm [34], [9]. In unsupervised anomaly detection, we assume no labeled data is available, and the goal is to detect anomalies based solely on patterns within the data [5], [30]. Common classical techniques include clustering and Isolation Forests. Clustering groups data points based on similarity, with anomalies detected as points far from cluster centroids [12], [1]. Isolation Forests, a tree-based algorithm, isolates anomalies by recursively splitting the data based on random feature values, where fewer splits indicate an anomaly [19], [18].

In high-dimensional spaces, autoencoders – neural networks trained to reconstruct their input – are often used for anomaly detection [23], [24]. Autoencoders learn compressed representations of normal data, and anomalies are detected when reconstruction errors for new data points are high [1], [20]. This concept extends to the quantum realm, where a quantum autoencoder can be used to compress and decompress quantum states, flagging quantum outliers based on reconstruction errors [16], [13].

III. Related Work

Several quantum-based approaches for anomaly detection have emerged recently, leveraging various quantum algorithms and machine learning techniques. Liu at al. [16] provided early evidence of the speedup and resource efficiency experienced with quantum anomaly detection. Building on this effort, Herr et al.[13] introduce quantum autoencoders trained with generative-adversarial networks. Both methods require structured queries or training processes, which prohibit their adaptability in unsupervised settings. Taking a hybrid quantum-classical approach, Sakhnenko et al. [29] propose supervised training-based solutions that require significant quantum-classical communication. Most recently, Hdaib et al.[12] propose quantum-enhanced anomaly detection with classical post-processing, still requiring circuit training.

Other works provide application-specific anomaly detection. For example, Ngairangbam et al. [21] utilize quantum classifiers that rely on supervised training for high-energy physics applications. On the other, Kukliansky et al.[14] develop quantum anomaly detectors for network anomalies. These approaches rely on domain-specific anomaly properties and are thus not generally applicable. *Thus, there is a strong need for a fully unsupervised, training-free generalized quantum anomaly detection method that leverages the unique strengths of quantum systems without the overhead of classical optimization.*

IV. Design

The design of Quorum leverages quantum dynamics to identify correlations among data features and detect anomalies by comparing quantum-transformed data samples. As shown in Fig. 1, Quorum is structured around several key stages: preprocessing, quantum embedding, bucketing, feature selection, and circuit-based statistical analysis. Each of these steps contributes to an efficient and scalable framework for anomaly detection using quantum methods.

A. Preprocessing and Normalization

Quorum begins with preprocessing the dataset, which involves a variety of steps depending on the dataset's initial

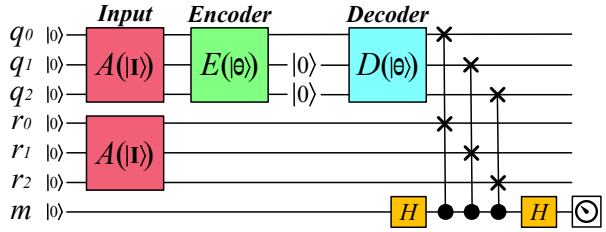

Fig. 2: Quorum's use of SWAP test to determine the similarity between the compressed and original data sample.

format. This typically includes transforming all non-numeric features into float values (e.g., via hashing), removing any label data that could indicate whether a sample is anomalous, and performing a range-based normalization. The normalization process is essential to ensure that all features contribute equally to the quantum state, which is critical for the subsequent quantum encoding.

Given a dataset with M features, Quorum normalizes each feature so that its maximum possible value is $\frac{1}{M}$. This ensures that the sum of the squares of all features for any sample does not exceed 1. The normalization is performed as follows:

$$\text{normalized feature value} = \frac{\text{raw feature value for sample}}{\text{max feature value}} \times \frac{1}{M}$$

This normalization serves two key purposes. First, it equalizes the contribution of all features to the final quantum state, preventing any feature from dominating due to its scale. Second, it simplifies the process of amplitude embedding for quantum states, as the normalized values now range between $[0, \frac{1}{M}]$ for all of the features.

B. Quantum Embedding

After normalization, Quorum embeds the data into quantum states using amplitude encoding. The normalized feature values are squared to convert them into probabilities, and an "overflow state" probability is added to account for any remaining probability mass, ensuring the total probability sums to 1. This ensures that the total probability mass of the quantum state is preserved.

A quantum circuit is then created to prepare a state vector corresponding to these probability amplitudes using amplitude embedding. This process is repeated for each data point (with 2^n features) using two sets of n qubits within the same circuit, creating two identical encodings: one for the transformation and one as a reference (Fig. 2). This dual encoding allows us to compare the transformed data with the original using a SWAP test (we'll discuss in Sec. IV-D why this is required).

Each quantum circuit consists of $2n + 1$ qubits, where the additional qubit serves as an ancilla for reading the SWAP test result. The SWAP test measures the similarity between the original and transformed quantum states, preserving the relative magnitudes of the features in the quantum state.

C. Bucketing and Feature Selection

Following the embedding process, Quorum employs a bucketing strategy and performs feature selection to prepare the data for anomaly detection. As shown in Fig. 3, the dataset is

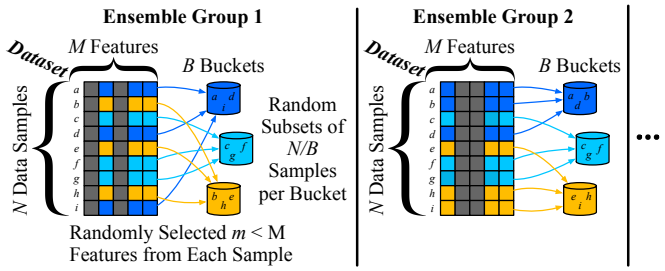

Fig. 3: Quorum's bucketing procedure for distributing the subsampled data samples across different ensemble groups.

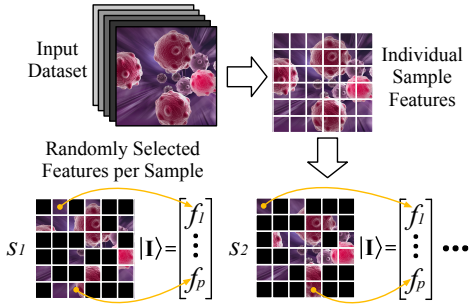

Fig. 4: Quorum subsamples features from the input space.

divided into a series of B random subsets, or buckets. Given a dataset of size N, there are N/B buckets. This bucketing strategy enhances the visibility of anomalies by allowing data points to be compared against smaller, more localized subsets of the dataset. The size of the buckets (B) is determined based on the total number of data points and the estimated proportion of anomalies, both of which determine the probability of having at least one anomaly in each bucket. By distributing the data into smaller buckets, Quorum increases the contrast between normal and anomalous points, making it easier to detect outliers (anomalous data points).

Feature selection is performed after bucketing to ensure that the data samples can fit on quantum circuits, with Quorum using a uniform random selection strategy (Fig. 4). Unlike traditional downsampling or dimensionality reduction techniques like Principal Component Analysis (PCA), random selection offers several advantages. *It is computationally faster, avoids bias towards features that might not indicate anomalies, and allows exploration of feature combinations that might otherwise be overlooked.* For each quantum circuit with n qubits, Quorum selects $m = (2^n - 1)$ features from the dataset, leaving room for an overflow state. This ensures the selected features fit within the quantum state space of n qubits.

D. Quantum Circuit Design and Ansatz

The core of Quorum's anomaly detection framework lies in the design of its quantum circuits. Unlike traditional quantum autoencoders, which train parameterized gate angles to optimize encoding-decoding processes, Quorum does not rely on learning optimal parameters. Instead, it utilizes random quantum transformations and applies statistical analysis to detect anomalies without training.

Each quantum circuit begins with an amplitude encoding of the data, as described above. The first set of encoded qubits

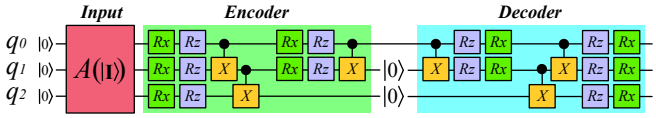

Fig. 5: The ansatz leveraged by Quorum for its autoencoder to establish correlations across input features.

is then passed through an ansatz, which consists of layers of RX and RZ rotations and CNOT gates. The ansatz performs random transformations on the encoded data, ensuring a high degree of variability in the quantum states (Fig. 5).

The ansatz includes three main components: an encoder circuit with randomly initialized parameters, a partial reset operation that simulates an information bottleneck by resetting a subset of qubits, and a decoder circuit that applies the inverse of the encoder. The random angles for the quantum gates in the encoder are initialized from a uniform distribution $U(0, 2\pi)$, and the decoder negates these angles to revert the transformations. A SWAP test is then performed between the transformed and original quantum states to measure their similarity. This similarity score forms the basis for detecting anomalies, as normal and anomalous data points will behave differently under random quantum transformations.

This design enables Quorum to compress data through the autoencoder and then decode it on the other end of the reset, with the anticipation that anomalous data would be more likely to deviate from the original state when the two states are compared using the SWAP test.

E. Ensemble Groups and Statistical Analysis

To ensure robustness, Quorum processes each data point through multiple ensemble groups. Each ensemble group involves randomly initialized quantum circuits (θs), ensuring that the data points are processed differently each time. Additionally, the dataset is divided into new buckets for each ensemble group, providing different perspectives on the data.

Each ensemble group also explores multiple compression levels (Fig. 6). The compression level, determined by the number of qubits reset in the partial reset operation, varies systematically from the highest compression (fewest qubits retained) to the lowest (most qubits retained). Quorum creates a multi-dimensional view of each data point's behavior under various quantum transformations. This approach leverages the principle of random projections, where projecting data into multiple random subspaces can reveal structural information that might not be apparent in any single projection. Each ensemble group, with its unique combination of buckets, feature subsets, circuit parameters, and compression levels, represents a different "quantum projection" of the data.

Statistical analysis is then performed on the SWAP test outputs. *A key innovation in Quorum's approach lies in how these quantum circuit outputs are analyzed to detect anomalies.* For each bucket and each run, the mean and standard deviation of the SWAP test results are calculated. The anomaly score for each data point is derived by calculating the normalized deviation from the bucket mean divided by the standard deviation. These deviations are summed across

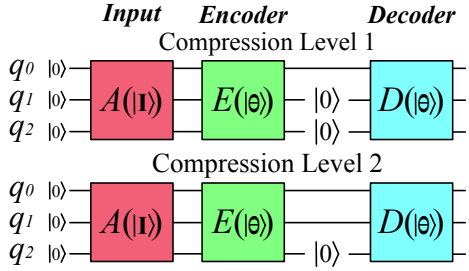

Fig. 6: Quorum leverages multiple compression levels across different ensemble groups to improve anomaly detection.

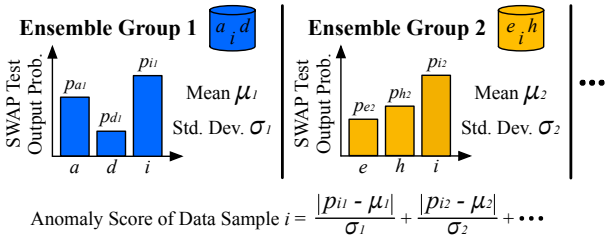

Fig. 7: Quorum's anomaly score calculates the statistical deviation of a data sample across ensemble groups.

all runs and buckets, producing an overall anomaly score for each data point (Fig. 7). A higher score indicates a greater likelihood of an anomaly.

The use of random angles in the quantum circuit is a critical aspect of Quorum's design. Rather than learning to reconstruct inputs accurately, this approach creates a random projection of the data in high-dimensional Hilbert space. The statistical analysis then captures how differently each data point behaves under these random quantum transformations compared to the average behavior of points in its various buckets.

This design allows Quorum to detect anomalies without explicitly learning the structure of normal data or performing any optimization, instead relying on the statistical properties of how data points respond to random quantum transformations. *The effectiveness of this approach lies in the fact that anomalous data points tend to behave differently under these transformations compared to normal data points, as the randomizations add more deviation to anomalous data compared to normal data.* By aggregating these behaviors across multiple random initializations, buckets, and compression levels, Quorum aims to build a comprehensive profile of each data point's response to quantum transformations, potentially unveiling subtle anomalies that more conventional techniques might miss.

F. Scalability and Flexibility

A significant advantage of Quorum's design is its inherent scalability and flexibility. While our initial experiments utilized 3-qubit encodings (resulting in 7-qubit circuits), the approach can be readily scaled to accommodate larger encodings. For instance, moving to 4-qubit or higher encodings would introduce additional "moments" to our results for each compression level, potentially capturing even more nuanced relationships in the data. This scalability allows users to tailor

TABLE I: Datasets used for Quorum's evaluation. The rightmost column refers to the likelihood of at least one anomaly being placed in each bucket.

Dataset	Samples	Anomalies	Features	Pr [Anomaly ∈ Bucket]
Breast Cancer	367	10	30	0.75
Pen-Global	809	90	16	0.6
Letter	533	33	32	0.95
Power Plant	1,000	30	5	0.75

the depth and complexity of the quantum transformations to their specific needs and computational resources.

Furthermore, the design of Quorum lends itself to extensive parallelization. Each ensemble group is entirely independent of the others, making the technique embarrassingly parallel. The scalability of Quorum extends beyond just increasing the number of qubits or ensemble groups. The flexibility in choosing the number of compression levels, the size of buckets, and the number of features selected allows users to fine-tune the balance between computational cost and the granularity of anomaly detection.

In the following section, we delve into the methodology used to obtain our evaluated results.

V. Experimental Methodology

Experimental Setup. We evaluate Quorum using Qiskit Aer's quantum circuit simulator. We use Python 3.10.12 and Qiskit 1.2, IBM's quantum computing language [3], which is used to run simulations of quantum circuits locally. Each quantum circuit is generated via a Qiskit QuantumCircuit object, and the quantum circuits are run through noiseless simulations. We run simulations with Quorum and competitors on a local research cluster with Ubuntu 22.04.2 LTS on a 32-core 2.0 GHz AMD EPYC 7551P processor with 32 GB RAM.

We also perform noisy simulations, where we model our hardware after IBM's Brisbane quantum computer to provide realistic error rates. The noise parameters were obtained directly from IBM's Brisbane backend specifications; median properties are as follows: coherence times ($T_1 = 230.42\ \mu$s, $T_2 = 143.41\ \mu$s), gate errors (single-qubit SX gate error = 2.274×10^{-4}, two-qubit gate error = 2.903×10^{-3}), and readout error (1.38×10^{-2}). Note: due to the over 100,000 runs required for Quorum's evaluation, it was cost-prohibitive to execute on real hardware. Thus, we use faithful simulations.

Datasets. We evaluate Quorum on four distinct datasets representing different anomaly detection scenarios (Table I). Three of the four datasets are directly derived from a related and widely-cited survey of classical unsupervised anomaly detection techniques by Goldstein and Uchida [10]. The fourth dataset, which contains measurements taken from a combined cycle power plant, was taken from UCI's machine learning repository [32]. For the power plant dataset, we inserted "plausible" anomalies into the dataset based on ranges of values that are possible for each feature. All datasets have labels stripped for all operations until the evaluation is performed to facilitate unsupervised anomaly detection.

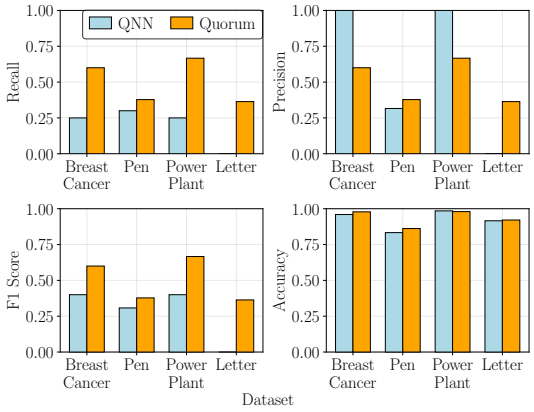

Fig. 8: Comparison of performance metrics between QNN and Quorum across four datasets. Note that the QNN did not detect any anomalies for the letter dataset, and thus, precision, recall, and F1 scores are all zero.

Experimental Framework. Each experiment consists of multiple ensemble groups, where an ensemble group represents a complete run of Quorum with different random initializations. We use 3-qubit encodings for our primary experiments, resulting in 7-qubit circuits (including the ancilla qubit). We chose this circuit size mainly due to limitations on our computational resources as we ran simulations on our local systems. For each dataset, we execute with 1,000 ensemble members, with each member using different random bucket assignments and feature selections. We executed 4,096 shots per circuit for measurements. Increasing both shot count and ensemble members has significant impacts on performance, with benefits diminishing as they increase past a certain point. For noisy simulations, we similarly executed 4,096 shots per circuit. We use different target probabilities for bucket size determination (see Table I) and provide an ablation study on the effect of bucket sizes for each of the different datasets.

Evaluation Metrics. We evaluate Quorum's performance using several metrics: (1) **Detection Rate/Accuracy** at various percentile thresholds, measuring the fraction of true anomalies captured in the top k% of anomaly scores. We chose to include this metric to showcase how well our technique separates anomalies from the rest of the dataset. (2) **Precision**, calculated as the ratio of correctly identified anomalies to the total number of samples flagged as anomalous. (3) **Recall**, measured as the ratio of correctly identified anomalies to the total number of true anomalies in the dataset. And (4) **F1 Score**, which is the harmonic mean of precision and recall.

Competitive Techniques. We compare Quorum against a state-of-the-art quantum anomaly detection technique that utilizes quantum neural networks to find anomalies in labeled datasets [14] (we refer to this technique as "QNN"). The technique is the most suitable among competitors as it shows improved performance over them and is designed for noisy quantum hardware, making it a practical benchmark. We adapted QNN for generic use since it was initially developed for network anomaly detection. Further, comparing against

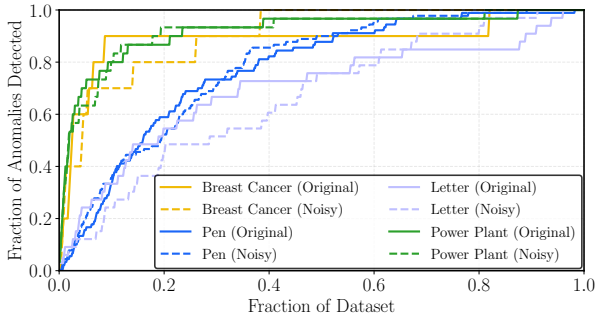

Fig. 9: Quorum groups anomalies consistently amongst data points with the highest absolute average deviations.

QNN's supervised, training-based approach helps demonstrate the advantages of our zero-training unsupervised method, particularly in scenarios where labeled data is unavailable. Note: no unsupervised, zero-training work exists to compare against as Quorum is the first of its kind in this domain.

VI. Evaluation

Our experimental results demonstrate the efficacy of Quorum's anomaly detection approach across diverse datasets.

Flagship Results. Quorum demonstrates balanced anomaly detection performance across all evaluated datasets – Fig. 8. The recall measurements particularly highlight Quorum's strengths, where it consistently outperforms the QNN method. While the QNN achieves perfect precision scores on both the breast cancer and power plant datasets, this comes at the significant cost of being overly conservative in anomaly detection, leading to its notably poor recall performance. Quorum thus achieves superior F1 performance across every dataset tested – 23% higher on average. Quorum's more nuanced approach leads to better overall detection capabilities while maintaining comparable accuracy levels across all datasets. *These results demonstrate that Quorum provides an effective approach to anomaly detection, successfully balancing precision and recall without sacrificing overall classification performance.*

Detection Rates. In Fig. 9, Quorum's detection rate curves exhibit notably steep initial gradients, particularly for the breast cancer and power plant datasets, which achieve approximately 80% detection rate within the first 10% of the highest deviation samples in noiseless simulations (see Fig. 10 for a detailed look at how Quorum grouped the breast cancer data samples). The performance hierarchy among datasets likely reflects their inherent separability characteristics, with the breast cancer dataset showing the most distinctive anomaly patterns (achieving near-perfect detection at the 10th percentile), followed by power plant data. The letter and pen datasets, while requiring a larger percentile of samples for complete detection, still maintain clear separation from random performance, achieving a roughly 60% detection rate within the top 20% of sample deviations for noiseless runs. When subjected to realistic quantum noise, Quorum demonstrates a high degree of resilience. Noisy simulations closely track their noiseless counterparts across all datasets, with only minimal degradation in performance.

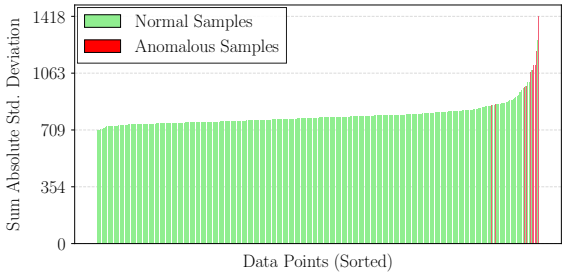

Fig. 10: An example of how Quorum separates anomalies from normal samples on the breast cancer dataset (16K shots).

TABLE II: F1 Scores for different bucket sizes (p is the probability of at least one anomaly in a bucket).

Dataset	$p = 0.5$	$p = 0.6$	$p = 0.75$	$p = 0.95$	$p = 0.98$
Breast Cancer	0.500	0.500	0.600	0.500	0.600
Pen Digits	0.333	0.389	0.367	0.389	0.389
Letter	0.152	0.182	0.242	0.273	0.273
Power Plant	0.600	0.600	0.633	0.533	0.600

Such inherent noise resilience is a significant advantage of Quorum for near-term applications, as Quorum can maintain its effectiveness even on noisy hardware without requiring high-overhead error mitigation or correction methods.

Bucket Size Ablation. Analysis of F1 scores across different bucket size configurations in Table II reveals that, as expected, very small bucket sizes generally lead to degraded performance. However, we observe that moderately sized buckets oftentimes outperform larger ones – for instance, the letter dataset achieves its peak F1 score of 0.273 at $p = 0.95$, while the breast cancer and power plant datasets show improved performance at $p = 0.75$. This behavior can be explained by the trade-off between statistical significance and local sensitivity - while larger buckets provide more robust statistical estimates, smaller buckets may better capture localized anomaly patterns by reducing the "averaging out" effect of mixing anomalous and normal samples from the datasets.

VII. Conclusion

In this paper, we introduced Quorum, a novel quantum anomaly detection framework that operates without requiring any training. The framework's design, which incorporates strategic data bucketing, feature selection, and ensemble analysis, proves particularly effective at identifying anomalies while remaining computationally efficient through its inherent parallelizability. Our evaluation shows that Quorum can achieve up to 80% detection rate within the first 10% of highest-deviation samples, demonstrating strong anomaly-detection power, and high resilience to noise on near term quantum systems. These results suggest that Quorum represents a promising and wholly quantum step forward in anomaly detection.

***Abstract*—Security verification of Network-on-Chip (NoC) systems is essential due to their intricate and high-concurrency structures. Traditional methods often fail to cover all scenarios or scale effectively, leading to prolonged verification and overlooked vulnerabilities. Our proposed solution, *InterConFuzz*, a hybrid hardware fuzzing technique, uses symbolic execution for extensive coverage. Developed on Universal Verification Methodology (UVM), *InterConFuzz* discovered five security flaws in the NoC architecture of the OpenTitan SoC—surpassing existing techniques by three—while reducing memory and computational needs by 24.4% and 29.5%, respectively. Furthermore, *InterConFuzz* furnished comparable functional coverage compared to existing NoC fuzzing approaches, proving its efficiency and robustness.**

***Index Terms*—Hardware Security, Network-on-Chip, Security Verification, Fuzzing**

I. Introduction

The increasing complexity of modern System-on-Chip (SoC) designs stems from the integration of a growing number of Intellectual Property (IP) blocks and sophisticated communication protocols that allow these components to interact efficiently. This complexity is managed by Network-on-Chip (NoC) systems, which are responsible for coordinating data flow, resource sharing, and communication across the SoC. While NoCs enhance performance and modularity, they also introduce potential security vulnerabilities due to the intricate interactions between multiple processing units. Flaws or weaknesses in NoC designs can expose sensitive data or lead to malfunctioning components, resulting in critical system failures. Such vulnerabilities and functional errors can have far-reaching consequences, including delays in product development and significant financial losses due to expensive silicon respins and redesigns, with over 70% of respins attributed to such issues [1], [2]. Therefore, comprehensive NoC verification is essential to identify and mitigate potential issues early in the design process, ensuring both the functional integrity and security of SoCs.

Despite advancements in fault-tolerant designs, the verification of NoC systems remains a significant challenge, particularly in ensuring that routing errors and communication faults are detected and mitigated. While simulation has been the traditional approach for verifying NoC designs, it is often insufficient for capturing the full scope of potential errors, especially as NoC systems become more intricate. Formal methods, although effective at verifying abstract models of NoC, struggle with the scalability and complexity of verifying Register Transfer Level (RTL) implementations. As routers interconnect to form larger networks, the verification of global NoC properties becomes exponentially more difficult, highlighting the need for more robust verification strategies.

This research was supported by the Technology Innovation Institute (TII), Abu Dhabi, UAE.

Nevertheless, given the limitations of formal methods in verifying larger and more complex NoC designs, simulation-based methodologies have become the preferred approach. In this context, the Universal Verification Methodology (UVM) is the industry-standard library for verification [3]–[5]. UVM provides a scalable and reusable framework that simplifies the generation of test cases and coverage analysis, thereby reducing the complexity associated with verifying intricate NoC architectures. However, the reliance on manually generated test cases still demands substantial human effort, making it challenging to achieve full coverage. As NoC designs continue to grow in complexity, the inefficiency of generating comprehensive test cases through manual methods becomes increasingly apparent.

Software fuzzing tools like libFuzzer [6] and AFL [7] have shown great promise in validating large and complex programs. When adapted for hardware verification, fuzzing has demonstrated significant potential [8]–[11]. However, hardware fuzzing techniques face several challenges that hinder their efficacy. These include the need for robust coverage monitoring to accurately measure and guide exploration, the challenge of efficiently directing the fuzzer to uncover new states without incurring excessive computational overhead, and the requirement for a reliable reset mechanism to ensure deterministic testing and manage the complex reset hierarchies of SoCs [11]. Furthermore, simulation tools like Verilator [12], which are often used in hardware fuzzing, present limitations in terms of scalability and compatibility with industrial verification environments. Another critical challenge is ensuring that the fuzzer can capture all hardware events, such as delays and clock generation in HDL, during simulation, as incomplete event tracking can lead to gaps in the verification process.

To address these challenges, we developed the *Interconnect Fuzzer* (*InterConFuzz*), a novel hybrid NoC fuzzing approach built on top of UVM that enhances coverage and operational efficiency while mitigating the limitations of existing simulation tools. Verilator [12], which cannot capture all hardware events, posed significant limitations. To overcome this, we opted for Vivado for simulation [13]. Although Vivado is slower than Verilator, it accurately simulates and captures critical hardware-specific events such as delays and clock generation, ensuring comprehensive event tracking during NoC architecture fuzzing. Furthermore, *InterConFuzz* employs a white-box verification model, enabling direct observation of internal variables within the NoC architecture, thus facilitating precise coverage monitoring and effective state tracking. A control flow graph (CFG) of the NoC is generated to capture branching information, guiding the placement of checkpoints that optimize state exploration. Integrating reset logic derived from the CFG into the RTL design reduces the need for frequent hard resets, ensuring deterministic tests while maintaining computational efficiency. *Moreover, InterConFuzz*

utilizes a two-step guidance mechanism that assesses the feasibility of reaching new states from the current state and employs the CFG to generate tailored seeds for exploring previously uncharted nodes of the NoC CFG. By addressing these challenges, including the need for comprehensive event tracking and the limitations of simulation tools, *InterConFuzz* significantly improves the scalability and effectiveness of NoC fuzzing in industrial verification settings. In this paper, our main contributions are:

- We present *InterConFuzz*, a fuzzing-based NoC verification methodology built upon UVM that systematically encompasses all states associated with the defined security properties. This facilitates its seamless integration into the hardware security development lifecycle (SDL).
- We develop a checkpoint mechanism using a reset operation, which reduces computational cost for executing the proposed NoC fuzzing approach. This enables partial reset to speed up the path exploration process through fuzzing.
- *InterConFuzz* is evaluated on the TL-UL NoC architecture used in the OpenTitan SoC [14], where it was able to identify five types of vulnerabilities, three more than the existing NoC verification methodology typically present in the NoC architectures.
- *InterConFuzz* demonstrates similar coverage gain with low variance compared to existing fuzzing-based verification approaches.

II. Background

A. Coverage-guided Fuzzing

Fuzzing generates tests to probe valid and invalid edge cases, identifying vulnerabilities by uncovering undefined behaviors [15], [16]. It uses mutation-based techniques, altering existing data, or generation-based methods, creating tests from protocols. Widely adopted, platforms like OSS-Fuzz and ClusterFuzz automate fuzzing, revealing security flaws in large codebases [17]–[22]. Coverage-guided fuzzing explores diverse program paths, leveraging run-time coverage data via instrumentation to refine inputs [23]–[26].

B. Symbolic Execution

Symbolic execution is a powerful technique for analyzing the relationship between program inputs and behavior [27]–[29]. Instead of concrete values, it uses symbolic representations for inputs, allowing the interpreter to create expressions that incorporate these symbols. Conditional branches are associated with constraints derived from symbolic values, representing the conditions under which different paths are executed. By solving these constraints, symbolic execution reveals how various inputs influence program execution, identifying which inputs lead to specific execution paths.

C. Universal Verification Methodology (UVM)

The UVM is a standardized framework based on SystemVerilog, designed to improve the verification process for complex digital designs, such as SoC architectures [3]. UVM promotes reusability, scalability, and flexibility by leveraging object-oriented programming principles, enabling the creation of reusable verification components like drivers and monitors. Its importance stems from its ability to streamline verification through constrained-random testing and functional coverage-driven techniques, ensuring comprehensive exploration of a design's behavior under various conditions. UVM's adoption across the verification industry is critical as it addresses the increasing complexity of modern designs while reducing development time and cost by reusing verification IPs. This aligns with industry demands for faster time-to-market and improved product reliability [3], [30], [31]. By offering a scalable and automated verification environment, UVM plays a crucial role in ensuring the functional correctness and robustness of semiconductor products. This is crucial since verification consumes a significant portion of the design flow.

III. Related Works

NoC architectures can be vulnerable to breaches with minimal impact [32], [33]. To secure SoC communication, methods like secure NoC fabric [34] and Design-for-Debug (DfD) features [35] are used. However, these security components can increase power and area costs, challenging the compact and energy-efficient design of SoCs.

Real-time detection and localization of denial of service (DoS) attacks have been proposed to prevent adversaries from exploiting the NoC architecture to execute DoS attacks on the SoC [36]. For example, network-based monitoring mechanisms utilizing unique hardware probes have been proposed to enable runtime observability of system-level security threats [37]. Furthermore, recent studies have explored methods for detecting NoC-based hardware Trojans at runtime [33], [38]. While various verification methods such as concolic testing [39], [40], fuzzing [8]–[10], information flow tracking [41]–[44], and runtime detection [45]–[47] have been developed for SoCs and IPs, few attempts have been made to develop a security verification method specifically tailored for NoC.

Despite these advances in ensuring security for NoCs, most techniques require architectural implementations to enforce security but lack verification strategies for assessing NoC security at the register-transfer level (RT-level). To address this gap, two methodologies have been developed for verifying NoC security: SeVNoC and NoC-Fuzzer [48], [49]. SeVNoC employs control flow graphs (CFGs) to identify vulnerabilities in inter-IP communication, while NoCFuzzer uses fuzzing techniques to verify the security of NoCs. However, these verification tools show limitations in coverage and bug detection capability as discussed in Section V.

IV. Proposed InterConFuzz Methodology

A. InterConFuzz Architecture

The *InterConFuzz* framework, illustrated in Fig. 1, integrates seamlessly into the UVM workflow for NoC security verification. The individual components are explained in the next paragraph; while a standard UVM verification environment consists of components ① to ⑥, *InterConFuzz* extends this with five additional blocks (⑦ to ⑪) to enhance the process through symbolic execution and input fuzzing. The fuzzing is introduced using UVM library functions, while symbolic execution is achieved with an SMT solver.

In a basic UVM verification workflow, the *Scoreboard* or ① is responsible for comparing the expected and actual outputs of the design under verification (DUV) ⑥ to verify its correctness. It typically receives predicted values from reference models and the actual values from the DUV, subsequently flagging any mismatches as errors. This ensures that the DUV behaves as intended according to the testbench specifications. The *UVM Sequencer* or ② generates and controls the flow of transaction-level stimuli to ⑥, managing the order and timing of test scenarios. It acts as a bridge between the testbench and the driver, ensuring proper data flow. The *UVM Driver* or ③ takes transactions from the sequencer and translates them into signal-level inputs for the DUV. It ensures that high-level commands are converted into physical stimuli, enabling the DUV to process the intended test cases. The *UVM Monitor* or ④ passively observes the DUV's interfaces, capturing signal activity and transaction data for analysis. It checks the DUV's behavior without interference and reports information for functional coverage

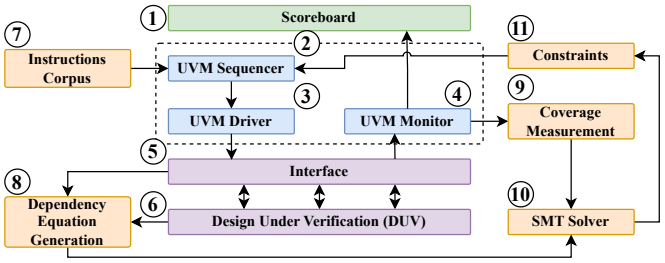

Fig. 1: *InterConFuzz* Architecture.

and checking, contributing to verification results. (6) is connected to (3) and (4) through the interface (5).

An instruction corpus (7), containing the necessary NoC function instructions, is compiled to verify the security of the NoC. This corpus is then linked with (2), enabling it to generate pattern sequences based on the corpus.

Dependency equations are extracted from the DUV through the Control Flow Graph (CFG) of the RTL design, which is generated using PyVerilog [50] to enable symbolic execution and enhance coverage. This process is illustrated by the connection of (8) with (5) and (6). These equations describe a Boolean relationship between the control registers and the I/O ports of the interface. The equations are then processed by the *z3-solver* [51] (10), an SMT solver, to generate and solve constraints (11). Additionally, a coverage measurement module (9) is linked to (4), evaluating the control register values to assess the achieved coverage. If the coverage remains stagnant for a user-specified duration, (9) triggers (10), which produces new constraints (11) to be integrated into (2).

B. InterConFuzz Algorithm

1) Defining UVM Sequencer and Driver: To randomize the instruction sequence for the NoC input, *InterConFuzz first defines a UVM sequencer tailored to the NoC architecture's specific instruction corpus.* The instructions are categorized based on their type, and each category's bit sequence is divided into components representing various commands, such as source address, destination address, opcode, flags, and more. For example, in the TL-UL bus protocol, the opcode is encoded in three bits, with an additional three bits allocated for parameters, a flag indicating data corruption, and such [52]. The protocol supports five message types: (1) *Get*, (2) *PutFullData*, (3) *PutPartialData*, (4) *AccessAck*, and (5) *AccessAckData*.

To execute specific functions, *InterConFuzz* begins by randomizing the input message sequences. Next, it identifies bit value packets such as addresses, data, and other fields. To perform fuzzing, *InterConFuzz* randomizes the values of these bit fields, generating diverse event scenarios while preserving the sequence structure. These modified inputs are then used by the UVM sequencer to drive the DUV with both functional and fuzzed input patterns.

To set up a complete UVM testbench, *InterConFuzz* first extracts the design interface from the NoC architecture, as described in detail in Algorithm 1, discussed in Section IV-B3. Upon defining the UVM sequencer, *InterConFuzz* attaches the sequencer to the UVM driver, and subsequently, the driver is connected to the design through the extracted interface. This integration establishes a fully functional UVM testbench, allowing for thorough testing of the NoC design.

2) Coverage Assessment: InterConFuzz uses control registers to measure coverage during fuzzing. Control registers dictate system behavior by controlling state transitions and monitoring specific operational parameters, enabling precise tracking in processes like

Algorithm 1: *InterConFuzz* Checkpoint Setup Algorithm.

Input: RTL Design, $\mathcal{D}$
Parameter: Interval, $\mathcal{I}$; Exit Threshold, Th
Output: Control Flow Graph, `CFG`; CheckPoints, `ChckPoints`

```
IF ← Extract(D)            /* IF = Interface */
CFG ←Generate— D;
Identify Branching Nodes;
Mark Control Registers;
for each Control Register, Reg_C do
    if branching at Reg_C > Br_th then
        append Reg_C to ChckPoints;
    end
end
Attach ChckPoints to CFG;
return CFG, ChckPoints
```

CFG traversal for coverage measurement. These registers offer a more accurate way to track coverage because they allow for precise monitoring of explored paths within the CFG, effectively capturing the test's progress and addressing coverage challenges commonly encountered in simulation.

Coverage is measured by running a simulation and analyzing the resulting dump file to see which paths were explored. Control registers are carefully monitored throughout this process as they define the sequence of states and transitions during the simulation. Since individual register values alone do not capture the full simulation dynamics—given the interactions between different control registers—it is essential to consider all possible combinations of these values. This approach allows a comprehensive measurement of coverage, with the total number of states calculated based on these register interactions.

To evaluate fuzzing coverage, *InterConFuzz* leverages control registers by generating a CFG from the RTL design. These control registers, which guide traversal through the CFG, enable precise coverage measurement, addressing associated challenges effectively. Following the simulation, the resulting dump file is analyzed to identify the paths explored during the test. *To ensure comprehensive state exploration, it is crucial to monitor these registers since they dictate the simulation's trajectory. Observing individual register values alone is insufficient due to potential interactions; therefore, all combinations of their values must be considered.* The total number of possible states is determined using the Eqn. 1.

$$No.\ of\ total_states = \prod_{j=1}^{N} (n_j) \tag{1}$$

In Eqn. 1, N denotes the total number of control registers, with n_j representing the possible states for control register j. Coverage is measured by comparing the total number of possible states to the number of states that have been reached.

3) Simulation Setup: InterConFuzz utilizes Algorithm 1 to configure the simulation environment. In this process, *InterConFuzz* simulates the DUV with a specified interval, $\mathcal{I}$, and an exit threshold, Th. $\mathcal{I}$ determines the number of clock cycles over which the simulation runs before recording the simulation outcome as a VCD file. The exit threshold, Th, specifies the maximum number of consecutive simulation dumps during which the DUV can remain in the same

Algorithm 2: *InterConFuzz* CFG Traversal Algorithm.

Input: Interface, `IF`; Control Flow Graph, `CFG`; CheckPoints, `ChckPoints`;
Parameter: Interval, $\mathcal{I}$; Exit Threshold, Th
Output: Report, $\mathcal{R}$

```
1  while All ChkPoints not Covered do
2      SimFile <-Dump VCD- Simulate(D) ;
3      Coverage <-Record- Read(SimFile) ;
4      if All states covered then
5          mark current ChckPoint as covered
6      end
7      if NoIncrement(Coverage) > Th then
8          identify(last covered state);
9          find (nearest ChckPoint);
10         while No New State can be reached do
11             find (previous ChckPoint in the CFG);
12         end
13         reset back to the ChckPoint;
14         Constraints ← SolveFor(newStateCondition);
15         Sequencer <-Apply- Constraints;
16     end
17     if Bug found then
18         R ← B_det        /* Bug Details, B_det, contain
               clock cycle time and violated property   */
19     end
20 end
21 return R
```

state; exceeding this limit prompts *InterConFuzz* to initiate symbolic execution for enhanced guidance. After completing the simulation, *InterConFuzz* produces a comprehensive bug report for the design.

InterConFuzz takes the RTL design of the NoC, $\mathcal{D}$, as its input. Initially, *InterConFuzz* extracts the I/O interface of $\mathcal{D}$ (line 1), enabling the attachment of the UVM driver to the RTL design. Following this, *InterConFuzz* generates the `CFG` of $\mathcal{D}$ (line 2) and identifies the branching nodes within this `CFG` (line 3). Subsequently, *InterConFuzz* identifies the control registers by determining those registers that influence the execution flow of the DUV (line 4). Using the `CFG`, *InterConFuzz* detects branch points and compiles a list of registers governing these branches. These registers are then classified as control registers and are employed to evaluate coverage metrics.

To avoid performing a full reset and ensure the fuzzer revisits specific points in the RTL design, InterConFuzz introduces checkpoints within the design's `CFG`. These checkpoints are strategically placed based on the design's branching structure. *InterConFuzz* selects nodes as checkpoints when the branching factor exceeds a predefined threshold, Br_{th}. Specifically, if a node and its subsequent sub-nodes generate more than Br_{th} branches, that node is marked as a checkpoint (lines 6-8). The threshold Br_{th} is configurable by the user: setting a higher Br_{th} results in fewer checkpoints, causing the fuzzer to revisit the same branches more often, while a lower Br_{th} increases the number of checkpoints, which demands more memory. Experimental results indicate that setting Br_{th} to three achieves an optimal balance for performance.

4) CFG Traversal and Constraint Generation: InterConFuzz follows Algorithm 2 to simulate $\mathcal{D}$, traverse through `CFG` and use symbolic execution to generate $Constraints$ to achieve higher coverage. Upon completion of the preliminary steps discussed in Section IV-B1, IV-B2, and IV-B3 *InterConFuzz* initiates a loop that continues until all checkpoints are covered (line 1). The initial step within this loop involves simulating until $\mathcal{I}$ is reached and subsequently generating a simulation record file (line 2). This record file is then processed by *InterConFuzz* to measure coverage using control register values (line 3). If the states associated with the current checkpoint are fully covered, *InterConFuzz* designates the checkpoint as "covered" (lines 4-6). Following this, *InterConFuzz* conducts a status check to assess the increase in coverage compared to previous checks.

In the absence of coverage improvement, InterConFuzz records the number of intervals during which coverage remains unchanged. When this count surpasses the designated exit threshold Th defined in Section IV-B3, InterConFuzz concludes that the fuzzer is experiencing stagnation and requires intervention to enhance coverage (line 7). To address this, *InterConFuzz* first identifies the most recent covered state by analyzing the latest simulation dump file and then determines the nearest checkpoint corresponding to this state (lines 8-9). Next, *InterConFuzz* initiates a procedure that navigates *upwards* in the CFG to locate the closest checkpoint leading to an unexplored state (lines 10-11). Here, *upwards* refers to moving toward the root node or initial default state within the CFG hierarchy. Once the appropriate checkpoint is found, *InterConFuzz* resets the simulation to this checkpoint (line 13) and uses the *z3-solver* [51] to establish constraints within the UVM sequencer (lines 14-15). These constraints guide the fuzzer's path, targeting the achievement of the newly identified state. By restricting specific sequences of NoC instructions, these constraints direct the UVM sequencer to produce input sequences that actively explore previously uncovered states. This guided approach allows *InterConFuzz* to generate instruction sequences with an increased probability of reaching unexplored states.

Conversely, if coverage improvement is detected, *InterConFuzz* continues fuzzing with the same setup. If a bug or property violation is identified during this process, *InterConFuzz* documents the specifics, including the clock cycle time and the violated property, and appends this information to the bug report, $\mathcal{R}$.

To execute checkpointing, *InterConFuzz* logs input pattern sequences as the fuzzer explores new states. When a checkpoint is reached, the sequence is recorded as the path to that checkpoint. If the fuzzer reaches a leaf node or a state with no further unexplored branches, *InterConFuzz* resets the design and replays the sequence to return to the checkpoint. Once all nodes from a checkpoint are visited, *InterConFuzz* removes the current checkpoint and promotes the previous one as the new target, repeating the process.

5) Bug Detection: InterConFuzz employs a property-based verification framework to identify security vulnerabilities in designs by leveraging a predefined set of properties that define key security requirements using the UVM monitor. During the fuzzing process, the simulator continuously monitors these properties for any violations. Upon detecting a breach, the UVM monitor generates a comprehensive report, including the name of the violated property, the precise simulation timestamp, the associated waveform, and the sequence of input vectors starting from activating the *reset* signal. This detailed information is then appended to $\mathcal{R}$.

V. Evaluation and Results

A. Evaluation Setup

We evaluated *InterConFuzz* using security vulnerability detection and coverage analysis. For security assessment, we compared *InterConFuzz* with SeVNoC [48] on the OpenTitan TileLink Unprivileged

TABLE I: Details for the Detected Bugs in the Benchmark SoC.

Bug No.	Bug Description	CWE Number	# of input vectors needed to detect the bug
01.	Omitted Wipe Operation After Transaction.	1331	5.85×10^5
02.	Modifying Destination.	668	4.39×10^5
03.	Modifying Source.	668	4.76×10^5
04.	False Transactions Leading to Denial-of-Service (DoS).	1315	7.38×10^4
05.	Corrupting Message Data	1331	6.34×10^5

(TL-UL) network [52]. For coverage evaluation, we benchmarked *InterConFuzz* against NoCFuzzer [49] on OpenPiton's [53] NoC.

1) Evaluation Platform Details: A server with AMD EPYC 7513 2.6GHz, 32C/64T, 128M Cache (200W) Processor, 16 DDR4-3200 64GB RDIMM, 3200MT/s, Dual Rank, 16 GB RAM, and four A100 SXM4 80GB 500W Nvidia GPUs was used to run the simulations. Xilinx Vivado is used as a simulator [13].

2) Parameter Setup: During fuzzing, the system is configured to dump simulation files at every third interval. An interval represents a user-defined number of clock cycles, which is 300 in this case. This setup strikes a balance between performance and resource utilization, ensuring *InterConFuzz* effectively saves the necessary simulation records for coverage analysis.

3) Evaluation Metrics: To assess the effectiveness of *InterConFuzz*, we concentrate on three metrics: (1) its bug detection capability, (2) coverage gain, and (3) computational resource consumption. We first compare the number of bugs *InterConFuzz* identifies against those found by existing fuzzing techniques. We then quantify the coverage achieved in terms of the number of coverage points–defined as the combined variations of control register values and input patterns generated. We also show the effect of symbolic execution and the performance in different parameter configurations, as well as the variance of achieved coverage to illustrate *InterConFuzz*'s efficacy. Moreover, we evaluate the computational resources and time required by *InterConFuzz* to verify the benchmarks in comparison to other methods, highlighting the efficiency of our approach.

B. Vulnerability Description

Table I summarizes the identified bugs, their CWE numbers, and the input vectors needed for detection. The following subsections provide detailed analysis and relevant RTL code snippets.

```
property reset_chk;
(@posedge clk_i) !rst_ni |-> !(|rdata);
endproperty
```

Listing 1: Security Property for clearing data.

a) ***Bug #1****:* This Bug prevents the system from clearing data in the buffers/registers after each transaction. As a result, residual data remains and gets overwritten with every new transaction.

Every new transaction overwrites the previous data, leading to potential data leakage. If the previous data was sensitive or critical, requesting another transaction can lead to storing the data in an unprotected memory address, leading to privacy violations. To detect this Bug, the property in Listing 1 is used, which dictates that upon a reset, `rdata` should be cleared.

b) ***Bug #2****:* This vulnerability allows alteration of a transaction's destination post-initiation. While the original transaction completes successfully, a copy of the data is covertly sent to an unauthorized location, like a UART port or another attacker-controlled channel. As shown in Line 2 and 3 in Listing 2, if the module's write data flag is raised, it sets the write request and data as adversary-defined.

```
1 if (!rst_ni) begin
2   wr_req_q <= (data_wr?) adv_req : 0;
3   wr_data  <= (data_wr?) adv_data : 0;
```

Listing 2: Writing Data to Another Destination.

This leads to a data breach, leaking confidential information to unauthorized locations. This major security threat was detected using the property shown in Listing 3, which requires `wr_req_q` and `wr_data` to be cleared upon reset.

```
property reset_chk;
(@posedge clk_i) !rst_ni |-> !(|wr_req_q)&&!(|wr_data);
endproperty
```

Listing 3: Security Property for Writing Data to Another Destination.

c) ***Bug #3****:* This security breach allows data injection into the system after a transaction starts. Initially, the system retrieves data from a legitimate source, but additional data is then injected from an attacker-controlled memory address. As shown in Line 3 and 4 in Listing 4, if the module's received flag is raised, it sets the receive source ID and source as the adversary's module ID and data size.

```
1 ...
2   reqid_q <= (data_r?) adv_id : 0;
3   reqsz_q <= (data_r?) adv_sz : 0;;
4   rspop_q <= AccessAck;
5   data_r  <= (@posedge clk_i) 0;
6 ...
```

Listing 4: Receiving Data from Another Source.

This can lead to data integrity issues, where unauthorized data is included in transactions. Such manipulation can result in incorrect or compromised data being sent, potentially disrupting operations or leaking sensitive information. This Bug was detected using the property in Listing 5, which asserts that `reqid_q` and `reqsz_q` should be cleared upon reset.

```
property reset_chk;
(@posedge clk_i) !rst_ni |-> !(|reqid_q)&&!(|reqsz_q);
endproperty
```

Listing 5: Security Property for Receiving Data from Another Source.

d) ***Bug #4****:* The bus initiates fake transactions, sending random values across the communication channel, causing congestion and delays for legitimate transactions, as shown in Listing 6. It initiates random write requests and data values if the adversary flag is raised.

```
1 wr_req_q <= (adv?) $RANDOM : 0;
2 wr_data  <= (adv?) $RANDOM : 0;
```

Listing 6: Initiating random write request to perform DoS attack.

This Bug leads to a Denial-of-Service (DoS) attack, in which the system's performance degrades significantly due to the time wasted processing these fake transactions. Legitimate tasks may experience delays or timeouts, reducing the overall system efficiency.

```
property reset_chk;
(@posedge clk_i) !rst_ni |-> !(|wr_req_q)&&!(|wr_data);
endproperty
```

Listing 7: Security Property for detecting DoS attack.

Here, the property in Listing 7 mandates that upon a reset signal, the `we_req_q` and `wr_data` should be set to Zero.

*e) **Bug #5**:* A rogue IP accesses the network and alters both inbound and outbound traffic, modifying data packets in transit and tampering with communication between components. As illustrated in Listing 8, the output write data register receives corrupted data before writing to the destination.

```
assign wdata_o=adv?`Mut_val^tl_i.a_data:tl_i.a_data;
```

Listing 8: Security property for error flag checking.

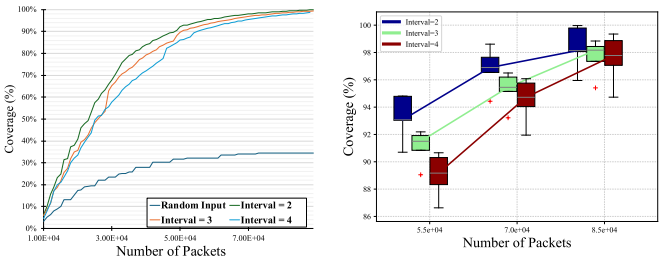
A rogue IP can manipulate exchanged data, compromising its integrity and introducing inaccuracies and security risks. This manipulation allows attackers to inject misleading data or responses, causing unintended operations. This property checks if `wdata_o` and `tl_i.a_data` are equal.

```
property reset_chk;
(@posedge clk_i) wdata_o == tl_i.a_data;
endproperty
```

Listing 9: Writing Data to Another Destination.

C. Comparative Analysis of InterConFuzz and SEVNoC

In this section, we present a comparative analysis of *InterConFuzz*'s detection capabilities relative to existing NoC security verification approaches, particularly SEVNoC [48]. Our findings reveal that while SEVNoC successfully detected certain bugs, it was unable to identify three significant issues: Bug #1, Bug #2, and Bug #3. *In contrast, InterConFuzz demonstrated a higher degree of reliability, detecting all five bugs within the NoC, indicating InterConFuzz's potential for comprehensive NoC verification.*



Our investigation found that SeVNoC overlooked Bug #1 because the buffers were often overwritten while evaluating the CFG of the SoC, resulting in an inability to detect mismatches due to not covering all corner cases. Furthermore, SeVNoC failed to identify Bug #2 and Bug #3 since SeVNoC considers a process safe if it completes functions without initially violating security properties. Consequently, these two bugs were not detected by SeVNoC. On the other hand, *InterConFuzz* detected all bugs by reaching the corner cases where the device was reset and initiated the transaction, causing previously written data in the buffer to be sent. Furthermore, *InterConFuzz* does not use a flagging technique to mark paths of the CFGs as secure. As a result, when the corner cases triggered Bug #2 and Bug #3, *InterConFuzz* flagged them as breaching security.

Finally, *our study found that InterConFuzz is more efficient, using 24.4% less memory and 29.5% less computational power compared to SeVNoC.* This demonstrates *InterConFuzz*'s enhanced effectiveness and efficiency in bug detection tasks.

D. Coverage Assessment

In this section, we provide a comparative study of the coverage furnished by *InterConFuzz* against existing approaches. To this end, we used control registers to assess coverage. Each branch of the control path is considered a coverage point for *InterConFuzz*. When multiple control path combinations are possible simultaneously, each combination of taken paths is considered a coverage point, as elaborated in Section IV-B2.

Randomness and Impact of Interval Parameter in Fuzzing: Figure 2 illustrates the coverage improvements of *InterConFuzz* and the variance in coverage gain. Figure 2a and Figure 2b show the coverage gain under different parameter configurations and the variance during three distinct fuzzing stages, respectively.

(a) Coverage comparison with existing fuzzing techniques.

(b) Variance of Coverage for Different Interval Configuration.

Fig. 2: Coverage comparison and variance profile.

Figure 2a underscores the impact of symbolic execution with different parameter configurations in guiding the fuzzing process. Random input generation without symbolic execution achieves only about 30% of the coverage attained with symbolic execution. *InterConFuzz* was tested with three configurations, altering the '$Interval$' parameter. Setting the '$Interval$' to 2, as shown in Figure 2a, results in better coverage but requires approximately 42.1% more processing power due to frequent SMT solver invocations. On the other hand, while setting the '$Interval$' value to 4 reduces processing power by 13.6%, the coverage gain is much slower. Therefore, realizing an '$Interval$' value of 3 provides the best outcome.

Figure 2b shows the variance in *InterConFuzz*'s coverage gain across different parameter setups. Within the selected data range, the impact of the initial randomness is settled down, and the fuzzing algorithm takes the primary effect. *InterConFuzz* displays a maximum coverage gain variance of 2.64%, indicating consistent performance. Notably, with an '$Interval$' value of 2, variance changes more frequently due to increased SMT solver invocations, leading to frequent coverage changes. Conversely, with an '$Interval$' value of 4, the coverage variance remains largely stable.

Comparison with NoCFuzzer: As shown in Figure 2a, the coverage improvement achieved by *InterConFuzz* aligns with the trends observed in the existing NoC fuzzing approach (NoCFuzzer) [49]. Moreover, *Figure 2b demonstrates the consistency of InterConFuzz's coverage, indicated by its low variance, confirming the reliability of InterConFuzz in delivering thorough and deterministic coverage.*

VI. Conclusion

This paper introduces *InterConFuzz*, a novel, coverage-directed hybrid hardware fuzzing framework specifically designed to enhance security verification for NoC architectures. By effectively combining coverage-directed fuzzing with symbolic execution, *InterConFuzz* strategically navigates the fuzzer into previously unexplored states of the NoC, optimizing both the efficiency and efficacy of the verification process. Integrated with UVM, *InterConFuzz* ensures seamless incorporation into existing security verification lifecycles, facilitating its adoption within industry practices. In evaluations conducted on a TL-UL bus network, *InterConFuzz exhibited superior bug detection capabilities, identifying three more bugs than current methodologies while reducing memory consumption by 24.4% and computational demands by approximately 29.5%.* Moreover, *InterConFuzz* achieved similar coverage when evaluated on OpenPiton's NoC architecture, underscoring its efficiency. These compelling results highlight *InterConFuzz*'s potential as a robust and efficient security verification framework for NoC architectures, positioning it as an exceptional option for integration into the security development lifecycle (SDL) of commercial SoC design flows.

***Abstract*—Quantum circuit execution often requires transpilation into hardware-compatible instructions, which can significantly alter the original design, making equivalence checking essential. However, existing approaches struggle with scalability and computational overhead. In this paper, we present ZXNet, a transformative framework for quantum circuit equivalence checking using ZX calculus-based graph abstractions. Leveraging graph neural networks, ZXNet captures complex equivalence patterns by integrating critical local and global circuit features. ZXNet achieves 99.4% validation accuracy, and up to 62× speedup over state-of-the-art methods, furnishing improvements of 45.83% in scalability, 42.22% in per-qubit verification time, and 5.94% in accuracy, outperforming state-of-the-art approaches.**

***Index Terms*—Quantum computing, equivalence checking, ZX calculus, graph neural networks.**

I. Introduction

Quantum computing represents a paradigm shift in computational science, offering significant speedups over classical computers by leveraging quantum mechanical principles such as superposition and entanglement, as demonstrated in Shor's and Grover's algorithms [1], [2]. Quantum computers operate on quantum bits (*qubits*), which are manipulated by quantum gates that apply unitary transformations to steer qubits toward desired states, with results determined probabilistically through measurement. The increasing demand for quantum computing, driven by applications in fields like cryptography, biochemistry, and machine learning [3]–[5], has led to the emergence of Quantum-as-a-Service (QaaS), allowing users to execute algorithms on cloud-based quantum hardware. However, given the constraints of current quantum hardware, such as limited connectivity and gate fidelity, the submitted algorithms undergo *quantum circuit transpilation* [6]. This process optimizes gate sequences, maps logical qubits to physical hardware, and decomposes complex gates into supported basis gates. While it ensures hardware compatibility, transpilation can significantly alter the original circuit's structure.

The modifications introduced to a quantum circuit during transpilation renders quantum circuit equivalence checking essential [7]. This process verifies that the transpiled circuit preserves the original quantum functionality by ensuring consistent output states and measurement probabilities across all possible inputs. Equivalence checking is particularly crucial for complex circuits, where even minor discrepancies can lead to significant computational errors [8]. As such, it acts as a safeguard to ensure that the executed quantum algorithm faithfully implements the user's intended operations.

To meet the growing demand for equivalence checking in increasingly complex quantum circuits, various frameworks have been developed, including Decision Diagrams, Matrix Product Operators, and simulation-based methods [9]–[11]. However, the existing approaches suffer from significant limitations in terms of time and memory overhead, which hinders their scalability and limits their applicability to complex quantum circuits, as explained in Section III. In addition to these methods, ZX calculus has emerged as a powerful framework for equivalence checking, utilizing its capability to represent quantum circuits as ZX graphs and systematically apply rewrite rules to transform these graphs into canonical forms that preserve circuit semantics [12].

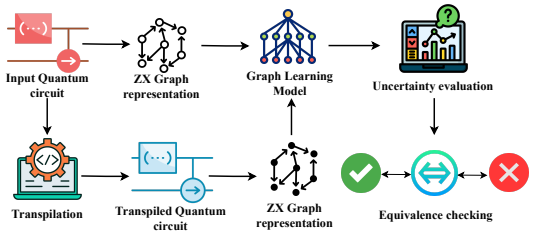

Fig. 1: Overview of our proposed equivalence checking framework using a novel graph learning method, ZXNet.

The graphical representation utilized by ZX calculus facilitates algebraic transformations and rule-based simplifications, enabling the identification of equivalence between circuits. Systematic transformations, such as full reduction, standardize equivalent circuits into near-canonical forms, enhancing the accuracy of equivalence detection. Additionally, ZX calculus effectively encodes both Clifford and non-Clifford operations, ensuring a comprehensive representation of diverse quantum transformations. While the standalone application of ZX calculus for equivalence checking poses computational challenges for large circuits due to extensive rule applications and complex pattern-matching processes, we observe its representation of quantum circuits is highly suitable for graph learning tasks. By encapsulating the circuit's structure and operations in a graphical format, ZX graphs provide a natural input for Graph Convolution Networks (GCNs), which excel at learning relational patterns and structural equivalence [13] [14] [15]. The ability of ZX graphs to represent both local gate operations and global entanglement patterns aligns well with the message-passing mechanisms of GCNs. This compatibility allows ZX calculus to act as a bridge between quantum circuit structures and machine learning, enabling scalable, efficient, and accurate equivalence checking for circuits with varying complexities.

In this paper, we present ZXNet, a transformative equivalence checking framework that, for the first time, leverages graph abstractions derived from ZX calculus, followed by the usage of a novel Graph Convolution Network (GCN) model designed for scalable and efficient quantum circuit equivalence checking. An overview

This work is supported by the National Science Foundation (NSF award #2343652).

of the proposed framework is depicted in Figure 1. ZXNet combines a unique encoding of features extracted from simplified ZX graphs, with a novel GCN architecture designed to learn intricate equivalence patterns efficiently. Furthermore, ZXNet incorporates a novel uncertainty-driven output validation mechanism and a Jaccard-adjusted loss function, which together enhance the model's robustness and accuracy, especially for hard-to-detect errors. *By leveraging ZX graphs to capture essential quantum transformations, ZXNet significantly improves scalability, reduces computational overhead, and establishes a reliable, adaptable solution for equivalence checking across quantum circuits of varying sizes and complexities.* Our main contributions are summarized as follows:

- We present ZXNet, a novel framework for equivalence checking that leverages simplified ZX graph representations of quantum circuits. ZXNet employs an innovative GCN architecture designed to effectively utilize extracted features, enabling efficient and accurate equivalence checking.
- To enhance the robustness of ZXNet, we propose a novel uncertainty-driven validation mechanism utilizing an edge-based Jaccard index value that enables the detection of minor infringements during the transpilation process and significantly improves error detection capabilities.
- ZXNet addresses the challenges of scalability and complexity by being able to learn and subsequently generalize equivalence relations, thereby being able to handle large and highly entangled quantum circuits with up to 120 qubits.
- Our evaluations on extensive benchmarks demonstrate that ZXNet significantly outperforms state-of-the-art equivalence-checking methods, achieving speedups of up to $801\times$ and an accuracy of up to 99.4%, establishing its reliability and effectiveness. ZXNet also surpasses existing techniques, achieving a 45.83% improvement in scalability, a 42.22% reduction in per-qubit verification time, and a 5.94% increase in accuracy.

II. Background and Motivation

A. Quantum Computing Basics

1) Qubits: A qubit, or quantum bit, is the fundamental unit of quantum information, analogous to a classical bit [16]. Unlike classical bits, which exist in either 0 or 1, a qubit can exist in a superposition of both states:

$$|\psi\rangle = \alpha\,|0\rangle + \beta\,|1\rangle \tag{1}$$

where $|0\rangle$ and $|1\rangle$ denote the basis states, and α and β are complex probability amplitudes such that $|\alpha|^2 + |\beta|^2 = 1$. This superposition property allows quantum computers to process a much larger state space than classical systems [17]. Qubits can also be entangled, enabling quantum circuits to perform powerful computations through correlated states. Measurement of a qubit collapses its state to either $|0\rangle$ or $|1\rangle$, with corresponding probabilities $|\alpha|^2$ and $|\beta|^2$.

2) Quantum Gates: Quantum gates are unitary operations that change the state of qubits. Mathematically, these gates can be expressed as matrices with dimensions of $2^n \times 2^n$, where n is the number of qubits. Depending on the number of qubits they are acting on, there are single-qubit gates (such as `X-gate`, `S-gate`, `H-gate`, *etc.*) and multi-qubit quantum gates (such as `CX-gate` and `CZ-gate`) [18].

B. ZX calculus

ZX calculus has emerged as a graphical language used to represent and reason about quantum circuits through structured diagrams

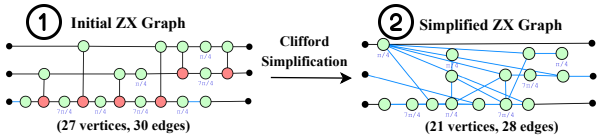

Fig. 2: Example of ZX graph representation and simplification.

instead of traditional gate sequences. It encodes quantum operations as graphs, where Z-spiders (green nodes) and X-spiders (red nodes) represent operations in different bases, and edges represent quantum entanglement or information flow [19] [20]. ZX calculus includes transformation rules—such as spider fusion, Hadamard edge transformation, and Clifford simplification—which simplify circuits while preserving equivalence. ZX calculus has been employed in various quantum computing applications. For instance, mixed quantum-classical optimization methods have utilized it to streamline computations, effectively bridging classical and quantum optimization techniques [21]. It has also been applied to optimize braided circuits on surface codes, demonstrating improvements in circuit efficiency [22]. In comparative studies, ZX calculus-based tools like PyZX have been benchmarked against Qiskit transpilation, where they have shown the potential to reduce gate counts significantly in certain scenarios [23]. An example of ZX graphs and their subsequent simplification is shown in Figure 2, where (1) is the initial ZX graph representation of a quantum circuit, which is subsequently simplified into (2) using Clifford simplification. These rules rooted in formalism render ZX calculus particularly valuable for tasks like circuit equivalence checking and quantum circuit simplification.

C. Graph Neural Networks for Quantum Circuit Equivalence

Our selection of Graph Neural Networks (GNN)s for quantum circuit equivalence checking with ZX graphs is motivated by their capability to directly and effectively process graph-structured data. [24]. Furthermore, unlike other ML models, GNNs natively handle variable-sized graph structures, preserving ZX graph topology and connectivity. Graph Convolution Networks are a type of GNNs, and they aggregate information from a node's neighbors, capturing local interactions (*e.g.*, entanglements) and propagating this information to model global structures [25] [26]. This propagation makes GCNs particularly effective for tasks like ZX graph equivalence checking, where small structural changes or variations in graph layouts (isomorphic graphs) must be handled robustly without being sensitive to the specific graph representation [27].

III. Related Work

Various algorithms have been developed to tackle the unique challenges of quantum circuit equivalence checking. However, they face several limitations, as discussed here. Decision Diagrams (DDs) are widely used for quantum circuit equivalence but struggle with exponential node growth and high memory usage for circuits exceeding 20 qubits [10]. They are also sensitive to variable ordering, which inflates diagram size and complicates verification. In contrast, the proposed ZXNet approach uses scalable, memory-efficient graph representations, effectively handling larger, highly entangled circuits without significant overhead.

Matrix Product Operators (MPO)-based equivalence checking approaches handle low-to-moderate entanglement efficiently using tensor networks, but face exponential scaling with high entanglement or depth, requiring costly tensor operations [9], [28], [29]. Furthermore, they struggle with non-local entanglement and error handling. ZXNet overcomes these challenges using efficient graph representations without intensive computations.

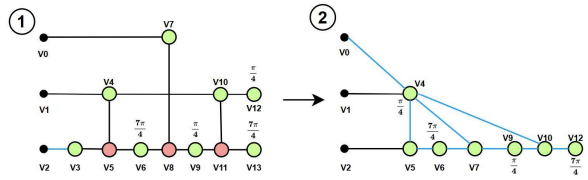

Fig. 3: ZX simplification reducing circuit complexity to enable critical feature extraction.

The existing ZX calculus-based equivalence checking approach struggles with deeply entangled or large circuits due to extensive transformations and inefficiencies [12]. They also lack flexibility for structural variations, limiting their applicability in complex circuits with high entanglement. These limitations primarily arise since this approach does not explicitly utilize any learning model to capture equivalence relations, and primarily relies on algebraic rule-based transformations [19]. In contrast to the existing approach, ZXNet embeds ZX graphs into a learnable framework using GCNs, eliminating exhaustive rule applications and enabling efficient, flexible verification for complex quantum circuits [30].

IV. Proposed ZXNet Framework

A. Feature extraction from ZX graph abstractions

Our approach begins by constructing ZX graph representations from quantum circuits, encoding the circuit's structure into a graphical form suitable for graph learning networks. We apply **full reduction on ZX graphs** to achieve a near-canonical representation, standardizing equivalent circuits and enhancing the model's learning capabilities. This approach preserves circuit equivalence while removing redundancies, thereby minimizing complexity. We have demonstrated an example of this simplification in Figure 3, where the initial ZX graph representation of a quantum circuit G, shown in (1) has 14 nodes, and is simplified to ZX graph (2) G' with 10 nodes, utilizing full reduction. Additionally, since full reduce supports both Clifford and non-Clifford gates, we ensure that the dataset effectively captures essential structural features for equivalence checking.

To design a graph-learning model capable of quantum circuit equivalence checking, we extract representative features from simplified ZX graphs G' that encode critical structural and functional information. This information is categorized into two types: *node features*, capturing critical properties of the vertices, and *edge features*, representing key relationships within the edges of the ZX graph. The extracted features from the simplified ZX graph (2) from Figure 3 are presented in Table I, with the corresponding features detailed subsequently.

a) Node features: These are denoted in columns one to six in Table I and their importance is detailed subsequently.

- **Vertex number**(v_i): The vertex number encodes positional and structural context within the ZX graph, enabling accurate node alignment and equivalence detection between quantum circuits.
- **Node type**(n_i): Node type in ZX graphs distinguishes Z and X-basis operations, ensuring consistent qubit mapping for equivalence checking and identifying mismatches in operation targets.
- **Row Index**(r_i): The row index captures operation sequence, ensuring temporal consistency critical for equivalence, as misalignment alters circuit behavior.
- **Degree**(d_i): The degree captures a node's connectivity and entanglement, aiding equivalence checking by identifying nodes with similar interaction patterns across circuits.

TABLE I: Feature Encoding of an Example Circuit.

Node Features						Edge Features	
Vertex Number (v_i)	Node Type (n_i)	Row Index (r_i)	Degree (d_i)	Phase (p_i)	Qubit Index (q_i)	Associated Edges (v_i, v_j)	Edge Type (e_i)
0	Boundary	0	1	0	0	(0, 7)	H
1	Boundary	0	1	0	1	(1, 4)	S
2	Boundary	0	1	0	2	(2, 5)	S
4	Z	2	3	0	2	(4, 5), (4, 7), (4, 10)	H, H, H
5	Z	2	3	1/4	1	(5, 2), (5, 4), (5, 6)	S, H, H
6	Z	3	2	7/4	2	(6, 5), (6, 7)	H, H
7	Z	4	3	0	2	(7, 6), (7, 9), (7, 4)	H, H, H
9	Z	5	2	1/4	2	(9, 7), (9, 10)	H, H
10	Z	6	3	0	2	(10, 9), (10, 12), (10, 14)	H, H, H
12	Z	7	1	7/4	2	(12, 10)	H

- **Phase**(p_i): The phase parameter encodes rotations or shifts, where differences signal distinct transformations and a lack of equivalence.
- **Qubit Index**(q_i): The qubit index specifies the target qubit of an operation, ensuring consistent qubit mapping and detecting mismatches during equivalence checking.

b) Edge features: These are detailed in columns seven and eight in Table I, with their importance mentioned as follows.

- **Associated Edges** (v_i, v_j): This feature defines connectivity and information flow, requiring identical source-target relationships for equivalence to preserve circuit functionality.
- **Edge type** (e_i): The edge type distinguishes regular connections from Hadamard transformations, and requires consistency across ZX graphs to avoid basis mismatches in equivalence checking.

B. GCN Model Design for Equivalence Checking

1) Model Construction: The ZX graph representation of quantum circuits, encoded into the node and edge features we extracted (Section IV-A), serves as the input for training our GCN model. The model processes pairs of ZX graphs $(\mathbf{G_1}, \mathbf{G_2})$ to produce a joint representation via graph convolutions and outputs a logit vector that indicates the likelihood of equivalence.

2) Model Training: The training process of our GCN model is outlined in Algorithm 1. The model parameters and the optimizer are initialized with a learning rate η to begin the training process (*line 1*). Following this, for each epoch, batches of graph pairs (G_1, G_2) and their labels (y) are extracted from the dataset. For each pair of graphs, the adjacency matrix $\mathbf{A_{N\times N}}$ and node feature matrix $\mathbf{X_{N\times F}}$ (where N represents the number of nodes in the graph and F refers to the number of features per node) are extracted, representing the structural and feature properties of the graphs (*lines 2–3*).

Graph Embedding: Each node $v \in V(G_1) \cup V(G_2)$ (where $V(G)$ denotes the set of all vertices in graph G) is initialized with an embedding $\mathbf{e_v}$, which is a learnable vector representation which encodes the node attributes and relationships (*lines 4–7*).

Graph Convolutional Layers: The embeddings are iteratively refined across L number of graph convolutional layers. At each layer, the embedding of each node v is updated using the operation shown in Equation 2 (*line 8*).

$$e_v^{(l)} = \texttt{AggregateNeighbors}(e_v^{(l-1)}, A, W_l) \tag{2}$$

In Equation 2, the function, `AggregateNeighbors`, combines the embeddings of the node v's neighbors, weighted by the adjacency matrix A and a layer-specific weight matrix W_l [31]. Following this, the updated embeddings are passed through an activation function (*line 9*). For our GCN model, we utilize the `ReLU` (Rectified Linear Unit) activation [32], as shown in Equation 3.

$$e_v^{(l)} = \texttt{ReLU}\left(W_l \cdot e_v^{(l-1)} + b_l\right) \tag{3}$$

In Equation 3, W_l is the learnable weight matrix for layer l, $e_v^{(l-1)}$ is the embedding of node v from the previous layer and b_l

Algorithm 1: GraphMatching Network Training with Jaccard-Adjusted Loss.

Input: Dataset $\mathcal{D}$ with ZX graph pairs (G_1, G_2) and labels y; learning rate η; uncertainty threshold τ; Jaccard index threshold J_{thresh}; scaling factor β
Output: Trained GraphMatching Network model

1 Initialize model parameters and optimizer with learning rate η;
2 **foreach** epoch **do**
3 **foreach** batch $(G_1, G_2, y) \subset \mathcal{D}$ **do**
4 Extract adjacency matrix $A_{N\times N}$ and node feature matrix $X_{N\times F}$ from each graph pair (G_1, G_2);
5 **foreach** node $v \in G_1 \cup G_2$ **do**
6 Initialize embedding e_v for node v;
7 **end**
8 **for** layer $l \in L$ **do**
9 Update $e_v \leftarrow$ `AggregateNeighbours` $(e_v, A_{N\times N}, W_l)$;
10 Apply activation $e_v \leftarrow$ `ReLU` (e_v);
11 **end**
12 Compute logits $f(G_1, G_2)$ via forward pass;
13 Compute softmax probabilities: $P(y|G_1, G_2)$;
14 $\mathcal{L}_{\text{base}} \leftarrow$ `CrossEntropyLoss` $(P(y|G_1, G_2), y)$;
15 $(\hat{y}, \delta, \mathcal{L}_{\text{Jaccard}}) \leftarrow$ `JaccardCheck` $(f(G_1, G_2), E_1, E_2, \tau, J_{\text{thresh}})$;
16 **if** $\delta > \tau$ **then**
17 $\mathcal{L}_{\text{total}} \leftarrow \mathcal{L}_{\text{base}} + \beta \cdot \mathcal{L}_{\text{Jaccard}}$;
18 **end**
19 **else**
20 $\mathcal{L}_{\text{total}} \leftarrow \mathcal{L}_{\text{base}}$;
21 **end**

Algorithm 2: Uncertainty Calculation with Jaccard Index Check.

Input: Model logits $f(G_1, G_2)$; edge sets E_1, E_2; uncertainty threshold τ; Jaccard index threshold J_{thresh}; scaling factor α
Output: Adjusted prediction $\hat{y}$, uncertainty δ, Jaccard penalty term $\mathcal{L}_{\text{Jaccard}}$

1 Compute: $P(y|G_1, G_2) = \text{softmax}(f(G_1, G_2))$;
2 Set confidence $\gamma \leftarrow \max(P(y|G_1, G_2))$;
3 Calculate sum of exponentials: $f_{\text{sum}} \leftarrow \sum_c e^{f_c(G_1,G_2)}$;
4 Compute uncertainty δ: $\delta \leftarrow -\log(f_{\text{sum}})$;
5 Initialize Jaccard penalty term: $\mathcal{L}_{\text{Jaccard}} \leftarrow 0$;
6 **if** $\delta > \tau$ **then**
7 Calculate edge intersection $E_\cap \leftarrow$ `Intersect` (E_1, E_2);
8 Calculate edge union $E_\cup \leftarrow$ `Union` (E_1, E_2);
9 Compute Jaccard index $J \leftarrow \frac{|E_\cap|}{|E_\cup|}$;
10 **if** $J > J_{\text{thresh}}$ **then**
11 Adjust prediction $\hat{y} \leftarrow$ equivalence class;
12 **end**
13 Update Jaccard penalty term: $\mathcal{L}_{\text{Jaccard}} \leftarrow \alpha \cdot |y - J|$;
14 **end**
15 **return** $\hat{y}$, δ, $\mathcal{L}_{\text{Jaccard}}$;

is the bias term that shifts the output of the linear transformation, allowing the model to represent features that are not centered at zero. The `ReLU` activation ensures that only positive values from the transformed embedding $W_l \cdot e_v^{(l-1)} + b_l$ contribute to the next layer's embedding $e_v^{(l)}$ (*line 10*). Taking only positive values through `ReLU` is important because it induces sparsity in the embeddings, reducing noise from less significant features (negative values) and focusing on meaningful contributions, which enhances model efficiency and robustness. After passing through all layers, logits $f(G_1, G_2)$ are computed via a forward pass, representing the model's predictions for equivalence classification (*line 11*). These logits are then converted into softmax probabilities for classification (*line 12*). The base cross-entropy loss, $\mathcal{L}_{\text{base}}$, is computed using the predicted probabilities and the true labels, quantifying the model's prediction error (*line 13*). However, there may be cases where the model's predictions are uncertain, indicating the model has low confidence associated with its prediction. In such cases, the **`JaccardCheck`** function is invoked (described in Section IV-C). This function computes the uncertainty metric δ and adjusts the loss term, if required, to include the Jaccard-adjusted loss $\mathcal{L}_{\text{Jaccard}}$. The adjustment is contingent on the Jaccard index threshold J_{thresh} and the uncertainty threshold τ (*line 14*).

When $\delta > \tau$, the total loss is updated, as shown in Equation 4 (*lines 15–17*):

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{base}} + \beta \cdot \mathcal{L}_{\text{Jaccard}} \tag{4}$$

In Equation 4, β is a scaling factor controlling the contribution of the adjusted loss, and can be treated as a hyperparameter of the GCN model we develop.

If the uncertainty δ is below τ, the total loss is set to the base cross-entropy loss $\mathcal{L}_{\text{base}}$ (*lines 18–20*). The Jaccard-based adjustment ensures that structural discrepancies in the graphs are penalized, thereby improving the robustness of the training process. Moreover, this adaptive loss adjustment enables the model to dynamically focus on hard-to-classify instances where structural similarity is a factor. The model parameters are updated via backpropagation using the total loss $\mathcal{L}_{\text{total}}$, gradually minimizing it over the course of training (*line 21*). After all the epochs are complete, the final trained model is returned, ready for validation and testing (*lines 22–24*).

C. Uncertainty-Driven Loss Adjustment

A central element of our methodology is a novel *uncertainty-driven Jaccard index validation* with loss adjustment, which enhances both the robustness and accuracy of equivalence checking. When our GCN model's prediction confidence drops below a predefined threshold, we incorporate the Jaccard index to serve as a secondary validation measure. The Jaccard index is utilized for its efficiency and effectiveness in capturing the overlap between the edge sets of graphs [33]. In the context of equivalence checking, it serves to identify discrepancies arising from subtle changes in the ZX graph representations, often caused by erroneous gate insertions in the original quantum circuit. We integrated the Jaccard index into a specially designed loss function during training, ensuring the model prioritizes learning in high-uncertainty scenarios. This process, (summarized as the `JaccardCheck` function in Section IV-B) is detailed in Algorithm 2. This algorithm can be broken down into *three* distinct phases, which are explained subsequently.

1) Uncertainty Threshold and Jaccard Index Validation: The GCN model outputs a probability distribution over the two classes (equivalent and non-equivalent) for each pair of graphs, represented in Equation 5 as follows:

$$P(y|G_1, G_2) = \text{softmax}(f(G_1, G_2)) \tag{5}$$

In Equation 5, $f(G_1, G_2)$ denotes the logits for the classes, and $P(y|G_1, G_2)$ is the probability that graphs G_1 and G_2 are equivalent. The *confidence score* and the *uncertainty* is computed are given by Equations 6 and 7, respectively, as follows:

$$\gamma = \max(P(y|G_1, G_2)) \tag{6}$$

$$\delta = -\log\left(\sum_c e^{f_c(G_1,G_2)}\right) \tag{7}$$

In Equation 6, the softmax probabilities $P(y|G_1, G_2)$ are computed to determine the model's predicted probabilities (*line 1*) in Algorithm 2. The model's confidence score γ is set to the maximum of these probabilities, representing the model's confidence in its prediction (*line 2*). Following this, the uncertainty score δ is calculated, as shown in Equation 7, using the sum of exponentials of the logits $f_c(G_1, G_2)$ for each class c, capturing the model's uncertainty in its prediction (*lines 3-4*) of Algorithm 2.

2) Jaccard Index Calculation and Threshold Adjustment: Let E_1 and E_2 be the edge sets of graphs G_1 and G_2. The Jaccard index $J(E_1, E_2)$ is defined in Equation 8:

$$J(E_1, E_2) = \frac{|E_1 \cap E_2|}{|E_1 \cup E_2|} \tag{8}$$

If the uncertainty score δ is above a set threshold τ, we proceed with calculating the Jaccard index J on the edge sets of the two graphs. The intersection $E_\cap$ and union $E_\cup$ of the edge sets E_1 and E_2 are calculated to compute J, (*lines 6-9*) of Algorithm 2. A threshold, J_{thresh} is selected empirically to maximize the separation between equivalent and non-equivalent pairs. If $J(E_1, E_2) > J_{\text{thresh}}$, we adjust the prediction $\hat{y}$ to indicate equivalence (*lines 10-12*).

3) Loss Function Modification with Jaccard Index: To incorporate the Jaccard index into training, we adjust the loss function based on both the uncertainty score and the Jaccard index value. Let $\mathcal{L}_{\text{base}}$ denote the standard cross-entropy loss for the GCN model, as shown in Equation 9:

$$\mathcal{L}_{\text{base}} = -\sum_{i=1}^{N} y_i \log P(y_i|G_1, G_2) \tag{9}$$

In Equation 9, y_i is the true label for the i-th example in the batch, and N is the batch size. A Jaccard-based penalty term $\mathcal{L}_{\text{Jaccard}}$ is defined to reinforce correct predictions for high-uncertainty cases. This term is based on the absolute difference between the model's prediction and the Jaccard index decision, shown in Equation 10:

$$\mathcal{L}_{\text{Jaccard}} = \alpha \cdot |\hat{y} - J(E_1, E_2)| \tag{10}$$

In Equation 10 α is a scaling factor that controls the impact of the Jaccard-based adjustment, and $\hat{y}$ is the model's predicted equivalence probability. This penalty term is updated (*line 13*). The total loss $\mathcal{L}_{\text{total}}$ is computed as:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{base}} + \beta \cdot \mathcal{L}_{\text{Jaccard}} \tag{11}$$

where the uncertainty-based weighting factor β is defined by:

$$\beta = \begin{cases} 1 & \text{if} \quad \delta > \tau, \\ 0 & \text{otherwise} \end{cases} \tag{12}$$

Our proposed loss function incorporates a penalty term for uncertain predictions, aligning the model's output with the Jaccard index for structurally similar graphs. This adjustment improves the GCN's accuracy and robustness by reinforcing learning in high-uncertainty cases where structural similarity is high.

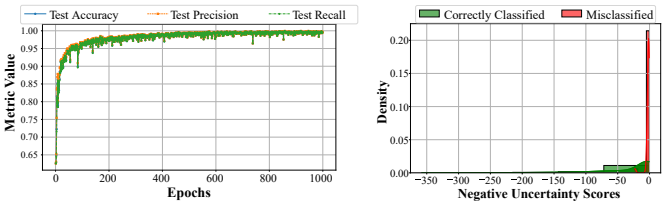
V. Evaluation of the Proposed Framework

A. Experimental Setup

Benchmarks for training: For training our proposed GCN model, we utilized 16 distinct benchmarks, with eight different transpilation configurations at different stages of compilation, obtained from MQTBench [34]. Furthermore, each benchmark circuit was considered for a range of four to sixteen qubits, to furnish a total of *1792* quantum circuits to allow our GCN model to adequately capture traits pertaining to equivalence of quantum circuits.

Benchmarks for evaluation: To evaluate our verification framework, we consider a total of 25 distinct benchmark circuits (*all scalable benchmarks*), with 4-120 qubits, available from MQTBench and their transpiled configurations, conducted on IBM Qiskit [35]. The circuits are converted into ZX graph representations using PyZX [36].

Model evaluation metrics: We assess our GCN model's performance using accuracy, precision, and recall: *accuracy* measures overall correctness in classifying circuit equivalence, *precision* evaluates the reliability of positive (equivalent) classifications, and *recall* gauges the model's ability to identify all actual equivalent circuits.



Comparison metrics: To compare the performance of our equivalence checking framework with existing models, we utilize *scalability* of the approach, signifying the number of qubits up to which we can verify quantum circuit equivalence, followed by *time consumption*, signifying the time taken to verify per qubit. Finally, we also compare the *accuracy* for verification of ZXNet with state-of-the-art.

B. Evaluation

For quantum circuit equivalence checking, we utilize our novel GCN model, which consists of *two graph convolutional layers with 64 hidden channels each*, a *single global mean pooling layer*, and *two fully connected layers* with ReLU activations. The architecture is designed to process paired ZX graph representations and output logits for equivalence classification. *It should be noted that our model conducts binary classification, where we feed the model with two quantum circuits to subsequently determine their equivalence.*

Figure 4a depicts the precision, recall, and accuracy of our model across epochs. The y-axis indicates the values each metric achieves across epochs, represented in the x-axis. From this figure, it can be observed that ZXNet furnishes accuracy, precision, and recall values of up to 99.4%, 99.2%, and 99.8%, respectively. Furthermore, the figure depicts a strong overlap among these metrics, indicating balanced performance across classes. This alignment suggests that our model effectively generalizes new data [37]. Additionally, the close values of precision and recall demonstrate that our model neither over-predicts equivalences nor misses true ones. This balance highlights the reliability of our approach in accurately identifying circuit equivalences.

Figure 4b illustrates the distribution of negative uncertainty scores for correctly classified and misclassified instances in our GCN model. The x-axis represents negative uncertainty scores, where lower (more negative) values denote higher model confidence, while values closer to zero indicate lower confidence. The y-axis shows the density of data points at specific uncertainty levels. The correctly classified instances, denoted by the green curve, span a wide range of scores from -350 to 0 with a modest peak density of 0.015, reflecting the model's ability to confidently classify across diverse uncertainty

(a) Accuracy, Precision, and Recall values during GCN model validation.

(b) Uncertainty distribution following GCN model training.

Fig. 4: GCN model evaluation of our proposed ZXNet framework.

TABLE II: Error detection accuracy using ZXNet for different benchmarks and induced errors.

Benchmark	Detection of Induced Error (%)					
	Add 10 CX gates	Remove 10 CX gates	Add 5 CX gates	Remove 5 CX gates	Add 1 CX gate	Remove 1 CX gate
Grover	98.21	97.46	97.1	97.3	96.6	96.18
Random walk	99.16	98.75	97.68	98.24	96.36	97.3
QPE-exact	98.88	98.24	97.25	97.25	96.2	96.01

levels. In contrast, the red curve, representing misclassified instances, is sharply concentrated near -0.1 with a peak density of 0.23, indicating that misclassifications primarily occur at low confidence levels. This separation highlights our model's robustness in distinguishing between confident predictions and uncertain misclassification.

C. Error detection using ZXNet

Accurate equivalence-checking frameworks must be sensitive enough to detect and distinguish even minor discrepancies that lead to non-equivalence between quantum circuits. To evaluate this capability, we assessed error detection using our ZXNet framework. Specifically, we introduced variations in quantum circuits by arbitrarily adding or removing `CX` gates and tested whether ZXNet could identify these changes. The results, summarized in Table II, highlight the framework's accuracy in detecting non-equivalence across various benchmarks. The first column lists the benchmark circuits (these were selected since they are commonly used algorithms with real-world applications), while the subsequent columns show detection accuracy for different types of errors. It should be noted that the errors of addition and removal of `CX` gates were conducted randomly throughout the quantum circuit, and the accuracy of detection was averaged over 10 executions to observe the general performance of ZXNet. `CX` gates were chosen for this study due to their significant impact on functional equivalence, making any modifications to their numbers during transpilation particularly impactful [38]. From the table, it can be observed that **ZXNet can detect errors with an accuracy of up to 99.16%** across the tested benchmarks. Moreover, ZXNet demonstrates remarkable sensitivity, **being able to detect discrepancies caused by the addition or removal of a single `CX` gate with up to 97.3% accuracy**, further underscoring the robustness of our framework.

D. Comparative analysis against state-of-the-art approaches

We compare ZXNet, our learning-based equivalence checking framework, against three state-of-the-art methods: MPO-based, DD-based, and rule-based ZX calculus verification [9], [10], [12]. The comparison evaluates two critical metrics: *scalability* and *runtime efficiency*. Parameterized two-local random circuits with linear entanglement are utilized as benchmarks to maintain consistency, as existing results for MPO-based methods are available exclusively for this circuit class. The results, illustrated in Figure 5, present a scalability analysis, with the x-axis representing the number of qubits and the y-axis denoting runtime. The figure demonstrates that ZXNet is consistently faster compared to state-of-the-art methods, **achieving speedups of up to 62×.** *Please note that since Parameterized Two-local random was the only available benchmark circuit that has been evaluated using all existing approaches*, we utilized it in this section for comparison.

TABLE III: Comparison vs state-of-the-art methods for verification.

Name	Gate Depth	Equivalent			Speedup (%)	Non-equivalent			Speedup (%)
		t_{zx} (s)	t_{dd} (s)	t_{zxnet} (s)		t_{zx} (s)	t_{dd} (s)	t_{zxnet} (s)	
Grover_n9	12482	12.15	0.14	0.1	**28.57**	3.16	8.26	0.31	**90.19**
Random walk_n8	14084	1289.13	0.57	0.3	**47.37**	78.91	62.2	2	**96.78**
QPE-Exact_n39	3823	3.19	>3600	0.32	**89.97**	2.89	>3600	0.3	**86.16**

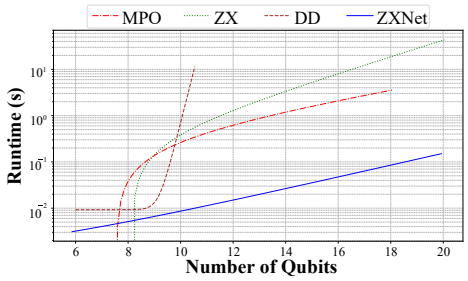


Fig. 5: Scalability comparison of ZXNet with state-of-the-art.

Next, we conduct a more detailed evaluation of ZXNet's performance and compare the results against rule-based ZX calculus and decision diagrams (DD) [10], [12]. The MPO-based method is excluded from this comparison because its results are limited to QFT circuits [9]. For brevity, the evaluation results are limited to three widely used benchmark circuits, previously analyzed by state-of-the-art methods, as depicted in Table III. In this table, columns one to three depict the name, number of qubits, and number of gates of the benchmark circuit, respectively. Columns four through six indicate the time taken by each approach to verify the functional equivalence of the transpiled benchmark with the original in cases when they are equivalent. Column seven showcases the speedup provided by our ZXNet framework over the state-of-the-art methods. Similarly, columns eight to eleven replicate the contents of columns four to seven, but for scenarios when the transpiled benchmark is not equivalent to the existing benchmark. From the table, it is evident that as gate depth increases, ZXNet, consistently outperforms the rule-based ZX verification and DD-based verification, **achieving speedups of up to 96.78%.** These findings demonstrate that ZXNet improves verification efficiency and scales effectively to handle larger and more complex quantum circuits compared to existing methods.

Furthermore, we conducted a comprehensive evaluation of our ZXNet framework across all the scalable benchmarks obtained from MQTBench, with qubit counts ranging from 4 to 120 [34]. Upon evaluation, ZXNet demonstrated its superiority over state-of-the-art methods by **successfully verifying quantum circuits with up to 120 qubits, achieving a 45.83% increase in circuit size, a 5.94% improvement in verification accuracy, and a 42.22% reduction in verification time**, compared to existing approaches. These results establish ZXNet as a more scalable, efficient, and accurate framework for quantum circuit equivalence checking.

VI. Conclusion

In this paper, we introduced ZXNet, a novel equivalence-checking framework for quantum circuits that leverages ZX graph representations in an encoded format for training a GCN model to verify the functional equivalence of quantum circuits. Our experimental results demonstrated that ZXNet achieves notable **accuracy, precision, and recall values of up to 99.4%, 99.2%, and 99.8%**, respectively. Compared to traditional equivalence-checking methods, ZXNet significantly improves computational efficiency, achieving a speedup of up to 62× over existing methods. Moreover, **our model furnishes improvements of up to 45.83%, 42.22%, and 5.94% in terms of scalability, time consumption, and accuracy**, respectively, over state-of-the-art methods. This establishes a robust framework for reliable quantum circuit verification by reducing computational overhead and enhancing the scalability and adaptability to varying circuit complexities.

***Abstract*—The increasing complexity of safety-critical hardware systems demands advanced methods for ensuring functional safety (FuSa). Traditional techniques like ATPG and BIST are intrusive, requiring additional hardware and disrupting operations, making them unsuitable for in-field testing. To address this, for the first time, we propose a machine learning (ML)-driven automated Self-Test Library (STL) generation for seamless in-field testing during idle periods, ensuring uninterrupted fault detection and high system performance. Utilizing reinforcement learning, the STL generates design-specific test patterns, achieving up to 57.57% improvement in fault coverage and up to 85% efficiency compared to existing pattern-based testing, enhancing FuSa in mission-critical applications.**

***Index Terms*—Functional Safety, Fault Injection Analysis, Test Pattern Generation, Self-Test Library Development.**

I. Introduction

With increasing design complexity, shrinking feature sizes, and accelerated time-to-market requirements, hardware systems are exposed to a broad spectrum of potential failures, primarily due to hardware faults. This has led to the development of Functional Safety (FuSa) standards, such as ISO 26262, which provide a technical framework for detecting and managing faults, ensuring safe operational states [1]. Faults in critical circuits can have severe consequences during operation, with the potential to cause catastrophic failures [2]. For instance, a fault in the control system of an autonomous vehicle could lead to uncontrollable acceleration, resulting in accidents or even loss of life, as shown in Figure 1. The severity of these faults depends on their location within the circuit and the structural characteristics of the design. Fault propagation is closely tied to these structural features, making it crucial to assess both the impact and criticality of faults in relation to their location within the design. This comprehensive approach is imperative for ensuring FuSa in mission-critical applications. A paradigm shift in safety assurance is anticipated with the prospect of machine learning (ML)-driven automation in FuSa. This is set to strengthen the strictness of fault management procedures in sectors that depend on risky, safety-critical hardware systems. With ramifications for the future of autonomous systems, the Internet of Things (IoT), and other mission-critical sectors, this research represents a crucial frontier. In addition to being a tempting opportunity, the ongoing investigation of ML for automated functional safety is also essential to stay up with the complexity of next-generation hardware.

The increasing complexity of modern E/E systems has rendered traditional fault injection and simulation techniques inadequate for ensuring FuSa. These methods face substantial timing overheads, are resource-intensive, and often fail to identify critical design components that could lead to functional failures. Furthermore, they lack the capability to quantify the varying degrees of criticality among circuit nodes, which is essential for prioritizing fault mitigation efforts. Conventional fault analysis techniques, therefore, fall short of addressing the growing intricacy of contemporary systems. To overcome these challenges, ML-based approaches have emerged as a necessary solution for enhancing FuSa [3]–[5]. By efficiently generating high-quality test patterns, these methods not only improve fault coverage but also provide a more systematic framework for detecting critical faults within complex designs. The use of graph-based analysis, specifically, has proven effective in understanding the structural features of E/E systems, allowing for more precise fault criticality analysis [6].

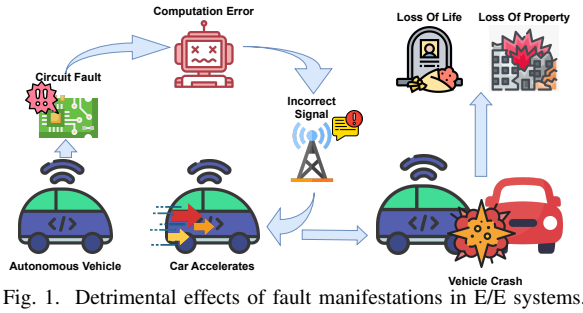

Fig. 1. Detrimental effects of fault manifestations in E/E systems.

The automotive functional safety standard ISO 26262 [1] and the industrial standard IEC 61508 [7] stipulate the necessity for evaluating both permanent and transient fault coverage during runtime operations. Attaining the requisite level of permanent fault coverage presents considerable challenges. There are three principal mechanisms available for achieving this coverage: (i) hardware redundancy, (ii) hardware-based Built-In Self-Test (BIST) mechanisms, and (iii) software-based BIST mechanisms. **While hardware redundancy is an effective method, it is generally eschewed in non-mission-critical modules due to the substantial area overhead it incurs. Hardware-based BIST mechanisms are frequently utilized; however, their implementation may not be feasible under certain conditions [8], [9].** For instance, a given module may not have been originally designed with BIST capabilities. Furthermore, such mechanisms necessitate that the device transitions into a scan/Automatic Test Pattern Generation (ATPG) mode.

The transition to ATPG mode requires the preservation of the complete Intellectual Property (IP) or module context prior to testing, along with its restoration afterward, to ensure seamless execution of the application. **This procedure may prove impractical within the constraints of the designated testing time window.** This invasive reconfiguration of the system into a non-operational state during testing not only disrupts system functionality but also risks overtesting, resulting in downtime and inefficiencies. Such interruptions render these techniques unsuitable, particularly in safety-critical systems

like automotive applications, where continuous operation is essential. **Therefore, non-scan-based methods, such as software-based self-test (SBST) mechanisms, offer a more flexible and practical approach to achieving the essential fault coverage required in contemporary systems [10].**

For in-field testing, where halting system operations is impractical, the invasive nature of design-for-testability (DfT) techniques presents a significant challenge. In contrast, SBST approaches, such as self-test libraries (STLs), provide a more efficient and less invasive solution [11], [12]. STLs execute functional programs to detect faults without altering the design or interrupting system operations. These libraries can be run at full operational speed, enabling fault detection during normal operation without any disruption. Moreover, STLs can divide the testing process into small segments during idle periods, making them ideal for in-field applications. This method not only prevents overtesting but also maintains system integrity and supports long-term functional safety, in line with stringent standards like ISO 26262. Therefore, the use of STLs allows for continuous and non-intrusive fault detection, ensuring the system's reliability and safety throughout its operational lifecycle without compromising performance or introducing inefficiencies. **Commercial STLs are proprietary, device-specific, and typically handcrafted for each target design. Therefore, it becomes incumbent to automate the STL generation based on the functional test patterns in order to optimize SBST overhead.** ML-based pattern generation can aid in this automated STL-based testing by increasing the fault coverage. This can reduce the memory requirement to periodically run tests on the device when it is in use.

In this work, we propose a novel framework for automated STL generation to ensure FuSa in mission-critical applications by enabling in-field testing with minimal operational disruption. Our framework introduces an innovative ML-based approach for generating functional test patterns without relying on scan-based test mode assertions, thereby avoiding operational disruptions. It leverages advanced machine learning techniques, such as Variational Autoencoders (VAE) and Reinforcement Learning (RL), to optimize test pattern generation. **Since this is the first automated STL generation technique, our approach is evaluated against random pattern generation methods.** Our key contributions in this work include:

- We introduce a novel, automated framework for STL generation that ensures FuSa in mission-critical applications by enabling in-field testing with minimal operational disruption.
- We propose an ML-driven framework to generate functional test patterns without the need for traditional scan-based testing methods.
- The proposed ML framework integrates VAE with RL, using VAE to initialize the RL-based pattern optimization process, ensuring effective exploration of the solution space.
- The proposed solution delivers high operational fault coverage, with up to 57.57% improvement over random pattern-based testing, while avoiding the pitfalls of test mode assertion and system downtime associated with ATPG-based techniques.

II. Background

In this section, we provide the essential background necessary to elucidate our proposed approach for machine learning-based test pattern generation and the development of STLs.

A. Self-Test Library

The Self-Test Library (STL) in VLSI testing is a suite of tools and methodologies designed to facilitate efficient on-chip testing of integrated circuits (ICs) [12]. It includes techniques like Built-In Self-Test (BIST) and non-scan-based testing to detect faults and ensure circuit functionality without external testing equipment. The STL allows for the embedded test circuitry to perform in-situ tests, which is particularly beneficial for detecting manufacturing defects and operational faults in complex VLSI circuits, reducing reliance on external testers and equipment.

Compared to traditional methods like BIST and ATPG, STLs offer advantages in terms of flexibility and scalability. BIST introduces test pattern generators and output response analyzers within the chip, providing autonomous testing but often at the cost of significant area, power, and timing overheads. ATPG, which typically uses scan chains to shift test patterns, also adds overhead in terms of area and performance but can be limited by the length and complexity of the scan chains. In contrast, STLs, especially those leveraging non-scan-based techniques, provide a more scalable solution that can adapt to both sequential and combinational circuits, reducing external resource dependence. For non-scan-based testing, techniques such as Linear Feedback Shift Registers (LFSRs) and pseudorandom pattern Generators (PRPGs) are employed to generate high fault coverage test patterns [13], [14]. These methods are effective in achieving high coverage with minimal area and test time overheads, as LFSRs and PRPGs efficiently produce large sets of pseudo-random patterns that can detect a wide range of faults. While these techniques do not completely eliminate the need for scan chains in some designs, they help significantly reduce the overhead associated with traditional scan-based testing.

Thus, STLs provide a robust mechanism to enhance the testability and reliability of VLSI circuits by combining the efficiency of on-chip testing with reduced dependence on external testing resources. This makes it a preferred choice for modern IC designs, particularly in domains requiring high reliability, such as automotive and aerospace systems [15], [16]. The manual and proprietary nature of commercial STLs, tailored specifically for individual designs, creates significant challenges in scalability and standardization. To overcome these issues, this work, for the first time, introduces an automated STL generation framework powered by machine learning, aiming to improve FuSa in mission-critical systems.

B. Variational Autoencoder

A Variational Autoencoder (VAE) is a type of generative model used for unsupervised learning, built on the foundation of traditional autoencoders [17]. To understand VAEs, it is essential to first grasp the concept of a standard autoencoder. An autoencoder is a neural network designed to learn a compressed, lower-dimensional representation (encoding) of input data, such as images or text, and then reconstruct the input from this representation. The goal is to learn useful features or patterns from the data by minimizing the difference between the original input and its reconstruction. This process is driven by a loss function (to represent the said difference), usually the mean squared error or cross-entropy.

The VAE extends this idea by introducing a probabilistic interpretation of the latent space (the space where the compressed data representation resides). Instead of learning fixed values for the compressed representation, the VAE assumes that the data is generated from an underlying probability distribution. In this way, the encoder network learns to output the parameters of this distribution (typically a mean and variance) rather than a single deterministic point. A key innovation in VAEs is the reparameterization trick, which allows for back-propagation through the stochastic sampling of the latent variables by expressing the randomness in a differentiable way. During training,

the VAE attempts to reconstruct the input data accurately and ensure that the learned latent space follows a known probability distribution (often a normal distribution). This is achieved by optimizing a loss function that includes two components: the reconstruction loss, which measures how well the VAE can recreate the input data, and a regularization term called the Kullback-Leibler divergence [18]. This term ensures that the learned distribution is close to the prior distribution, which allows for efficient sampling of new, unseen data points from the model after training. This combination of learning a probabilistic latent space and reconstruction capability makes VAEs a powerful tool for generating new data and discovering underlying patterns in complex datasets, which we exploit for our proposed test pattern generation procedure.

C. Reinforcement Learning

Reinforcement Learning (RL) is a specialized area of machine learning that focuses on enabling agents to learn optimal behaviors through interactions with their environment [19]. Distinct from supervised learning, where models learn from labeled datasets, RL requires agents to make decisions within uncertain and dynamic settings to maximize cumulative rewards over time. The core components of an RL framework include the agent, the environment, states, actions, and rewards. In this paradigm, the agent represents the learner or decision-maker, while the environment encompasses all external factors influencing the agent. States reflect the current condition of the environment, and actions are the choices available to the agent that may alter this condition. Upon executing an action, the agent receives a reward, quantifying the immediate benefit derived from that action. The primary objective is to derive a policy—a mapping from states to actions—that maximizes expected cumulative rewards.

Reinforcement Learning algorithms typically utilize trial-and-error methods to explore the environment, balancing exploration (trying new actions) with exploitation (selecting known advantageous actions). Common strategies to achieve this balance include the epsilon-greedy approach and Upper Confidence Bound (UCB) algorithms. Notable RL methodologies encompass model-free techniques, such as Q-learning and Policy Gradient methods, and model-based approaches, which involve constructing a model of the environment's dynamics. Q-learning, a value-based method, estimates the expected utility of actions in given states, while Policy Gradient methods directly optimize the policy, accommodating complex action spaces.

Reinforcement Learning has demonstrated effectiveness across diverse domains, including robotics, game playing, and resource management, due to its capacity for handling intricate decision-making tasks and adapting to dynamic environments. Therefore, we translate our STL generation process into an RL-based optimization for enhancing FuSa analysis.

III. Methodology

In this section, we present a comprehensive methodology for generating STLs comprising high-quality functional test patterns aimed at enhancing fault coverage in hardware systems. Our approach integrates advanced machine learning techniques, including VAE and RL, to optimize test pattern generation as illustrated in Figure 2. Moreover, this framework incorporates an STL generation process that enables non-intrusive, in-field testing without halting system operations.

A. VAE-Based Learning for Functional Pattern Generation

In this section, we describe the process of developing and using a VAE to generate new test patterns for high fault coverage in E/E

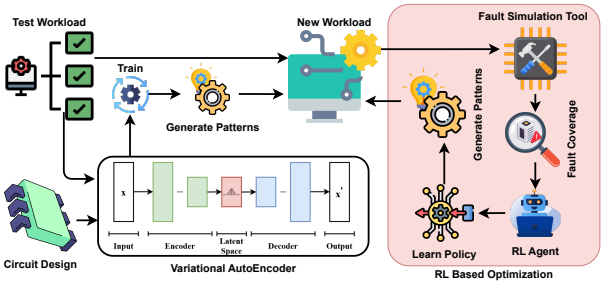

Fig. 2. Overview of the proposed test pattern generation framework.

systems. The prposed approach leverages both the structure of the design and the existing set of functional test patterns. The primary goal is to learn the underlying distribution of the test patterns and generate new patterns that effectively target critical regions of the design.

We start by preparing the input data, which includes a set of test patterns P and the design netlist graph G. The netlist graph is first encoded into a feature representation, G_{features}, using a graph neural network, where the node features represent the circuit components and the edges capture the connectivity. This encoding allows us to incorporate the structural information of the design into the learning process. Once G_{features} is obtained, we concatenate it with each test pattern P from the pattern set. This combined representation $[P, G_{\text{features}}]$ is then passed through the encoder of the VAE, which transforms it into a latent vector z by approximating the posterior distribution using a multivariate Gaussian:

$$z \sim q_\phi(z|[P, G_{\text{features}}]) = \mathcal{N}(\mu_\phi([P, G_{\text{features}}]), \sigma_\phi([P, G_{\text{features}}])) \tag{1}$$

Here, μ_ϕ and σ_ϕ are the mean and standard deviation vectors learned by the encoder, parameterized by ϕ.

Next, we sample the latent vector z from this distribution and pass it through the decoder to generate a reconstructed test pattern $\hat{P}$:

$$\hat{P} = \text{Decoder}_\phi(z) \tag{2}$$

This process allows the VAE to reconstruct patterns that are similar to the original ones but with variability introduced by the latent space, thus encouraging the generation of novel test patterns.

To ensure that the generated patterns are meaningful, we define a reconstruction loss L_{recon}, which measures the difference between the original patterns P and the reconstructed patterns $\hat{P}$. This is typically computed as the mean squared error:

$$L_{\text{recon}} = \frac{1}{B} \sum_{i=1}^{B} \|P_i - \hat{P}_i\|^2 \tag{3}$$

where B is the batch size of patterns processed during training. In addition to the reconstruction loss, we impose a Kullback-Leibler (KL) divergence term L_{KL} to regularize the latent space. The KL divergence ensures that the learned distribution $q_\phi(z|P)$ remains close to a standard normal distribution $p(z)$:

$$L_{\text{KL}} = D_{\text{KL}}(q_\phi(z|P) \| p(z)) \tag{4}$$

The total loss L that we minimize during training is a combination of the reconstruction loss and the KL divergence, weighted by a hyper-parameter λ:

$$L = L_{\text{recon}} + \lambda L_{\text{KL}} \tag{5}$$

This regularization not only prevents overfitting but also ensures that the latent space is smooth and can generate a wide variety of test

Algorithm 1 VAE Learning from Pattern Set

Input: Pattern set $\mathcal{P}$, design netlist graph $\mathcal{G}$, learning rate α, number of epochs E, batch size B

1: Initialize VAE model VAE_ϕ with parameters ϕ
2: Initialize optimizer for VAE_ϕ
3: **for** each epoch $e = 1$ to E **do**
4: Shuffle the pattern set $\mathcal{P}$
5: **for** each mini-batch of patterns P_b from $\mathcal{P}$ **do**
6: Encode $\mathcal{G}$ into a graph feature representation G_{features}
7: **for** each pattern $P \in P_b$ **do**
8: Concatenate pattern P with G_{features}
9: Pass data through VAE encoder to obtain latent vector z
10: Decode latent vector z to reconstruct pattern $\hat{P}$
11: **end for**
12: Compute reconstruction loss $\mathcal{L}_{\text{recon}}$ between P_b and $\hat{P}_b$
13: Compute KL divergence loss $\mathcal{L}_{\text{KL}}$
14: Total loss $\mathcal{L} = \mathcal{L}_{\text{recon}} + \lambda\mathcal{L}_{\text{KL}}$
15: Back-propagate and update VAE parameters ϕ
16: **end for**
17: **end for**
18: **Output**: Trained VAE model VAE_ϕ

Algorithm 2 Reinforcement Learning for Pattern Generation

Input: Design netlist $\mathcal{D}$, fault analysis tool $\mathcal{F}$, pre-trained VAE model VAE_ϕ

1: Initialize policy model π_θ with random weights θ
2: Initialize best fault coverage $C_{\text{best}} \leftarrow 0$
3: Initialize reward $r \leftarrow 0$
4: **for** each episode $t = 1$ to T **do**
5: Sample $z \sim \mathcal{N}(0, I)$ from the VAE's latent space
6: Decode z to generate an initial pattern $P_0 = \text{VAE}_\phi(z)$
7: Apply pattern P_0 compute initial fault coverage C_0
8: **for** each step $k = 1$ to K **do**
9: Perturb P_{k-1} using π_θ to generate P_k
10: Apply pattern P_k to compute new fault coverage C_k
11: Calculate reward: $r_k = C_k - C_{k-1}$
12: Update policy model π_θ using the reward r_k
13: **if** $C_k > C_{\text{best}}$ **then**
14: Update $C_{\text{best}} \leftarrow C_k$
15: **end if**
16: **if** reward $r_k \leq 0$ (no improvement) **then**
17: Break the loop and stop perturbing
18: **end if**
19: **end for**
20: **end for**
21: **Output**: The pattern P_{best} that achieves the highest coverage C_{best}

patterns. By training the VAE on the existing pattern set P, we effectively learn a latent space that captures the essential features of the design and its corresponding test patterns. Once training is complete, we can generate new test patterns by sampling from the latent space $z \sim \mathcal{N}(0, 1)$ and decoding them into test patterns using the decoder ($\hat{P}_{\text{new}} = \text{Decoder}_\phi(z)$).

The VAE-based learning and pattern generation is outlined in Algorithm 1, that begins by initializing the VAE model with parameters ϕ and setting up an optimizer for the VAE model (lines 1-2). Then, for each epoch from 1 to E, the pattern set P is shuffled to ensure randomness in the training process (lines 3-4). Next, for each mini-batch of patterns P_b drawn from the shuffled pattern set, the design netlist graph G is encoded into a graph feature representation G_{features} (lines 5-6). Subsequently, each pattern P in the mini-batch is concatenated with G_{features} to create the input data for the VAE encoder (lines 7-8). The concatenated data is then passed through the VAE encoder to generate a latent vector z, which is sampled from the encoder (line 9). The latent vector is decoded to reconstruct the pattern $\hat{P}$ (line 10). Subsequently, the reconstruction loss L_{recon} is calculated between the original patterns and their reconstructed versions (line 12), followed by the computation of the KL divergence loss L_{KL} for latent space regularization (line 13). The total loss L is then computed as the sum of the reconstruction loss and the regularization loss (line 14). Finally, the VAE parameters ϕ are updated using back-propagation through the optimizer (line 15). The process repeats over the mini-batches for each epoch until the VAE model is fully trained, at which point the trained VAE model VAE_ϕ is output (lines 16-18).

These newly generated patterns are tailored to the specific characteristics of the design and provide enhanced test coverage by targeting regions of the design that may not have been fully excited by the original patterns.

B. RL-based Functional Test Pattern Optimization

In this section, we elaborate on the integration of a trained VAE with a RL framework to efficiently generate high-quality functional test patterns. The VAE, which learns the underlying distribution of existing test patterns, is used to sample potential new patterns, while the RL agent optimizes the selection and refinement of these patterns to maximize fault coverage. This combined approach leverages the generative capabilities of the VAE and the optimization power of RL to dynamically adapt the pattern generation process, improving overall testing efficiency.

The VAE model samples patterns from a latent space, represented by $z \sim \mathcal{N}(0, 1)$, and decodes this latent vector into test patterns $\hat{P} = \text{Decoder}(z)$. These generated patterns are then evaluated by the RL agent, which learns a policy $\pi(a_t|s_t)$ to decide how to use the patterns in the context of the design. Here, s_t represents the system state at time step t, which encodes critical design information, such as circuit netlist features G_{features} and current fault coverage metrics. The agent's action a_t, chosen from a predefined action space, can involve sampling a new test pattern from the VAE, modifying an existing one, or reapplying a previously used pattern, depending on the current state.

The reward function for the RL agent is tied to improvements in fault coverage. At each time step, the reward r_t is calculated as the increase in coverage from the previous step:

$$r_t = \text{Coverage}(t) - \text{Coverage}(t-1) \tag{6}$$

This reward structure encourages the agent to prioritize actions that lead to significant fault coverage improvements, penalizing ineffective or redundant actions. The RL agent's goal is to maximize the cumulative discounted reward R_t, defined as:

$$R_t = \mathbb{E}\left[\sum_{k=t}^{T} \gamma^{k-t} r_k\right] \tag{7}$$

where γ is the discount factor. Policy gradient methods, such as Proximal Policy Optimization (PPO), are employed to iteratively refine the agent's policy $\pi(a_t|s_t)$, ensuring that the agent learns to select actions that yield optimal test coverage.

The RL-based test pattern optimization is detailed in the Algorithm 2, which starts by initializing the policy model π_θ with random

weights θ, setting the best fault coverage C_{best} to 0, and initializing the reward r to 0 (lines 1-3). For each episode from 1 to T, a latent vector z is sampled from the VAE's latent space, where z follows a normal distribution $N(0, I)$ (lines 4-5). This latent vector is decoded by the pre-trained VAE model VAE_ϕ to generate an initial test pattern P_0 (line 6). The generated pattern P_0 is applied to the design netlist D, and its initial fault coverage C_0 is computed using the fault analysis tool F (line 7). Next, for each step from 1 to K, the current pattern P_{k-1} is perturbed by the policy model π_θ to generate a new pattern P_k (line 9). This new pattern P_k is applied to the design netlist D, and the updated fault coverage C_k is calculated using the fault analysis tool F (line 10). The reward r_k is then computed as the difference between the new fault coverage C_k and the previous fault coverage C_{k-1} (line 11). The policy model π_θ is updated based on the reward r_k (line 12). If the new fault coverage C_k surpasses the best fault coverage C_{best}, the best fault coverage C_{best} is updated to C_k (lines 13-14). However, if the reward r_k is less than or equal to 0, meaning no improvement in fault coverage, the loop is terminated, and further perturbation stops (lines 16-17). This process repeats for each episode until all episodes are completed (lines 19-20). Finally, the algorithm outputs the pattern P_{best} that achieved the highest fault coverage C_{best} (line 21).

C. Self-Test Library (STL) Generation for In-Field Testing

In this section, we outline the methodology for generating a STL from functional test patterns to facilitate efficient in-field testing of VLSI designs. The STL enables continuous fault detection and real-time fault coverage evaluation without halting system operations, as illustrated in the Figure 3.

The process begins with the utilization of functional test patterns, $P = \{p_1, p_2, \ldots, p_N\}$, generated by the RL-VAE approach. Each pattern p_i consists of an input-output mapping derived from the design's expected behavior, $f_{\text{design}} : I \rightarrow O$, where I represents the set of input signals and O the corresponding output signals.

These patterns are transformed into machine-executable instructions by translating the RTL description of the design into a higher-level programming language, typically C or C++. The transformation can be expressed as:

$$C_{\text{design}} = \mathcal{T}(V_{\text{design}}) \tag{8}$$

where $\mathcal{T}$ represents the transformation function that converts the Verilog representation V_{design} into its C/C++ equivalent C_{design}.

Once transformed, the STL generation process automates the creation of testbenches. For each pattern p_i, the corresponding input vector I_i is assigned to the input signals of the testbench, which drives the evaluation of the C++ design model. The process involves repeatedly evaluating the system's response to each input vector:

$$O_i^{\text{actual}} = f_{\text{STL}}(I_i) \tag{9}$$

where f_{STL} represents the behavior of the design under test as executed by the generated STL. The actual output O_i^{actual} is compared against the expected output O_i^{expected} to detect discrepancies or faults:

$$\Delta O_i = O_i^{\text{actual}} - O_i^{\text{expected}} \tag{10}$$

If $\Delta O_i \neq 0$, the test reveals a fault.

The STL is integrated into the system's memory, enabling non-intrusive execution during idle cycles or specific test periods. This reduces the performance overhead by running tests concurrently with normal operations.

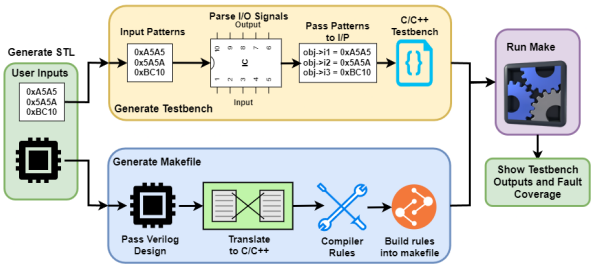

Fig. 3. Flow of processes to generate STL.

IV. Experimental Evaluation

A. Experimental Setup

The proposed framework is evaluated using four distinct designs: a Synchronous Dynamic Random Access Memory (SDRAM) Controller, the OpenCores Memory Controller Main Timing (OCMCMT) module, the OpenRISC 1200 instruction fetch (ORIF) module, and a Single Port Synchronous RAM (ORSPRAM) module. These designs represent a variety of circuitry and critical functionalities, providing a comprehensive basis for evaluating the framework's effectiveness.

To construct the initial dataset, each design's register-transfer level (RTL) representation is synthesized into a gate-level netlist using Synopsys Design Vision. Fault injection experiments are then conducted using Cadence Xcelium [20], which simulates the circuit and injects faults across different input vectors (workloads). Fault detection reports are generated, detailing fault criticalities and coverage metrics. These reports are compiled into a dataset that is used to train a VAE, which learns the latent distribution of test patterns and generates new synthetic patterns. Upon training, the VAE is used in the RL-based framework to generate high-quality test patterns aimed at maximizing fault coverage. For generating the STL, we employ Verilator [21], an open-source tool known for its efficiency in converting high-level hardware designs into cycle-accurate simulations, thus facilitating the rapid verification of the design during STL development.

B. Performance Metrics

Model performance is assessed using fault coverage, representing the percentage of detected faults by the applied functional test patterns. We also use the number of patterns needed as another metric to showcase the efficiency of the pattern-generation process. A higher fault coverage indicates better model performance, while a lower number of required patterns shows the efficiency of the pattern generation approach.

C. STL Generation

The process of generating an STL involves the use of a script that takes a Verilog RTL design and an input pattern set as its primary inputs, producing four essential output files. To ensure compatibility, these input files must adhere to a specific format. Below, we detail the STL generation procedure using the ORIF design as an example.

In this process, great care is taken to avoid conflicts with the module's port names. Each signal in the generated files is distinctly separated, and comments are carefully structured to avoid the use of reserved keywords such as *input* and *output*, minimizing the risk of errors or ambiguities during module port parsing. This precaution ensures a smooth and error-free generation process.

The four files produced by the script are the `Makefile`, `Makefile_obj`, `inputs.vc`, and a C++ testbench. The `Makefile` is responsible for compiling the C++ executable using Verilator, that converts RTL designs into C++ models. It handles

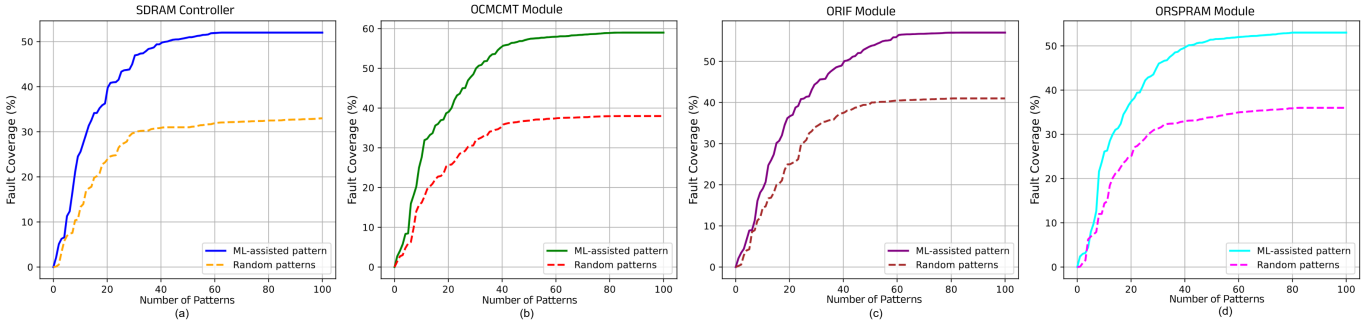

Fig. 4. Fault coverage analysis across various designs: (a) SDRAM controller, (b) OCMCMT module, (c) ORIF module and (d) SPRAM module.

Snippet of the generated testbench

```
void test_or1200_if() {
    Vor1200_if *tb = new Vor1200_if;
    // Initialize all input signals to 0
    tb->clk = 0;  tb->rst = 0;
    tb->icpu_dat_i = 0;
    tb->icpu_adr_i = 0;
    ...
    // Apply input patterns
    // Pattern 1
    tb->rst = 1;
    tb->icpu_dat_i = 0xAAAA;
    tb->icpu_adr_i = 0x1000;
    ...
    tb->clk = !tb->clk;
    tb->eval();
    // Simulate time progression
    Verilated::timeInc(1);
    //Add more test patterns
    delete tb;}
```

the setup of basic compiler flags and initiates the Verilation process, which translates RTL signals into C++ object representations. The `Makefile_obj` file manages the building and linking of the Verilated design objects referenced during the compilation process. It specifies the necessary compilation flags, linking rules, and execution procedures for the C++ hardware executables. Additionally, the script generates an `inputs.vc` file, which imports the required libraries and directories. This file is modular, allowing for easy modification and management of project imports, ensuring that all dependencies remain organized.

Finally, the input pattern set is used to generate a C++ testbench, which is employed to simulate the RTL design and conduct fault coverage analysis. Paired with the `Makefile` and `Makefile_obj`, the testbench enables the complete execution of the STL, simulating the functionality of the design based on the provided input test patterns. Through this simulation process, the STL aids in verifying the design's fault coverage and ensuring its operational integrity. We will open source the framework upon acceptance.

D. Fault Coverage Results

In our evaluation, we examined four distinct hardware designs to assess the efficacy of our fault coverage improvement method compared to random patterns for a specific number of patterns, which is set to 100 for our analysis, to reduce the overhead (often associated with ATPG-based techniques as discussed in Section I). Table I compares fault coverage achieved by two pattern generation methods: ML-assisted and random pattern generation. It includes design details, the number of gates and flip-flops, fault coverage for each method, and the improvement provided by the ML-assisted approach. The

TABLE I
COMPARISON OF FAULT COVERAGE ANALYSIS.

Design	Gates	Flip-flops	Maximum fault coverage (%) with 100 patterns		# ML functional patterns to match random coverage
			Random	ML	
SDRAM Controller	312	91	33%	52%	15
OCMCMT Module	873	188	38%	59%	18
ORIF Module	238	67	41%	57%	25
ORSPRAM Module	625	132	36%	53%	19

results emphasize the superior performance of ML-assisted pattern generation in enhancing fault detection.

For the SDRAM Controller, random patterns achieved 33% fault coverage with 100 test patterns. In contrast, ML-assisted patterns improved fault coverage to 52%, as shown in Figure 4(a). Moreover, using only 15 ML-assisted patterns achieved the same 33% fault coverage as 100 random patterns, demonstrating an 85% efficiency improvement.

The OCMCMT module showed 38% fault coverage with random patterns, while ML-assisted patterns increased coverage to 59%, as illustrated in Figure 4(b). Remarkably, 18 ML-assisted patterns matched the 38% coverage of random patterns, yielding an 82% efficiency gain while maintaining baseline performance.

For the ORIF module, random patterns achieved 41% fault coverage, which improved to 57% with ML-assisted patterns, as shown in Figure 4(c). Similarly, the SPRAM module exhibited 36% fault coverage with random patterns, while ML-assisted patterns raised coverage to 53%, as depicted in Figure 4(d).

The comparative analysis presented in Table I demonstrates that ML-assisted pattern generation significantly improves fault coverage across all evaluated designs. These improvements include up to a 57.57% increase in fault coverage compared to random patterns and an efficiency enhancement of up to 85%. These results underscore the effectiveness of ML-assisted methodologies in optimizing fault detection capabilities in integrated circuit designs.

V. CONCLUSION

The proposed ML-driven STL generation framework addresses the limitations of traditional fault detection techniques by enabling seamless, non-intrusive in-field testing for safety-critical hardware systems. Unlike commercial STLs, our approach automates the STL generation, enabling less manual effort. By leveraging reinforcement learning, the STL generates design-specific test patterns that achieve up to a 57.57% improvement in fault coverage and up to 85% testing efficiency compared to random pattern-based methods. This approach ensures uninterrupted system operation during fault detection, making it highly suitable for mission-critical domains such as automotive, aerospace, and medical devices. These results demonstrate the framework's potential to significantly enhance functional safety in increasingly complex hardware systems.

ANGraph: A GNN-Based Performance Prediction Framework for Asynchronous Neuromorphic Hardware

Yuan Hua†, Jian Zhang†, Jilin Zhang, Xiang Zhang, and Hong Chen*
School of Integrated Circuits, Tsinghua University
Beijing China
hongchen@tsinghua.edu.cn

***Abstract*—Design space exploration (DSE) through system-level simulation is essential for designing energy-efficient asynchronous neuromorphic hardware, which is increasingly promising in edge AI applications. However, there are significant mismatches between system-level predictions and gate-level simulations, resulting in low precision when predicting performance during the DSE process for asynchronous neuromorphic hardware. To address this issue, we put forward ANGraph, a graph neural network (GNN)-based performance prediction framework for asynchronous neuromorphic hardware. In the ANGraph framework, we transform the intermediate representation of system-level simulations into graphs, collect gate-level circuit simulation results to build benchmarks with over one million samples, and train a GNN model to predict hardware latency for asynchronous neuromorphic hardware. Additionally, we use a residual network (ResNet)-based method to predict the power consumption of asynchronous neuromorphic hardware. We evaluate these two models on additional datasets without extra training across different scales, process nodes, and traffic patterns of input data. Compared to the latency predictions from the state-of-the-art simulator, we improve the R-square score by 0.69 and reduce root mean square error (RMSE) by 76% on average across all datasets. We also achieve an R-square score of 0.98 and a mean absolute percentage error (MAPE) of 0.88% for the power consumption prediction task. The benchmarks and models are available at https://github.com/HuaGuaiGuai/ANGraph.**

***Index Terms*—asynchronous neuromorphic hardware, performance prediction, graph neural networks, benchmark**

I. Introduction

Recently, most neuromorphic hardware has been designed with asynchronous circuits to improve energy efficiency, exploiting their event-driven feature to match sparse computation of spikes, such as Loihi2 [1], ANP-I [2], ANP-G [3], and many others in [4, 5, 6]. To assist in efficient design space exploration (DSE) for asynchronous neuromorphic hardware, system-level simulators such as CanMore [7] and TrueAsync [8] have been developed.

The TrueAsync simulator is a fully asynchronous system-level simulator developed with an actor-based concurrent programming model, offering over 2× runtime speedup compared to the cycle-accurate CanMore simulator. However, even though manufacturing process-related circuit details are considered in the modeling of these simulators, their system-level performance prediction results remain significant mismatches against gate-level simulations of circuit netlists, as illustrated in Figure 1.

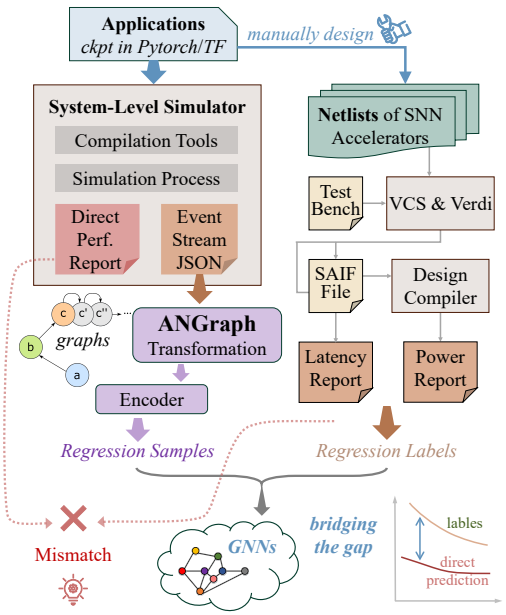

Fig. 1. The overall performance prediction workflow.

Predicting performance for asynchronous neuromorphic hardware using system-level simulations is challenging for two main reasons. First, many gate-level circuit details are ignored in system-level modeling to reduce runtime, resulting in inconsistence in performance predictions. Second, hardware latency predictions for synchronous circuits are accurate when system-level cycle-accurate simulations align with gate-level circuit cycles. However, asynchronous circuits do not have global

†Yuan Hua and Jian Zhang contributed equally to this work.
*Hong Chen is the corresponding author.

clocks or cycles. Thus, if system-level simulators for asynchronous circuits are required to predict fine-grained timing down to nanoseconds or even picoseconds, we must assume a relationship between simulation runtime and hardware latency. For instance, the TrueAsync simulator builds a fully asynchronous actor system to model the clock-free asynchronous circuits, where one second of simulation runtime corresponds to 1 μs of circuit latency. In fact, the mismatches between system-level models and gate-level circuits are reasonable. The mean absolute percentage error (MAPE) and root mean square error (RMSE) of the hardware latency system-level prediction results by the TrueAsync are 50.06% and 7113, respectively, compared to the gate-level simulation results.

Generally, hardware latency and power consumption are the two key metrics in performance predictions. To predict the hardware performance at system-level, many studies focus on using graph neural network (GNN)-based approaches to avoid the execution of time-consuming and expensive simulations, analyses or experiments [9]. Examples include a GNN-based timing engine to predict arrival time and slack at timing endpoints [10], high-level synthesis (HLS) performance prediction methods using GNNs by representing C/C++ programs as graphs [11], and a preplacement prediction flow with estimators on both net length and timing by customized GNN [12]. However, previous performance prediction methods for asynchronous circuits still rely on analytical models and have not applied promising machine learning techniques [13, 14, 15].

In this paper, we propose a novel performance prediction framework for asynchronous neuromorphic hardware, which transforms the intermediate representation (IR) of the TrueAsync simulator into asynchronous neuromorphic graphs and predicts hardware performance including latency and power consumption. Our main contributions are as follows:

- **Transforming.** We introduce a method to analyze event streams and define asynchronous neuromorphic graphs as IRs. By transforming the event streams into graphs, we bridge system-level simulation and graph-level representations, enabling GNN training and inference for hardware latency predictions.
- **Benchmarking.** We design register-transfer level (RTL) and netlist circuits for asynchronous neuromorphic hardware at various scales and manufacturing process nodes. These gate-level netlists are simulated using diverse compiled input data from different applications. By pairing system-level event streams from the TrueAsync simulator with gate-level hardware performance results, we build a standard benchmark suite with more than one million samples, including hardware latency and power consumption prediction tasks.
- **Predicting.** We put forward the GNN-based *ANGraph-L* and the residual network (ResNet)-based *ANGraph-P* models for predicting hardware latency and power consumption, respectively. Compared to the latency prediction results from the TrueAsync simulator, we improve the R^2 score by 0.69 and reduce RMSE by 78%. Furthermore, we evaluate these two models on additional datasets without extra training across different scales, input traffic patterns, and process nodes. *ANGraph-L* achieves an average R^2 score of 0.96, while *ANGraph-P* achieves an average R^2 score of 0.98 and a MAPE of 0.88%.
- **Opensource.** The benchmarks and models are available at https://github.com/HuaGuaiGuai/ANGraph.

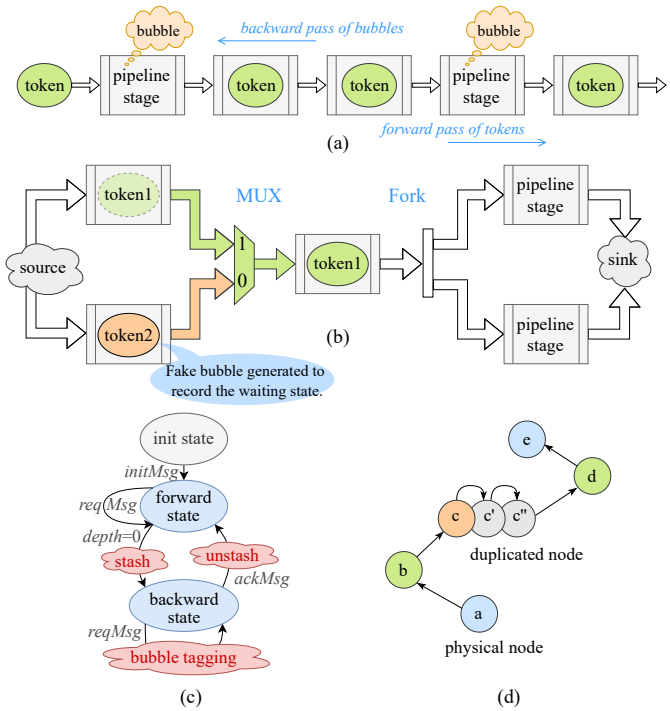

Fig. 2. (a) In asynchronous pipelines, data tokens move forward while bubbles move backward, resulting in forward and backward pass asynchronous events. (b) The fake bubble event occurs at the MUX point of asynchronous pipelines when data tokens are congested. (c) The finite-state machine of asynchronous controllers we designed is able to simulate fake bubble events. (d) Duplicated nodes are copies of a physical node.

II. Transforming Event Streams into Graphs

To enable GNN-based performance predictions, we reconstruct essential information during the system-level simulation of asynchronous neuromorphic hardware from the perspective of asynchronous events. We define and generate asynchronous neuromorphic graphs with encoded features, as depicted in Figure 1.

A. Event Stream Extraction

As we know, events are crucial in analyzing event-driven asynchronous circuits. The TrueAsync simulator builds a fully asynchronous, high-concurrency actor system to model the asynchronous circuits, which recognizes two types of events during its finite-state machine (FSM)-based modeling and simulation, including forward and backward pass events. These two events describe the flow of data tokens, with the backward pass event occurring in a high congestion state of circuits and

having a higher latency than the forward pass event, as shown in Figure 2(a).

However, another asynchronous state of data tokens, the waiting state, must be considered when transforming dynamic real-time simulations into static event streams. To address this, we introduce a new asynchronous event, the fake bubble event, to represent the waiting states of data tokens in asynchronous pipelines, as illustrated in Figure 2(b). Assuming all pipeline stages are initially empty, each pipeline stage generates the forward pass and the backward pass events for data tokens that pass through it. Tokens in congestion are held in place, where the pipeline stage generates a fake bubble event for each congested token. These three asynchronous events describe all the system-level behaviors of asynchronous pipeline stages with respect to data tokens, including forward pass event, backward pass event, and fake bubble event.

Different from the TrueAsync simulator, we design FSM-based asynchronous controllers that incorporate the fake bubble feature, as shown in Figure 2(c). At the end of a simulation, a JSON file is generated containing all the asynchronous events occurred during the simulation, preparing for transformation into graphs.

B. Asynchronous Neuromorphic Graph

Following the movement of a data token in the asynchronous pipeline, we define an asynchronous neuromorphic graph G, consisting of a set of nodes V representing the circuit modules that a data token passes through, and a set of edges E describing the direction of the node sequence. The structure of G is denoted by an adjacency matrix $A \in \mathbb{R}^{|V|\times|V|}$, where $A_{uv} = 1$ if there is an edge $(u, v) \in E$ exists and 0 otherwise. In asynchronous neuromorphic graphs, each data token generates an independent graph, traveling from source to sink and passing through several circuit modules as graph nodes. Therefore, the asynchronous neuromorphic graph for a data token is an unweighted directed acyclic graph (DAG) with a single start point, as shown in Figure 2(d).

We encode the node features based on the inherent features of circuit modules (e.g., delays) and the event streams of the data token. Each node $v \in V$ has a feature vector $X_v \in \mathbb{R}^F$, where F denotes the feature dimension. All feature vectors are collected in the matrix:

$$X = [X_1^\intercal, X_2^\intercal, \ldots, X_{|V|}^\intercal]^\intercal \tag{1}$$

where $\intercal$ is the transpose operation. Since event stream lengths vary among different circuit modules, we set the dimension F to 100 to standardize of size of matrix X. For the event stream whose length exceeds dimension F, we duplicate the graph node to encode additional events as node features, as illustrated in Figure 2(d). The duplicated nodes help avoid a matrix X that has too many zero elements or is excessively large due to unbalanced and varying event stream lengths. Meanwhile, in order to reduce simulation runtime, we limit the maximum event stream length to $10k$ by splitting the input data tokens from the source into several subtasks and predicting the overall performance by summing them up.

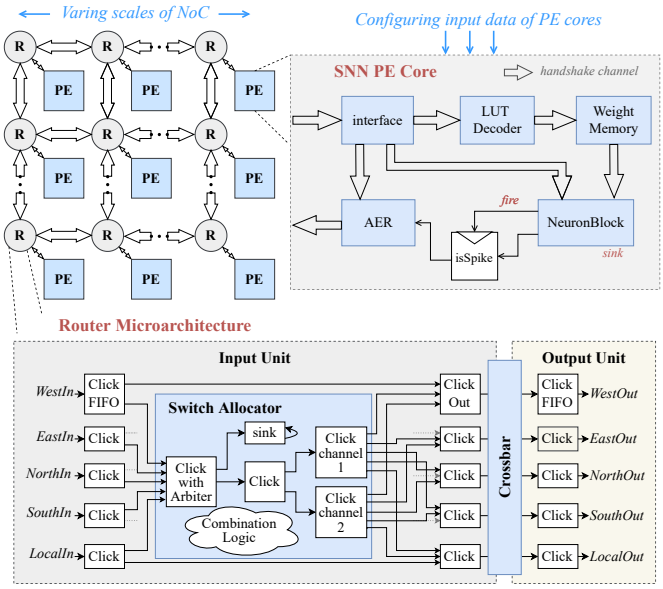

Fig. 3. The microarchitecture of fully asynchronous neuromorphic hardware.

III. Benchmarking for Asynchronous Neuromorphic Hardware

We establish a standard benchmark suite for performance prediction by ANGraph in asynchronous neuromorphic hardware across various network scales, traffic patterns of input data, and manufacturing process nodes. The overall workflow of benchmarking is depicted in Figure 1.

A. Asynchronous Neuromorphic Hardware

The fully asynchronous neuromorphic hardware used in this work is depicted in Figure 3, inspired by the spiking neural network (SNN) accelerator in [4]. The mesh-based network-on-chip (NoC) architecture consists of multiple routers connected to SNN processing element (PE) cores. Thses cores can be configured as different applications by adjusting the LUT decoder, weight memory, and address-event representation (AER) modules. For example, to create the training dataset named L/P-MNIST-4×4-T180, we design fully asynchronous neuromorphic hardware with 4×4 SNN inference cores and mesh-based NoC routers, configured as a two-layer fully connected network for MNIST classification [16], where *L* for latency prediction dataset and *P* for power prediction dataset. Meanwhile, configure the hardware as another five-layer convolutional network for MNIST classification to extend the training dataset.

B. Workflow with EDA Tools

Aimed at providing comprehensive benchmarks for performance predictions, we design asynchronous neuromorphic hardware from RTL to netlists using design tools reported in [17] and the Synopsys Design Compiler (DC) . Through gate-level simulations with Verilog compile simulator (VCS) and Verdi tools, we obtain detailed analysis results of our

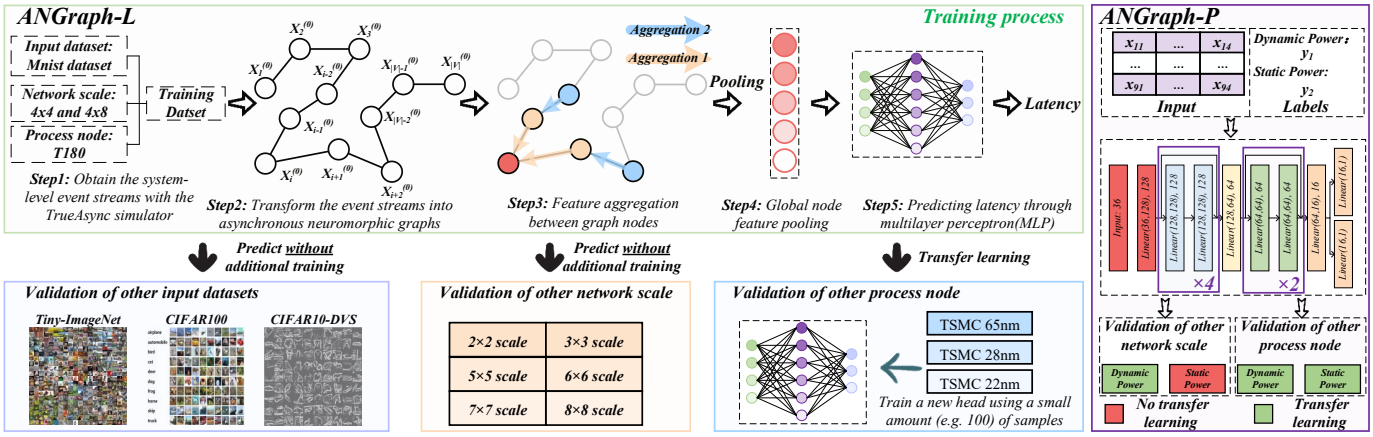

Fig. 4. The structure diagram of the ANGraph framework.

netlists, including the latency of each data token (in picoseconds) and static and dynamic power consumption.

After obtaining the system-level event streams from the TrueAsync simulator, we transform them into asynchronous neuromorphic graphs for the latency prediction task using the transformation method discussed earlier. For the power prediction task, we create activity matrices by recording asynchronous events for each module during the system-level simulation. By pairing gate-level analysis results as labels with system-level graphs and activity matrices as samples, we build nineteen datasets with two types of tasks: latency prediction as shown in Table I and power prediction as shown in Table II in Section V.

C. Extended Datasets

In addition to using a specific combination of circuits, input traffic patterns, and manufacturing process nodes to train our GNN model, we test the model on additional datasets with varying circuit scales, input traffic patterns, and process nodes. To create datasets with different network scales of asynchronous neuromorphic hardware, we adjust the number of PE cores and NoC routers, rearranging the mesh array from 2×2 to 8×8. Since the circuit testbenches compiled from applications for the same task (e.g., MNIST classification) may have certain input traffic patterns, we generate additional datasets using various asynchronous neuromorphic hardware configured as different applications and input datasets, such as CIFAR10-DVS [18], CIFAR100 [19], and Tiny-ImageNet [20]. All the datasets are generated with hardware netlists synthesized with the TSMC 180nm process, as well as TSMC 65nm, 28nm, and 22nm, where latency and power consumption vary significantly across different process nodes.

IV. Predicting with ANGraph Framework

In this section, we describe the structure of the ANGraph models used in this paper. The overall structure of the ANGraph framework is shown in Figure 4. We propose a GNN-based *ANGraph-L* model for latency predictions to learn from asynchronous neuromorphic graphs. In addition, since the power consumption prediction task deals with activity matrices instead of graphs, we propose a ResNet-based *ANGraph-P* for power consumption predictions.

A. ANGraph-L for Latency Prediction Task

ANGraph-L leverages a general inductive framework that efficiently generates node features for previously unseen data, relying solely on the feature information of nodes, which are the system-level event streams extracted from the TrueAsync simulator [21]. This approach demonstrates robust generalization capabilities, particularly when dealing with different input traffic patterns and varying scales of asynchronous neuromorphic hardware. For the input X in Equation (1), *ANGraph-L* follows the steps outlined below to predict latency.

Feature Aggregation. The *ANGraph-L* uses mean graph convolution to integrate the feature information of a node and its neighboring nodes, generating an updated feature for the node X_i. It can be represented as:

$$X_i^{(k+1)} = \sigma(W_1 X_i^{(k)} + W_2 \text{mean}_{j \in \mathcal{N}(i)} X_j^{(k)}) \tag{2}$$

where σ is activation function and W_1, W_2 are learnable parameters. $X_i^{(k)}$ represents the output of the i-th node at the k-th layer of graph convolution. $\mathcal{N}(i)$ stands for the set of neighboring nodes of the i-th node. After stacking k layers of graph convolution, *ANGraph-L* performs feature aggregation on nodes, summing up the node features from k graph convolutions to obtain the aggregated node features, expressed as:

$$Y_j = \sum_{i=1}^{k} X_j^{(i)} \tag{3}$$

where $Y = [Y_1, Y_2, \ldots, Y_{|V|}]$ represents the aggregated node features.

By stacking graph convolutional layers, the receptive field of the model can be enlarged. With each additional layer, node features aggregate information from further neighborhoods, helping the model capture long-range dependencies. Through

hierarchical feature aggregation, multi-level node features in the graph can be integrated, which allows node representations to include not only local information but also higher-order neighbor information. This provides the model a more comprehensive understanding of the relationships between nodes. In *ANGraph-L*, the number of stacked graph convolutional layers $k = 5$.

Global Pooling and Prediction. After feature aggregation, each node obtains its corresponding aggregated node feature Y_i. *ANGraph-L* integrates the aggregated features Y_i of each node into a graph-level feature $G \in \mathbb{R}^F$ through global sum pooling, which can be represented as:

$$G = \sum_{i=1}^{|V|} Y_i \tag{4}$$

The next step is to learn the final predictor using the multilayer perceptron (MLP). For each graph-level feature G, we can obtain its corresponding latency through the predictor.

As we adopt stacked graph convolution and feature aggregation learning methods, *ANGraph-L* is able to understand relationships among event streams. This approach enables *ANGraph-L* to effectively predict latency performance across datasets of varying scales and process nodes with diverse traffic patterns, demonstrating great generalization capabilities. Moreover, it is unnecessary to retrain the model with a large dataset for different process nodes. Structure-based transfer learning is employed to learn the fundamental features of new process nodes. During the transfer learning process, only a small number of samples are used to train a new predictor, achieving high performance while preserving the learned relationships among event streams.

B. ANGraph-P for Power Prediction Task

In order to predict both the dynamic and static power consumption of the circuit at the same time, we implement a ResNet structure with dual output heads, as shown in Figure 4. For the input $X \in \mathbb{R}^{L=36}$, when it is fed into *ANGraph-P* for power consumption prediction, $Y = [y_1, y_2]$ will be obtained, where y_1 represents the dynamic power consumption and y_2 represents the static power consumption. The total power consumption is equal to the sum of static and dynamic power consumption.

V. Experimental Results

A. Experimental Setup

We implement the GNN model with Pytorch Geometric [22]. During the training process, we use the Adam optimizer with a learning rate of 0.001, dropout set to 0.5, and the loss function is HuberLoss with delta=5. In the transfer learning process, *ANGraph-L* only needs to learn new predictors, while the rest of the parameters remain unchanged. *ANGraph-P* only requires relearning the dynamic power output head and the static power output head.

We compare the prediction results with the TrueAsync simulator by implementing the same hardware models as circuits and simulating the same input data. Comparison results are shown in Table I, with improvements listed in the parentheses. For instance, 0.99 (↑0.16) of R^2 score indicates that *ANGraph-L* achieves 0.99, improving by 0.16 compared to TrueAsync, and an RMSE of 1530 (↓78%) indicates that *ANGraph-L* achieves 1530, reducing by 78% compared to TrueAsync.

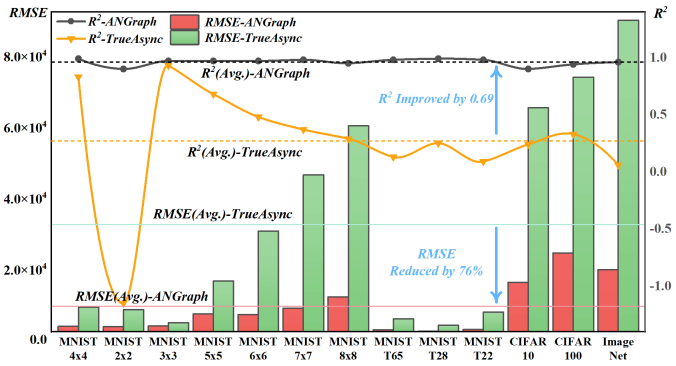

Fig. 5. The latency prediction results with ANGraph-L comparing to those from the TrueAsync simulator.

B. Latency Prediction Results with ANGraph-L

We conduct experiments to predict hardware latency on various datasets with *ANGraph-L* and compare the results to those from the TrueAsync simulator, as shown in Figure 5

On the training dataset, we randomly split the L-MNIST-4×4-T180 dataset into 80% train, 10% validation and 10% test for the latency prediction task. As shown in Table I, the *ANGraph-L* model achieves an R^2 score of 0.99. Compared to the prediction results from the TrueAsync simulator, the ANGraph method improves $R2$ score by 0.16 and reduces RMSE by 78.49%.

On the scale-testing datasets, we directly test datasets of varying scales from 2×2 to 8×8 without additional training or tuning. Results in Table I show that the *ANGraph-L model* achieves R^2 scores of over 0.9, with an average of 0.96, demonstrating that the model can accurately predict the latencies of asynchronous neuromorphic hardware at various scales.

On the traffic-testing datasets, to show that the *ANGraph-L* model adapts to different traffic patterns of input data, we test datasets compiled from various classification tasks, such as CIFAR10-DVS, CIFAR100, and Tiny-ImageNet. Results in Table I show that the *ANGraph-L* model achieves R^2 scores of over 0.9, with an average of 0.93 on these three datasets, indicating that the model is not biased toward specific input traffic patterns, enabling the prediction of the latency performance for asynchronous neuromorphic hardware with various applications.

On the process-testing datasets, we train new predictors for the *ANGraph-L* model with a few new samples to learn the basic features of different process nodes, as shown in Table I. After transfer learning, the tested model achieves an average R^2 score of 0.98 across these three datasets, demonstrating that *ANGraph-L* is able to predict latency of hardware with various

process nodes after transfer learning using a small number of new samples.

Comparing to the TrueAsync predictions, the *ANGraph-L* model improves the R^2 score by 0.69 and reduces the RMSE by 76% on average across all datasets of the latency prediction task. Higher R^2 scores and lower RMSE values indicate a better model fit for these regression tasks.

C. Power Consumption Prediction Results with ANGraph-P

For power consumption predictions, we use *ANGraph-P* to train and test on various datasets. The power consumption predictions cannot be compared since the state-of-the-art (SOTA) TrueAsync simulator is unable to predict it.

On the training dataset, we randomly split the P-MNIST-4×4-T180 dataset into 80% train, 10% validation and 10% test for power consumption prediction task. As shown in Table II, the *ANGraph-P* model achieves an R^2 score of 0.99 and a MAPE of 0.21%. The ResNet architecture of *ANGraph-P* is well-suited to handling matrix inputs such as activity matrices, leading to the high R^2 score and low MAPE.

On the scale-testing datasets, we test the *ANGraph-P* model on the P-MNIST-2×2-T180 and P-MNIST-8×8-T180 datasets without additional training. Results in Table II show that the *ANGraph-P* model achieves R^2 scores of 0.99 and 0.98, with MAPE values of 0.31% and 0.98%, respectively, indicating that it is capable of predicting the power consumption of hardware at various scales.

On the process-testing datasets, similarly, we train new predictors for the *ANGraph-P* model with a few new samples, as shown in Table II. After transfer learning, the tested model achieves an R^2 score of 0.98 and a MAPE of 1.25% on average across these three datasets. As a result, we can transfer train the *ANGraph-P* model to predict the power consumption of hardware with different process nodes.

VI. CONCLUSION

The system-level performance prediction methods for asynchronous circuits have been studied for decades. However, these methods still rely on analytical models and face challenges due to the complexity of asynchronous systems. In this paper, ANGraph presents a promising GNN-based approach to predict the latency performance of asynchronous neuromorphic hardware, bridging the gap between system-level predictions and gate-level simulations. We put forward a transformation method that extracts event streams from system-level simulations and converts them into graphs. Additionally, we provide a standard benchmark suite for predicting the performance of asynchronous neuromorphic hardware across various network scales, process nodes, and input data. Using these benchmarks, we introduce the GNN-based *ANGraph-L* and ResNet-based *ANGraph-P* model to predict latency and power consumption of asynchronous neuromorphic hardware, respectively. For the latency prediction task, we achieve an average R^2 score of 0.96 on all datasets. Compared to the direct prediction results from the SOTA simulator, the *ANGraph-L* model improves R^2 score by 0.69 and reduces RMSE by 76%. For the power consumption prediction task, we achieve an R^2 score of 0.98 and a MAPE of 1.21% on average across all datasets. Moreover, with the ANGraph framework, we can accurately predict the performance of asynchronous neuromorphic hardware at different scales, process nodes, and traffic patterns of input data, demonstrating its robust generalization ability.

***Abstract*—Mixture-of-experts (MoE) technique holds significant promise for scaling up Transformer models. However, the data transfer overhead and imbalanced workload hinder efficient deployment. This work presents PIMoE, a heterogeneous system combining processing-in-memory (PIM) and neural-processing-unit (NPU) to facilitate efficient MoE Transformer inference. We propose a throttle-aware task offloading method that addresses workload imbalance between NPU and PIM, achieving optimal task distribution. Furthermore, we design a near-memory-controller data condenser to address the mismatch of sparse data layout between NPU and PIM, enhancing data transfer efficiency. Experimental results demonstrate that PIMoE achieves 4.5× speedup and 13.7× greater energy efficiency compared to the A100, and 1.4× speedup over a state-of-the-art MoE platform.**

I. Introduction

Transformer-based large language models (LLMs) have performed remarkably across various natural language processing tasks. This exceptional performance is largely due to the unprecedented growth in model sizes over recent years [1], [2]. However, increasing model capacity results in higher computational costs and memory requirements, making training and deployment increasingly challenging.

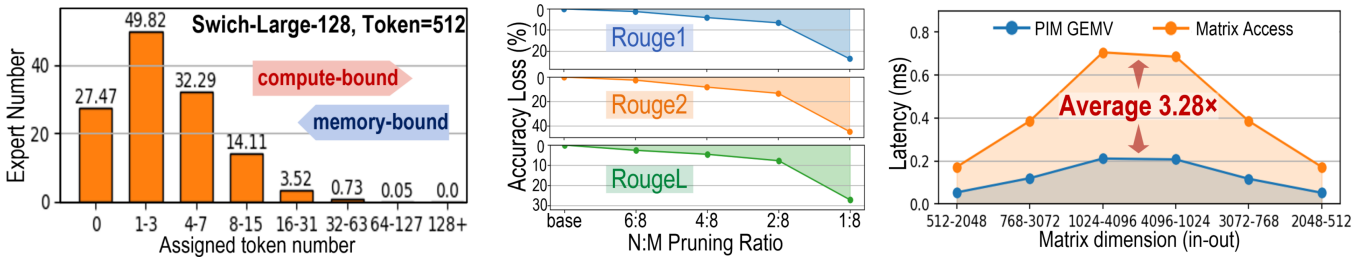
The Mixture-of-Experts (MoE) technique has emerged as a promising approach to scaling model sizes while minimizing proportional increases in computational overhead [3]–[7]. In MoE-based Transformers, the sparse gating mechanism allows only a subset of experts to process an input token, resulting in lower computational expenses compared to non-MoE models with equivalent parameter counts. Consequently, MoE Transformer has been practically applied to LLM productions [2].

Although MoE Transformers significantly increase model capacity without greatly raising computation costs, deploying these models for inference faces two main challenges: data transfer overhead and workload imbalance. Firstly, the limited on-chip buffer capacity causes frequent eviction and reloading of expert parameters, leading to significant data transfer overhead. This issue is worse for experts that receive few tokens, resulting in low parameter reuse and memory-bound tasks that increase inefficiencies and latency. Secondly,

(a) (b)

Fig. 1. (a) Diagram of Transformer block with MoE FFN layer. (b) Multi-levels of expert offloading in a heterogeneous NPU-PIM system.

the dynamic sparse allocation in MoE Transformers causes workload imbalance, with some experts overburdened while others are underutilized. This is particularly problematic in heterogeneous multi-core systems, where imbalanced token distribution leads to latency bottlenecks in the critical path.



Many works have integrated xPU (NPU/GPU) with PIM to address data transfer and memory overhead. IANUS [8], AttAcc [9], NeuPIMs [10] propose offloading memory-bound matrix-vector multiplications to PIM devices, leveraging the high bandwidth. Cambricon-LLM [11] proposes a NPU-NAND hybrid architecture to support tremendous storage demand. While designed for general transformer models, these works do not fully concern the specific expert imbalance in the MoE context. MoNDE [12] proposes a near-data-processing (NDP) approach for MoE Transformers. It trade-off parameter movement with activation movement based on the workload characteristics of different experts. Duplex [13] proposes a new HBM device with increased TSV amount to enlarge the NDP's bandwidth for better computing throughput.

In this work, we present PIMoE, a co-optimized NPU-PIM system for efficient MoE Transformer deployment. In summary, this paper makes the following contributions:

- We fully leverages the all-bank parallelism of commercial PIM products, addressing the memory-bounded expert computation associated with MoE FFN.
- We propose a throttle-aware task offloading method designed to optimize the distribution of experts be-

tween PIM and NPU, mitigating performance bottlenecks caused by imbalanced workloads.

- We propose a near-memory-controller data condenser that addresses the mismatch between DRAM and NPU sparse data layouts. Condensing transfer data also alleviates NoC congestion and enhances data transfer efficiency.
- PIMoE achieves a 4.5× speedup and 13.7× energy efficiency compared to the A100. It also delivers a 1.4× speedup over a state-of-the-art NDP MoE platform.

II. Background and Motivation

A. MoE-based Transformers

The Mixture-of-Experts (MoE) technique [14] partitions a complex task into separated sub-tasks, enhancing the model's fitting ability. Sparse MoE [3] further introduces a gating network that selectively activates a subset of experts for each workload. As for Transformer models, the sparse MoE has been applied to the feed-forward layers (FFNs) [6], [7] to relax computation as the model increasingly scales up. Fig. 1 illustrates a typical MoE-based FFN (dubbed MoE FFN) within a Transformer block. The MoE FFN replicates the original FFN into N experts, each comprising two linear layers with an activation layer in between. At the block's entrance, the gating function infers the probability of each input token being allocated to the N experts. Then the token is routed to the top-K experts for inference. The results from each expert are weighted according to their corresponding probabilities and aggregated at the output.

The token workloads across FFN experts feature uneven distribution. We profile the switch-large-128 model [6] consisting of 128 experts and operates with 512 tokens. Fig. 2(a) shows the histogram of experts by allocated token count. Nearly half of the experts are allocated fewer tokens (i.e., 1-3), featuring memory-bound characteristics with limited weight reuse. In contrast, those experts with heavier token allocations are compute-bound, dominated by matrix multiplication.

Besides the sparse expert selection, the expert can further benefit from weight pruning, particularly the N:M method that selects N significant weights from each M-element vector. As indicated by Fig. 2(b), this approach reduces on-chip buffer overhead without severe degradation in performance. Furthermore, this weight sparsity can be effectively leveraged to accelerate computation by skipping the zero operation.

B. Commercial PIM Platforms

Processing-in-memory (PIM) covers a variety of techniques that deploy computing resources near or within DRAM devices. Among them, the all-bank (AB) paradigm, which deploys processing units besides the DRAM banks, has gained favor among several semiconductor manufacturers (PIM-HBM [15], AiM [16]). AB-PIM fully utilizes the internal bus bandwidth without intrusive change to the memory cell, striking a balance between throughput and storage density.

Commercial AB-PIM (e.g., PIM-HBM, AiM) prioritizes compatibility with existing protocols: High-level computing commands are converted into low-level JEDEC commands (write/read) to initiate PIM execution, typically managed by the memory controller. Therefore, both the PIM computation and the normal memory access occupy the memory controller, incrementally increasing the latency.

To characterize the PIM's performance, we profile the PIM-HBM with the corresponding PIMSimulator [17]. As shown in Fig. 2(c), the latency of per token matrix-vector multiplication (GEMV) linearly scales with the size of the weight parameters. Moreover, the throughput ratio between PIM computation and regular memory access is also nearly in proportion. Specifically, an N-to-M GEMV achieves 3.28× higher throughput than loading an $N \times M$ weight parameter. This falls short of the ideal 8× bank-level parallelism in PIM-HBM, due to PIM-specific overheads like activation writes and barrier insertions. This result indicates that PIM is well-suited for 'cold' experts with fewer tokens. For 'hot' experts with many tokens, the PIM's efficiency diminishes.

C. Motivation

To efficiently accommodate experts with diverse workloads, we propose an NPU-PIM hybrid system that leverages the PIM's weight-stationary feature and bank-level parallelism, as well as the NPU's high computational throughput. To prevent system performance from being throttled by critical experts on specific components, we propose a throttle-aware task offloading method that optimizes task allocation based on a latency model of the heterogeneous components. Furthermore, even though the NPU can effectively leverage sparsity, current PIMs do not well support sparse FFN inference, where the sparse weights have to be stored in a structured pattern. To bridge the gap of sparse data layout between NPU and PIM, and

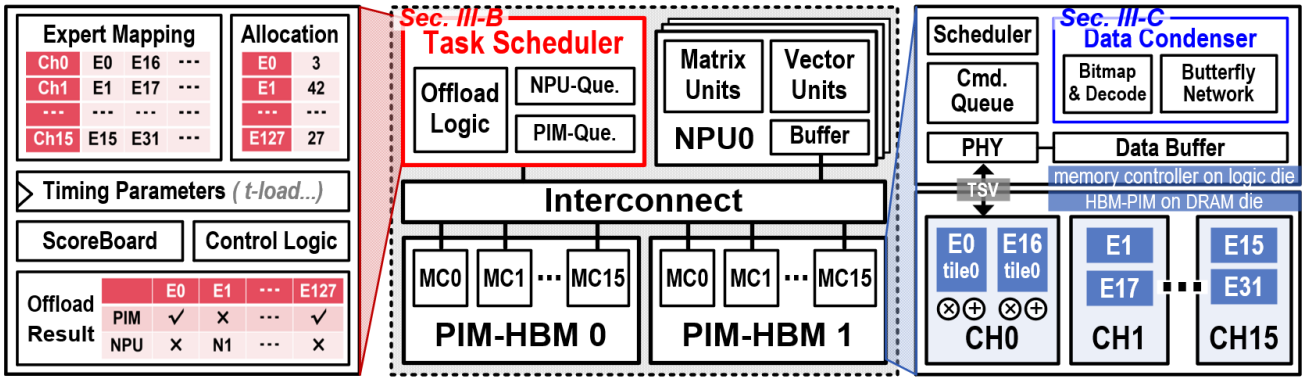

Fig. 3. The overall architecture of PIMoE. The task scheduler is explained in section III-B. The data condense is elaborated in section III-C.

enhance the bandwidth utilization for preventing congestion, we propose a near-memory-controller data condenser.

III. PIMoE

This section introduces the architecture of PIMoE, the throttle-aware task offloading method that optimizes the heterogeneous system, and the near-memory-controller data condenser that improves transfer efficiency.

A. PIMoE Architecture

Fig. 3 illustrates the overall architecture of the proposed PIMoE, the components of which are introduced below.

NPU: The NPU consists of matrix units (MUs), vector units (VUs), and scratchpad buffers. The MUs perform matrix multiplications involved in the gating function and the two linear layers within FFN experts. The MU is designed as a systolic array that supports sparse acceleration. The weights are pruned using the N:M scheme and are densely stored in the buffer, along with the corresponding bitmap. During computation, the activations pass through a gather unit that decodes the bitmap to select N non-zero elements from M inputs [18], while the multiply-accumulate (MAC) unit calculates the inner product of the condensed vectors. The VUs handle the element-wise operations including bias addition, residual addition, activation function, and weighted sum of multiple experts' results.

PIM: PIMoE adopts Sumsang's commercial product, PIM-HBM [15], which is based on HBM2 DRAM that consists of 16 channels, offering a total of 1024 I/O pins and a maximum bandwidth of 307GB/s. Each channel contains 16 banks, with PIM-HBM deploying 8 processing units among these banks. Due to the limited routing resources in DRAM devices, it is preferable to localize the computation with the channel to minimize the global communication and synchronization overhead. Therefore, each expert's parameters are consecutively mapped within the channel's address range and only tiled across different DRAM devices to fit the per-channel storage limit. To support straightforward scaling of the number of experts, the experts are interleaved across channels, with the E_{th} expert being mapped to the channel $E_{th}\%N_{chan}$. Each DRAM channel includes a memory controller that supports both normal memory access and PIM-specific commands. The memory controller is equipped with a data condenser, as discussed in Section III-C, to efficiently transfer structured weight parameters sparsely stored in DRAM to the sparsity-optimized NPU that requires a dense weight format.

Task Scheduler: The task scheduler dispatches the experts across the NPUs and PIMs based on the runtime token distribution. It takes the results of the gating function as input and decides each expert's computing medium according to the throttle-aware offloading method described in Section III-B. For the NPU-offloaded expert, it requests the DMA to load the parameters from DRAM to the on-chip buffer and triggers the matrix multiplication once the data is prepared. For the PIM-offloaded task, it issues the PIM commands to the target memory controller according to the expert address and loop for each assigned token. To avoid inefficiency caused by frequent mode switching, the task scheduler inserts barriers between two types of tasks.

Network-on-chip: The NoC manages data transfer between the DRAM and NPU. It employs a 2D mesh topology with NPUs and memory controllers as nodes. For PIM-offloaded tasks, the NPU initiates the transfer, sending activation data to the target DRAM partition. For NPU-offloaded tasks, expert parameters are loaded from DRAM to the target NPU.

B. Throttle-Aware Task Offloading Method

The heterogeneous platform introduces more factors regarding workload imbalance, which can be categorized as PIM-throttle and NPU-throttle within the context of PIMoE.

PIM throttle: For a batch of input tokens offloaded to PIM, each DRAM channel handles those allocated to the subset of experts within its address range. The memory controller operates in parallel, with the critical channel managing the largest number of tokens. Due to the requirement for output synchronization across experts, the critical channel constrained the execution latency of the PIM-offloaded MoE FFN.

NPU throttle: For those experts offloaded to NPU, their parameters are loaded from the DRAM to the on-chip buffer. As the number of loaded experts increases, the latency of the critical NPU may exceed that of the PIM latency, causing the latter to wait for the completion of the NPU.

Existing work, such as IANUS [8] and MoNDE [12], employs a straightforward offloading method, not fully accounting for potential runtime throttle. IANUS offloads a task

Algorithm 1: throttle-aware offloading method

Input: $M_{CH\text{-}EP}$, $M_{EP\text{-}TK}$, $threshold$
Output: $M_{EP\text{-}PIM}$

$M_{EP\text{-}PIM} = [EP]$;
Initialize($[t_{CH}]$, $[t_{NPU}]$, $M_{EP\text{-}TK}$);
// Until NPU becomes the throttle
while $max([t_{CH}]) < max([t_{NPU}])$ **do**
  $CH_{thro} = argmax([t_{CH}])$;
  $EP_{candi} = M_{CH\text{-}EP}[CH_{thro}] \cap M_{EP\text{-}PIM}$;
  if $EP_{candi} \neq \emptyset$ **then**
    $N_{EP\text{-}TK} = M_{EP\text{-}TK}[EP_{candi}]$;
    $EP_{thro} = argmax(N_{EP\text{-}TK})$;
    $t_{PIM} = GetPimLatency(EP_{thro})$;
    if $N_{EP\text{-}TK}[EP_{thro}] > threshold$ **then**
      // Offload the expert to NPU
      $M_{EP\text{-}PIM} = M_{EP\text{-}PIM} \setminus EP_{thro}$;
      $NPU_{target} = argmin([t_{NPU}])$;
      $t_{NPU}[NPU_{target}]$ += t_{LD};
      $t_{CH}[CH_{thro}]$ += $t_{LD} - t_{PIM}$;
    else
      break; // The CH has optimized
    end
  else
    break; // No experts left for PIM
  end
end

to PIM if its latency is lower than that of on-chip execution. MoNDE adjusts the number of experts to offload to NDP based on the bandwidth ratio between the NDP and PCIe. We thus propose a throttle-aware offloading method to address performance limitations caused by PIM and NPU throttle.

Given that the memory controller processes normal access and PIM commands sequentially, each DRAM channel latency (t_{CH}) includes two components: the expert loading latency (t_{LD}) and the PIM execution latency (t_{PIM}). The latency t_{PIM} for a given expert is the product of the number of offloaded tokens N_{TK} and the latency for one PIM-based FFN, t_{FFN}, which itself includes matrix-vector multiplication latency t_{GEMV} and element-wise operation latency t_{ELEM}. The loading latency t_{LD} is determined by the parameter size S_{EP} and the channel's effective bandwidth BW. As for the NPU latency, it is approximated by the product of the number of offloaded experts N_{EP} and the loading latency t_{LD}, considering the tiled pipeline execution and data transfer bottleneck. The timing model is given below:

$$t_{CH} = \sum t_{LD} + \sum t_{PIM} \begin{cases} t_{LD} = S_{EP} \div BW \\ t_{PIM} = N_{TK} \times t_{FFN} \end{cases} \quad (1)$$

$$t_{NPU} = N_{EP} \times (t_{LD} + t_{EXE}) \approx N_{EP} \times t_{LD} \quad (2)$$

Algorithm 1 depicts the process of the proposed offloading algorithm. The expert-channel mapping table ($M_{CH\text{-}EP}$) and expert-token allocation table ($M_{EP\text{-}TK}$) are taken as inputs to generate the PIM-expert table ($M_{EP\text{-}PIM}$), which represents the set of experts offloaded to PIM. Initially, all experts are offloaded to the PIM. The algorithm iteratively selects a target expert to offload to the NPU until the NPU becomes the bottleneck. It begins by identifying the channel with the highest latency and checking for any active experts in that channel. If there are experts whose workloads exceed the defined $threshold$ (the latency ratio of matrix loading to PIM-GEMV, as noted in Section II-B), the expert with the most tokens is selected. It is then offloaded to the NPU with the least latency, and the latency scoreboards for both the NPU and PIM are updated according to the predefined model.

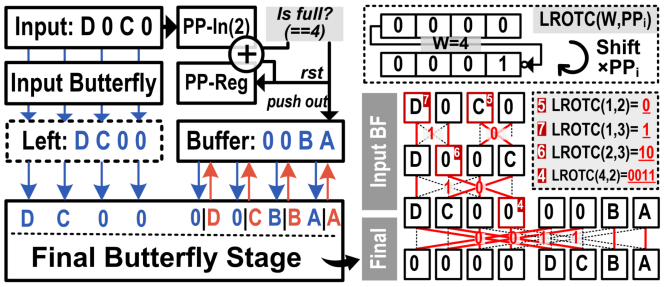

Fig. 4. Diagram of the near-memory-controller data condenser.

At the circuit level, the offloading algorithm is hardcoded. The timing parameters (i.e., t_{LD}/t_{GEMV}/$threshold$) are implemented as registers, which can be programmed with measured values. The offloading logic looks up the parameters and places the task into the target queue for dynamic scheduling.

C. Near-memory-controller Data Condenser

Given DRAM's limited logic budget, PIM struggles with irregular, non-extreme sparse GEMV, whereas NPUs can reorganize sparse computation into a densified pattern. Additionally, DRAM transfers are triggered in bursts, accessing consecutive data that may contain zero elements. This brings a mismatch in data layout between PIM and NPU, and leads to underutilization of NoC bandwidth and potential congestion.

To address this, we deploy a near-memory-controller data condenser to filter out zero elements from the input buffer, injecting dense 256-bit flits into the NoC. The condenser's core is a butterfly network reorganizing scattered non-zero elements into a consecutive sequence. As shown in Fig. 4, the butterfly network consists of multiple switch layers, each controlled by a bit to determine whether to swap the inputs. Using the input vector's bitmap and the rightmost offset, the LROTC (left rotate and complement on wrap) operation [19] recursively generates configuration bits for each switch layer, implemented through nested bitwise barrel rotators. A counter tracks the number of non-zero elements in the output buffer to align the inputs and outputs. This counter provides the offset to guide the LROTC within the input stage of the butterfly network, which permutes the input vector. The final butterfly stage further consolidates the reordered input into the output buffer. After each input cycle, the counter is incremented by the input's pop-count (i.e., the number of non-zero elements). Once the counter reaches its threshold, indicating that the

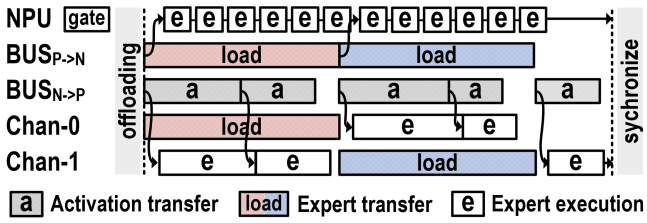

Fig. 5. Behavior model of the PIMoE simulator.

buffer is fully populated with dense elements, the data is pushed to the output queue, and the counter resets.

IV. Evaluation

A. Experimental Setup

Methodology: To evaluate the performance of the PIMoE platform, we develop a simulator composed of several subsystems. For the PIM subsystem, we use Samsung's open-source PIM-HBM simulator, PIMSimulator [17], which is based on the cycle-accurate DRAMSim [20]. PIMSimulator implements a PIM-specific command set to support common PIM testbenches, such as GEMV and element-wise computations. Regarding the execution latency of a PIM-offloaded expert, we simulate the two linear layers and an intermediate activation layer. With barriers inserted between each phase, the total latency is computed as the sum of the individual phases, which are executed sequentially. For the NPU subsystem, a pipelined scheme is adopted for weight loading and computation, where the expert is tiled for fine-grained execution. Therefore, the data transfer determines the latency, which is also evaluated by the PIMSimulator. For the NoC subsystem, we utilize the noxim simulator [21] to evaluate the congestion. We generate synthetic traffic patterns to represent the practical transfer workload in PIMoE. The injection rate is determined by the ratio of the DRAM channel's I/O throughput to the product of flit size (i.e., the NoC bus width, set as 256 bits) and the packet size (set as 8). The behavior model of PIMoE for simulating MoE FFN execution is illustrated in Fig. 5. Initially, the simulator determines the offloading based on the proposed throttle-aware offloading method. Then it tracks the state of each processing unit based on the pre-evaluated latencies. Once the occupancy of a unit is released, the simulator schedules a new task for execution.

TABLE I
PIMoE System Configuration and Workload Details

PIMoE	Composition	4 NPU, 2 PIM-HBM
NPU	Frequency	1GHz
	Matrix Unit	4096 MAC units, 8.2 TFLOPS
	Scratchpad	Activation 3MB, Weight 1MB

	Timing parameters	tCK=1ns, tCCDS=2ns, tCCDL=4ns, tRAS=33ns, tWR=16ns, tRP=14ns, tRCDRD=14ns, tRCDWR=10ns
	Processing Unit (PU)	300MHz, 8 PUs per channel 9.6 GFLOPS per PU

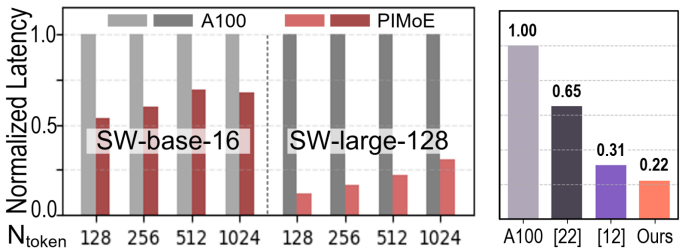
Model	d_{model}	d_{ff}	N_{expert}	Expert Params
Switch-Large-128	1024	4096	128	48 GB
Swicth-Base-16	768	3072	16	1.7 GB

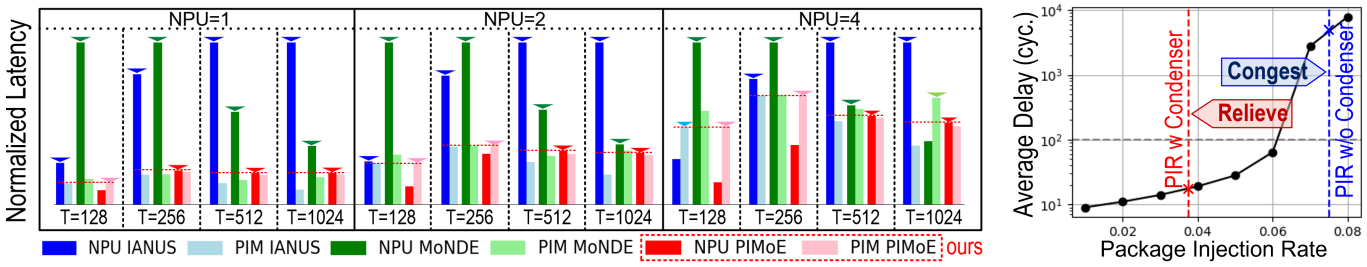
Implementation: Table I presents the configuration of the PIMoE system. To accommodate an entire MoE FFN layer on PIMoE, we integrate two PIM-HBM devices with a total capacity of 4GB. This capacity is sufficient to store the layer-wise weight parameters (2GB per switch-large-128 MoE FFN layer), intermediate results, bitmaps, and other necessary data. Each expert is tiled along the output channels, enabling concurrent execution across the two devices. For GPU comparison, we measure the latency of the MoE layers using PyTorch's CUDA Event API, placing hooks at the entry and exit points of the inference process. To evaluate the energy consumption, we refer to the physical parameters provided in [23]. To evaluate the area overhead of the data condenser on the logic die, we implement it with RTL using a commercial 28nm technology library and synthesize it with Design Compiler.

Workloads: We evaluate PIMoE using the pre-trained Switch Transformers in the Hugging Face repository. We adopt the bfloat16 datatype, which is widely adopted for inference tasks. Since PIMoE is primarily customized for MoE tasks, we conduct our experiments solely on the MoE FFN layers. The details of the model are listed in Table I. As for the datasets, we choose the C4 dataset, a large-scale web-crawled text collection designed for evaluating language models. When evaluating performance under different token numbers, we disable padding and truncate sequences that exceed the target token count. This ensures that only effective tokens are considered during execution.

B. Experimental Analysis

Comparison of Performance. Fig. 6 compares the execution latency of an MoE FFN layer. Each scenario is normalized to the GPU baseline, NVIDIA's A100. For the switch-base-16 model, PIMoE achieves an average of $1.6\times$ speedup compared to the A100. For the larger switch-large-128 model, PIMoE demonstrates a significant latency reduction of $8.47 \sim 3.25\times$ across various token numbers. The results indicate that, with fewer total tokens, the memory-bound cold experts become more prominent, allowing PIM execution to yield greater





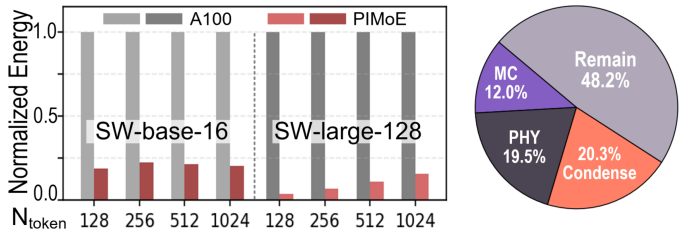


Fig. 6. Comparison of normalized latency (a) between A100 and PIMoE (b) between FLAME [22], MoNDE [12], and PIMoE.

(a) (b)

Fig. 7. (a) Comparison of the performance between the proposed offloading method and other NPU-PIM systems. (b) Congestion condition of the NoC under different packet injection rates (PIR).

(a) (b)

Fig. 8. (a) Comparison of energy efficiency between A100 and PIMoE across different scenarios. (b) Area breakdown of the logic die.

performance gains. We also compared PIMoE with other state-of-the-art accelerators for MoE transformers, specifically FLAME [22] and MoNDE [12]. We use their reported results normalized to the same GPU baseline (i.e., A100). Results show that PIMoE achieves an average improvement of 1.4× over MoNDE. PIMoE benefits from the higher bandwidth of bank-wise parallelism, unlike the channel-wise parallelism adopted in MoNDE. Additionally, PIMoE's tighter coupling between NPU and PIM bypasses the PCIe bottleneck in the GPU and CXL-based DRAM.

Comparison with other offloading scheme. Fig. 7(a) compares the effect of the proposed throttle-aware offloading scheme with the load balancing methods introduced in IANUS [8] and MoNDE [12], respectively. We implement their schemes on the PIMoE hardware baseline to ensure an apples-to-apples comparison. Each scheme's NPU and PIM latencies are shown separately to intuitively highlight the system's throttle points, indicated by a triangular arrow at the top of the corresponding bar. We also evaluate the sensitivity to varying numbers of NPUs and token workloads. For each scenario, the latencies are normalized to the highest value for comparison. The results show that throttle-aware offloading maintains a balance between NPU and PIM, particularly under heavy total token workloads and fewer NPU resources, leading to optimal performance across various configurations.

Effect of the data condenser. The number of effective packets injected into the NoC can be reduced through near-memory-controller data condensing. Particularly, the injection rate is halved with a 4:8 pruning. This prevents the NoC congestion under concurrent expert weight loading. Fig. 7 shows the average delay of data transfer under different packet injection rates (PIR). When no condensing is applied, the injection rate reaches 0.075, resulting in significant delays (over 5000 cycles) and indicating severe congestion. In contrast, with the condenser, NoC saturation is postponed. At an injection rate of 0.0375, the average delay is reduced to around 16 cycles, resulting in a negligible impact on overall performance.

Area and Power Consumption. As shown in Fig. 8, PIMoE achieves an average 4.8× and 13.7× improvement in energy efficiency compared to the A100 for the switch-base-16 and switch-large-128 models, respectively. This energy saving is attributed to the reduced external data transfer energy enabled by near-bank PIM. As for the near-memory-controller data condenser, we compare its area requirements with those of the memory controller, PHY, and the available area on the logic die. By efficiently utilizing the area budget, the condenser alleviates NoC congestion with a modest 20.3% overhead.

C. Discussion on Scalability

As the expert amount scales up, additional PIM-HBM devices can be added, with each expert tiled across the devices. While this increases NoC complexity, the data condensers mitigate the NoC's transfer burden, preventing congestion in larger configurations. Additionally, the proposed throttle-aware offloading method analyzes and schedules the complex expert distribution, optimizing resource usage and minimizing bottlenecks. This enables efficient handling of larger models and expert configurations while maintaining performance. By programming the timing parameters, this method can be applied to different NPU-PIM platforms.

V. Conclusion

In this paper, we presented PIMoE for efficient MoE Transformer deployment. By leveraging all-bank parallelism, PIMoE effectively addresses memory-bound challenges in MoE FFN computations. The throttle-aware task offloading mitigates workload imbalances between PIM and NPU. Additionally, the near-memory-controller data condenser improves data transfer efficiency by compressing sparse weight parameters from DRAM. Our experimental results show that PIMoE achieves 4.5× speedup and 13.7× greater energy efficiency compared to the A100, and 1.4× speedup over a state-of-the-art MoE platform. These results demonstrate the potential of PIMoE for improving performance and energy efficiency in large-scale MoE Transformer systems, providing a solid foundation for future developments in this area.

***Abstract*—Three-dimensional integration technologies present a promising path forward for extending Moore's law, facilitating high-density interconnects between chips and supporting multi-tier architectural designs. Cu-Cu hybrid bonding has emerged as a favored technique for the integration of chiplets at high interconnect density. This paper introduces YAP, a yield model for wafer-to-wafer (W2W) and die-to-wafer (D2W) hybrid bonding process. The model accounts for key failure mechanisms that contribute to yield loss, including overlay errors, particle defects, Cu recess variations, excessive wafer surface roughness, and Cu density. We also develop an open-source yield simulator and compare the accuracy of the near-analytical yield model with the simulation results. The results demonstrate that YAP achieves virtually identical accuracy while offering over 10,000x faster runtime. YAP enables the co-optimization of packaging technologies, assembly design rules, and overall design methodologies. We used YAP to examine the impact of bonding pitch, compare W2W and D2W hybrid bonding for varying chiplet sizes, and explore the benefits of tighter process controls, such as improved particle defect density.**

***Index Terms*—yield modeling, hybrid bonding, wafer-to-wafer (W2W), die-to-wafer (D2W), 3D integration, chiplet, roughness, pad recess, peeling stress, particle defects, overlay, warpage/bow.**

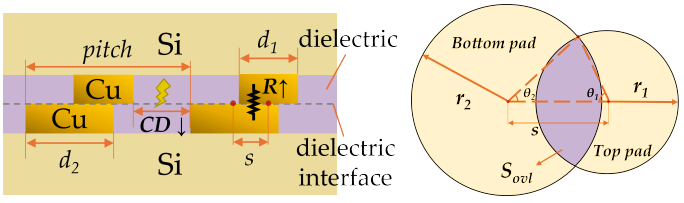
I. Introduction

As we approach the physical and economic limits of scaling in two-dimensional integrated circuits, Three-Dimensional Integrated Circuits (3D-ICs) have emerged as a promising solution to sustain the momentum of Moore's Law. By stacking multiple layers of devices vertically, 3D-ICs offer significant benefits such as reduced interconnect lengths, enhanced performance, lower power consumption, and higher integration density. A pivotal technology that enables 3D-ICs is hybrid bonding (HB) which facilitates reliable fine pitch interconnections, making it highly suitable for high-bandwidth memory, logic-memory integration, and advanced sensor applications [1]–[4]. The two popular HB variants are Wafer-to-wafer (W2W) which allows for a higher alignment accuracy and die-to-wafer (D2W) bonding which allows for better leveraging of pre-tested known-good-die [1].

Accurate, predictive yield modeling for advanced packaging is essential is key to identifying potential failure mechanisms early in the technology development cycle, enabling system-technology co-optimization, and guiding the development of the chiplet interconnect repair strategy [6]. The overall assembly yield model for advanced integration is determined by multiple components, including chiplet yield, hybrid bonding yield, and through-silicon via (TSV) yield. Though full system yield with simplified underlying models has received a lot of attention [7]–[10], models of the yield of hybrid bonding have largely been overly simplistic. [7], [8] propose system-level yield models specific to 3D stacked ICs, However, [7] does not extend its yield model to include the bonding process, and [8] assumes the bonding yield as a constant, which is also done by [10] when building an assembly yield for a chiplet system. None of these studies considers the complex physical failure mechanisms or derives a concrete yield model for the HB process. Such modeling becomes even more important as the industry strives to rapidly scale down the bonding pitches in the next decade.

Failure mechanisms for hybrid bonding are complex which makes analytical modeling of yield challenging. This paper proposes YAP, a physical mechanism-driven near-analytical yield model. To the best of our knowledge, YAP is the first yield model tailored for the HB process, which provides a detailed analysis and modeling framework to predict and optimize bonding yield. The main contributions are summarized as follows:

- To the best of our knowledge, we present the first yield model specifically for the HB process. This model incorporates critical failure mechanisms contributing to yield loss, including overlay errors, particle defects, Cu recess variations, surface roughness of wafers and dies, and excessive Cu density.
- We construct a yield simulator based on the distribution parameters of various failure mechanisms to validate the proposed yield model and assess its predictive accuracy.
- We perform case studies examining various factors that impact yield, compare the yield performance of W2W and D2W HB approaches, and demonstrate the necessary process control for a high yield performance.

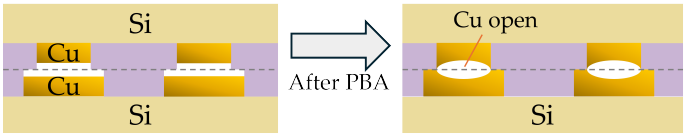


The remainder of the paper is organized as follows: Section II introduces key failure mechanisms of HB processes. Section III proposes modeling methodologies for W2W HB and extends it to D2W HB. Section IV describes the experiment setting, compares the results from the near-analytical model and the simulator, and conducts case studies on critical yield-influencing factors. Finally, Section V concludes the paper and gives suggesting directions for future research.

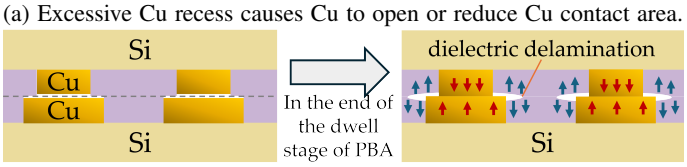
II. Overview of Failure Mechanisms of Hybrid Bonding

This section provides an overview of the primary failure mechanisms in HB processes, including overlay errors, Cu recess variations, and particle defects. Each mechanism contributes to yield loss when bonding parameters are inadequately controlled, and understanding these mechanisms is critical for optimizing the process yield.

A. Overlay Errors



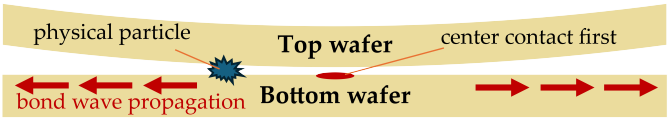
Ensuring the quality of the Cu connection formed during the HB process is critical for the electrical properties of the design. Misalignment of Cu pillars of the top and bottom wafers inevitably exists due to the robot arm calibration error, the warpage induced by thermal stress difference, etc. The misalignment influence on yield loss is increasingly pronounced as we are shrinking the pad size and using the sub-micron pitch [11]. As shown in Fig.1, the excessive misalignment will



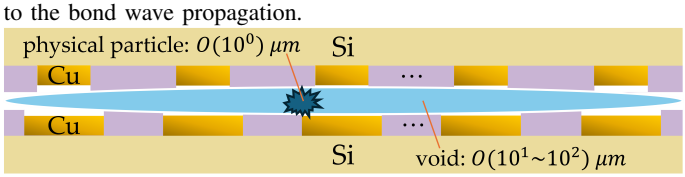
(a) Misalignment leads to resistance increase and dielectric breakdown.

(b) Contact area calculation given the misalignment.

Fig. 1: Failure mechanism of Overlay errors.



(a) Excessive Cu recess causes Cu to open or reduce Cu contact area.



(b) Insufficient Cu recess may cause dielectric delamination, depending on the dielectric bonding strength, Cu density, and annealing temperature, etc.

Fig. 2: Failure mechanism of Cu recess variations.

(a) The presence of particle will form a main void and a void tail due to the bond wave propagation.

(b) Void formation can fail the dielectric and Cu bonding. A particle of a few microns can form a main void of hundreds of microns [38].

Fig. 3: Failure mechanism of particle defects.

decrease the contact area (S_{ovl}) of the Cu interface, hence increasing the contact resistance and triggering electromigration-related defects [12]. Also, the probability of dielectric breakdown will increase due to the reduced critical distance (CD), causing thinner insulating film between the upper and lower pads of adjacent pillars [2]. It is defined as the pitch being p, the pad being circular, and the top and bottom pad diameters being $d_1 = 2r_1$ and $d_2 = 2r_2$. The critical distance between two perfectly aligned Cu pillars is defined as $CD = p - d_2$, i.e., the distance between two neighboring pads. In some designs, the top pad size is set smaller than bottom pad size to increase the misalignment tolerance [28]. Overlay errors are typically classified as pad-level random errors and systematic errors.

B. Cu Recess Variations

The CMP process will result in Cu recess effects, forming a concave shape on the Cu pad surface. As presented in Fig. 2a, excessive Cu recess will decrease the bonding quality or even incur Cu connection failure after post-bond annealing (PBA) [17], [18]. Meanwhile, Cu protrusion and insufficient Cu recess can degrade the yield. Excessive wafer surface roughness decreases the effective contact area of the dielectric during low-temperature bonding, which lowers the density of covalent bonds after PBA, thereby weakening the bonding strength and energy per unit area at the dielectric interface [18]–[20]. In fine-pitch designs, high Cu density and insufficient Cu recess can incur an undesirable peak peeling stress at the dielectric interface at the end of the annealing dwell stage [21]–[24]. As can be seen in Fig. 2b, if the dielectric interface bonding is unable to withstand the peeling stress, dielectric delamination or cracking can occur, leading to bonding failure [25]–[27]. In summary, to achieve a high yield, especially for a chiplet with a large number of Cu pads, a well-controlled Cu recess variation of the top and bottom pad within a range determined by Cu pattern density, surface roughness, etc. is necessary.

C. Particle Defects

The HB process requires high-standard cleanliness to prevent the presence of physical particles, which will incur void formation at the bonding interface [1], [38]. In addition to physical particles, gas condensation during the bonding process can incur edge voids in the wafer bevel region. The outer edge region is usually removed by a sawing process and silicon dies or chips located inward from the wafer edge will not be influenced, therefore, there will be no yield impact [37]. In the defect model, the emphasis is on the yield loss resulting from the particle-induced void formation. As presented in Fig. 3, in the W2W HB process, due to the bond wave propagation, the presence of a particle at the bonding interface will result in a *main void* with a trailing *void tail* extending radially [38].

III. YAP Yield Model

In this section, we introduce our yield modeling methodology for W2W HB and then extend the model to D2W HB. To validate our derived model, we compare the modeling results with the simulation results across 300 parameter sets. The workflow of simulation and model validation is illustrated in Fig. 4. The detailed experiment setting will be discussed in Section. IV.

A. Overlay Model

Our proposed overlay model estimates the yield loss caused by the Cu pad misalignment. We assume the bonding misalignment is normally distributed with zero mean and process-specific σ_1 [13]. Then, the possibility of survival (POS) of one single pad can be calculated as

$$POS_{ovl,pad} = \frac{1}{\sigma_1\sqrt{2\pi}} \int_{-\delta}^{\delta} e^{-\frac{u^2}{2\sigma_1^2}} \mathrm{d}u \tag{1}$$

where u denotes the random overlay error of the top and bottom pad, and δ represents the maximum allowed overlay error to ensure the pad's survival. δ should be determined by the contact area constraints and the critical distance constraints. We assume s as the systematic overlay error of a Cu connection caused by three distortion components: *translation*, *rotation*, and *magnification* [14]. The translation and rotation mainly originate from the equipment precision limitations, and the magnification mainly comes from the wafer warpage/bow induced by thermal expansion mismatch of multiple materials [21]. We define the translation errors as T_x, T_y in x, y directions, respectively, and the rotation error as α. Typically, the warpage of bonded wafers can range from a few micrometers to over 100 μm, which can be optimized to $\sim$10 μm through run-out compensation [16]. Let B represent the warpage of the bonded wafer. It can be observed that the magnification factor E is linearly correlated to B [15], [16]. We can build a linear model to characterize the magnification factor E as

$$E = k_{mag} \cdot B \tag{2}$$

where k_{mag} is the fitting parameter of the model. The parameter is related to the Cu pad depth, Cu area density, bonding process temperature, etc [21]. We model the systematic misalignment $\Delta x, \Delta y$ in x, y directions respectively by

$$\begin{cases} \Delta x(x,y) = T_x - \alpha \cdot y + E \cdot x, \\ \Delta y(x,y) = T_y + \alpha \cdot x + E \cdot y. \end{cases} \tag{3}$$

The systematic overlay error s at the location (x, y) is by

$$s(x,y) = \sqrt{[\Delta x(x,y)]^2 + [\Delta y(x,y)]^2} \tag{4}$$

As Fig. 1b shows, the contact area of two Cu pads is by

$$S_{ovl} = \begin{cases} \pi r_1^2, & s < r_2 - r_1 \\ \theta_1 r_1^2 + \theta_2 r_2^2 - s r_1 \sin\theta_1, & r_2 - r_1 \le s \le r_1 + r_2. \\ 0, & s > r_1 + r_2 \end{cases} \tag{5}$$

If we assume that, to ensure the pad survival, the contact area should exceed k_{ca} times the surface area of the top pad interface, i.e., $S_{ovl} > k_{ca}\pi r_1^2$, and the critical distance CD should be greater than k_{cd} times the ideal critical distance, i.e.,

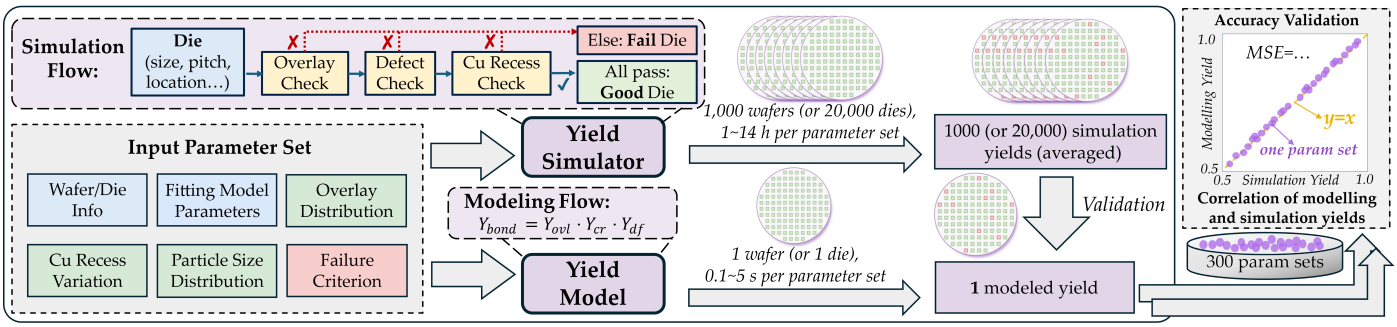


Fig. 4: Simulation workflow and the validation of modeling yield on various input parameter sets.

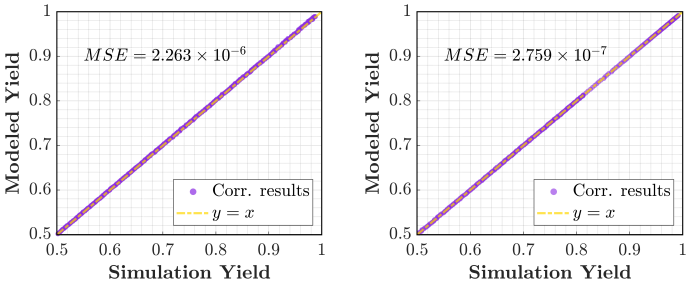
$CD > k_{cd}(p - d_2)$, then δ can be given by

$$\delta = \min \left\{ \frac{\theta_1 r_1^2 + \theta_2 r_2^2 - k_{ca}\pi r_1^2}{r_1 \sin\theta_1}, \right. \\ \left. (1 - k_{cd})p - \frac{1}{2}d_1 + \left(k_{cd} - \frac{1}{2}\right) d_2 \right\} \tag{6}$$

Given above, the POS of a die with N pads is given by

$$POS_{ovl,die} = \frac{1}{\sigma_1\sqrt{2\pi}} \min_{i\in[1,N]} \left\{ \int_{-\delta - s_i}^{\delta - s_i} e^{-\frac{u^2}{2\sigma_1^2}} \mathrm{d}u \right\} \tag{7}$$

where s_i denotes the systematic overlay residue of the i-th pad in one die. Assuming one wafer has M dies, the overlay die yield of the wafer can be calculated as



$$Y_{ovl,W2W} = \frac{1}{M} \sum_{j=1}^{M} POS_{ovl,die,j} \tag{8}$$

We vary input parameters for both the model and simulator, including factors such as translation error, rotation error, warpage, die size, and others. The 300 comparison results (purple points) and the mean squared error (MSE) in Fig. 5a demonstrate that our model aligns closely with the simulation data, confirming its reliability and accuracy.

B. Cu Recess Model

We can assume the pad height after the CMP process is normally distributed according to [28], [30]. Let the dielectric surface be zero reference. The height will be negative for the recessed pad and positive for the protruded pad. It is evident that the sum of the top and bottom pad heights also follows a normal distribution. Let h represent the sum of pad heights of two corresponding pads. The mean value of this distribution is denoted by μ_h, and the variance by σ_h^2. It is noticed that h should be clamped within a range of (ζ_-, ζ_+) so that the Cu bonding failure and dielectric delamination can be avoided. Below the calculation of ζ_- and ζ_+ is discussed.

a) Calculation of ζ_-: Based on the observation in [30]–[32], the height difference due to Cu expansion during annealing is linearly correlated to the annealing temperature. The *lower bound* ζ_- of the total Cu heights required to form a qualified Cu bonding area is determined by the sum of Cu expansion after PBA so that the gap between two pads caused by the recess is adequately filled with Cu.

(a) Overlay model. (b) Cu recess model.

Fig. 5: Correlation results of the overlay model and the Cu recess model with the simulation data for W2W HB.

b) Calculation of ζ_+: The critical condition for delamination is that the sum of heights equals ζ_+. It is noticed that surface roughness will decrease the effective contact area of two surfaces. We use the asperity-based roughness model proposed by [19], [33] to calculate the normalized effective contact area $A_b^*(\sigma_z, R_z, E_d, w)$ given roughness and bonding parameters such as the standard deviation of asperity height σ_z, asperity cap radius R_z, Young's modulus of contact surface material E_d, and fully contact bonding energy w [1]. The maximum tolerable peeling stress σ_{tol} to avoid delamination can be given by

$$\sigma_{tol} = A_b^*(\sigma_z, R_z, E_d, w) \times \sqrt{\frac{2E_d w}{t_d}} \tag{9}$$

where t_d denotes the thickness of the surface material [35]. As the ambient temperature changes during the PBA, the thermal expansion mismatch between metal and dielectric will incur various stresses on the bonding interface [27]. Among different interfaces, dielectric-dielectric (e.g. SiO_2-SiO_2) interface is more inclined to delaminate due to relatively lower bonding strength and higher peeling stress at the end of the annealing dwell stage [22], [25]. For simplification, we use a fitting model to evaluate dielectric interface peeling stress dependence by

$$\sigma_{peel} = k_{peel} \cdot D_{Cu} \cdot (h - h_0) \tag{10}$$

where D_{Cu} denotes the Cu pattern density, h_0, k_{peel} are fitting parameters, and k_{peel} is related to the annealing temperature, pad shape, pad arrangement, pad structure, etc. [22], [23], [27]. To prevent delamination, one should have

$$\sigma_{tol} \geq \sigma_{peel} \Rightarrow h \leq h_{peel} \tag{11}$$

Additionally, given the Cu protrusion after CMP will incur delamination, the *upper bound* of the sum of heights is by

$$\zeta_+ = \min\{0, h_{peel}\} \tag{12}$$

To summarize, the POS of this pad during PBA is given by

$$POS_{cr,pad} = \frac{1}{\sqrt{2\pi\sigma_h^2}} \int_{\zeta_-}^{\zeta_+} e^{-\frac{(h-\mu_h)^2}{2\sigma_h^2}} \mathrm{d}h \tag{13}$$

The die yield, as the POS of a die with N pads with respect to the factor of the Cu recess variations is given by

$$Y_{cr,W2W} = POS_{cr,die} = POS_{cr,pad}^N \tag{14}$$

We vary input parameters of Cu recess, pitch, roughness, etc. to validate the Cu recess model. Fig. 5b presents the correlation of the proposed Cu recess model with the simulation data.

C. Defect Model

The relationship between a particle's properties and void size is complex. Due to the significant discrepancy between theoretical and experimental results, it is more practical to develop a fitting model to predict the void size given the particle information. Additionally, for a particle of a specific size and material, it is shown in [3], [38], that the main void size and the void tail length are linearly correlated with the particle's location and the square root of particle thickness. We model

[1]To model the interaction of two rough surfaces, the surface roughness σ_z and Young's modulus E_d need to be normalized [34].

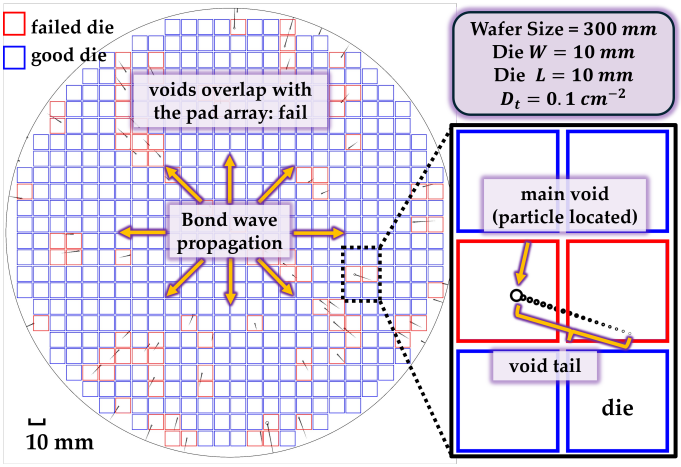


Fig. 6: Visualization of the void formation simulation.

the size r_{mv} of the main void that is located with the distance L $(0 \leq L < R)$ from the wafer center by

$$r_{mv} = (k_r L + k_{r_0}) t^{1/2} \tag{15}$$

where t is the particle thickness. Similarly, the void tail length l can be modeled by

$$l = k_l L t^{1/2} \tag{16}$$

where k_r, k_{r_0}, k_l are fitting parameters. Fig. 6 visualizes the simulation of the void formation, which is similar to the scanning acoustic microscopy images of voids in [38]. Since the average void tail length on the wafer can achieve a few millimeters, more than 10 times the scale of the main void size (a few hundred μm in W2W HB, the defect shape can be reasonably simplified as a line as illustrated in Fig. 7. Additionally, a die is considered to have failed if the void tail overlaps the pad array area, as the void size is typically much larger than the pitch ($\leq$ 10 μm).

We assume the thickness distribution of particle defects as $D(t)$. A typical form of $D(t)$ can be [39]

$$D(t) = D_t \cdot \frac{(z-1) \cdot t_0^{z-1}}{t^z}, \qquad t > t_0 \tag{17}$$

where t_0 is the smallest particle thickness, and D_t is the total number of particles of all thicknesses per unit area on the die. The curve shaping parameter z is typically assumed to be between 2 and 3 [40], [41]. By Eq. 16, 17, the distribution of void tail length is given by

$$f_l(l) = \begin{cases} \dfrac{2D_t(z-1)l}{z k_l^2 R^2 t_0}, & l \leq k_l R t_0^{1/2} \\ \dfrac{2D_t(z-1)(k_l^2 R^2 t_0)^{z-1}}{z l^{2z-1}}, & l > k_l R t_0^{1/2} \end{cases} \tag{18}$$

where R denotes the radius of the wafer. The comparison of the derived $f_l(l)$ and the simulating distribution is shown in Fig. 8a, confirming the formula's accuracy. The critical area calculation method is presented in Fig. 7. The average critical area regarding the line defect with a length l across all directions, i.e., $0 < \phi < 2\pi$, can be given by

$$A(l) = ab + \frac{2}{\pi}(a+b)l \tag{19}$$

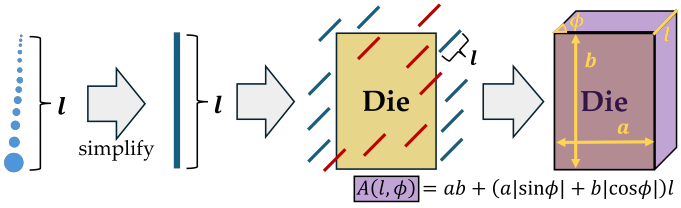
Hence, the average number Λ of particle-induced void tail defects that will fail a die can be given by

$$\Lambda = \int_0^\infty A(l) f_l(l) \mathrm{d}l = D_t ab + \frac{8D_t(z-1)}{3\pi(2z-3)} \cdot (a+b) k_l R t_0^{1/2} \tag{20}$$

Using the Poisson yield model [43], the yield with respect to the particle-induced void formation is given by

$$Y_{df,W2W} = \exp(-\Lambda) \tag{21}$$

We vary input parameters of particle defect density, die size, wafer size, etc. to validate the defect model. Fig. 8b demonstrates the correlation of the defect yield with the simulation results.



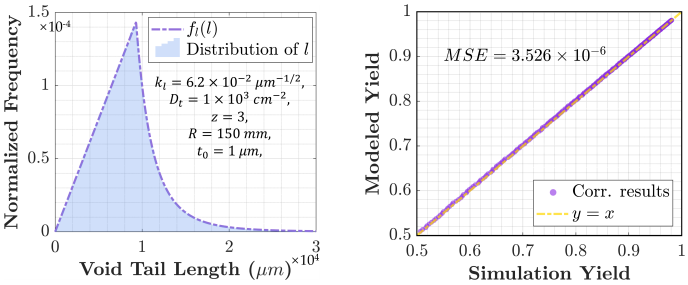


Fig. 7: Critical area calculation. Die size: $a \times b$. Void tail length: l. Void tail direction: ϕ.

(a) Void tail length distribution. (b) Defect model.

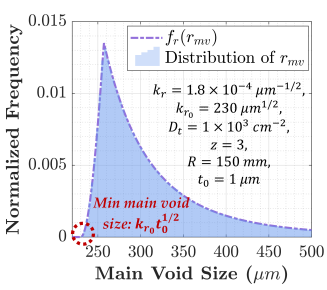
Fig. 8: Correlation results of the void tail length distribution and the defect model with the simulation data for W2W HB.

D. Overall Bonding Yield Model

To develop the overall bonding yield model for W2W hybrid bonding, we assume the overlay error, Cu recess variations, and particle defects have independent impacts on the die yield. By combining the Eq. 8, 14, 21, the assembly yield is

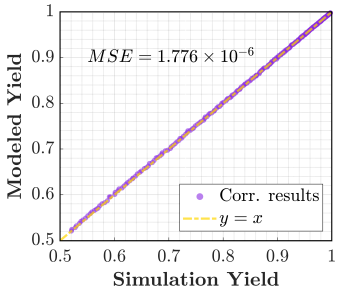
$$Y_{W2W} = Y_{ovl,W2W} \cdot Y_{cr,W2W} \cdot Y_{df,W2W} \tag{22}$$

E. D2W Hybrid Bonding Yield Models



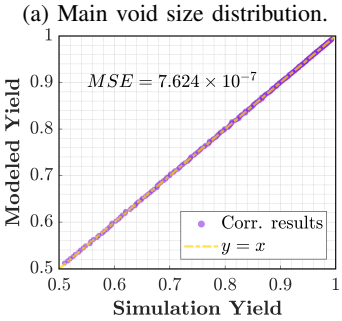
Here we extend the yield model for D2W HB. We assume that the Cu expansion mechanism during PBA in W2W HB remains consistent in the D2W HB case. However, the yield terms regarding the overlay error and particle defects should be revised to account for the differences in bonding approaches.

1) Overlay Model: In D2W hybrid bonding, the systematic overlay error independently happens die-to-die. Given that the die is much smaller than the wafer, the same marker alignment errors at the die edge result in a larger rotation error α and magnification error E than that on average in W2W HB. The overlay yield can be represented by the POS of the die as

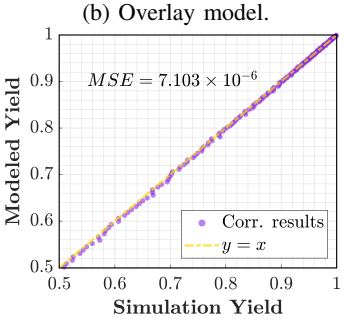


$$Y_{ovl,D2W} = \frac{1}{\sigma_1\sqrt{2\pi}} \min_{i\in[1,N]} \left\{ \int_{-\delta-s_i}^{\delta-s_i} e^{-\frac{u^2}{2\sigma_1^2}} \mathrm{d}u \right\} \tag{23}$$

2) Defect Model: Since the die scale is much smaller than the wafer's, the formation of the void tail is unlikely to occur. Therefore, we only consider the main void-induced failure in the D2W defect model. Combining Eq. 15, 17, the PDF of the main void size r_{mv} can be given by



$$f_r(r_{mv}) = \begin{cases} \dfrac{D_t(z-1)t_0^{z-1}}{k_r^2 R^2} \times [\dfrac{2r_{mv}}{z t_0^z} + \dfrac{2k_{r_0}^{2z}}{z(2z-1)r_{mv}^{2z-1}} \\ - \dfrac{2k_{r_0}}{(z-\frac{1}{2})t_0^{z-\frac{1}{2}}}], \quad k_{r_0} t_0^{1/2} < r < (k_r R + k_{r_0}) t_0^{1/2}, \\ \dfrac{2D_t(z-1)t_0^{z-1}(k_r R + k_{r_0})^{2z-2}}{r_{mv}^{2z-1}} - \\ \dfrac{2D_t(z-1)^2 t_0^{z-1}}{k_r^2 R^2 r_{mv}^{2z-1}} \times [\dfrac{(k_r R + k_{r_0})^{2z} - k_{r_0}^{2z}}{z} \\ - \dfrac{2k_2(k_r R + k_{r_0})^{2z-1} - 2k_{r_0}^{2z}}{z - \frac{1}{2}} + \\ \dfrac{k_{r_0}^2(k_r R + k_{r_0})^{2z-2} - k_{r_0}^{2z}}{z-1}], \quad r \geq (k_r R + k_{r_0}) t_0^{1/2}. \end{cases} \tag{24}$$



(a) Main void size distribution.

(b) Overlay model.

(c) Cu recess model.

(d) Defect model.

Fig. 9: Correlation results of main void size distribution and the yield model with the simulation data for D2W HB.

where R is the effective radius of the die, i.e., $R = (ab/\pi)^{1/2}$, aiming to remain the average number of particles within the die area. The good alignment between $f_r(r_{mv})$ and the simulated distribution is shown in Fig. 9a. To simplify the critical area calculation, we assume the defect and pad shape are square. The side lengths of voids and top pads are defined as $2r_v, 2r_1$, respectively. The critical area of the main void is given by

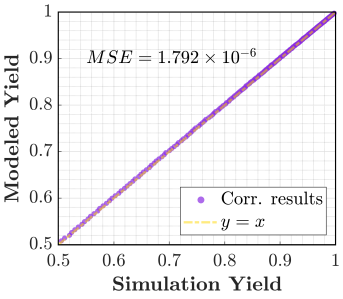
$$A(r_v) = \begin{cases} 4N(r_v + r_1)^2, & 2(r_v + r_1) \le p \\ [a + 2(r_v + r_1)] \cdot [b + 2(r_v + r_1)], & 2(r_v + r_1) > p \end{cases} \tag{25}$$

By Eq. 24, 25, the average number Λ of particle-induced main void defects that will fail a die is given by

$$\Lambda = \int_0^\infty A(r_{mv}) f_r(r_{mv}) \mathrm{d}r_{mv} \tag{26}$$

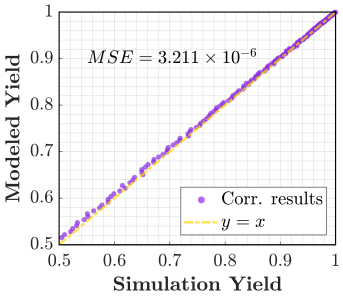
Using the Poisson yield model [43], the yield with respect to the particle-induced void formation for D2W HB is given by

$$Y_{df,D2W} = \exp(-\Lambda) \tag{27}$$



3) Overall Bonding Yield Model: Similarly, we assume the overlay error, Cu recess variations, and particle defects influence the die yield independently for D2W HB. Fig. 9b, 9c, 9d show the correlation results of three yield terms, respectively. By combining Eq. 14, 23, 27, the bonding yield is by

$$Y_{D2W} = Y_{ovl,D2W} \cdot Y_{cr,D2W} \cdot Y_{df,D2W} \tag{28}$$



IV. Experimental Results

To validate the derived model, we developed a simulator focusing on Cu-SiO_2 hybrid bonding process. Table I presents the baseline model parameters, with additional details available in our code. These are the parameter values used in our experiments unless otherwise stated.

Fig. 4 outlines the simulation workflow. Overlay error, Cu recess, and particle data are sampled from their respective distributions. Particles are uniformly distributed across the wafer or die, and the void tails are generated based on the fitting model from [38], simulating bond wave propagation (Fig. 6). A die survives only if Cu pillar misalignment is within the safe range (*Overlay Check*), no void overlaps the Cu contact (*Defect Check*), and no dielectric delamination or Cu connection failure occurs (*Cu Recess Check*). The simulation results are closer to the actual conditions with less approximation compared to the model. However, to obtain an accurate yield prediction, simulation requires 1000 wafer samples (20,000 die samples)

(a) Yield of W2W HB.

(b) Yield of D2W HB.

Fig. 10: Correlation of bonding yield with the simulation.

for W2W (D2W) HB, taking 12.2 hours (0.5 hours) on a single CPU (AMD Ryzen 9 8945HS). In contrast, the yield model achieves virtually identical accuracy shown in Fig. 10 in 0.5 s (0.07 s) for W2W HB, offering over *10,000x runtime improvement* and enabling its usage in yield optimization and pathfinding optimization loops.

Below we discuss a few example case studies using the YAP model indicating its strengths in system-technology co-optimization. We vary particle defect density (0.01 cm^{-2}, 0.1 cm^{-2}), pitch (1 μm, 6 μm), and chiplet sizes (10 mm^2, 50 mm^2, 100 mm^2) in the experiment. The yield breakdown and the overall bonding yield are reported in Fig. 11 (W2W setup) and Fig. 12 (D2W setup).

A. Impact of Particle Defect Density

The HB process demands strict elimination of particles at the bonding interface. Fig. 11, 12 show that for the relaxed bonding pitch (6μm), bonding yield is completely defect-limited. Furthermore, W2W HB is more sensitive to particle contamination due to void tail formation during bond wave propagation, resulting in a larger critical area per die. As can be seen from the results, a 10X improvement in defect density (e.g., by following a more stringent cleanroom standard) ensures near-perfect bonding yield for both W2W and D2W for all chiplet sizes.

TABLE I: Baseline parameters in yield modeling and simulation

Parameter	Value
Pad pitch [27]	6 μm
Bottom, Top pad size [27]	3 μm, 2 μm
Die size [47]	10 mm $\times$ 10 mm
Wafer size	300 mm
Random misalignment [46]	5 nm (10 nm)*
System x,y translation [46]	5 nm (10 nm)*
System rotation [46]	0.1 μrad (0.05 μrad)*
Bonded wafer warpage [16]	10 μm (3 μm)*
System magnification [16]	0.9 ppm (0.07 ppm)*
Particle defect density [47]	0.1 cm^{-2}
Minimum particle thickness [38]	1 μm
Shaping factor (z) in Eq. 17 [40], [41]	3
Bottom/Pad recess [22], [28]	10.0 nm (1.0 nm)*
Roughness (σ_z) [20], [45]	1 nm
Adhesion energy (SiO_2-SiO_2) [18], [25]	1.2 J/m^2
Young's modulus (SiO_2) [22], [27]	73 GPa
Dielectric thickness [44]	1.5 μm
contact area constraint k_{ca} in Eq. 6 [11]	0.75
critical distance constraint k_{cd} in Eq. 6 [2]	0.75
k_{mag} in Eq. 2 [16]	0.09 m^{-1}
k_{peel} in Eq. 10 [22]	6.55$\times$ 10^{15} N·m^{-3}
h_0 in Eq. 10 [22]	75 nm
k_r in Eq. 15 [38]	1.8$\times 10^{-4}$ $\mu m^{-1/2}$
k_{r0} in Eq. 15 [38]	230 $\mu m^{1/2}$
k_l in Eq. 16 [38]	6.2$\times 10^{-2}$ $\mu m^{-1/2}$

Note: Distribution parameters with * are shown in Mean (Std.).

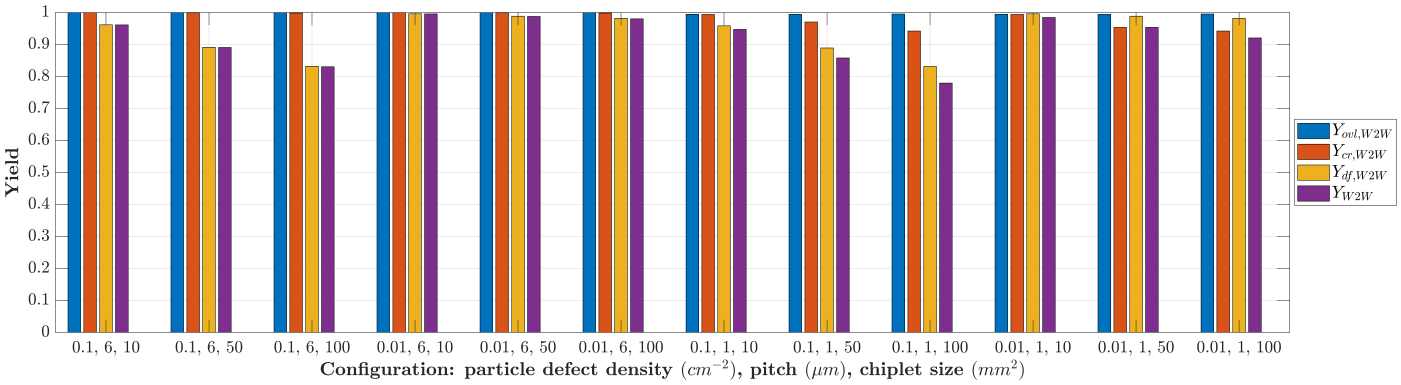


Fig. 11: W2W case studies for various configurations.

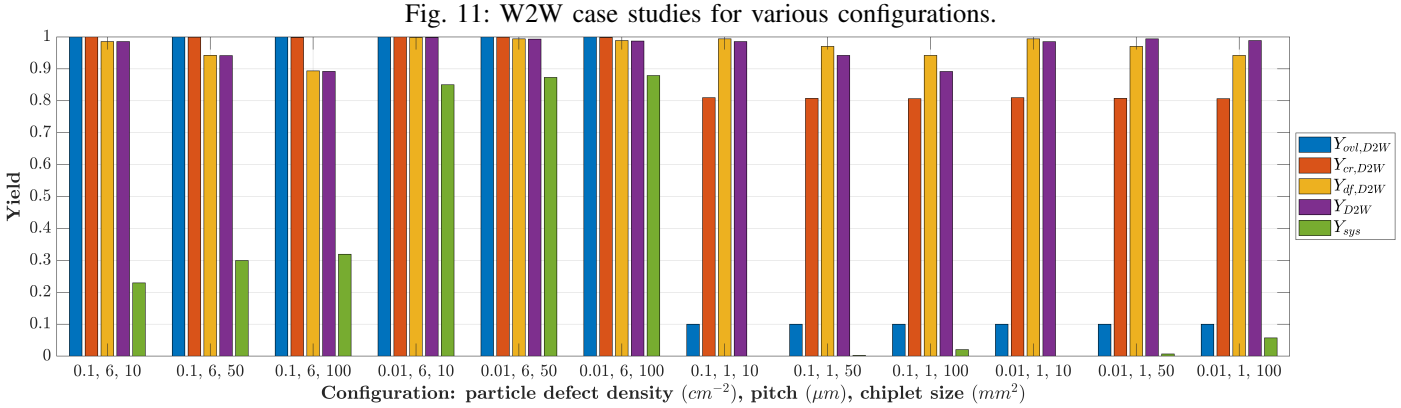

Fig. 12: D2W case studies for various configurations.

B. Impact of Bonding Pitch

In this experiment, the bottom pad size is set to half of the corresponding pitch. As shown in Fig. 11, 12, reducing the pitch from 6 μm to 1 μm leads to a noticeable yield decrease across various chiplet sizes, with the effect being more pronounced in D2W HB. In D2W HB, the primary yield loss stems from increasing overlay errors, as smaller pitches heighten sensitivity to Cu pillar misalignment. For overlay errors, the error α and E resulting from the marker alignment errors scale inversely with the maximum edge distance from the center, which is smaller for a chiplet in D2W HB than for a full wafer. For W2W HB, chiplets closer to the wafer center are more likely to survive, therefore achieving a higher $Y_{ovl,W2W}$. Meanwhile, reducing the pitch significantly increases the number of pads, amplifying the yield's sensitivity to Cu recess variations. For W2W HB increased yield loss is mainly driven by a decrease in Y_{cr} when bonding pitch is decreased. Defect yield, remains largely unaffected, as void size significantly exceeds the pitch, leaving the critical area unchanged.

Another observation is that W2W bonding fares far better than D2W bonding at finer pitches and the difference is even more pronounced at low defect densities. This primarily stems from the ease of high-accuracy alignment for the W2W case.

C. Analyzing Yield Limiters with Varying Chiplet Size

The bonding yield drops with increasing chiplet size for both D2W and W2W bonding, primarily driven by worsened copper recess yield (due to more number of pads per die) and defect yield.

D2W HB can be employed in 2.5D integration to assemble large chiplet systems. Therefore, just looking at a single chiplet yield can be misleading. Though our focus is not full system assembly yield modeling, we add a system yield (Y_{sys} in Fig. 12) calculated simply as $Y_{D2W}^{\#chiplets}$, in absence of any redundancy, for a nominal system size of 1000 mm^2. This approach reflects the cumulative probability of all chiplets bonding successfully in the system. Increasing the chiplet size, which reduces the number of chiplets required for system assembly, helps mitigate the compounding effect of Y_{D2W} losses. Interestingly, even though Y_{D2W} decreases as the chiplet size increases, Y_{sys} remains higher.[2]

V. Conclusion

This work presents YAP: a comprehensive yield modeling framework for W2W and D2W hybrid bonding in advanced packaging. YAP models overlay errors, particle-induced void defects, and Cu recess variations and is validated against a physics-inspired yield simulator[3]. The proposed YAP yield model accurately predicts bonding yield across various chiplet sizes, pitches, and pad configurations and achieves a 10,000-fold speed improvement over direct simulations while maintaining negligibly small mean square error. YAP enables fast system-technology co-optimization. Case studies using it highlight key differences between W2W and D2W HB, offering insights into yield-limiting failure mechanisms motivating future technology development and system architecture choices.

Our future work directions include incorporating YAP into a comprehensive system assembly yield model; extending YAP to model other forms of fine-pitch bonding such as thermal-compression bonding; evaluating some of the approximations made in YAP in the context of ultra-fine pitch bonding processes; and developing fault tolerance and yield improvement techniques leveraging YAP.

Acknowledgement

The authors thank Alexander Graening and Krutikesh Sahoo at UCLA and Nicolas Pantano at IMEC for their inputs during the early stages of the work. This work was supported in part by CHIMES, one of the seven centers in JUMP 2.0, a Semiconductor Research Corporation (SRC) program.

[2]Note that this does not account for any worsened yield of a larger chiplet. A more complete system yield model can be found, for example, in [10] albeit with an oversimplified bonding yield model.

[3]The code of the yield model and simulator is available open-source at `https://github.com/nanocad-lab/YAP`.

SuperCopyback: Revisiting Copyback on Modern High-Performance NAND Flash-based SSDs

Dong Huang, Bo Ding, Wei Tong✉*, Dan Feng*✉
Key Laboratory of Information Storage System, Engineering Research Center for Data System and Technology, Ministry of Education
Wuhan National Laborotory of Optoelectronics, Huazhong University of Science and Technology
{*haltz,boding,tongwei,dfeng*}*@hust.edu.cn,* ✉*Corresponding Authors*

***Abstract*—NAND flash-based SSDs have emerged as a critical storage solution due to their exceptional performance and cost-effectiveness. However, the sequential write limitation of NAND flash blocks necessitates garbage collection (GC) to reclaim space occupied by stale data. Nevertheless, the extensive data migration involved in GC significantly impacts performance and Quality of Service (QoS) of SSDs. To mitigate this issue, copyback has been proposed as a means to accelerate GC by eliminating off-chip data movements. Specifically, copyback reads data into on-plane latches and immidiately re-writes it into another page on the same plane.**

However, in the case of modern high-performance SSDs, copyback is rarely utilized due to the following challenges: (1) Copyback operates at the page-level and thus fails to effectively reclaim invalid data within the context of subpage-level mapping; (2) Copyback eliminates off-chip data movements, preventing data pages from being read out for Redundant Array of Independent NAND (RAIN) parity computation, thereby compromising SSD reliability. In this study, we introduce SuperCopyback as a solution that efficiently addresses these issues for modern SSDs. Firstly, we propose a Multiple-Read-One-Write (MROW) copyback approach through lightweight latch circuit modifications to enable subpage-level copyback implementation; additionally, we propose an orchestrated GC method to effectively utilize MROW copyback. Furthermore, we present a novel copyback-based RAIN scheme that conceals data pages readout latency in write operations and relocates parities to support efficient copyback. The experimental results on both synthetic and real traces demonstrate that SuperCopyback achieves a performance comparable to an ideal scenario where data movement of 4KB takes only 1ns.

***Index Terms*—NAND Flash Memory, Solid State Disk, Copyback.**

I. Introduction

NAND flash-based Solid-State Disks (SSDs) have emerged as the predominant storage medium for many applications due to their significantly superior performance compared to hard disks, primarily attributed to the inherent abundant parallelism [1]–[4]. Typically, an SSD comprises multiple channels, each of which is shared by multiple chips. Each chip consists of multi-planes and multi-plane commands can be used for simultaneous read/write operations on all planes [19]–[23]. Multiple blocks from different chips are organized into a superblock, with pages at identical offsets from these blocks grouped as superpages. The utilization of superpage-based management not only maximizes the exploitation of abundant parallelism and simplifies data management, but also facilitates the cross-chip Redundant Array of Independent NAND (RAIN) stripe organization, which significantly enhances the reliability of SSDs [5]–[8].

Due to the inherent sequential write constraint of flash blocks, Garbage Collection (GC) is essential for reclaiming space occupied by invalid data in order to accommodate incoming writes [9]–[11]. Specifically, GC entails the selection of a candidate block, migration of valid data to another available free block, and subsequent erasure of the candidate block. The performance, endurance, and Quality of Service (QoS) of SSDs are significantly influenced by GC due to its extensive data migration.

Copyback is an effective strategy for accelerating garbage collection (GC) by eliminating off-chip data movements through channels. Specifically, copyback reads data to on-plane data latches (i.e., page register) and then immidiately re-writes it to another page on the same plane. The effectiveness of copybacks have been validated by previous research [9], [10], [12]. This optimization significantly enhances GC performance, particularly in scenarios where a channel is shared by multiple high-performance NAND chips.

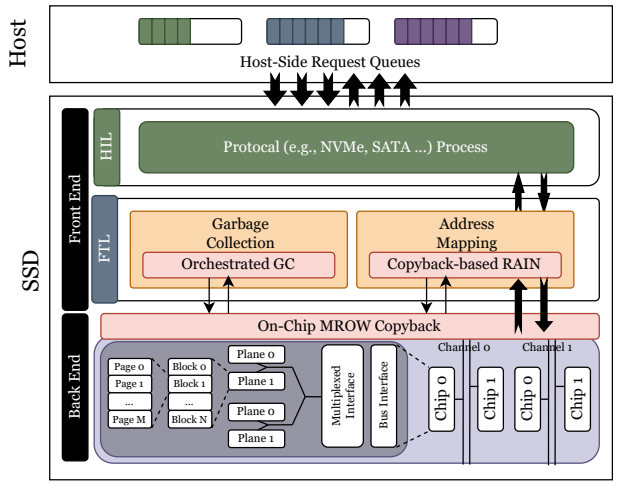

Fig. 1: Overview of SSD Archiecture and SuperCopyback

However, modern SSDs present notable challenges when employing copyback. ***Challenge #1 partial-valid page copyback:*** In the context of modern SSDs, pages typically possess a larger size (e.g., 16KB) compared to the host's I/O granularity of 4KB. To mitigate the resulting write amplification caused by this mismatch, SSDs employ subpage-level mapping, resulting in partial-validity within a page where certain subpages are valid while others remain invalid [13], [14]. As copyback operations occur at the page level, SSDs exclusively programme invalid data or resort to normal GC. ***Challenge #2 Parity Computation:*** Modern SSDs employ RAIN as a means to ensure data reliability in cases where ECC fails to correct errors [15], [16] or die-level failures occur [6], [8], thereby mitigating potential risks. Since the parity write operation requires XOR computation on other data pages in the stripe, the RAIN scheme cannot be used during copyback due to the elimination of off-chip data movements. This dilemma presents a tradeoff between performance and reliability.

In this paper, we propose ***SuperCopyback*** to tackle the challenges. As shown in Figure 1, SuperCopyback includes an efficient subpage-level copyback called ***Multiple-Read-One-Write (MROW) copyback***. MROW copyback is implemented via lightweight hardware modifications (i.e., a few transistors used to act as switches). The core of MROW is that multiple partial-valid pages can be merged into a full-valid page on the chip. We also propose an ***orchestrated GC scheme*** implmented in GC unit to use MROW copyback efficiently. Furthermore, SuperCopyback includes a novel ***copyback-based RAIN scheme*** implemented in address mapping unit. Copyback-based RAIN scheme relocates parities to avoid copyback stalls and hide the data readout latency in write operations. Our experimental results on both synthetic and real traces demonstrate that compared to an SSD with GC using off-chip data movements, SuperCopyback can achieve up to 1.346x throughput (1.263x on average), meanwhile significantly enhancing QoS by reducing 28.4% 99-th percentile latency on average, which is comparable to an ideal

scenario where data movement of 4KB takes only 1ns. In summary, we make the following contributions in this paper:

- We highlight the challenges associated with implementing copyback operations in modern SSDs, including limitations in the context of subpage-level mapping and potential conflicts with RAIN scheme.
- We propose SuperCopyback, which introduces a subpage-level copyback operation called MROW copyback, implemented through lightweight hardware modifications. Additionally, we present an efficient approach for utilizing MROW copybacks. Furthermore, we propose a novel copyback-based RAIN scheme to enable RAIN functionality within the context of MROW copybacks.
- We conducted comprehensive experiments to demonstrate the advantages of SuperCopyback. The experimental results reveal that SuperCopyback increases up to 34.6% throughput and reduces 28.4% 99-th percentile latency on average, compared to an SSD with GC using off-chip data movements.

II. Background

A. SSD Overview

Typically, an SSD is structured into three layers, as depicted in Figure 1 [1], [17]. The front-end encompasses host-interface logic (HIL) and flash translation layer (FTL). HIL receives and responds to requests from the host based on protocols (e.g., NVMe, SATA). FTL operates on a microprocessor and processes I/O requests while sending/receiving flash operations to/from the backend. FTL serves as the core of SSD firmware and is responsible for address mapping, garbage collection, wear leveling, etc. The backend consists of a hierarchically organized NAND flash array with multiple channels which transfer data between the front-end and back-end. Each channel is connected to multiple flash chips, each composed of multiple planes. A plane comprises numerous NAND blocks, with each block containing many pages. Page is the minimum read and program unit while block is the minimum unit of erase. Pages in a block must be sequentially programmed, causing GC problem.

B. GC and Copyback

Due to the sequential programming nature of NAND blocks, FTL typically employs a method of data writes by appending data to the block and recording the page location in a mapping table. Stale data pages are marked as invalid, and to reclaim these pages, FTL performs GC that involves migrating valid data from one superblock (referred to as victim) to another superblock before erasing the victim superblock. A physical page not only carries data but also metadata including Logical Page Address (LPA) and ECC (Error Correction Code) parity. During GC, the controller reads both the data and metadata, corrects errors using ECC parity, allocates a new address to LPA and updates the mapping table; finally, it writes the corrected data into NAND flash memory.

The impact of GC on I/O performance is widely acknowledged [9]–[11], [18], prompting NAND flash vendors to propose the use of copyback as a means to accelerate GC. Copyback involves reading a page to the plane register and immediately re-writing it on the same plane, thereby eliminating off-chip data movement through channels, as shown in Figure 2. While copyback holds significant potential, its current applicability in modern SSDs is limited, as discussed in Section III.

C. Characteristics of Modern NAND Flash-based SSD

Modern high-performance NAND Flash-based SSDs typically exhibit abundant parallelism through the utilization of multiple channels, chips, and planes. In order to fully harness this parallelism, SSDs commonly employ superpage-based data management. This approach involves grouping blocks at identical offsets from each plane to form a superblock, and then further grouping pages at the identical offset from each block to form a superpage. Allocation of pages from superpages is carried out in a round-robin manner. Superpage-based management can maximize the utilization of parallelism while also simplifying data management [5]–[8]. To fully exploit plane-level parallelism, independent multi-plane read is proposed to read multiple pages simultaneously from different offsets on planes [19]–[21]; for writes, buffer-based multi-plane write is proposed [22], [23]. In this paper, these approaches are also used to accelerate SSD performance.

Furthermore, superpage also facilitates the generation of RAIN parity, a technique commonly employed to enhance SSD reliability [6], [8], [24], [25]. Similar to RAID, RAIN organizes data pages into stripes and calculates a parity for each stripe using XOR. In the event of data page corruption due to ECC failure or chip-level failure, RAIN reads all other pages in the stripe and performs an XOR operation to recover the corrupted data page. A single superpage can be divided into one or multiple stripes. As flash block does not allow in-place updates, once generated, the parity is never updated, bringing in minimal overhead. Currently, enterprise-level SSDs typically employ a RAID-5 style RAIN to achieve full read performance [8], [24], [25], which is also used in this paper.

In addition, modern SSDs typically use 16KB pages, representing a fourfold increase from the 4KB pages employed for host I/O requests. This disparity results in significant write amplification and performance degradation. To address this issue, state-of-the-art high-performance SSDs implement subpage-level mapping [13], [14], [26]. Subpages are aggregated in the buffer and subsequently written to NAND memory once they can form a complete physical page. In our study, we adopt 4KB subpages while maintaining physical pages at 16KB.

III. Motivation

Modern solid-state drives (SSDs) commonly employ subpage-level mapping and superpage-based management techniques to optimize performance and ensure reliability. However, incorporating copyback into such SSDs presents unique challenges. In this section, we discuss these challenges and review the existing works.

A. Challenges

As shown in Figure 2, the first challenge arises from the limitation that conventional copyback operations can only be performed at a page level and cannot handle partial-valid pages effectively. While recent advancements like SOML enable reading of subpages across different pages within a plane, they are constrained by block decoder limitations preventing target locations from sharing same block [27]. As a result, these techniques cannot be utilized for GC reads. If invalid subpages are skipped, this would result in accelerated depletion of available storage space, leading to increased write amplification and diminished overall performance and lifespan of SSDs.

Second, as RAIN parity necessitates a XOR operation on all data pages within a cross-chip stripe, the use of copyback inevitably compromises reliability since it eliminates off-chip data transfer. Consequently, a trade-off between performance and reliability arises with the coexistence of either copyback or RAIN.

B. Existing Works

Copyback can accelerates data movement during GC. However, traditional copyback methods are unable to rectify bit errors. To address this issue, FastGC [10] and rcFTL [9] proposed a threshold-based copyback scheme to prevent uncorrectable errors. This strategy is also employed in this paper. The limitations in their design is

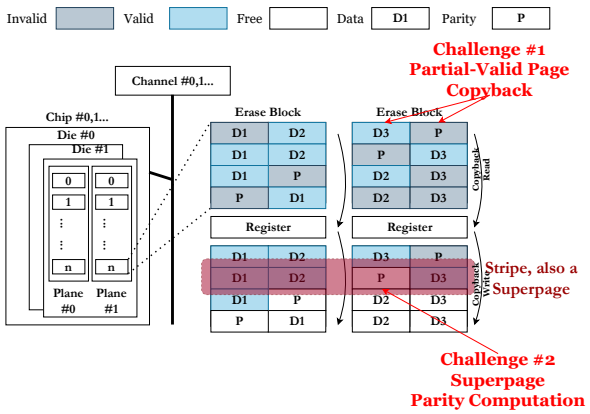

Fig. 2: The challenges in superpage-based SSDs.

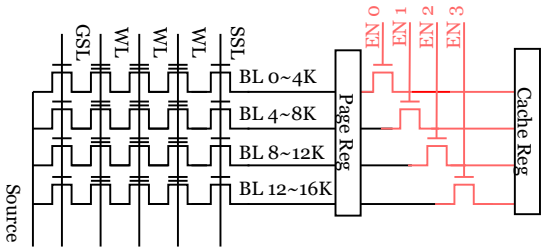
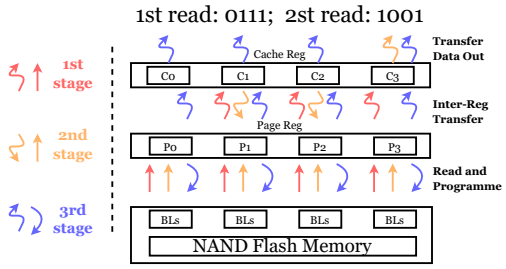
that they are for conventional SSDs without superpage management, subpage-level mapping and RAIN protection, making them inadequate to address the aforementioned challenges. DecoupledSSD [18] interconnects channels to mitigate DRAM bus contention, although it still necessitates off-chip data movements during GC. Other interconnection-based approaches [28], [29] address channel contention by enhancing path diversity but at the expense of substantial architectural and hardware modifications. Besides, these approaches are based on conventional SSDs and therefore cannot effectively address the unique challenges posed by superpage-enabled SSDs. For instance, in superpage-enabled SSDs, garbage collection is executed simultaneously across all chips, which presents a significant challenge for path reservation in the interconnect network. Additionally, due to the absence of an intermediate buffer, the target chip's register must be idle to accept data; otherwise, the source chip can only wait, resulting in a sacrifice of chip-level parallelism. Furthermore, even if a dedicated path is always available, there still exists latency in data transfer through the links. These difficulties make using interconnect network during GC for superpage-enabled SSDs challenging. Hence, we focus on using copyback to accelerate GC from another perspective.

To the best of our knowledge, SuperCopyback represents a pioneering effort in enabling efficient copyback on modern SSDs to mitigate the detrimental impact of off-chip data movements during GC. We believe that this makes SuperCopyback novel and a significant contribution to the field.



IV. Design

A. Overview



SuperCopyback enables efficient copyback on modern SSDs, as shown in Figure 1. First, it implments on-chip MROW copyback by lightweight hardware modifications. MROW copyback supports not only full-valid page copyback but also partial-valid page copyback. Then, an orchestrated GC is implemented in GC unit to exploit MROW copyback to accelerate GC. In the end, to ensure sufficient reliability when using copyback, a copyback-based RAIN scheme is implemented in the address mapping unit, which hides the data readout latency in program operations during MROW copyback and relocates parity pages to avoid copyback stalls.

B. Subpage Copyback

We propose a subpage-level copyback called Multiple-Read-One-Write (MROW) copyback. The core idea of MROW is that it first uses independent multi-plane read to read pages from all planes to the plane registers. Then, MROW performs a second read for each

(a) Subpage-level inter-register transfer.

(b) Steps of a MROW copyback.

Fig. 3: Implementation of MROW copyback.

plane to read another page to replace the invalid subpages in the first read page.

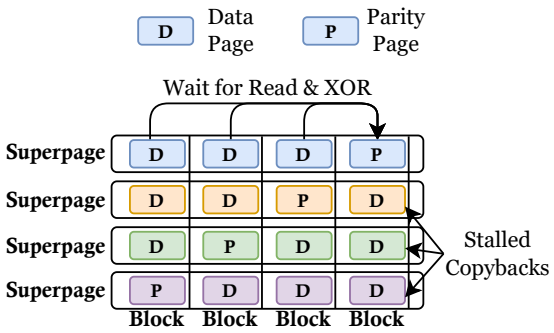
Two-Latches Meachanism: To enable on-chip merge of read data, we implement a lightweight subpage-level inter-register transfer. We exploit the existing two-latches mechanism in flash chip [3], [30]. Conventionally, a bit-line is connected to a data latch; and a data latch is connected to a cache latch. In a read operation, data bits are sensed through bitlines to data latches; and then transferred to cache latch if cache latches are empty. If possible, channel controller transfers data out from cache latches; meanwhile, chip can still read bits into data latches, accelerating reads through a pipelined style. The writes can also be accelerated in a similar style.

Subpage-level Inter-Register Transfer: To implement subpage-level inter-register transfer, we divide the bitlines, data latches and cache latches in a plane into multiple groups at subpage granularity, as shown in Figure 3a. For each group, we add a transistor and connect it to the *EN* inputs of all cache latches. Then, for target groups, we enable the transistor so the cache latches can store bits from data latches; for other groups, we disable the transistor so the corresponding cache latches can hold the original bits. Similarly, another four transistors can be connected to data latches to enable a symmetric cache-to-data subpage-level inter-register transfer. Since a latch typically only takes a few cycles to store a bit, the latency overhead is negligible. With subpage-level inter-register data transfer, we can read two partial-valid pages, merge the valid subpages into one full-valid page and programme it into NAND cells. If two pages have valid subpages at the same offset (we call it conflict subpages), we read out the one in the first read and write it as the normal GC such as the read out latency can be hided by the second read. MROW can also support full-valid page read by eliminating the first read.

Metadata Readout: To update the mapping table, the metadata of pages must be transferred out. Fortunately, we observe that page program latency is significantly higher than the data transfer latency. Hence, hiding data transfer latency during program operations is possible. Specifically, the chip awaits for the end of reads in copyback

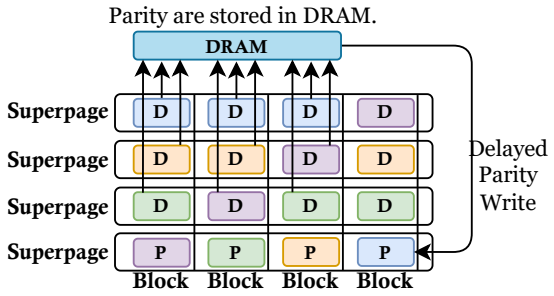
(two reads for partial-valid pages or one read for full-valid pages) and the end of conflict subpages readout (see the example below for details); then, the controller sends copyback write command to the chip; simultaneously, the chip informs the controller that the data on cache register is ready for readout.

Command Support: The existing copyback commands can be leveraged to support the MROW copyback by adding four bits to each plane address in the command. These bits are used to indicate the validity of subpages. Hence, the inter-register transfer can be properly enabled to implement MROW copyback.



Illustrative Example: Figure 3b illustrates an example, where a page has four subpages. Assume the first read page has three valid subpages (the last three ones, tagged as 0111) and the second read page has two valid subpages (the first and last one, tagged as 1001). The page register and cache register are divided into four groups (P0 P4, C0 C4). In the first stage, the controller sends the first copyback read command to read the first page into page register same as a normal read operation; when read ends, the last three valid subpages are transferred from page register (P1-P3) to cache register (C1-C3). In the second stage, the controller sends the second copyback read command and readout data from C3 if possible. Once read operation ends, valid data are transferred from C1, C2 to P1, P2 to form a full-valid page. In the third stage, all data are copied from page register to cache register; then the data in page register are programmed into NAND cells and the data in cache register are transferred out when channel becomes idle. Notice that for a full-valid page, the first read is eliminated and MROW can be simplified by starting from the second stage.

C. Orchestrated GC Based on Subpage Copyback



We employ a greedy algorithm to orchestrate copybacks in GC, aiming for the fewest readouts in the second stage. It is important to note that the copyback write operation must wait for the completion of readouts in the second stage. Given that read latency is comparable to data transfer latency, it is not always possible for read operations to effectively conceal data transfer latency. This motivates us to seek ways to minimize readout occurrences in the second stage of MROW copyback.

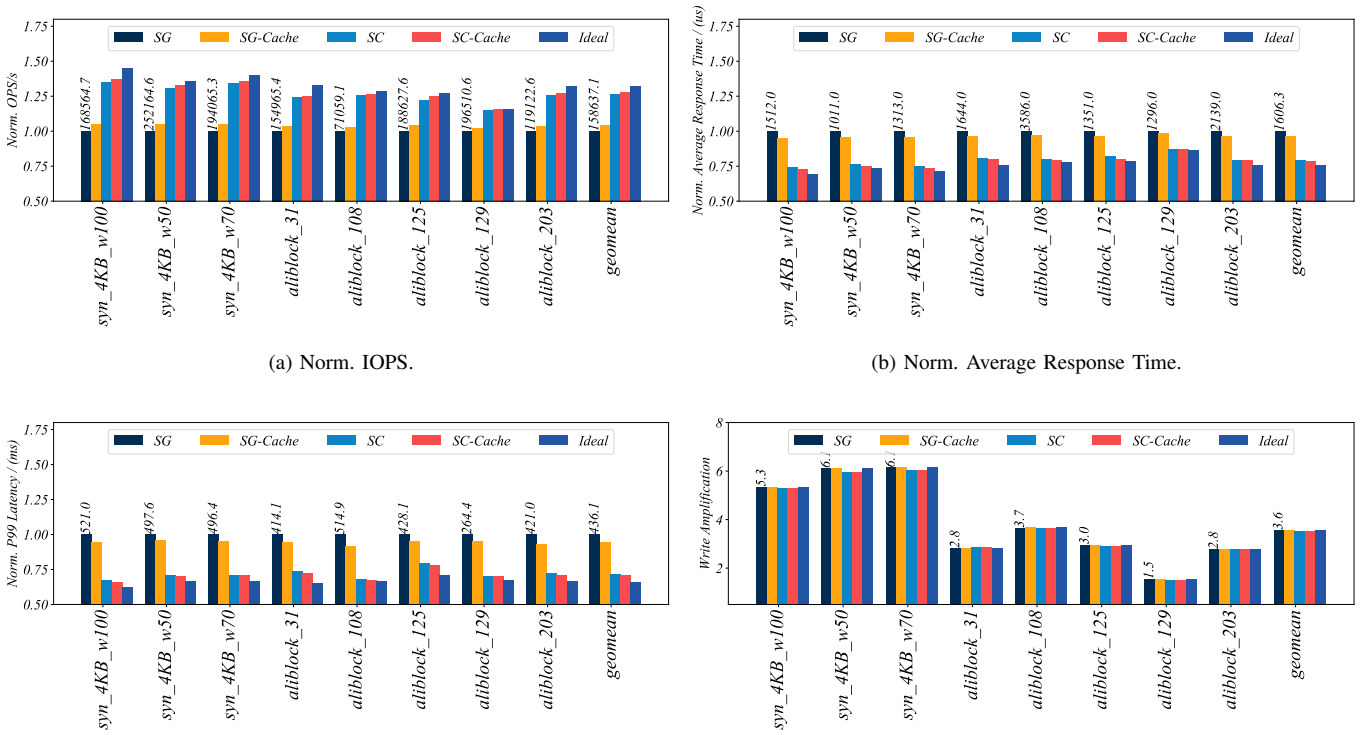
In order to adhere to the maximum number of successive copybacks, we record the executed copyback counts as page metadata and implement a threshold-based copyback scheme, similar to previous studies. Put simply, if the copyback counts exceed the pre-defined threshold, the subpage is migrated via conventional GC. Additionally, we use one bit in DRAM to record the copyback feasibility of each subpage (1 indicating that this subpage can be migrated through copyback), allowing for indication of the subpages' copyback feasibility in a page with a 4-bits bitmap. As the copyback count metadata is read during GC, the copyback feasibility bit can be updated by comparing it with the copyback counts against the threshold. Prior to performing GC, all valid pages of a plane are grouped into 16 lists corresponding to various 4-bits bitmap values.

For the target chip, we select either one full-valid page or two partial-valid pages on each plane to execute MROW copybacks. To begin, we iterate through the list starting with a bitmap value of *1111* (representing full-valid pages in copyback). If this is not feasible, we search for viable matches from the list *0001* to *1110*. Specifically, for a list with a bitmap of *abcd*, we can identify its corresponding optimal matches (i.e., no readout required in the second stage) within the list *1111-abcd*. In case the list *1111-abcd* is empty, we explore other lists with complementary bitmaps *a'b'c'd'* (i.e., where *a'b'c'd' or abcd = 1111*). If such a match cannot be found, normal GC procedures are employed as fallback.

(a) Conventional RAIN layout based on RAID-5.

(b) Copyback-based RAIN layout.

Fig. 4: Comparison between conventional RAIN and copyback-based RAIN.



In addition, to maintain superpage management after GC operations, we impose an upper limit on the maximum number of copybacks per chip, which is $\frac{N_{validsubpages}}{Size_{superpage}}$. Once this limit is reached, GC on that chip reverts back to normal mode. Such a limit can also prevent potential delays in GC due to an imbalance in the distribution of valid subpages across different chips. While rare, this scenario remains a possibility and warrants consideration.

The subpage in the second read, if valid but not feasible for copyback, may overwrite the corresponding subpage in the first read designated for copyback. To prevent such exceptional cases, we ensure that the copyback feasibility bitmap matches the validity bitmap (i.e., all valid subpages in the second read are feasible for copyback). Additionally, in order to fully exploit plane-level parallelism through multi-plane operations, if no feasible match is identified on any plane, the corresponding chip also reverts to normal GC. It is worth noting that independent multi-plane read, a prevalent technique in modern NAND chips [19], [20], [31], is used to eliminate the identical page offset requirement in a multi-plane read. This enables full utilization of plane-level parallelism during copyback reads and eliminates the need to align read pages on all planes during MROW copyback. Multi-plane program during copyback is also used as conventional superpage-enabled SSDs.

D. Parity Computation and Storage

In this section, we elaborate on the implementation of efficient RAIN schemem in copyback-based GC.

The computation of parity, which involves XOR computation on all data pages in the stripe, necessitates the controller to read both metadata and data during copybacks. We can observe that the latency associated with these transfers is considerably lower than

(a) Norm. IOPS.

(b) Norm. Average Response Time.

(c) Norm. 99-th Percentile Latency.

(d) Write Amplification.

Fig. 5: Performance Comparison between Different SSDs. The results are normalized to SG.

program latency. To mitigate the impact of data transfer overhead, we strategically execute it during write operations. For a 1.6GB/s channel, transferring 64KB data consumes 40μs while program latency typically is higher than 300μs even for modern high-performance flash chips. Hence, we can effectively conceal this transfer latency by performing data transfers concurrently with program operations. As illustrated in Figure 3b, during the 3rd stage of MROW copyback, not only do we transfer page metadata but also the entire page data.

Furthermore, we propose an optimized RAIN layout to mitigate copyback stalls. In the conventional RAID-5 based RAIN layout, both data and parity are stored within the same superpage (refer to Figure 4 where different colors mean different stripes). However, during GC, the process of writing parity is delayed due to the necessity of reading and computing other data pages using XOR operation in the stripe. The subsequent data copyback are stalled since NAND blocks allow only sequential page writes. To address this challenge, our proposed approach relocates all parity pages to the end of NAND blocks.

As depicted in Figure 4, similar to conventional SSDs, data pages are read into DRAM and controller uses XOR to compute parity. However, instead of immediately writing the parity, we temporarily store it in DRAM until all data pages have been written. This strategy ensures that copybacks are not stalled by parity writes, enabling uninterrupted high-speed copyback operations. Notice that RAIN layout remains fixed, which means that once a page is corrupted, the controller can find other pages in its stripe based on the pre-defined layout. Besides, the parity page still resides in the same plane as original (i.e., only its page offset is changed). This eliminates needs for additional mapping and ensures recovery from page-level or chip-level failures as fast as original RAIN scheme.

E. Overhead

The SuperCopyback technique introduces a acceptable overhead. In the case of MROW, this overhead primarily arises from the modifications made to the control circuits of the data and cache latches, involving only a few transistors as a switch. Considering that each plane register comprises hundreds of thousands of data/cache latches, each composed of tens of transistors, the additional overhead is negligible.

In the case of orchestrated garbage collection (GC), the primary source of overhead arises from the DRAM utilization for an additional copyback feasibility bitmap. Considering that each subpage (4KB in this study) only requires one bit, the total memory overhead for a 1-TB SSD amounts to 32MB. It is worth noting that this bitmap can be stored at the end of the superblock and loaded into DRAM when this particular superblock is chosen as the victim for GC, similar to how a bitmap indicating page validity is stored in usual SSDs [13]. Consequently, if implemented in such a manner, the memory overhead becomes negligible (e.g., 64KB for a 2GB superblock). The main overhead of the proposed RAIN scheme arises from the buffer used for temporarily storing delayed parity writes. In our configuration, the memory overhead amounts to 64 MB ($\frac{2GB(superblocksize)}{32(stripesize)}$). For larger stripes, the memory consumption is reduced.

Typically, a 1-TB high-performance SSD (especially enterprise-level SSD) contains more than 1-GB DRAM, making the overall DRAM overhead acceptable from our perspective. It is worth noting that the consumed DRAM can also be substituted with cost-effective memory options such as PCM and SLC NAND or host memory through HMB technology to enhance cost-effectiveness. This substitution does not impact performance since PCM or SLC NAND still offer significantly faster speeds compared to TLC NAND, and parity/bitmap writes only constitute a minimal proportion of total I/O.

TABLE I: SSD Parameters

# of channels	4	# of chips	8
# of blocks	based on trace footprint	# of planes	4
RAIN Stripe	32	# of pages	1024
Channel BW	1.6GB/s	Page/Subpage Size	16KB/4KB
Read Latency	45 μs	Program Latency	320 μs
Block Erase Latency	3 ms	Over-Provision	15%

TABLE II: Workload Statistics

Trace	Requests	Average Size(KB)	Read Ratio (%)	Footprint (GB)
syn_4KB_w100	13107200	4	0	128
syn_4KB_w70	13107200	4	30	128
syn_4KB_w50	13107200	4	50	128
aliblock_31	3959045	9.22	0.29	54.6
aliblock_108	3249302	24.37	47.21	39.8
aliblock_125	8980886	9.21	19.07	58.2
aliblock_129	4285829	16.11	21.69	99.9
aliblock_203	4722134	12.40	2.25	30.4

In addition, in the event of a power failure, the bitmaps and parity can be reloaded or recomputed, eliminating the need for capacitors or batteries in DRAM to ensure persistence.

V. Evalution

A. Experimental Environment

We use MQSim, which is a widely-used simulator [17], to model a high-performance TLC SSDs. The detailed configuration of the SSD is listed as Table I. SSD performs GC when there is only one free superblock. We adjust the device capacity based on the footprint of each trace to avoid too large over-provison space. We extend MQSim to support subpage-level mapping and RAID-5 based RAIN scheme. We compare the following schemes: (1) SG, a superpage-based SSD using normal GC. (2) SG-Cache, an SG SSD with cache read/program using on-chip cache latches, (3) SC, an SSD using SuperCopyback that the maximum number of successive copybacks is 8 for GC, (4) SC-Cache, SC SSD with cache read/write for non-copyback IO, (4) Ideal, an SSD same as SG-Cache but its 4KiB data transfer overhead during GC is 1ns, which is used to emulate the ideal scenario.

We select both synthetic and real traces to evaluate the performance benefits. The synthetic traces are generated 4KiB uniform random workloads with different write ratios (50%, 70%, 100%) with 50GB size in total on a 128GB SSD. The real traces are widely-used block traces from Alibaba Cloud [32]. The characteristics of trace are listed as Table II. We ignore the I/O timestamps to make traces intensive. To avoid too much over-provision space, we adjust the device capacity based on trace foorptints.

B. Performance

In this section, we assess the performance advantages of SuperCopyback in terms of throughput, average response time, tail latency at the 99th percentile and write amplification (Figure 5). The following observations can be made. Firstly, in comparison to SG, SC achieves a maximum of 1.346x (34.6%) higher IOPS with an average improvement of 1.263x (26.3%); it reduces the average response time by up to 25.7% with an average reduction of 20.9%; and it decreases p99 latency by up to 32.8% with an average decrease of 28.4%. These results demonstrate that SuperCopyback not only significantly enhances throughput but also improves the QoS for SSDs. Furthermore, in comparison to SG-Cache, SC-Cache also demonstrates comparable performance benefits; similarly, when compared to SC, SC-Cache exhibits marginal performance advantages. This implies that

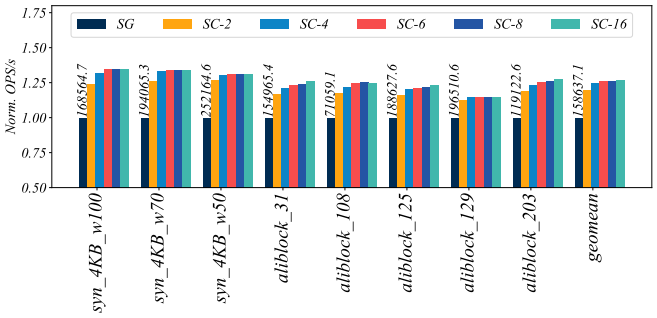


Fig. 6: The Impact of Copyback Threshold.

SuperCopyback can still derive advantages from cache read/write operations during the execution of user I/O requests; however, compared to cache read/write activities, SuperCopyback significantly enhances GC performance. Moreover, the SC-Cache achieves a performance close to Ideal (96.9% IOPS of Ideal), indicating that SuperCopyback effectively and efficiently mitigates the detrimental effect associated with data movements during GC. In the end, the write amplification of all schemes are nearly identical, indicating that SuperCopyback does not exert any adverse impact on the endurance of the SSD; the performance benefits of SuperCopyback also exhibit a positive correlation with write amplification, as higher write amplification leads to more severe GC and consequently increased data movements, thereby exacerbating its detrimental effects.

C. The Impact of Copyback Threshold

In this section, we assess the impact of varying copyback thresholds (i.e., the maximum number of consecutive copybacks for a subpage before ECC becomes unable to correct errors) on system performance. We explore copyback thresholds ranging from 2 to 16 (SC-2 to SC-16), and present the corresponding experimental results in Figure 6. The experimental results demonstrate that even with a copyback threshold of 2, SuperCopyback still exhibits significant performance benefits (1.198x IOPS). Furthermore, as the copyback threshold increases, the performance advantages of SuperCopyback also increase. When the copyback threshold reaches 6, SC achieves comparable performance to that obtained under higher copyback thresholds. This implies that in order to fully exploit SuperCopyback, it is only necessary for the ECC to ensure that at least 6 copybacks can be performed before ECC failures occur. We believe this is possible according to the results in prior works [9], [10].

VI. Conclusion

In this study, we propose SuperCopyback to mitigate the adverse impacts of off-chip data movements. SuperCopyback implements MROW copyback to support subpage-level copyback via lightweight hardware modifications; in addition, an orchestrated GC scheme is proposed to exploit MROW copyback. Furthermore, a copyback-based RAIN scheme is introduced to support efficient copyback, achieving both high reliability provided by RAIN and high performance provided by copyback. The experimental results on both real and synthetic traces demonstrate that SuperCopyback can significantly enhance the performance of modern SSDs.

***Abstract*—While Last-Level Cache (LLC) side-channel attacks often target inclusive caches, directory-based attacks on non-inclusive caches have been demonstrated on Intel and ARM processors. However, the vulnerability of AMD's non-inclusive caches to such attacks has remained uncertain, primarily due to challenges in reverse-engineering cache addressing, constructing eviction sets, and evicting private cache lines.**

This paper addresses these challenges and demonstrates the feasibility of conducting LLC side-channel attacks on AMD's non-inclusive caches. We first reverse-engineer the cache addressing functions for the L2 set index, L3 slice, and L3 set index. Leveraging this insight, we construct the first eviction sets on AMD processors. We then introduce the first LLC side-channel attack on AMD's Zen series CPUs. The effectiveness of our approach is validated by attacking OpenSSL's AES T-table.

I. Introduction

Encryption is essential for data confidentiality, but side-channel attacks exploit physical characteristics of cryptographic implementations—such as execution time [1]–[3] and power consumption [4]—to extract secret information like cryptographic keys. These attacks leverage subtle hardware implementation details without software vulnerabilities.

The LLC has become a key target for side-channel exploits, with the Prime+Probe attack [1] being particularly notable. This method is especially concerning because it does not require the attacker to share a core or memory with the victim, lowering prerequisites and increasing the likelihood of success.

Prime+Probe attacks have traditionally targeted Intel's inclusive LLCs. Techniques for inclusive caches are not directly applicable to non-inclusive caches. In non-inclusive caches, evicting data from L3 does not necessarily evict corresponding data from L1 and L2, reducing attack effectiveness. Specifically, an attacker on one core cannot evict data from another core's private cache (Figure 1).

It has been demonstrated that in non-inclusive cache architectures, Intel's directory structure can be exploited to conduct conflict-based cache attacks on the LLC [5]. This approach enabled the first cross-core Prime+Probe attack on non-inclusive caches by exploiting the shared directory (Figure 2).

In contrast, this method is ineffective on AMD's non-inclusive cache architecture due to fundamental differences in directory structures. Intel uses a shared, capacity-constrained directory across all cores, whereas AMD assigns a core-partitioned shadow tag [6] in the L3 cache for each L2 cache entry. Consequently, AMD's cache directories prevent attackers from inferring a victim's cache activities through a shared directory.

To date, no LLC-based cache attacks without shared resources have been successfully carried out against AMD's non-inclusive caches. This raises a critical research question:

> **Research Question**: Is AMD's non-inclusive cache architecture inherently secure and immune to last-level cache side-channel attacks?

Challenge: Addressing this question involves three key challenges. *First*, AMD's cache addressing structure is undocumented, complicating the mapping of memory addresses to specific cache sets and slices. *Second*, no methods exist for constructing eviction sets on AMD's non-inclusive caches, which are essential for cache side-channel attacks. *Third*, cache lines cannot be evicted from private caches on other cores, limiting cross-core attacks.

Experiment Setup: All experiments were conducted on an AMD Ryzen 9 5900X (Zen 3). Starting with the Zen series, AMD has employed non-inclusive caches [7]. While addressing functions may vary between CPUs, the overall cache structure remains consistent, allowing our reverse engineering and attack methods to be adapted across the AMD Zen lineup.

Contribution: Our contributions are threefold. *First*, we comprehensively reverse-engineer the cache addressing functions for the L2 set index, L3 slice, and L3 set index on AMD's Zen series processors, revealing how physical addresses map to cache sets. Our methods are architecture-independent and not limited to AMD CPUs. *Second*, building on this reverse engineering, we propose the first effective algorithm for constructing eviction sets on AMD processors. *Third*, we introduce a method for cross-core eviction of private cache lines, enabling LLC side-channel attacks on

AMD's non-inclusive caches. We successfully demonstrate this approach by attacking OpenSSL's AES T-table, revealing potential vulnerabilities in these systems.

Disclosure: We have responsibly disclosed our findings to the AMD PSIRT team. AMD has acknowledged our work.

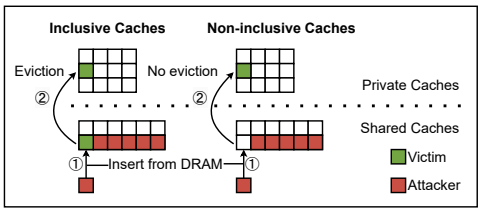

Fig. 1: Eviction attempts in (non-)inclusive cache architectures. In inclusive caches, inserting a new cache line into the LLC (step ①) evicts the corresponding line from the private cache (step ②). In non-inclusive caches, the victim cache line remains in the private cache despite the attacker's insertion.

II. Background and Related Work

LLC Side-Channel Attacks: Prime+Probe [1] introduced the concept of performing cache attacks on the LLC without shared memory. An attacker first fills specific cache sets with their data (prime) and then measures access latencies after the victim's execution (probe) to reveal memory access patterns. This method applies only to inclusive caches. Yan et al. [5] conducted directory-based attacks on Intel non-inclusive caches by targeting the Extended Directory (ED). By constructing eviction sets mapped to the same cache slice and the ED set, they force the victim's cache line from the private cache to the shared LLC, allowing detection of victim accesses through increased latencies. A similar attack has been performed on ARM processors [8]. Evict+Spec+Time [9] targets speculative attacks on Intel and AMD processors but replaces evict with the flush instruction in their implementation. This changes the threat model, as flush requires shared memory between attacker and victim, unlike eviction. On non-inclusive caches, flush and evict differ fundamentally, as eviction involves constructing sets and removing private cache lines—issues not fully explored in prior work.

Hardware Defenses Hardware approaches such as cache randomization [10] and partitioning [11] have not yet been widely adopted in commercial processors, leaving systems vulnerable to cache side-channel attacks. AMD has recommended software-based mitigation strategies. However, achieving universal and efficient protection remains challenging. Applying these techniques [12], [13] to arbitrary software is inherently complex and imposes a substantial burden on developers to safeguard sensitive data across diverse microarchitectures.

Reverse Engineering of Cache Addressing Functions: Initial efforts to reverse-engineer Intel LLC slice functions were presented in prior work [14], [15]. Specifically, two methods were proposed [15]: one utilizing the Performance Monitoring Unit (PMU) and another using latencies of the flush instruction. Subsequent research reverse-engineered the L2 set index of the Apple M1 processor using an eviction set [16]. An automated method for reverse-engineering nonlinear functions was also introduced in later studies [17]. However, these approaches have limitations when applied to AMD's non-inclusive caches, as discussed in Section III.

Construction of Eviction Sets: In inclusive caches, addresses are iteratively removed from a set, and if removing one stops evicting the target address, it is part of the eviction set [1]. Several improvements [18]–[20] have accelerated this pruning process. Various algorithms [5], [21] have also been proposed for Intel's non-inclusive caches; however, due to a lack of understanding of AMD's cache addressing, these algorithms have not been implemented on AMD processors. Specific details are discussed in Section IV.

III. Reverse Engineering

In this section, we address the first challenge: reverse engineering the cache addressing structure of AMD processors.

A. Cache Slicing

Two methods for reverse-engineering cache slicing on Intel CPUs were proposed: one based on Performance Monitoring Units (PMUs) and another on timing measurements of the flush instruction [15]. However, the PMU-based method is not applicable on AMD platforms due to the lack of relevant PMUs (e.g., LLC_LOOKUP events).

The principle of the timing-based method is that performing a flush operation on the slice closest to the core typically takes the least time. We found that this method cannot be directly applied to AMD CPUs because the time differences for flush operations across different slices are insufficient to provide conclusive results, as demonstrated in previous research [17]. We conducted a detailed analysis to understand the underlying reasons and subsequently enhanced the method.

Our analysis revealed that the execution time of the first 1,500 flush operations on each core is relatively short, but time increases significantly afterward (Figure 3). If we follow the original algorithm and frequently switch cores, the flush operations remain within the shorter time range, leading to insufficient differentiation between slices.

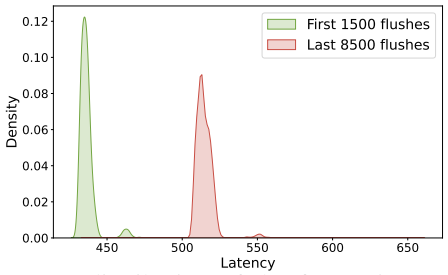

Fig. 3: Latency distribution of the first 1,500 and last 8,500 flushes on AMD cores.

To address this issue, we modified the algorithm to incorporate a warm-up phase and complete all address tests on each core before switching. This adjustment improves the reliability of the results. Although Gerlach et al. [17] proposed an eviction-based method to collect data on AMD CPU, it

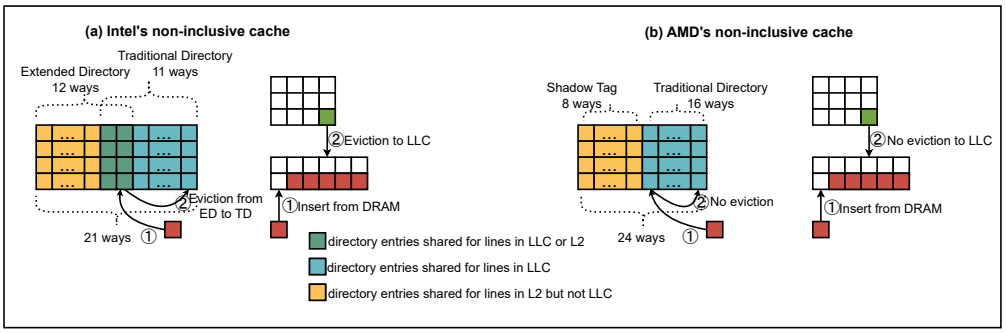

Fig. 2: Intel and AMD use distinct directory structures for non-inclusive caches. (a) Intel's shared directory allows LLC eviction through directory conflicts. (b) AMD's per-L2-line shadow tags prevent LLC eviction through the directory.

requires 23 hours to gather sufficient data for analyzing the slice-addressing hash function, whereas our method requires only 30 minutes.

On the Ryzen 9 5900X processor, we faced a unique challenge: the processor has six physical cores but eight cache slices in one CCX (CPU Complex). During our timing measurements, we observed that if a core flushes an address and the time is the shortest, we increment a count corresponding to that core-slice mapping. For certain addresses, we noticed that the counts between two cores were approximately equal, indicating that these addresses correspond to the extra two slices, as they do not uniquely map to a single core.

With the mapping between addresses and slice indexes established, we iterated through memory addresses, flipping the i-th bit (starting from bit 6, as bits 0–5 correspond to the cache line offset) in each address (`addr1`) to generate a new address (`addr2`). By comparing their index bits, we incremented the corresponding position in the count matrix if a difference was detected. This process tracks how flipped address bits affect index bits, revealing their relationship, as shown in Table I.

The threshold is calculated as:

$$\text{Threshold} = \left\lfloor \frac{N_{\text{addr}}}{2^B} \right\rfloor$$

where N_{addr} is the total number of addresses, and B denotes the number of address bits involved in hashing. This threshold determines whether a specific address bit contributes to the hash computation. The same formula is used to determine the involvement of address bits in Section III-B and III-C.

TABLE I: Correspondence between physical address bits and slice value bits.

Slice Bit	b6	b7	b8	b9	b10	b11	b12
0	23162	0	0	0	0	0	0
1	7216	11412	22290	6	8	13	10
2	11234	22448	97	7	14	19	16

Analyzing the count matrix, we derived the corresponding hash function. Previous studies [8], [15], [17] indicate that cache-addressing hash functions predominantly use XOR operations, so we focused exclusively on XOR-based functions in the analysis. Unlike previous work using an AMD Ryzen 9 5900HX [17], we found no bits involved in CCX selection on the Ryzen 9 5900X.

The specific hash function is as follows:

$$\{s_2, s_1, s_0\} = \{b_6 \wedge b_7,\ b_6 \wedge b_7 \wedge b_8,\ b_6\}$$

B. L2 Index Addressing

It is commonly assumed that cache set index bits correspond to the base-2 logarithm ($\log_2$) of the number of sets, as in Intel processors [5]. However, we found that on AMD processors, L2 and L3 cache indexing may involve the most significant bits (MSBs) of the address, contrary to this assumption.

This prompted us to investigate which bits contribute to L2 cache addressing on AMD processors. Similar patterns exist on other architectures; for instance, previous work showed that the Apple M1 CPU also uses high-order address bits for cache indexing [16]. Their method involved constructing eviction sets—a technique unavailable for AMD processors before our work. Moreover, our eviction set construction algorithm relies on insights gained from reverse-engineering these addressing functions. Similarly, the reverse engineering of snoop filter addressing on ARM processors relied on specific PMU events [8], which are not available on AMD processors. Our method does not depend on architecture-specific knowledge, making it broadly applicable to other architectures.

We conducted experiments to identify the bits involved in L2 cache indexing. Sixteen nodes were added to a linked list with physical addresses spaced at regular intervals. By adjusting the interval between addresses, we ensured that the physical addresses differed by only four bits (see Figure 4). If these bits do not contribute to the L2 set index computation, access latency increases due to multiple addresses mapping to the same cache set, exceeding the 8-way associativity. As shown in Figure 5, when the interval was set to 2^{16} and 2^{17}, access latency increased; when the interval was increased to 2^{18}, latency decreased, indicating that the addresses no longer mapped to the same cache set. We deduced that bits 6–15 and bits 21–27 of the physical address collectively determine the L2 cache index on AMD processors.

To further investigate the impact of higher-order address bits, we reverse-engineered the L2 cache addressing function using Algorithm 1. We first established two addresses:

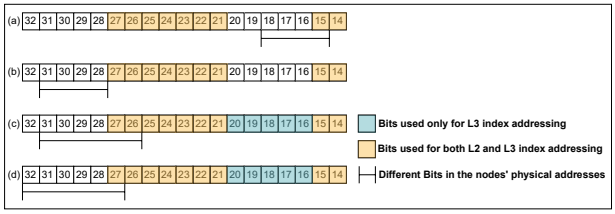

Fig. 4: Using a sliding window to control the bits of physical address differences among nodes in a linked list.

Addr1: Defined by a base address, an offset (gap), and varying cache sets.

Addr2: Defined by the base address and different cache sets.

Algorithm 1: Algorithm for determining the relationship between the L2 set index and the physical address.

Input : Memory region `mem`, range from `begin` to `end`, step size `gap`, number of nodes `num`
Output: Results of each test

```
base ← starting address of mem;
for offset from begin to end step gap do
    for j from 0 to number_of_L2_set do
        Addr1 ← base + offset + (j ≪ 6);
        AppendNodes(Addr1, num/2);
        for k from 0 to number_of_L2_set do
            count ← 0;
            Addr2 ← base + (k ≪ 6);
            AppendNodes(Addr2, num/2);
            ShuffleList();
            for trial from 0 to 9 do
                avg_time ← TraverseList() ;
                if avg_time exceeds threshold then
                    count ← count +1;
            if count >5 then
                same_set ← 1;
```

For each address, we constructed linked lists containing eight nodes, each separated by a gap of 0x10000. This setup ensured that the nodes within each list were identical in the bits relevant to the L2 cache index.

We measured the access latency by traversing these linked lists. If the combined latency exceeded a predefined threshold, it indicated that both lists mapped to the same L2 cache set, confirming how bits 21-–27 affected bits 6—15.

This analytical approach mirrors the method used in our cache-slicing analysis. After mapping addresses to L2 set indexes, we flipped specific address bits to generate new addresses and recorded the relationship between differing index bits and address bits, producing a count matrix (Table II).

Using the count matrix, we derived a hash function that employs XOR operations. Given the address bits:

$$b_i = (\text{addr} \gg i)\,\&1 \quad \text{for } i \in [6, 15] \cup [21, 27]$$

Each bit of the L2 index is defined as follows:

$$index_i = \begin{cases} b_6 & \text{if } i = 0, \\ b_{i+6} \oplus index_{i-1} & \text{if } 0 < i < 3, \\ b_{i+6} \oplus b_{i+18} \oplus index_{i-1} & \text{if } 3 \le i \le 10. \end{cases}$$

C. L3 Index Addressing

Reverse engineering the index addressing for the L3 cache follows the same principles as for the L2 cache but involves differences in identifying specific bits in the calculation. A linked list of 64 nodes was constructed, with physical addresses spaced at regular intervals. By adjusting the intervals, we ensured that the physical addresses differed by exactly six bits, as shown in Figure 4. Cache lines were evicted from private caches before each traversal, as detailed in Section V-A. As depicted in Figure 5, the results showed that with a 2^{26} interval, the 64 nodes spanned four L3 sets, each containing 16 cache lines. In contrast, with a 2^{27} interval, the nodes occupied only two L3 sets, exceeding the associativity limit and increasing access latency. These observations indicate that L3 set indexing is determined by bits 9–27.

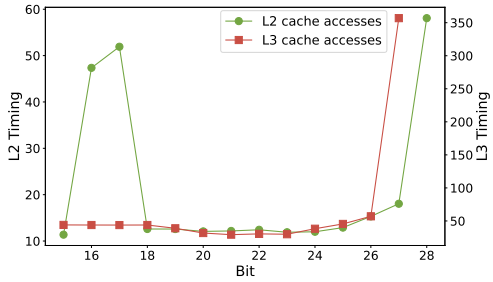

Fig. 5: Relationship between the interval in physical addresses of linked list nodes and memory access timing.

Similar to reversing the L2 set index, given the address bits:

$$b_i = (\text{addr} \gg i)\,\&1 \quad \text{for } i \in [9, 27]$$

Each bit of the L3 index is defined as follows:

$$index_i = \begin{cases} b_9 \oplus b_{21} & \text{if } i = 0, \\ b_{i+9} \oplus b_{i+21} \oplus index_{i-1} & \text{if } 0 < i \le 7, \\ b_{i+9} \oplus index_{i-1} & \text{if } 7 < i \le 12. \end{cases}$$

IV. Eviction Set Construction

An eviction set is a group of memory addresses that map to the same cache set; in cache attacks, accessing these addresses forces the eviction of specific cache lines through the cache replacement policy. In this section, we analyze why previous eviction set construction algorithms fail on AMD Zen processors and introduce a new method based on reverse-engineering cache addressing.

Firstly, algorithms designed for inclusive caches are not effective on AMD's non-inclusive cache architecture. An eviction set construction algorithm for inclusive caches [1] iteratively removes addresses from a candidate set U and observes whether the target address x still experiences eviction. If removing an address x' prevents eviction of x, then x' is necessary for the eviction set. However, on non-inclusive caches like those in AMD processors, some addresses in the minimal eviction set U may reside only in private caches and not in the LLC. They cannot conflict with x in the LLC, which results in false negatives when constructing eviction sets [5].

TABLE II: Correspondence between the physical address bits and L2 set index bits.

Secondly, existing algorithms for non-inclusive caches also face limitations on AMD processors. The L2 occupy set was introduced to address false positives in non-inclusive caches [5]. It evicts addresses from private caches to ensure that all candidate addresses reside in the LLC and can conflict with x. It is effective on Intel's non-inclusive caches because flipping the 16th bit of the physical address allows the L2 occupy set and the L3 eviction set to be mapped to different slices, preventing false positives. However, our reverse-engineering of AMD's cache addressing revealed that all cache lines in the same L2 cache set are mapped to the same LLC slice, making this method inapplicable to AMD architecture.

Through reverse-engineering in Section III, we determined that in Zen 3 processors, the L2 set index is derived from bits 6—15 and 21—27 of the physical address, LLC slice addressing is determined by bits 6—8, and L3 set indexing is based on bits 9—27. Addresses within the same L2 set and slice must also belong to the same L3 set. Therefore, we can adapt the L2-driven Candidate Address Filtering method [21] for AMD processors.

To construct the L3 eviction set, we first identify the L2 eviction set EV'. After obtaining the L2 eviction set EV', we filter the address set U to select those addresses that share the same L2 set as the target address, using them as candidates for the L3 eviction set. The L3 eviction set EV is then constructed by ensuring that all candidate addresses are evicted into the L3 cache, avoiding false negatives. Finally, we construct the L3 eviction set from these candidates. The whole process is shown in Algorithm 2.

In this approach, the L2 eviction set serves as the occupy set. Since it is a subset of the full eviction set, this structure prevents false positives and enables effective eviction set construction on AMD's non-inclusive caches.

Algorithm 2: Eviction set construction algorithm

Input : Target address x, Address set U
Output: Eviction set EV
1 $EV' \leftarrow$ `FindEV`$(x, U, L2_Threshold, \varnothing)$;
2 $U' \leftarrow$ `CheckConflict`(U, EV');
3 $EV \leftarrow$ `FindEV`$(x, U', L3_Threshold, EV')$;

In our experiments, the `FindEV` function used the $O(n^2)$ algorithm, proposed in previous work [1], but more efficient algorithms can be applied. Figure 6 shows the cumulative success rates: 98% after 7 attempts on 1GB pages and 78% after 8 attempts on 4KB pages.

Fig. 6: Cumulative success rate of eviction set construction on 1GB and 4KB pages.

V. Side Channels

A. Eviction from Private Caches

It was observed that a context switch on Intel processors may flush cache data to memory [22]. This allows an attacker to evict a victim's cache lines to memory by inducing a context switch, for example, by sending a signal. If both processes share the same user ID, no special privileges are required to send a signal to a process running on a different core.

However, our experiments on AMD CPUs revealed different behavior. As shown in Figure 7, we measured the cache latency of accessing cache lines from the same L2 and L3 cache sets, both under normal conditions and after the process received a signal. Under normal conditions, when the number of entries was below 24 (the combined associativity of the L2 and L3 caches), accesses hit the cache, resulting in low latency. When the number of entries exceeded 24, cache misses occurred, leading to a significant increase in latency.

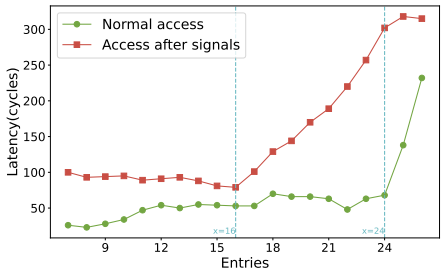

Fig. 7: Comparison of cache access latency under normal conditions and after receiving signals.

Interestingly, after receiving a signal, no significant increase in latency was observed, suggesting that the data remained in the L3 cache. When the number of entries exceeded 16 (the L3 cache associativity), latency increased, indicating that the

L2 set was not involved. This suggests that the signal caused cache lines to be evicted only from private caches.

Thus, we conclude that on AMD platforms, the signal mechanism can be exploited to flush the victim's private caches while retaining data in the L3 cache, presenting a unique opportunity for cache-based side-channel attacks.

B. *Prime+Signal+Probe*

Based on these findings, we propose a cache attack targeting the LLC in AMD's non-inclusive cache architecture. In this attack, the attacker first identifies the victim's target LLC sets, utilizing power spectral density to detect periodic accesses to the LLC sets in the frequency domain [21]. Once the target LLC sets are identified, the attack proceeds as follows.

The attacker constructs an eviction set, either through an eviction set construction algorithm or by selecting cache lines from a 1GB large page. The relevant cache sets are primed to establish a known state. A signal is sent to the victim process, triggering a context switch that evicts the victim's cache lines from private caches. The attacker then probes the cache sets by measuring access latency. By analyzing these latency measurements, the attacker can determine whether the victim accessed specific cache lines. If the victim accessed cache lines containing secret data, the attacker's corresponding cache lines would be evicted, leading to increased access latency. This process is illustrated in Figure 8.

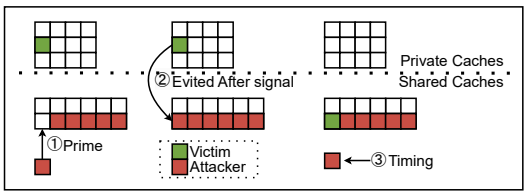

Fig. 8: Overview of the Prime+Signal+Probe attack. The attacker primes the cache set with their data (step ①), and sends a signal to the victim, triggering a context switch that evicts the victim's cache lines from the private L2 cache to the shared LLC if they were accessed by the victim beforehand (step ②). Finally, the attacker probes for increased latency to detect if specific lines were accessed by the victim (step ③).

We selected the AES T-table implementation as our side-channel attack target. Despite countermeasures [23]–[25] that mitigate most cache side channels in AES implementations, the T-table approach remains widely used for examining emerging side-channel attacks compared to earlier methods [3], [26], [27]. Drawing from similar attack scenarios [1], [21], our Prime+Signal+Probe technique also applies to other cryptographic algorithms, including RSA, ElGamal, and ECDSA.

The T-table implementation optimizes AES by converting SubBytes, ShiftRows, and MixColumns into 16 memory lookups from four precomputed tables. In the first round, table accesses are made to entries $T_j[p_i \oplus k_i]$, where $i \equiv j \mod 4$ and $0 \leq i < 16$, allowing attackers to infer possible key-byte values (k_i) when the plaintext (p_i) is known.

We conducted a known-plaintext attack on the AES T-table implementation in OpenSSL. By analyzing whether the victim accessed specific T-table entries, we inferred possible key-byte values. For each round, we recorded the results of 1024 AES encryptions. Figure 9 illustrates a cache template generated from 1024 encryptions, revealing a discernible pattern.

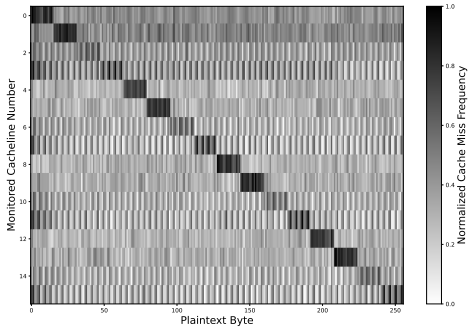

Fig. 9: Cache templates showing the cache miss frequency of the eviction set.

We performed multiple rounds of the attack, applying majority voting to the results. Scenarios included selecting cache lines from the same L3 set on a 1GB page and constructing eviction sets with the proposed algorithms on 1GB and 4KB pages. Figure 10 shows the accuracy of majority voting: on 4KB pages, accuracy reached 100% with zero standard deviation when the vote count exceeded 16, allowing key-byte inference. For 1GB pages, achieving 100% accuracy required a majority vote count of 30 when constructing eviction sets and 22 when selecting cache lines directly.

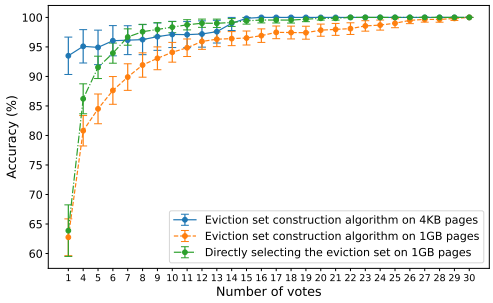

Fig. 10: Accuracy of majority voting on 1GB and 4KB pages.

VI. Conclusion

We analyzed the security of AMD's non-inclusive caches. By reverse-engineering the cache addressing functions, developing an eviction set construction algorithm, and employing signals to evict cache lines from private caches, we successfully execute the last-level cache side-channel attack on AMD processors. Given the challenges of applying software mitigation to arbitrary applications, our findings highlight the need for hardware-based defenses in commercial processors.

***Abstract*—Disaggregated memory (DM) architecture physically separates computing and memory resources into distinct pools interconnected via high-speed networks within data centers, with the aim of improving resource utilization compared to traditional architectures. Most existing range indexes for DM that support variable-length keys are based on adaptive radix trees. However, these indexes exhibit suboptimal performance on DM due to excessive network round trips during tree traversal and inefficient node-based caching mechanisms.**

To address these issues, we propose Sphinx, a novel hybrid index for DM. Sphinx introduces an Inner Node Hash Table to minimize the network round trips during index operations by replacing the sequential tree traversal with parallel hash reads. Sphinx incorporates a Succinct Filter Cache to further minimize network overhead while keeping the computing-side cache small and coherent. Experimental results show that Sphinx outperforms state-of-the-art counterparts by up to 7.3× in the YCSB benchmark.

I. Introduction

Disaggregated Memory (DM) architecture [1]–[5] has gained significant attention in both academia and industry in recent years. DM separates the memory and computation resources into distinct pools. This separation allows for independent scaling of these resources, which addresses the problem of low resource utilization in modern data centers. Since the memory side has minimal computing power, clients on the computing side typically access memory resources on the memory side via high-speed networks such as RDMA [6] and CXL [7], which enables clients to directly read from or write to remote memory without involving remote CPUs.

The Adaptive Radix Tree (ART) [8], [9] is a widely used index structure in many data center applications, such as key-value storage systems and transaction processing systems, due to its efficient support for variable-length keys. However, existing ARTs [9]–[12] exhibit suboptimal performance on DM due to excessive network round trips and the inefficient node-based caching mechanism. Specifically, executing index operations on tree-based indexes like ART requires traversing the hierarchical tree structure [13]. On DM, this traversal involves multiple network round trips between computing-side clients and the memory-side index. Since accessing remote memory remains significantly slower than accessing local memory, these excessive round trips result in high latency and become the primary performance bottleneck during index operations.

Existing ART for DM [10] attempts to reduce tree traversal round trips by caching certain inner nodes on the computing side. However, this node-based caching mechanism is inefficient on DM. Firstly, the computing side of DM has limited memory resources, allowing only a small subset of inner nodes to be cached. As a result, node-based caching fails to effectively reduce network round trips, leading to diminished performance. Furthermore, node-based caching introduces potential cache coherence issues, as remote inner nodes may be modified by other clients, causing inconsistencies between the computing-side cache and the memory-side index.

To address these issues, we propose Sphinx, a hybrid index designed to minimize network overhead during index operations while keeping the computing-side cache small and coherent. To reduce network round trips, Sphinx incorporates an *Inner Node Hash Table* to store the essential metadata of ART inner nodes. This allows clients to directly access inner nodes through reading hash entries in parallel, rather than traversing the tree sequentially. To achieve optimal performance with limited computing-side memory resources, we propose the *Succinct Filter Cache*. The succinct filter cache further reduces the network overhead by minimizing hash entries read to one in most cases. Instead of caching the full content of inner nodes, the succinct filter cache employs a succinct (space-efficient) data structure (e.g., cuckoo filter [14]) to track only the existence of inner nodes. As a result, the succinct filter cache significantly improves memory utilization and preserves coherence when remote inner nodes are modified by other clients.

The contributions of this paper are summarized as follows:

- We thoroughly analyze existing ARTs on DM, demonstrating that they provide inferior performance due to excessive network round trips introduced by traversing the hierarchical tree structure and the unsuitable node-based caching mechanism.
- We propose Sphinx, a hybrid range index supporting variable-length keys on DM. By introducing the *Inner Node Hash Table*, Sphinx minimizes network round trips by replacing the sequential tree traversal with reading hash entries in parallel.
- We propose the *Succinct Filter Cache*, which further reduces the network overhead of Sphinx and enables it to achieve optimal performance with limited computing-side memory resources.
- We conduct extensive evaluations of Sphinx and compare it with the state-of-the-art range indexes for variable-length keys on DM. Experimental results show that

Sphinx outperforms existing systems in terms of both throughput and latency.

II. Background And Motivation

A. Disaggregated Memory Architecture

Disaggregated memory (DM) architecture physically separates computing resources (e.g., CPU cores) and memory resources (e.g., DRAM) into distinct pools within data center, which aims to improve the resource utilization in traditional data center architectures [5], [15], [16]. In a DM setup, Compute Nodes (CNs) contain extensive computing resources but have limited memory. Conversely, Memory Nodes (MNs) are equipped with substantial memory resources but only wimpy computing power. CNs and MNs are interconnected via high-speed networks such as RDMA [6] and CXL [7].

RDMA is a promising solution for disaggregated memory architecture in modern data centers, as it not only offers high bandwidth (e.g., 200 Gbps) and low latency (e.g., 2 μs) [17]–[19] but also provides a set of one-sided operations (`RDMA Read/Write/CAS` (`Compare And Swap`) /`FAA` (`Fetch And Add`)), allowing clients in CNs to directly access remote memory without requiring CPU intervention on the MN side. This capability is particularly beneficial for DM, where minimizing CPU overhead on MNs with limited computing resources is critical.

B. Adaptive Radix Tree

The Adaptive Radix Tree (ART) [8] is a space optimized variant of the radix tree [20]. As shown in the memory nodes of Fig. 1, each inner node in ART represents a unique prefix of a key stored in the tree. This characteristic allows it to efficiently support variable-length keys. To improve space utilization, ART employs inner nodes with different capacities (e.g., 4, 16, 48 and 256) to store their children, allowing them to grow dynamically as new keys are inserted into the tree. To reduce tree height and enhance the performance of index operations, ART incorporates a path compression mechanism to merge multiple inner nodes with only one child into a single inner node (e.g., the inner node marked as *LYR* in Fig. 1) and eliminate inner nodes along the path to a single leaf node (e.g., the path from *LYR* to *LYRICS* in Fig. 1).

Existing ARTs [9], [10], [12] exhibits suboptimal performance on DM due to excessive network round trips. ARTs follow a hierarchical structure [13], in which a node can only be accessed after its address is retrieved from its parent node. In DM architectures, the index resides on the MN side with sufficient memory, which is separated from the clients on the CN side. This separation necessitates excessive network round trips during tree traversal, resulting in high latency and early saturation of network resources.

Existing ART for DM [10] attempts to mitigate this issue by caching certain inner nodes. During index operations, the client first traverses the tree formed by the cached inner nodes locally, then proceed to traverse the remote tree from the deepest node reached in the local traversal. However,

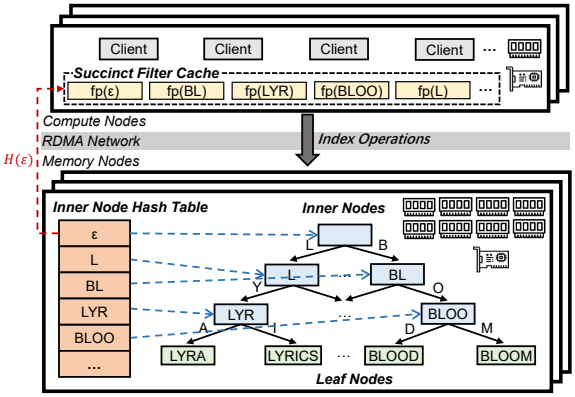

Fig. 1: Overview of Sphinx.

this node-based caching mechanism is inefficient in memory-limited CNs. First, node based caching requires a significant amount of memory to achieve optimal performance, which is impractical for memory-limited CNs. For example, as shown in Sec. V-B, SMART [10], the state-of-the-art ART on DM, still deliver suboptimal performance even with a cache size set to 17.6% of the dataset size. Second, node-based caching can lead to cache coherence issues, as remote ART nodes may be updated by other clients. Although SMART mitigates this issue by preallocating a space of Node-256 for each inner node and employing an associated reverse checking mechanism, it incurs significant memory overhead on the MN side. The overhead ranges from 2.1–3.0× in our experiments, as detailed in Sec. V-D.

III. Design

Based on the above analysis, we propose Sphinx, a hybrid index for variable-length keys on DM, designed to minimize network overhead in index operations while keeping the CN-side cache small and coherent.

The architecture of Sphinx is illustrated in Fig. 1. The ART Nodes of Sphinx are evenly distributed across MNs by consistent hashing [21]. To minimize network round trips during index operations, each MN in Sphinx employs an *Inner Node Hash Table* to store the addresses and lightweight metadata of ART inner nodes allocated to that MN. This reduces network round trips during index operations by replacing the sequential tree traversal with reading hash entries in parallel. To further reduce the network overhead, Sphinx introduces a *Succinct Filter Cache* that efficiently filter out unnecessary hash entry reads, thereby reducing network bandwidth consumption. The succinct filter cache adopts a succinct data structure (e.g., cuckoo filter [14]) to track the existence of inner nodes, rather than storing their full content. This approach not only minimizes memory consumption on the CN side, but also eliminates cache coherence issues that could arise from directly caching the inner nodes.

A. Inner Node Hash Table

To reduce network round trips, Sphinx introduces an MN-side *Inner Node Hash Table* for the ART, designed to break

the serial dependencies between ART nodes. As illustrated in Fig. 1, we construct a hash table for the inner nodes of the ART, where the key is the full prefix of each inner node, while the value stores the node's address and its associated metadata. During index operations, instead of sequentially fetching each inner node through tree traversal, the client is able to read all the hash entries of these inner nodes in parallel. Based on these hash entries, the client then retrieves the deepest inner node with another network round trip.

With the inner node hash table, locating the value corresponding to a key can be optimized in a parallel manner. Specifically, for a given key K (e.g., *LYRICS* in Fig. 1), the client retrieves all hash entries corresponding to the prefixes of K (*LYRICS*, *LYRIC*, ..., L) in parallel to find the deepest inner node corresponding to K. This approach stems from the path compression mechanism [8] used in ART, which prevent the client from directly determining the existence of each inner node, necessitating a read of all possible hash entries (can be further optimized to only read one hash entry in most cases, as described in Sec. III-B). We adopt RACE hashing [22] as the index of the inner node hash table, which allows each hash entry to be retrieved within a single network round trip. By further utilizing the doorbell batching mechanism [23], which allows sending multiple RDMA operations to the NIC in a single batch, reading all these hash entries can be performed in a single round trip.

To further retrieve the value of K with these hash entries, the client then identifies the valid hash entry corresponding to the longest prefix (*LYR*), which represents the deepest inner node. Next, the client retrieves this deepest inner node from MNs using the metadata and address stored in the hash entry. Finally, the client retrieves the target leaf node through this deepest inner node and extracts the value from the leaf node.

The inner node hash table incurs only a slight memory consumption on the MN side. Specifically, it is significantly smaller than the inner nodes themselves, as each hash entry only stores the address of the inner node and associated metadata (e.g., a short fingerprint and node type as shown in Fig. 3), fitting within just 8 bytes. In comparison, an ART inner node consumes 40–2056 bytes of memory. Our experiments in Sec. V-D show that the inner node hash table incurs only 3.3–4.9% additional memory usage on the MN side.

B. Succinct Filter Cache

Although reading inner nodes directly from the inner node hash table reduces network round trips, it does not alleviate bandwidth consumption. Specifically, for a key of length L, the client must read $\Theta(L)$ hash entries to locate the deepest inner node, offering no advantage over tree traversal. Additionally, similar to tree traversal, reading multiple hash entries generates a significant load on network, as the NIC must process a substantial number ($\Theta(L)$) of network packets for each index operation. This high load accelerates the saturation of network resources, ultimately diminishing throughput of the system.

To address the above issue, we propose the *Succinct Filter Cache*, a lightweight per-CN cache based on cuckoo filter [14].

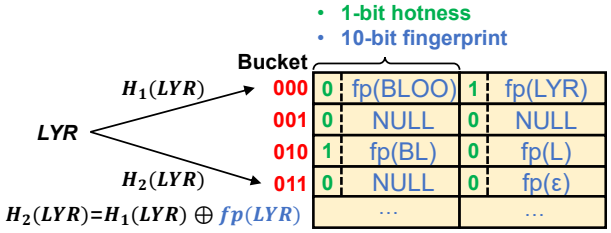

Fig. 2: Succinct Filter Cache.

The succinct filter cache reduces the number of hash entry reads per index operation from $\Theta(L)$ to one in most cases, while maintaining minimal space consumption and preserving cache coherence. The succinct filter cache tracks the existence of inner node prefixes in the remote index using a cuckoo filter, a succinct data structure. This allows the client to locally determine the prefix of the deepest inner node for the key with minimal CN-side memory usage. Consequently, the client only needs to fetch a single hash entry corresponding to the deepest inner node, significantly reducing network overhead associated with reading multiple hash entries. Additionally, the succinct filter cache maintains coherence when remote inner nodes are modified, as it does not store their content.

As illustrated in Fig. 2, the succinct filter cache follows the structure of cuckoo filter. To perform an existence check (i.e., to determine whether a given prefix exists in the succinct filter cache), the client computes the hash values (H_1 and H_2) of the prefix and checks if the corresponding hash fingerprint (fp) is present in the candidate buckets determined by the hash values. During index operations, for a given key K (e.g., *LYRICS*), the client first performs existence checks for all prefixes of K (*LYRICS*, *LYRIC*, ..., L) in the succinct filter cache and identify the longest prefix P that exists in the succinct filter cache (*LYR*). The client then only fetches the hash entry of P from remote inner node hash table. Finally, the client retrieves the deepest inner node and further retrieves the leaf node to extract the value corresponding to K.

In most cases, as described above, an index operation can be performed in three network round trips: reading the hash entry, reading the inner node, and retrieving the leaf node. Due to the probabilistic nature of cuckoo filter, in false-positive cases (<1%), the succinct filter cache may incorrectly indicate that a prefix exists in the remote index when it does not. Nevertheless, both the performance and correctness of index operations remains unaffected by these rare cases. As illustrated in Fig. 3, both the hash entry and the inner node contain metadata that allows the client to avoid traversing the tree starting from an unmatched inner node. For example, the hash entry includes a 12-bit hash fingerprint (fp_2), while the inner node header provides a 42-bit full prefix hash. In the rare scenario where both the fp_2 and the full prefix hash collide, Sphinx may traverse the tree starting from an unmatched inner node U. However, the correctness is still guaranteed, as the client will eventually reach a leaf node to retrieve the corresponding value. At this point, the client computes the common prefix between the key used in the index operation

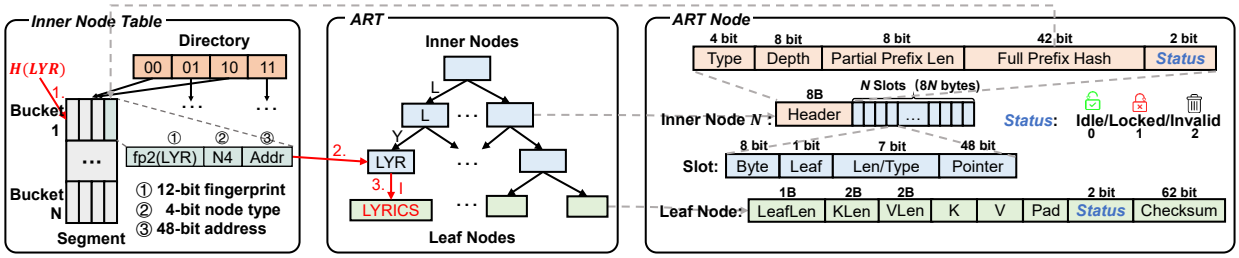

Fig. 3: Detailed data structures of Sphinx

and the key stored in the leaf node. If the common prefix is shorter than the prefix associated with U, the client identifies the false positive and retries the index operation with a shorter prefix from the succinct filter cache. Since such cases are extremely rare ($<$0.01%), the overall performance remains unaffected.

To address scenarios where the dataset size is so large that even tracking the existence of all inner nodes in CNs becomes infeasible, as illustrated in Fig. 2, we further propose a lightweight mechanism to identify hot prefixes in the succinct filter cache. This mechanism is inspired by the second chance page replacement policy [24], which approximates the LRU algorithm using only one additional *hotness* bit per entry. Specifically, when a new prefix is inserted, its *hotness* bit is initialized to 0, indicating it has not been recently used. The *hotness* bit is set to 1 when the entry is accessed, marking it as recently used. During insert operations, if both candidate buckets are full, the client randomly selects an entry with the *hotness* bit set to 0 for replacement. If all entries in both candidate buckets have their *hotness* bits set to 1, the client adopts the cuckoo hashing mechanism [25] to relocate existing entries and make space for the new one. During relocation, the *hotness* bits of all relocated entries are reset to 0, indicating they are eligible for future eviction.

The succinct filter cache is particularly well-suited for DM. First, as demonstrated in prior work [14], using a 10-bit fingerprint per item is sufficient to achieve a low false positive rate ($<$1%) for existence checks, making it significantly more space-efficient than the node-based caching mechanism, which require 40–2056 bytes of memory to cache a single inner node. Second, the succinct filter cache inherently maintains coherence even when inner nodes in the remote memory are modified by other clients. These modifications impact only types, slots, and partial prefixes of inner nodes, leaving their full prefixes unchanged. Consequently, they have no effect on the coherence of the succinct filter cache, which exclusively tracks the existence of full prefixes.

C. Concurrency Control

Sphinx employs a lightweight concurrency control mechanism that enables lock-free read operations and node-grained locks for write operations. To further reduce network overhead in update operations, Sphinx adopts a checksum-based in-place update scheme for leaf nodes.

For concurrency control, as illustrated in Fig. 3, most components (e.g., hash entries, headers and slots) of Sphinx fit within 8 bytes, enabling clients to modify them atomically using the `RDMA CAS` operation. In the inner node hash table, both read and write operations are executed without acquiring locks, as a write operation only affects an 8-byte hash entry and can be performed atomically. For the ART, Sphinx resolves write-write conflicts using a node-grained lock (status) and stores lightweight metadata (e.g., the type and depth of the inner node) in the header of inner nodes to synchronize lock-free reads with a write.

With the consistency maintained in both the ART and the inner node hash table, the correctness of Sphinx is ensured in most cases. The remaining correctness issue arises when a client reads an outdated hash entry while another client is performing a *node type switch*. In ART, a node type switch occurs when a client attempts to insert a new key into a full inner node. In such cases, a new inner node with more slots is allocated, and the original node is replaced by the new one. However, after the original node is removed from the ART, a client may still access it through the inner node hash table before the change propagates to the hash table, resulting in a temporary inconsistency. To address this issue, as shown in Fig. 3, the client sets the status field of the old inner node to *Invalid* following a node type switch. Readers retrieving an inner node from MNs check the status field before use. If the status field is marked *Invalid*, the reader retries the index operation.

For the update operation, if the new value fits within the original leaf node, the client performs an in-place update to reduce network overhead. As shown in Fig. 3, the client begins the in-place update by locking the leaf node, setting its status field to *Locked* using one `RDMA CAS` operation. Sequentially, the client writes the new value, updates the status field to *Idle* and computes the new checksum of the leaf node locally. Finally, the client writes the entire leaf node back to corresponding MN using a single `RDMA Write` operation. To avoid reading partially modified data, all clients verify the checksum of a leaf node before using it. This in-place update scheme eliminates an RDMA operation during an update operation by combining the lock release with the value write, thereby reducing network overhead.

IV. Index Operations

In this section, we present the detailed implementation of the index operations in Sphinx. By leveraging the inner node hash table and succinct filter cache, Sphinx achieves high performance in index operations, primarily by replacing the

sequential tree traversal with a single hash entry read. This substantially reduces network overhead in terms of both round trips and bandwidth consumption.

Search (K). The client first calculates the hash values of all prefixes of K and identifies the longest prefix P exists in the succinct filter cache. As shown in Fig. 3, the client then fetch the corresponding hash bucket from the inner node hash table in one round trip. To avoid additional network round trips in determining the address of buckets through the directory, each CN maintains a local directory cache, which is small enough to fit within limited CN-side memory (typically 2–5% of the succinct filter cache size). The client then iterates through the hash bucket and fetch all the inner nodes whose hash entry has the same 12-bit fingerprint (fp_2) as P. Typically, there is only one candidate hash entry, as discussed in prior works [26]. Finally, the client performs tree traversals starting from the fetched inner nodes, ultimately reaching the leaf nodes, where the value corresponds to K is extracted. In most cases, the tree traversal requires only one additional network round trip, as the succinct filter cache enables the client to determine the deepest inner node of K. In rare cases, the client may fetch an inner node that is not the deepest due to the structural modifications made by other clients to the remote ART. In such case, the client updates the succinct filter cache for any prefixes not present in the cache to maintain its freshness.

Insert (K, V). The client begins by locating the deepest inner node following the search procedure, and then traverses the tree starting from the node until it reaches a leaf node, verifying that the inner node prefix matches K. Subsequently, the client writes the new leaf node with the new key-value pair using an `RDMA write`. If the operation triggers a node type switch or a node split, the client also writes a new inner node with a slot pointing to the newly created leaf node. To ensure consistency, the client acquires node-grained locks on the affected inner node by setting its status field to $Locked$ with an `RDMA CAS`. This lock acquisition is piggybacked onto the write using doorbell batching [23] to reduce network round trips. Once the lock is acquired, The client makes the insertion visible by atomically install the pointer to the new node in the parent node's slot with an `RDMA CAS`, followed by a piggybacked lock release using another `RDMA CAS`.

After the operation is completed, the client updates the succinct filter cache if the operation triggers a node split, where a new inner node with a new prefix is added to the index. The client updates only its local succinct filter cache, while the synchronization of caches on other CNs is deferred until their clients encounter the corresponding inner node during tree traversal, as described in the search procedure. Similarly, the inner node hash table is updated after a node type switch or a node split to reflect changes applied to the ART. This update can be performed atomically using an `RDMA CAS`, as the client modifies only one 8-byte hash entry.

Update (K, V). The client first retrieves corresponding leaf node following the search procedure. The structure of the leaf node is shown in Fig. 3. Similar to prior works [10], [22], the size of the leaf node is aligned to 64 B, and the unit of the $LeafLen$ field is 64 B. If the leaf node has sufficient space to store V (i.e., the required size is within $64 \times LeafLen$ B), the client performs an in-place update as described in Sec. III-C. Otherwise, the client performs an out-of-place update similar to the insert operation.

Delete (K). The client retrieves the leaf node following the search process and sets its status to $Invalid$ using an `RDMA CAS` operation. The client then updates corresponding slot of its parent node to NULL similar to the insert operation.

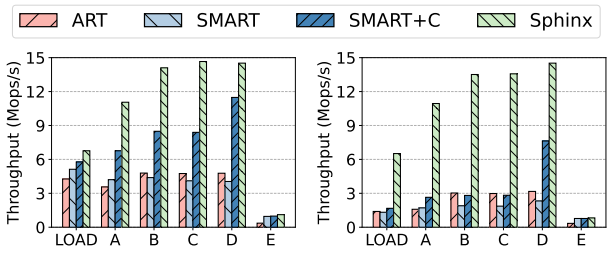
Scan (K_1, K_2). The client traverses the tree starting from the root node, retrieves all leaf nodes with keys between K_1 and K_2, and adds extracted key-value pairs to the result set.

V. Evaluation

A. Experimental Setup

Testbed. We emulate an RDMA-based DM cluster with three dual-socket machines, each equipped with 128GB of DRAM, two 2.6GHz Intel Xeon Gold 6348 CPUs (each with 28 cores), and one 2×100 Gbps dual-port Mellanox ConnectX-6 NIC. To save machine resources, we run both a CN and an MN on each machine, as in prior works [10], [27]. We manually limit the index cache memory usage on CNs and the CPU core usage on MNs to simulate a DM cluster.

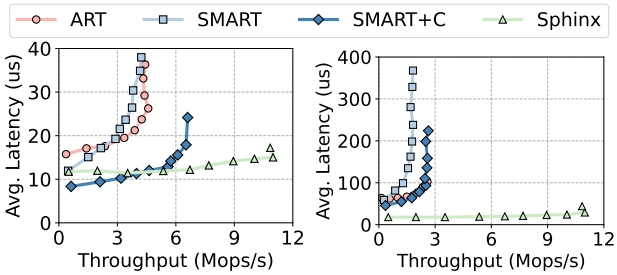
Workloads. We evaluate Sphinx using the YCSB benchmark [28]. Specifically, we use six types of workloads: A (50% read, 50% update), B (95% read, 5% update), C (100% read), D (95% latest read, 5% update), E (95% Scan, 5% insert), and an additional LOAD workload (100% insert). By default, the workloads follow a zipfian key distribution with a skewness factor of 0.99. The size of the value for each key-value pair is set to 64 bytes.



Datasets. Two datasets are used for evaluation: *u64* and *email*. The *u64* dataset consists of 8-byte fixed length integers generated from a uniform distribution, while the *email* dataset comprises publicly available email addresses [29] with sizes ranging from 2 to 32 bytes (an average size of 18.93 bytes).

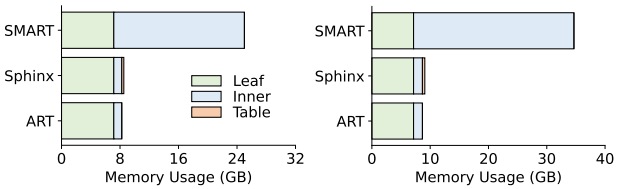
Comparisons. We compare Sphinx with *SMART* [10], the state-of-the-art range index supporting variable-length keys on DM. Additionally, We port the original *ART* to DM and use it as a baseline. Similar to Sphinx and SMART, *ART* also adopts one-sided RDMA operations to access and modify the index and data stored in remote memory. The CN-side cache size of SMART and Sphinx is set to 20 MB, which is 4.2% of the u64 dataset size and 1.8% of the email dataset size. To further demonstrate the high performance of Sphinx with limited cache size, we also compare Sphinx with *SMART+C*, which has a CN-side cache size of 200 MB (41.7% and 17.6% of the u64 and email datasets, respectively).

B. Overall Performance



In this section, we evaluate the overall performance of Sphinx with the YCSB benchmark. Fig. 4 displays the throughput of the systems under the YCSB benchmark using the *u64* and *email* datasets.

Base Operations (YCSB A-D, LOAD). As shown in Fig. 4, Sphinx achieves 1.2–3.6× higher throughput on the u64



(a) u64 (b) email

Fig. 4: The throughput under the YCSB benchmark.

(a) u64 (b) email

Fig. 5: The scalability in the write-intensive YCSB-A workload.

(a) u64 (b) email

Fig. 6: The memory usage across different datasets

dataset and 1.9–7.3× higher throughput on the email dataset than SMART, SMART+C and ART. By combining the *Inner Node Hash Table* and *Succinct Filter Cache*, Sphinx effectively minimizes network round trips and bandwidth consumption during index operations by replacing the sequential tree traversal with a single hash entry read. This is especially beneficial for the email dataset, where larger key sizes and deeper tree structure exacerbate traversal costs. In contrast, SMART and ART suffer from excessive network round trips during index operations, leading to lower throughput. Furthermore, Sphinx outperforms SMART+C with only 10% of its CN-side cache, demonstrating the efficiency of the *Succinct Filter Cache* in achieving high performance with limited CN-side memory space. Finally, Sphinx maintains consistent performance across both u64 and email datasets, indicating its suitability for variable-length keys.

Range Query (YCSB E). For both the u64 and email datasets, Sphinx, SMART and SMART+C achieve 2.3–3.1× higher throughput than ART, primarily due to the use of the doorbell batching mechanism [23], which hides the latency associated with reading nodes. The performance of Sphinx, SMART and SMART+C is comparable, as the main bottleneck of the workload lies in reading the leaf nodes rather than in tree traversal.

C. Scalability

In this section, we evaluate the scalability of the systems using the YCSB-A workload (50% read, 50% update, skewed) with both the *u64* and *email* datasets. Following prior works [10], [27], [30], we adopt coroutines to hide latency associated with polling the completion queue across all systems, with each coroutine treated as a worker. Fig. 5 presents the throughput-latency curve of the systems under the YCSB-A workload with various numbers of workers in CNs (6–192 workers, evenly distributed across 3 CNs). Sphinx scales well as the number of workers increases in CNs, achieving up to 2.6× higher throughput and 2.2× lower average latency on the u64 dataset, and up to 6.1× higher throughput and 11.7× lower average latency on the email dataset. This performance gain is primarily attributed to the inner node hash table and succinct filter cache, which minimize network overhead in terms of both round trips and bandwidth consumption, thereby preventing premature saturation of network resources.

D. Space Consumption

In this section, we evaluate the MN-side space consumption of the systems across different datasets. We insert 60 million key-value pairs into each system and measure the resulting MN-side memory usage. As shown in Fig. 6, the inner node hash table incurs only a slight increase in memory consumption compared to the original ART, with a 3.3% increase for the u64 dataset and a 4.9% increase for the email dataset. In contrast, SMART consumes 2.1–3.0× more memory than the original ART, as it preallocates a space of Node-256 for each inner node to prevent potential cache coherence problems.

VI. Conclusion

In this paper, we propose Sphinx, a novel hybrid index supporting variable-length keys on DM. Sphinx introduces an *Inner Node Hash Table* to break the serial dependency in ART, offering an opportunity to mitigate the excessive network round trips during tree traversal with parallel hash entry reads. Sphinx further employs a *Succinct Filter Cache* to significantly reduce network bandwidth usage during index operations while keeping the CN-side cache succinct and coherent. Our evaluations demonstrates that Sphinx outperforms existing counterparts by up to 7.3× in YCSB benchmark.

***Abstract*—Transformer-based neural networks have achieved remarkable performance. Designing energy-efficient and high-speed accelerators for the attention mechanism, which dominates the energy and latency in Transformers, has become increasingly significant. Existing attention accelerators commonly use algorithm-hardware co-design to achieve higher energy efficiency and speed. However, deeply customized algorithms make these accelerators dependent on a particular application. Therefore, optimizing hardware architecture is crucial for achieving general-purpose acceleration. We observe two limitations in the hardware architecture of existing attention accelerators. First, the widely used input stationary, weight stationary, and output stationary systolic arrays (SAs) can't balance data reuse, register saving, and utilization, which hinders to build more energy-efficient and faster SA-based accelerators. Second, layer-by-layer operation ordering introduces high SRAM access overhead of intermediate results. To address the first limitation, we propose the "Balanced Systolic Array", which improves energy efficiency by 40% compared to conventional systolic arrays and achieves a utilization rate of 99.5%. To address the second limitation, we propose "Multi-Row Interleaved" operation ordering, which reduces the SRAM energy by 31.7%. By integrating two techniques, the proposed attention accelerator achieves a 39% improvement in energy efficiency and a 38% enhancement in throughput×energy efficiency compared to previous works.**

I. Introduction

Transformer-based neural networks have demonstrated superior model performance over RNNs and CNNs in fields such as natural language processing[1][2][3] and computer vision[4]. In Transformers, the attention mechanism dominates the energy and latency[5][6][7]. Therefore, designing energy-efficient and high-speed accelerators for the attention mechanism has become increasingly significant. The computation process of the attention mechanism is shown in Fig.1, where n represents the token length, and d represents the word embedding dimension. The attention score matrix S is obtained by multiplying Q with K^T. After S is dequantized, scaled, processed with Softmax, and quantified, the attention probability matrix P is generated. Finally, P is multiplied by the V to generate the output matrix Z. The data formats for matrix

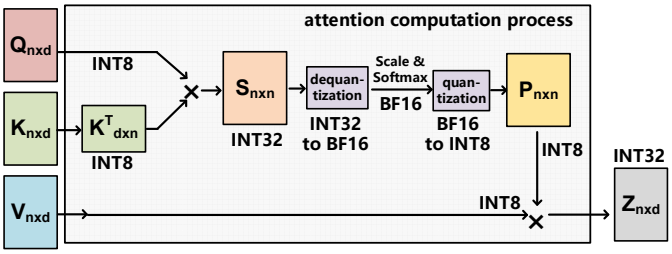

Fig. 1. Computation process of attention mechanism.

multiplication(MM), accumulation, Softmax are INT8, INT32, and BF16, respectively[17]. Existing attention accelerators commonly use algorithm-hardware co-design to achieve higher energy efficiency and speed. [7][9][10][11][12] exploit matrix P sparsity to introduce sparse computing, while [5][6][8] exploit the weak relevances token to introduce approximate computing. However, deeply customized algorithms tie them to a particular application[13]. Therefore, focusing on hardware architecture optimizations alone is vital for general-purpose acceleration.

We observed two hardware architecture limitations in existing attention accelerators, which introduce new challenges. As shown in Fig.2, **the first limitation** is the widely used input systolic (IS), weight stationary (WS), and output stationary (OS) SAs fail to balance data reuse, register saving, and utilization. Data reuse and register saving affect energy efficiency, as they affect the energy of memory[15], and register write energy[16]. Utilization impacts speed, as it affects throughput[13]. Therefore, the limitation restricts to build more energy-efficient and higher-speed SA-based accelerators. Specifically, for data reuse, OS-SA maximizes data reuse by using the outer product for MM[10][18], while IS-SA (or WS-SA) has lower data reuse, as it uses the inner product for MM. For register saving, OS-SA requires registers for accumulation and systolic, whereas IS-SA and WS-SA only need registers for systolic. For utilization, SAs require preloading data (IS-SA or WS-SA), offloading results (OS-SA), and filling pipeline(IS-SA, WS-SA, OS-SA), all of which introduce idle cycles that reduce utilization.

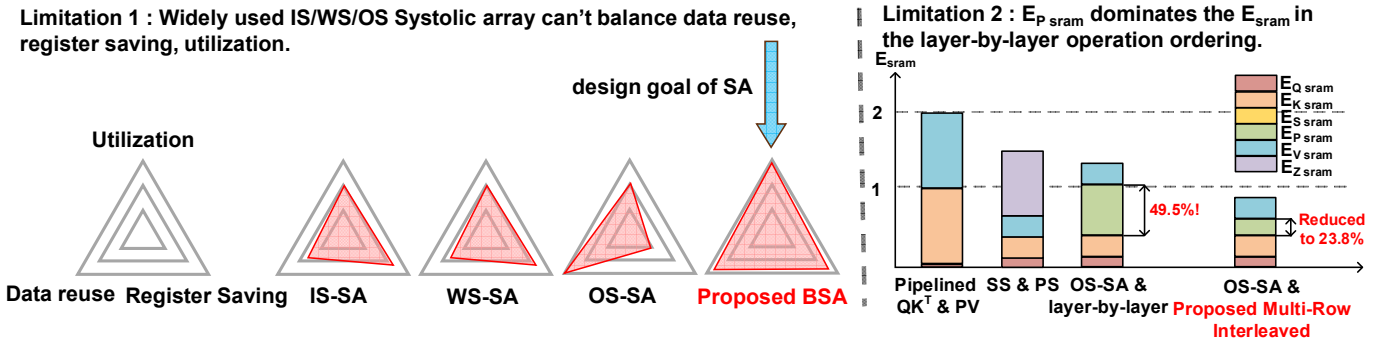

Fig. 2. Two Limitations of hardware architecture in existing attention accelerators.

Therefore, designing an SA that balances data reuse, register saving, and utilization introduces the first challenge.

The second limitation is the layer-by-layer operation ordering introduces significant SRAM access overhead of intermediate results. The right side of Fig.2 shows the total SRAM energy profile of the previous attention accelerator with different architectures(E_{sram}, unit: J, $E_{sram}=E_{Q\ sram}+E_{K\ sram}+E_{S\ sram}+E_{P\ sram}+E_{V\ sram}+E_{Z\ sram}$). The first architecture pipelines $Q\times K^T$ and $P\times V$(pipelined QK^T & PV)[5][6][7]. Although this architecture eliminates SRAM access of intermediate results ($E_{S,P\ sram}=0$), it weakens the spatial reuse of $Q\times K^T$ and $P\times V$ since the multipliers are split into two arrays, resulting in the highest E_{sram}. The second architecture uses reconfigurable SA which configures OS-SA when $Q\times K^T$ and IS-SA when $P\times V$(S stationary & P stationary, SS & PS)[8][10]. Although it not only avoids multiplier splitting but also eliminates SRAM access of intermediate results, the shape of the array for optimal data reuse for IS-SA and OS-SA is different, and IS-SA introduces inner product that weakens data reuse. The third architecture uses OS-SA and layer-by-layer operation ordering to compute $Q\times K^T$ and $P\times V$(OS-SA & layer-by-layer)[12]. Although it not only avoids multiplier splitting but also remains the optimal shape of the array for data reuse, the layer-by-layer operation ordering introduces large energy of SRAM access of intermediate results($E_{P\ sram}$ accounts for 49.5%). Therefore, designing an operation ordering to reduce $E_{P\ sram}$ introduces the second challenge. To address the above challenges, we made three contributions:

- We propose the "Balanced Systolic Array" to address the first challenge, which balances data reuse, register saving, and utilization, further improving energy efficiency and speed of SA.
- We propose a mathematical formula to determine the optimal data reuse for OS-based arrays with the inner-outer-mixed product.
- We propose the "Multi-Row Interleaved" operation ordering to address the second challenge, which significantly reduces $E_{P\ sram}$, further improving energy efficiency for attention accelerators.

The rest of this paper is organized as follows: Section II presents the background on three approaches for matrix multiplication and systolic array. Section III details the proposed attention accelerator architecture, including the "Balanced Systolic Array" and "Multi-row Interleaved" operation ordering. Section IV compares different systolic arrays and architecture of attention accelerators in terms of energy, energy efficiency, and utilization. Section V concludes the paper.

II. Background

A. Approaches for Matrix Multiplication(MM)

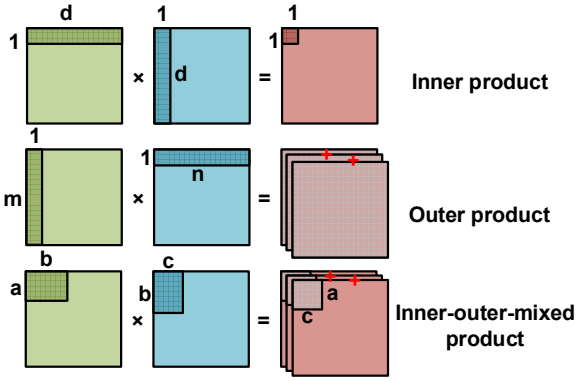

Fig. 3. Three approaches for matrix multiplication computation.

Fig. 3 shows three approaches for MM of an m×d matrix and a d×n matrix. In the output matrix, intensified red represents the result, while gray represents partial sums (psum).

The inner product approach is characterized by obtaining an element of the output matrix by taking the dot product of a row of the m×d matrix with one column of the d×n matrix. In hardware implementation, the inner product is characterized by two or more psums required for one output element to be generated in parallel. Outer product approach which is optimal in input reuse and output reuse, resulting in the highest data reuse[18], where a column of the m×d matrix is multiplied by a row of the d×n matrix to yield a psum matrix. Summing all psum matrices produces the final output matrix. In hardware implementation, the outer product is characterized by the psums required for one output element that are not generated in parallel, and the elements of both m×d matrix and d×n matrix are spatially reused by multiple multipliers. Inner-outer-mixed product approach generates a psum matrix block by multiplying a block from the m×d matrix and a block from the d×n matrix. Summing all corresponding psum matrix blocks yields the final output matrix. In hardware implementation, it has characteristics both of inner product and outer product.

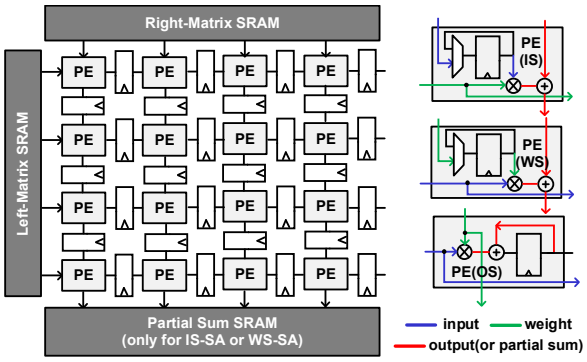

Fig. 4. Typical architecture of systolic array.

B. *Conventional Systolic Array*

Fig.4 shows a typical systolic array(SA) and specific PE structures of IS-SA, WS-SA, and OS-SA. SAs consist of many homogeneous processing elements (PEs), and data is transmitted between PEs through registers, thereby achieving spatial reuse. In IS-SA (or WS-SA), inputs (or weights) need to be preloaded into the registers of the PEs and then latched. After that, weights (or inputs) flow horizontally to the SA, while psums are propagated and summed vertically. The pipeline is filled when weights(or inputs) reach all PEs. In OS-SA, there is no preload process. Inputs flow horizontally to the OS-SA, weights flow vertically to the OS-SA, and each PE accumulates psum locally. Once inputs and weights reach all PEs, the pipeline is filled. The matrix multiplication result is offloaded through accumulators in OS-SA.

In our proposed systolic array, we combine the advantages of good data reuse of the outer product and register saving of the inner product by using the inner-outer-mixed product. We also combine the good register saving of broadcast and the good scalability of systolic. Furthermore, we improve the utilization of the SA by overlapping computation and offload.

III. Proposed Hardware Architecture

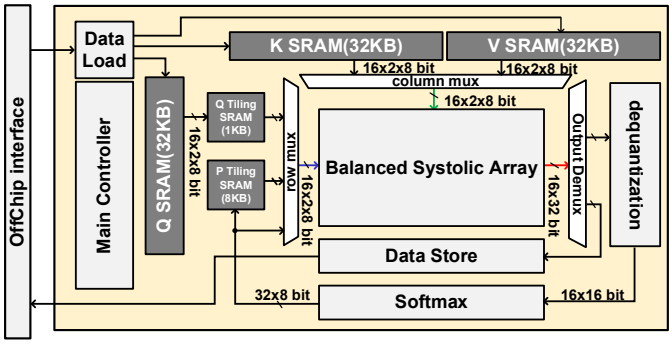

Fig. 5. Top-level of proposed attention accelerator architecture.

A. *Overview*

Fig. 5 shows the top-level architecture of the proposed attention accelerator. The memory mainly includes Q, K, V, Q Tiling, and P Tiling SRAMs. The Q, K, and V SRAMs store the Q, K, and V data, which are loaded by the Data Load module. The computational components consist of a balanced systolic array (BSA) and the Softmax module. The row mux and column mux (col mux) dynamically select the source data to feed into the BSA. The BSA contains 512 multipliers and 512 adders, with INT8 for the multipliers and INT32 for the accumulators. Two input matrices, represented by blue and green lines, are fed into the BSA, and the matrix multiplication results are output along the red line. The $Q \times K^T$ result S is fed into a dequantization module, while the $P \times V$ result Z is output via the Data Store module to the chip's I/O. The Softmax module has 16 exponent function units in BF16 format, which receives the data from the dequantization module and generates the P data. The Q Tiling SRAM and P Tiling SRAM enable data tiling for Q and P data, sourced from Q SRAM and the P data from the Softmax module. The $Q \times K^T$ and $P \times V$ are time-interleaved computed on the BSA.

B. *Proposed Balanced Systolic Array*

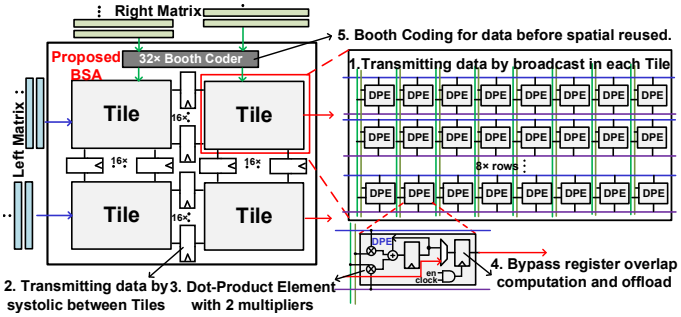

Fig. 6. The structure of the proposed Balanced Systolic Array.

Fig.6 shows the structure of the balanced systolic array which has three features.

Feature1: Inner-Outer-Mixed Product Broadcast Systolic Array (IOM-BSA, labeled 1, 2, 3 in Fig.6). IOM-BSA improves energy efficiency by balancing data reuse and register saving which is a variant of OS-SA. In IOM-BSA, each element of the left (or right) matrix is spatially reused by multipliers in the same row(or in the same column), which achieves outer product to obtain good data reuse. The array is divided into four tiles. In each tile, using broadcast to save registers for systolic and reduce systolic cycles which reduces pipeline filling cycles. Between tile and tile, using registers to transmit data, maintaining the scalability of the systolic array. Each tile contains an 8×8 array of Dot-Product Element (DPE) units. The dot-product operation achieves inner product to save accumulators compared to OS-SA. In summary, the shape of the array is set to 16×16 units, each with two multipliers. We have two considerations for setting the number of multipliers in DPE to 2.

Proposed mathematical formula: In order to determine the optimal data reuse for OS-based arrays with the inner-outer-mixed product, we discuss matrix multiplication $C_{m\times n}=A_{m\times d}B_{d\times n}$, and consider that the data format of the multiplier and accumulator are INT8, INT32, respectively. The SRAM for storing A, B, and Psum (or C) are denoted as A SRAM, B SRAM, and Psum SRAM. Therefore, if an array has

no spatial reuse at all, then it needs to access m×n×d×8 bits from A SRAM(read), m×n×d×8 bits from B SRAM(read), and 2×m×n×d×32 bits from Psum SRAM(write and read). In addition, we denoted the number of rows of the array as a (B is spatially reused a times), the number of multipliers in a unit as b (Psum is spatially reused b times), and the number of columns as c (A is spatially reused c times). Then when performing MM, the access of A SRAM is 8mnd/c bits. The access of B SRAM is 8mnd/a bits. The psum memory access is 0 since output-stationary. Therefore, the total SRAM access is:

$$\frac{8mnd}{a}+\frac{8mnd}{c} \quad (1)$$

Since a×b×c=number of multipliers, substituting abc=512 into the formula(1) leads to a basic inequality, as shown in formula(2).

$$\frac{8mnd}{a}+\frac{mnd}{64}ab \geq \frac{mnd\sqrt{b}}{\sqrt{2}} \left(when\ a=\frac{16\sqrt{2}}{\sqrt{b}}, c=\frac{32}{\sqrt{2}\sqrt{b}}\right) \quad (2)$$

Formula(2) shows that as b increases, data reuse decreases. Therefore, to maintain good data reuse, we prefer to select b=2. At the same time, we can determine the optimal shape of the array for data reuse is 16 rows and 16 columns.

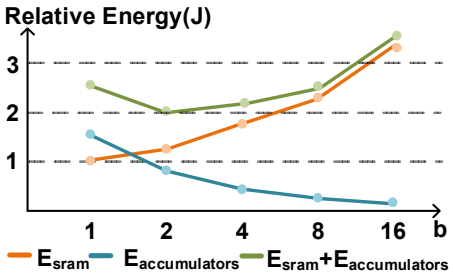

Fig. 7. Energy of SRAM and accumulators versus b.

As shown in Fig.7, to further balance data reuse and register saving, we evaluated the energy curve of SRAM (E_{sram}) and the energy curve of the accumulator ($E_{accumulator}$) as b increases while computing $Q\times K^T$. E_{sram} + $E_{accumulator}$ reaches its minimum value when b = 2. Therefore, we set two multipliers in each DPE based on formula(2) and Fig.7.

Feature 2: Bypass Register (labeled 4 in Fig.6) to balance utilization. Each DPE contains a bypass register with three behaviors: 1) Copying the value of the accumulator in each DPE, 2) Transmitting the bypass register value from the left DPE to the right DPE, and 3) Gating. The offloading task is accomplished through the bypass register by copying the accumulator result to the bypass register, allowing computation and offloading to overlap. Utilization is improved since the latency caused by offloading is hidden. The bypass register only works during the offload phase and is turned off via clock gating at other times. The additional register write energy due to the bypass register is negligible, as offload cycles are much less than computation cycles.

Feature 3: Booth Sharing (labeled 5 in Fig.6). Booth Sharing further improves energy efficiency. In conventional matrix multiplication arrays, each INT8 multiplier typically contains a Booth encoder circuit to implement a high-speed multiplier. We observed that the outer-product-based array shares the same operands across rows and columns, which introduces duplicate Booth coding. Therefore, we encode the operands in each column once and then spatially reuse the encoded operands, reducing the number of Booth encoder circuits. Booth Sharing decreases multiplier energy, improving energy efficiency. Specifically, we reduced the number of Booth encoder circuits from 512 to 32 through Booth sharing.

C. *Proposed Multi-Row Interleaved Operation Ordering*

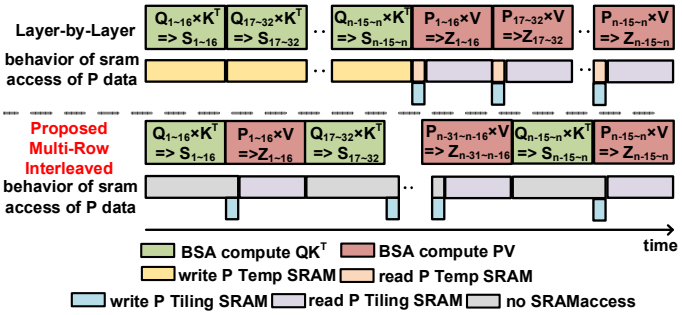

Fig. 8. Comparison between layer-by-layer and proposed Multi-Row Interleaved operation ordering.

Fig.8 shows the proposed Multi-Row Interleaved operation ordering and compares it with layer-by-layer operation ordering, where n is the token length. The P SRAM in Fig.2 includes both the P Temp SRAM and P Tiling SRAM in Fig.8.

Multi-Row Interleaved means that multiple rows of the S matrix and the Z matrix are processed alternately using the same array. Specifically, in the top-level architecture of Fig.5, the BSA is first used to compute the $Q\times K^T$, and the 16 rows of Q are written into the Q Tiling SRAM. The row mux selects the Q data from the Q Tiling SRAM, and the col mux selects the K data from the K SRAM. BSA computes $Q\times K^T$ and outputs the 16 rows of S, which enter the Softmax. When the computation of 16 rows of S is completed, The 16 rows of P from Softmax will also be ready. The row mux selects the P data from Softmax, and the col mux selects the V SRAM. Then, the BSA jumps from the $Q\times K^T$ to the P×V, and P data will be written to the P Tiling SRAM to provide the subsequent data for P Tiling. When the computation of 16 rows of Z is completed, the BSA jumps back from the P×V to the $Q\times K^T$. Therefore, $Q\times K^T$ and P×V are executed interleaved until the entire computation is completed. Multi-Row Interleaved significantly reduces the $E_{P\ sram}$, as it eliminates the access overhead of P Temp SRAM compared to layer-by-layer. Typically, the access overhead of P Temp SRAM is higher than that of P Tiling SRAM due to its larger capacity. Specifically, the capacity of P Temp SRAM and P Tiling SRAM are n×n×8 bits, and 16×n×8 bits, respectively.

IV. Evaluation

A. *Experiment Setup*

We evaluate the proposed hardware architecture and compare it with previous works in 28nm technology. The clock

TABLE I. SETTINGS OF SRAMS IN Q×K^T

SA / SRAM	Q	Q Tiling	K	S
IS-SA	32KB (2048×128)	none	32KB (1024×256)	32KB (512×512)
WS-SA	32KB (1024×256)	none	32KB (2048×128)	32KB (512×512)
OS-SA	32KB (2048×128)	1KB (64×128)	32KB (1024×256)	none
Proposed IOM-BSA	32KB (1024×256)	1KB (32×256)	32KB (1024×256)	none

TABLE II. SETTINGS OF SRAMS IN P×V

SA / SRAM	P	P Tiling	V	Z
IS-SA	256KB (16384×128)	none	32KB (1024×256)	4KB (64×512)
WS-SA	256KB (8192×256)	none	32KB (2048×128)	32KB (512×512)
OS-SA	256KB (2048×128)	8KB (512×128)	32KB (1024×256)	none
Proposed IOM-BSA	256KB (8192×256)	8KB (256×256)	32KB (1024×256)	none

frequency of all architectures is fixed at 500MHz and the power supply voltage is fixed at 0.9V. The energy consumption of the multipliers, adders, SRAMs, and registers is obtained using a 28nm Standard Cell Library, commercial SRAM compiler and Synopsys Design Compiler 2013. The utilization of different architectures is determined by dividing the ideal computing cycles by the actual computing cycles. To compare the energy efficiency fairly, we fixed the number of multipliers and adders to 512, and the data format of the multiplier and accumulator are INT8 and INT32. The evaluation model is BERT-base. For the BERT-based model, the token length of 512 can cover most applications [12], so evaluation under the token length n=512. TABLE I and II shows the settings of SRAMs for evaluating total energy of SRAM (E_{sram}) in different SAs, including capacity and shape. The format of the shape is depth×width. The array shape of IS/WS/OS-SA is set to 32×16[10][14][12], and all SAs use data tiling as much as possible to reduce the E_{sram}.

B. The Evaluation of Proposed BSA

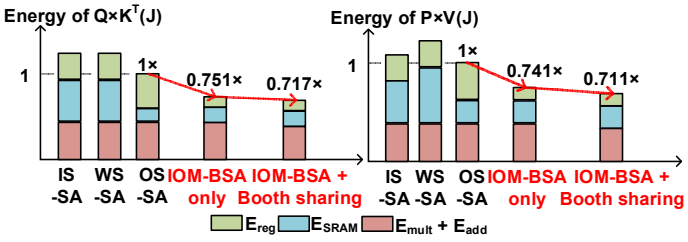

Fig. 9. Evaluation of the energy of BSA.

Fig.9 compared the energy of BSA to conventional SAs in Background. The energy of multiplier E_{mult} and the energy of adder E_{add} are equal since using the same data format and arithmetic circuit. In BSA, IOM-BSA and Booth sharing are techniques to improve energy efficiency. The E_{sram} of IOM-BSA is close to that of OS-SA and better than IS/WS-SA as it takes advantage of outer product. The total register energy E_{reg} of IOM-BSA is better than that of IS/WS/OS-SA since inner product and broadcast significantly reduce the overhead of accumulators and registers for systolic. IOM-BSA achieves a maximum energy reduction of 25.9% (0.741× in Fig.8) compared to the SA with the smallest total energy (E_{sram}+E_{reg}+E_{mult}+E_{add}). Booth sharing further reduces E_{mult}, lowering the total energy by an additional 4%. As the SA scales, larger arrays will amplify the benefits of Booth sharing.

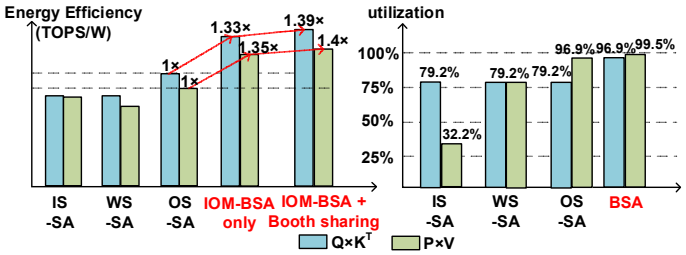

Fig.10. Evaluation of the energy efficiency and utilization of BSA.

The left side of Fig.10 compares the energy efficiency of BSA with conventional SAs. The proposed IOM-BSA achieves up to a 35% improvement in energy efficiency compared with OS-SA, with Booth sharing providing an additional 5% boost. The right side of Fig.9 compares the utilization of BSA with conventional SAs. The high utilization of the proposed BSA is attributed to two factors: 1) tiled broadcast reduces the number of systolic cycles, and 2) the bypass register overlaps offloading and computation, allowing BSA to maintain the highest utilization in both Q×K^T and P×V.

C. Comparison with Previous Hardware Architecture

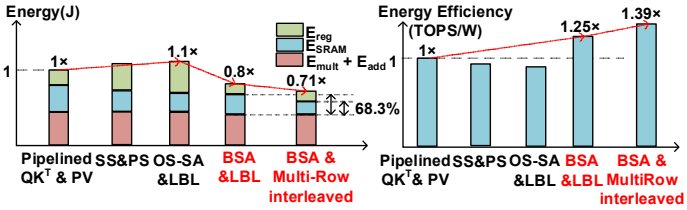

Fig.11. Evaluation of the energy of the proposed architecture.

The hardware architecture and Multi-Row Interleaved operation ordering are evaluated in this section. We compare five attention accelerator hardware architectures: three of them are pipelined QK^T & PV, SS & PS, and OS-SA & layer-by-layer (OS-SA & LBL) in Fig.2. The fourth architecture is BSA & LBL, used to evaluate the improvement brought by BSA, and the fifth architecture is BSA & Multi-Row Interleaved, used to evaluate the improvement brought by Multi-Row Interleaved. In the pipelined QK & PV architecture, we follow the design from [7], where Q×K^T uses an input stationary matrix-vector multiplication(IS-MVM) array with a shape of 64×4, and P×V uses a Broadcast-based outer product array with a shape of 4×64. The array shape of SS & PS is 32×16[8][10]. In the OS-SA & layer-by-layer(LBL), the shape of OS-SA is 32×16[12].

The left side of Fig.11 evaluates the energy of different architectures. OS-SA & LBL has the lowest E_{sram}, as both Q×K^T

and P×V use the outer product, but the overhead from a large number of registers results in the highest total energy. Although the E_{sram} of pipelined QK^T & PV architecture is the highest, it does not incur the overhead of registers for systolic, which greatly reduces E_{reg}, leading to lower total energy compared to SS & PS and OS-SA & LBL. BSA reduces total energy by 20% compared to the pipelined QK^T & PV architecture, which has the lowest energy in previous work. Multi-Row Interleaved eliminates the access overhead of P Temp SRAM, reducing E_{sram} to 68.3% of the E_{sram} of layer-by-layer. BSA & Multi-Row Interleaved reduces the total energy by 29%. The right side of Fig.11 evaluates the energy efficiency of different architectures. BSA improves the energy efficiency by 25%. Multi-Row Interleaved further improves the energy efficiency by 14%.

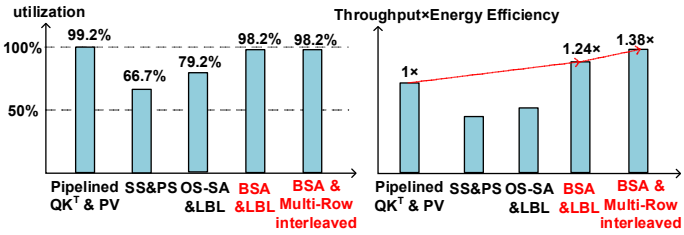

Fig. 12. Evaluation of utilization and throughput×energy efficiency of the proposed architecture.

The left side of Fig. 12 shows the utilization of the five architectures. The pipelined QK^T & PV achieves the highest utilization, reaching 99.2%. SS & PZ has the lowest utilization due to idle cycles of the multiplier caused by pipeline filling, which account for a significant proportion of the P×V. OS-SA & LBL also exhibit low utilization due to the low utilization of the OS systolic array. BSA & LBL can maintain a high utilization of 98.2% due to the high utilization of BSA. Multi-Row Interleaved does not reduce the utilization compared to layer-by-layer while increasing energy efficiency, as it does not introduce idle cycles. Consequently, BSA & LBL architecture and BSA & Multi-Row architecture Interleaved achieve the same high utilization. With improved overall utilization and energy efficiency, the proposed architecture achieves a 38% improvement in throughput×energy efficiency compared to the previous architecture.

V. Conclusion

This paper proposes a hardware architecture for the attention mechanism in Transformer, focusing on optimizing energy efficiency and utilization solely through hardware design. The proposed BSA balances data reuse, register saving, and utilization, achieving up to a 40% improvement in energy efficiency compared to conventional SAs while maintaining 99.5% utilization.The proposed Multi-Row Interleaved reduces E_{sram} by 31.7% and further enhances energy efficiency by 14%. By combining the two techniques, the attention accelerator proposed in this paper achieves a 39% improvement in energy efficiency and a 38% improvement in throughput×energy efficiency compared to previous works.

***Abstract*—Quantum readout error is the most significant source of error, substantially reducing the measurement fidelity. Tensor-product-based readout error mitigation has been proposed to address this issue by approximating the mitigation matrix. However, this method inevitably encounters the dynamic generation of the mitigation matrix, leading to long latency. In this paper, we propose DyREM, a software-hardware co-design approach that mitigates readout errors with an embedded accelerator. The main innovation lies in leveraging the inherent sparsity in the nonzero probability distribution of quantum states and calculating the tensor product on an embedded accelerator. Specifically, using the output sparsity, our dataflow dynamically downsamples the original mitigation matrix, which dramatically reduces the memory requirement. Then, we design DyREM architecture that can flexibly gate the redundant computation of nonzero quantum states. Experiments demonstrate that DyREM achieves an average speedup of $9.6\times \sim 2000\times$ and fidelity improvements of $1.03\times \sim 1.15\times$ compared to state-of-the-art readout error mitigation methods.**

I. Introduction

In the current Noisy Intermediate-Scale Quantum (NISQ) era, various sources of errors hinder the full realization of quantum computing advantage [1], [2]. Among these, readout error is a significant source of noise, with error rates ranging from 1% to 10% on state-of-the-art superconducting quantum processors [2]–[4]. Consequently, mitigating readout error is essential to ensure high fidelity in both NISQ quantum processors and future fault-tolerant quantum systems.

Several mitigation approaches have been proposed, including matrix-based mitigation [5]–[7], machine learning [8], and measurement subsetting [9]. Among these, matrix-based mitigation is widely used, employing matrix-vector multiplication (MVM) to improve measurement fidelity. However, this approach is computationally intensive as the mitigation matrix size grows exponentially with the number of qubits [10]. To address the memory issue, the tensor-product-based approach provides a more general formulation by decomposing the mitigation matrix into a tensor product of sub-mitigation matrices. Each sub-mitigation matrix is independently characterized based on the specific subset of qubits. This formulation avoids constructing and storing the full-dimensional mitigation matrix, making it inherently scalable.

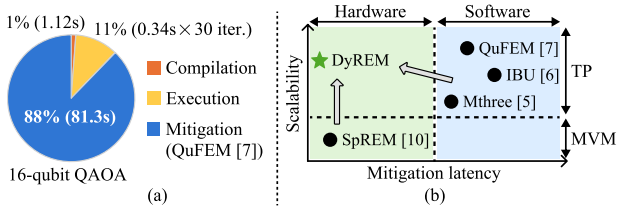

Fig. 1. (a) Breakdown of end-to-end latency for the 16-qubit QAOA on the 156-qubit ibm_fez quantum processor. (b) The tradeoff between scalability and latency for MVM-based method SpREM [10] and tensor-product-based (TP) methods Mthree [5], IBU [6], and QuFEM [7].

However, current tensor-product-based approaches still face limitations, including low accuracy, insufficient flexibility, and high latency. For example, Mthree [5] and IBU [6] calculate the mitigation matrix using 2×2 qubit-independent sub-mitigation matrices. However, these 2×2 sub-mitigation matrices fail to consider qubit crosstalk, severely reducing fidelity. To improve fidelity, QuFEM [7] groups physical qubits and utilizes grouping matrices to approximate mitigation matrix. However, QuFEM lacks the adaptability to varying measured qubits, as its grouping matrices are static and require predetermination. Furthermore, the inherently time-intensive nature of tensor product operations results in significant latency across these approaches. For example, as shown in Figure 1(a), the mitigation time of QuFEM accounts for 88% of the end-to-end latency for a 16-qubit QAOA circuit. Overall, as shown in Figure 1(b), current methods face a tradeoff between scalability and mitigation latency.

In this paper, we propose DyREM, a software-hardware co-design approach that dynamically mitigates readout errors with an embedded accelerator. The key innovation of DyREM lies in exploiting the inherent sparsity in the nonzero probability distribution of quantum states and calculating the tensor product on an embedded accelerator. To adapt to varying measured qubits, our dataflow dynamically downsamples the original mitigation matrix to obtain the required mitigation matrix. Then, we introduce nonzero state-oriented computation

*Corresponding author

to compress and calculate the mitigation matrix efficiently. Finally, we design DyREM architecture to support our dataflow, which can flexibly gate the redundant computation of nonzero quantum states.

The contribution of this paper can be summarized as follows:

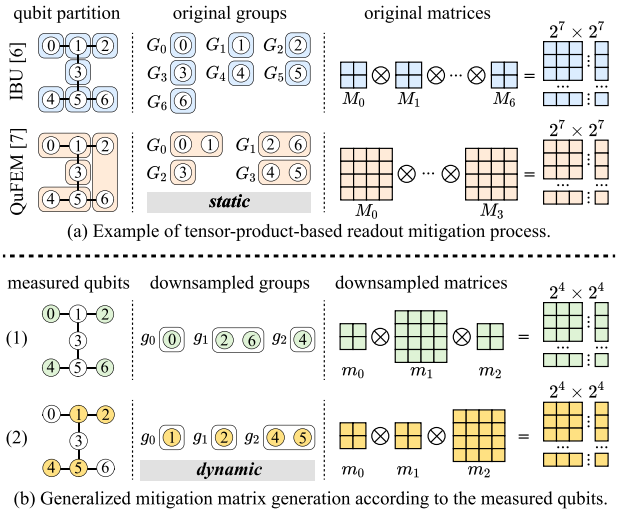
- We propose DyREM, a software-hardware co-design approach that dynamically mitigates readout error with an embedded accelerator, leveraging the inherent sparsity in the nonzero probability distribution of quantum states.
- We introduce a dataflow that dynamically downsamples the original mitigation matrix, dramatically reducing the memory requirement. We further design DyREM architecture that flexibly gates the redundant computation of nonzero quantum states.
- We evaluate the effectiveness of DyREM by comparing it with state-of-the-art readout error mitigation methods. The results demonstrate the superiority of DyREM, achieving an average of $9.6\times \sim 2000\times$ speedup and $1.03\times \sim 1.15\times$ fidelity improvement.

II. Background

A. Matrix-Based Readout Error Mitigation

After the measurement operation, the readout error maps the ideal probability distribution P_{ideal} into a noise probability distribution P_{noisy}. This process can be mathematically represented as a linear transformation, where P_{ideal} is multiplied by a noise matrix. To mitigate readout error, we need to multiply P_{noisy} by a mitigation matrix M:

$$P_{miti} = M \cdot P_{noisy} \tag{1}$$



where the size of M is $2^n \times 2^n$ (n refers to the number of qubits). After the mitigation, the probabilities of the ideal states are expected to increase, while those of the noisy probabilities are reduced. However, the size of M scales exponentially with n, exhibiting poor scalability. For example, a 30-qubit mitigation matrix requires 32,768 PB of memory, which is $46.8\times$ the capacity of the world's fastest supercomputer Frontier (700 PB) [11].

B. Tensor-Product-Based Readout Error Mitigation

To address the memory issue, tensor-product-based readout error mitigation has been proposed. The key idea is to approximate the full-dimensional mitigation matrix M using a series of tensor-product operations [5]–[7]:

$$P_{miti} = (M_1 \otimes M_2 \otimes \cdots \otimes M_k) \cdot P_{noisy} \tag{2}$$

where $M_1, M_2, \cdots, M_k$ are sub-mitigation matrices obtained by partitioning the measured qubits into k groups. As illustrated in Figure 2(a), IBU [6] regards each physical qubit as an independent unit and approximates M using a tensor product of seven 2×2 mitigation matrices (i.e., $M_0 \sim M_6$). However, IBU achieves only limited mitigation accuracy because it neglects the measurement crosstalk between qubits.

(a) Example of tensor-product-based readout mitigation process.

(b) Generalized mitigation matrix generation according to the measured qubits.

Fig. 2. (a) Tensor-product-based readout mitigation process. (b) Generalized mitigation matrix generation by dynamically computing the downsampled groups.

To consider crosstalk effects, QuFEM [7] proposes a more general formulation by grouping physical qubits to approximate M accurately. As shown in Figure 2(a), seven qubits on the device are partitioned into four groups (i.e., $G_0 \sim G_3$) by quantifying the interactions between qubits. Each group is then characterized to produce its own mitigation matrix (i.e., $M_0 \sim M_3$). However, the groups and their mitigation matrices are ***static*** as they must be pre-determined before the mitigation process begins.

C. Motivation

In practical quantum circuit execution, the set of measured qubits varies due to differing levels of transpiler optimization, as shown in Figure 2(b). Consequently, the groups of measured qubits are dynamic, rendering the pre-determined mitigation matrices unsuitable for reuse during mitigation.

This limitation motivates us to develop a new approach to enable dynamic readout error mitigation. To this end, we introduce the concept of *downsampled group*, denoted by g_i. We dynamically determine the downsampled group g_i based on the measured qubits and original groups G_j. Then, we calculate the downsampled matrices m_i for g_i by deriving them from the original matrices M_j. Finally, we calculate the mitigation matrix based on the downsampled matrices m_i and perform the MVM step to complete mitigation.

III. DyREM Dataflow

A. Mitigation Dataflow Overview

Figure 3 illustrates an example of DyREM mitigation dataflow. The input consists of measured qubits and noisy distribution. The output is mitigated distribution P_{miti}. The dataflow is divided into three steps. **Step 1.** downsampled groups generation: we partition the measured qubits '①②④⑤' according to the original groups $G_0 \sim G_3$. Then, we obtain four downsampled groups $g_0 \sim g_3$, which serve as the input for matrix downsampling. **Step 2.** matrix downsampling: we categorize the downsampled groups

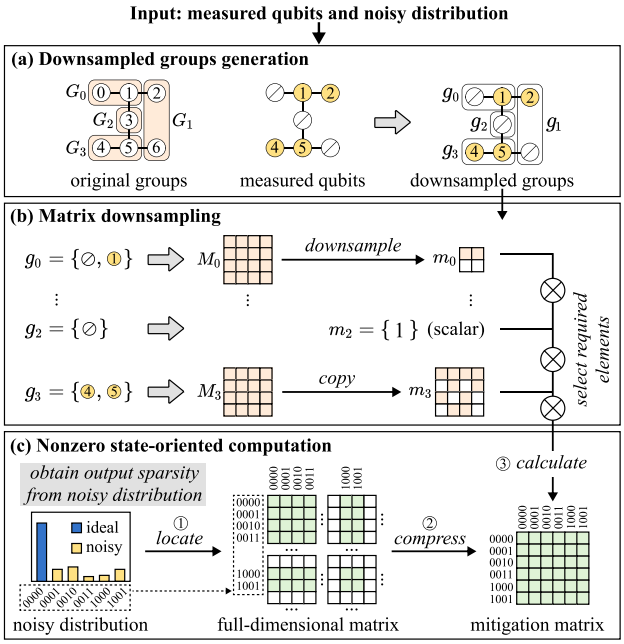


Fig. 3. Example of DyREM mitigation dataflow.

$g_0 \sim g_3$ into three types. Then, we adopt three strategies to generate the downsampled matrices $m_0 \sim m_3$, serving as the input for nonzero state-oriented computation. **Step 3.** nonzero state-oriented computation: we first obtain the output sparsity from the noisy distribution. Then, we compress the full-dimensional matrix based on the output sparsity. Next, we calculate the mitigation matrix by selecting the required elements from the downsampled matrices $m_0 \sim m_3$ and performing multiplication. Finally, we perform matrix-vector multiplication to mitigate the readout error.

In the following sections, we explain the details of **step 2** and **step 3**, respectively.

B. Matrix Downsampling

As depicted in Figure 3(a), some physical qubits are not measured (denoted by ⊘) in circuit execution. Therefore, the downsampled groups $g_0 \sim g_3$ are not identical to the original groups $G_0 \sim G_3$. To consider this variation, we categorize the downsampled groups into three types: (1) unmeasured (e.g., g_2), (2) fully measured (e.g., g_3), and (3) partially measured (e.g., g_0 and g_1). As shown in Figure3(b), we employ tailored strategies to generate downsampled matrices for each type of group. For 'unmeasured' g_2, we set its downsampled matrix to scalar '1', which does not influence the computational result. For 'fully measured' g_3, we directly copy the original matrix M_3 to obtain the downsampled matrix m_3 without additional computation. For 'partially measured' g_0 and g_1, we apply a convolution kernel to downsample the original matrix.

Figure 4 presents the downsampling of the original matrix M_0. Figure 4(a) illustrates the process of deriving the marginal probability distribution (MPD) of variable X from the joint probability distribution (JPD) of two variables X, Y. By taking cross sections of the JPD along the x-axis and performing integration, the probability distribution of variable X is obtained. This process inspires us to use convolution kernels to downsample the original matrix, as the original matrix M_0 essentially represents the JPD of discrete variables (e.g., qubits). Figure 4(b) presents the detailed process. To obtain the convolution kernel, we first generate the valid coordinates based on g_0, where the value at measured qubit ① is fixed at 0, and the value at ⊘ is filled sequentially from '00' to '11'. The values at the valid coordinates are set to 1, while all other positions are set to 0. Then, we extract the maximal sub-coordinate '10', convert it to decimal, and add one to obtain the kernel size. Next, we determine the stride based on g_0 by setting ⊘ to 0 and measured qubit ① to 1. We then convert '01' to decimal to obtain the stride (e.g., 1). Finally, we scan M_0 using the kernel and normalize each row to obtain the downsampled matrix m_0.

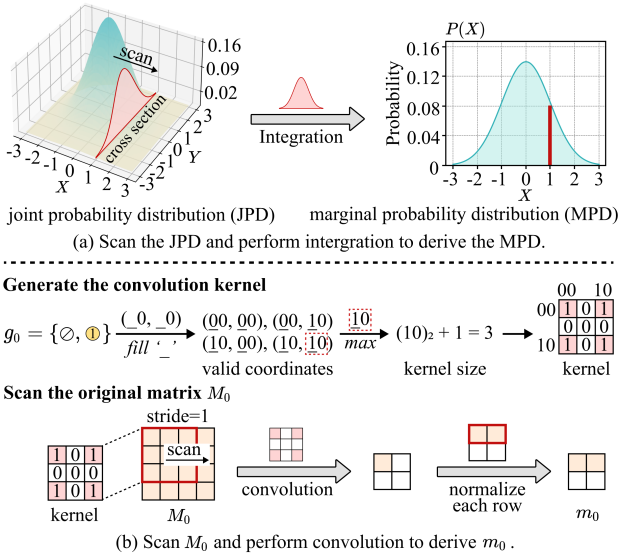

Fig. 4. Inspiration and an example of the matrix downsampling for partially measured groups.

C. Nonzero State-Oriented Computation

To enable on-chip calculation of the mitigation matrix, we propose nonzero state-oriented computation, comprising two steps: mitigation matrix compression and nonzero state similarity detection.

Mitigation matrix compression. A straightforward approach to obtain the mitigation matrix is to compute the tensor product of the downsampled matrices m_0 to m_3. However, this approach is time-consuming and resource-intensive. We observe that the ideal distribution usually lies in the noisy distribution, which only contains a few nonzero values. Therefore, we exploit this output sparsity from the noisy distribution to compress the mitigation matrix. By confining the mitigation process to the noisy space, we reduce the mitigation matrix size from exponential to linear. For example, in Figure 3(c), the mitigation matrix size is reduced from 16×16 to 6×6 based on the output sparsity.

Nonzero state similarity detection. After compression, we cannot simply perform a tensor product of downsampled matrices to calculate the mitigation matrix. Figure 5 shows

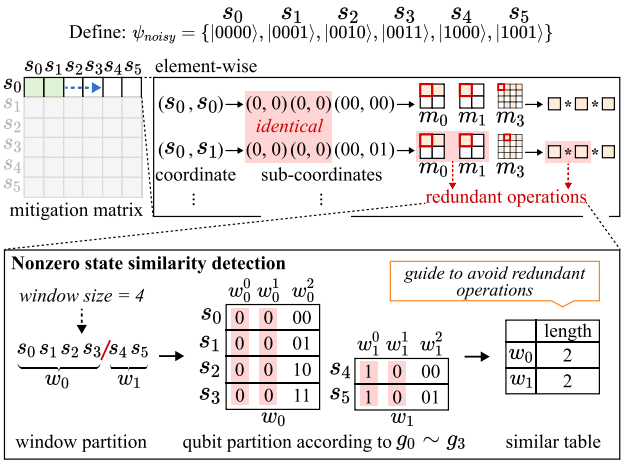

Fig. 5. The element-wise calculation process of mitigation matrix and the illustration of nonzero state similarity detection.

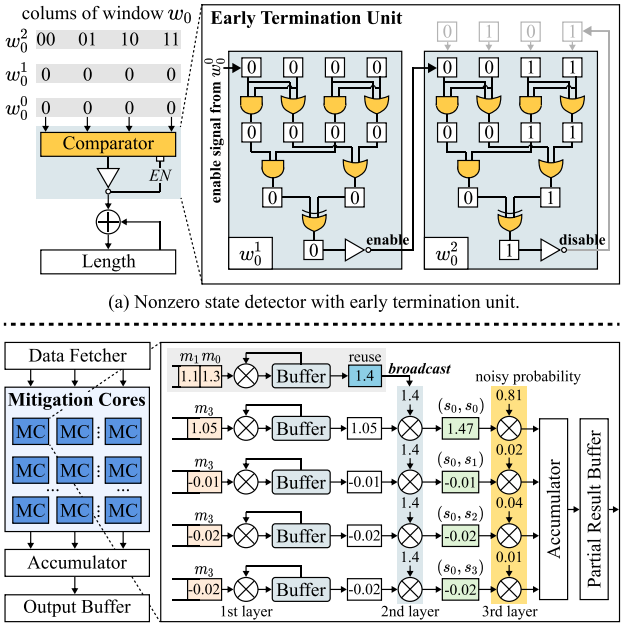

a straightforward approach to compute the mitigation matrix elements individually: for each element, its coordinates are divided into sub-coordinates based on the downsampled groups $g_0 \sim g_3$; the corresponding elements are then extracted from the downsampled matrices $m_0 \sim m_3$ and multiplied cumulatively to obtain the matrix element. However, we find that this approach involves many redundant operations. For example, the first two sub-coordinates of (s_0, s_0) and (s_0, s_1) are identical, which means the extraction and multiplication for (s_0, s_1) are redundant.

To eliminate redundant operations, we introduce nonzero state similarity detection. Specifically, we use a window to partition the noisy states sequentially. Note that we assume the noisy states are ordered according to their binary values. Then, we partition the qubits of noisy states according to the downsampled groups $g_0 \sim g_3$. Within each window, we identify the longest identical segment and obtain its length to construct a similar table. We can generate this table once we receive the noisy distribution. Then, we utilize this table to guide the calculation of the mitigation matrix, thereby eliminating redundant operations. Accordingly, we compute each row of the mitigation matrix window-wise rather than element-wise.

Figure 5 shows the process of computing a similar table for a mitigation matrix. First, we set the window size to 4. Then, the noisy states are partitioned into two windows (i.e., w_0 and w_1). In each window, the noisy states are partitioned into three columns according to the downsampled groups $g_0 \sim g_3$. Clearly, in w_0, the largest identical segment is (w_0^0, w_0^1), while in w_1, it is (w_1^0, w_1^1). Next, we record the length of these two segments in a similar table (i.e., 2 and 2). After applying the nonzero state similarity detection, we reduce the extraction and multiplication operations required for 6×6 mitigation matrix calculation by 44% and 33%, respectively.

IV. Architecture Design

We design an accelerator architecture to implement DyREM, primarily consisting of two components: a nonzero state detector and a mitigation core array. The nonzero state

(a) Nonzero state detector with early termination unit.

(b) The mitigation module with dedicated mitigation core.

Fig. 6. The hardware design details of DyREM.

detector efficiently calculates the length of the longest identical segment for each window. The mitigation core array receives the values from downsampled matrices and noisy probabilities. Each mitigation core (MC) employs a three-layer multiplier to integrate the mitigation matrix calculation with the MVM step.

A. Nonzero State Detector

As shown in Figure 6(a), the nonzero state detector integrates an early termination unit with an adder. The early termination unit consists of a comparator and a NOT gate. The comparator receives the columns of each window and determines whether the bits in each column are identical. The comparator consists of a series of logic gates (AND, NOT, and XOR gates), forming a hierarchical tree. If the comparator outputs '0', it indicates that all bits in the column are identical; otherwise, they are not. Specifically, the output then passes through a NOT gate to generate an enable signal, indicating whether the subsequent comparison should proceed. In other words, if the bits in the previous column are not identical, there is no need to perform further comparisons. After each comparison, the adder receives the output from the NOT gate, accumulating them to obtain the identical table.

Figure 6(a) shows an example of the nonzero state detector operating on window w_1. The comparator first receives the bits in w_0^0 and determines they are identical, enabling the comparison of w_0^1. Meanwhile, the length increases by one. Similarly, the comparison result of w_0^1 enables the comparison of w_0^2, while incrementing the length to 2. Since each element in w_0^2 contains two bits, we divide w_0^2 into two parts and sequentially input them into the comparator. As shown in Figure 6(a), the first part is not identical. Thus, the output of the comparator is 1, disabling the comparison of the second part. Consequently, the length is incremented by 0. Finally, the length is 2, indicating w_1 has two identical columns.

TABLE I
THE HARDWARE PERFORMANCE COMPARISON.

Baseline	Technical feature	VQE [12]		QAOA [13]		DJ [14]	
		Latency (s)	Q-throughput (states/s)	Latency (s)	Q-throughput (states/s)	Latency (s)	Q-throughput (states/s)

B. Mitigation Core

As depicted in Figure 6(b), the mitigation module comprises a data fetcher, a mitigation core array, an accumulator, and an output buffer. The data fetcher receives the similar table and the noisy distribution. Then, it extracts the values from the downsampled matrices and passes them to the mitigation core array. We allocate 4KB of on-chip SRAM for the downsampled matrices to support quick random accesses, with each element stored in FP16 format.

Each MC is responsible for a single window, including calculating the mitigation matrix elements and performing the mitigation. Within the MC, we set up a FIFO for each multiplier (1st layer) to stockpile the values from downsampled matrices. In particular, the FIFO in the first row is used to calculate the reused data. Each remaining FIFO corresponds to the calculation of a mitigation matrix element. After obtaining the reused data, we broadcast it to the multipliers in the 2nd layer. Then, we perform multiplication to calculate the mitigation matrix elements within the window. Finally, we execute mitigation by multiplying noisy probabilities and the mitigation matrix elements. The accumulator receives the results from each multiplier and sends the accumulated result to the partial result buffer. The results of the MCs within a row are accumulated to yield one mitigated probability.

Figure 6(b) illustrates an example of the MC processing w_0. The values 1.1 and 1.3 correspond to the sub-coordinates $(0, 0)$ and $(0, 0)$ of (s_0, s_0) in Figure 5, respectively. The multiplication result 1.4 is reused to compute mitigation matrix elements within w_0. After obtaining the values of $(s_0, s_0) \sim (s_0, s_3)$, we perform multiplication with noisy probabilities and accumulate the results to obtain the mitigated result of w_0.

V. EVALUATION

A. Evaluation Setup

Hardware implementation. We develop DyREM accelerator using Xilinx High-Level Synthesis (HLS) C++ and implement it with Vitis 2023.1. We evaluate its hardware performance on the Xilinx U50 FPGA, operating at 300 MHz.

Benchmarks. The benchmarks include Variational Quantum Eigensolver (VQE) [12], Quantum Approximate Optimization Algorithm (QAOA) [13], Feedback-Based Quantum Optimization (FALQON) [15], and Deutsch-Jozsa (DJ) [14] algorithms, with two layers set for both VQE and QAOA.

Baselines. We compare DyREM with state-of-the-art readout error mitigation methods, including Mthree [5], SpREM [10], IBU [6] and QuFEM [7]. For Mthree, SpREM, and IBU, we set the Hamming distance to 3. The convergence tolerance of IBU is set to 10^{-4}. The iteration number and pruning threshold of QuFEM are set to 2 and 10^{-4}. The window size of DyREM is set to 4 to achieve a high data reuse rate.

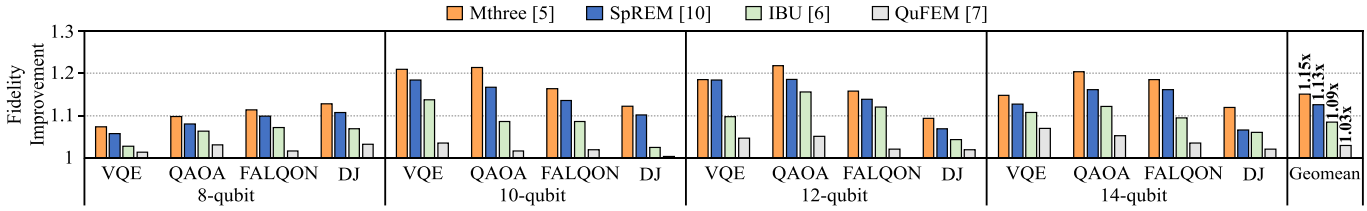
Evaluation platform. We perform error mitigation experiments on the 136-qubit Quafu [16] quantum platform, where the readout error rate is 4.5%. We utilize QuFEM [7] to perform qubit partition and mitigation matrix characterization, with the number of qubits in a group set to 2. We implement Mthree [5] and IBU [6] on NVIDIA A100 GPU (using `cuBLAS` v12.4 and `JAX-GPU` v0.4.13, respectively). QuFEM is a software-friendly approach, and we implement it on an AMD EPYC 9554 64-core CPU (using `NumPy` v1.24.3). We implement SpREM accelerator on the Xilinx U50 FPGA using HLS C++, operating at 300 MHz.

B. Evaluation of Hardware Performance

Table I shows the average hardware performance comparison of DyREM with baselines, evaluated on the VQE, QAOA, and DJ algorithms, using 16, 20, 24, and 28 qubits.

Latency: DyREM achieves a geometric average speedup of $9.6\times \sim 2000\times$ over baselines. Such a high speedup compared to conventional computing platforms (CPU and GPU) is attributed to the specialized computational architecture, which effectively detects and avoids redundant operations while generating the mitigation matrix. Although SpREM [10] exploits the Hamming sparsity to avoid operations involving zero values, it fails to eliminate redundant computations based on the noisy distribution. In contrast, DyREM compresses the mitigation matrix based on the output sparsity and detects redundant operations, achieving a maximum speedup of $73.8\times$ in the VQE algorithm compared to SpREM.

Q-throughput: We define q-throughput, measured in states per second (states/s), as a metric to evaluate mitigation performance. The geometric average q-throughput of DyREM for VQE, QAOA, and DJ algorithms reaches 4.2×10^6 states/s, 3.5×10^6 states/s, and 5.3×10^6 states/s, representing an improvement over baselines of $2.4\times \sim 2726\times$, $2.3\times \sim 2420\times$, and $1.5\times \sim 2002\times$, respectively. In particular, DyREM achieves $2.4\times$, $2.3\times$, and $1.5\times$ mitigation performance improvements over the custom accelerator SpREM [10]. Rather than relying on external memory to obtain the mitigation matrix (i.e., SpREM), DyREM utilizes the downsampled matrices to calculate the mitigation matrix on-chip. This strategy



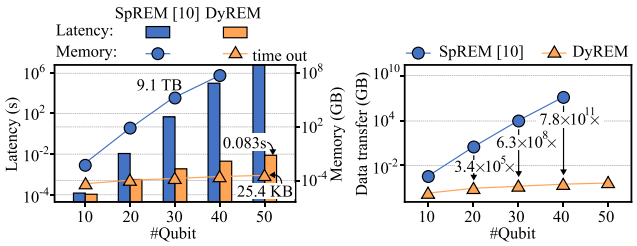


Fig. 7. Fidelity improvement over Mthree [5], SpREM [10], IBU [6], and QuFEM [7] on the benchmarks.

(a) Latency and memory usage of mitigating the DJ algorithm.

(b) Data transfer volume of mitigating the DJ algorithm.

Fig. 8. Comparison between SpREM [10] and DyREM on the DJ algorithm.

effectively reduces the bandwidth demand and improves the utilization of compute units, thereby enhancing throughput.

C. Evaluation of Fidelity

Although DyREM demonstrates outstanding hardware performance, it does not compromise on mitigation accuracy. Figure 7 illustrates the fidelity improvement of DyREM over the baselines. DyREM achieves an average fidelity improvement of 1.15×, 1.13×, 1.09×, and 1.03× over Mthree [5], SpREM [10], IBU [6], and QuFEM [7], respectively. The improvement comes from the fact that DyREM confines the mitigation space and utilizes the group matrices that consider the crosstalk. Conversely, Mthree and IBU use 2×2 mitigation matrices to construct the full-dimensional tensored mitigation matrix, failing to consider crosstalk between qubits. SpREM sets a large number of elements in the mitigation matrix to zero using Hamming distance, introducing system errors and reducing mitigation accuracy. Compared to QuFEM, DyREM confines the mitigation within the noise space, facilitating the convergence of noise probabilities towards ideal probabilities.

D. Comparison with SpREM

Figure 8 presents the mitigation performance comparison between SpREM [10] and DyREM on the DJ algorithm, with the number of qubits ranging from 10 to 50.

Latency and memory usage. Figure 8(a) shows the latency and memory usage comparison between SpREM [10] and DyREM. Based on nonzero state-oriented computation, DyREM achieves linear time and space complexity. For instance, in the 50-qubit DJ algorithm, DyREM requires only 0.083 seconds of latency and 25.4 KB of memory, whereas SpREM fails to output the mitigation results. The scalability of DyREM stems from the on-chip generation of the mitigation matrix, which circumvents the limitations imposed by finite bandwidth. In contrast, SpREM relies on reading the mitigation matrix from off-chip memory, where the matrix size grows exponentially with the number of qubits, making bandwidth a bottleneck that limits its fast mitigation.

Data transfer. Figure 8(b) compares the data transfer volume between SpREM [10] and DyREM. The data transfer volume of DyREM is linearly increased with the number of qubits, from 0.63 KB (10-qubit) to 37.8 KB (50-qubit), while SpREM exhibits exponential complexity. This is because DyREM only needs to retrieve the measured qubits and noisy distribution from off-chip memory and calculate the mitigation matrix on-chip. Conversely, the mitigation matrix for SpREM is too large to store on-chip (e.g., 9.1 TB for 30-qubit), leading to increased data transfer volume.

VI. Related Work

Matrix-based readout error mitigation. Mthree [5] and SpREM [10] exploit Hamming distance to compress the mitigation matrix. To implement scalable mitigation, IBU [6] utilizes a series of 2×2 qubit-independent sub-mitigation matrices to construct the mitigation matrix. To improve fidelity, CTMP [17] leverages Markovian noise models to mitigate correlated crosstalk errors. QuFEM [7] formulates the mitigation process as a tensor product using grouping matrices.

Other error mitigation techniques. Jigsaw [9] executes quantum programs in two models and employs a Bayesian post-processing step to mitigate measurement errors. HAMMER [18] combines the structure of quantum errors with a reclassification protocol to improve fidelity. Q-BEEP [19] introduces a Hamming spectrum model for characterizing localized and distant clustered Hamming errors. QuTracer [1] traces the states of qubit subsets to mitigate both gate and measurement errors.

VII. Conclusion

This paper proposes DyREM, a co-design approach that dynamically mitigates readout error with an embedded accelerator. The key innovation lies in exploiting the inherent sparsity in the nonzero probability distribution of quantum states and calculating the tensor product on an embedded accelerator. To adapt to varying measured qubits, our dataflow dynamically downsamples the original mitigation matrix. We then design DyREM architecture that flexibly gates the redundant computation of nonzero quantum states. DyREM achieves remarkable improvements compared to other readout mitigation methods.

***Abstract*—Custom accelerators enhance System-on-Chips' performance through hardware specialization. High-level synthesis (HLS) can automatically synthesize accelerators for given kernels but requires manual selection and extraction of kernels from applications. This paper proposes Cayman, the first end-to-end framework to synthesize high-performance custom accelerators with both control flow and data access optimization. Cayman automatically selects kernels for hardware acceleration based on a hierarchical program representation, which captures kernel candidates with general control flows. Besides, Cayman optimizes accelerators with specialized processor-accelerator interfaces for data access acceleration. Cayman further introduces a novel accelerator merging mechanism to synthesize reusable accelerators. Experiments on various benchmarks demonstrate that Cayman outperforms two state-of-the-art frameworks by 8.0× and 14.4×.**

I. Introduction

Integrating accelerators has emerged as a critical strategy for augmenting the performance of modern applications. Specialized tasks are offloaded from the CPU core to accelerators for faster execution. Customizing accelerators encompasses two principal processes: *candidate selection* decides on the offloaded programs regions for acceleration, and *hardware design* implements the hardware accelerator. Manual accelerator design [8] is inefficient owing to the inherent complexity of applications and the intricacy of hardware design. Candidate selection frameworks [29], [30] only explore candidate regions based on accelerator models without synthesizing hardware. High-level synthesis (HLS) tools [11], [15], [25], [26] can synthesize accelerator hardware design from software descriptions. Accelerators' performance, power, and area can be further optimized via design space exploration [20], [27], [28]. However, HLS frameworks rely on designers to manually select the candidate for acceleration, which is time-consuming and often leads to sub-optimal solutions for a complex application.

Prior works attempted to develop an end-to-end flow to synthesize custom accelerators. However, they have severe limitations: they either exclude control flow and data access from accelerated kernels or only synthesize sequential and unoptimized implementation, inhibiting performance improvement. Specifically, custom functional unit synthesis frameworks [2], [5], [6], [10], [16], [19], [21] only accelerate dataflow graphs (DFGs) from target application programs. In other words, they do not accelerate code regions including any control flow or data access to memory. Off-core accelerator synthesis frameworks [4], [22], [23], [31] synthesize accelerators with control flow and memory access support. However, they solely synthesize sequential control flow implementation and adopt slow processor-accelerator interfaces for data access. As a result, they fail to achieve satisfying performance speedup.

This paper proposes Cayman, the first end-to-end framework that synthesizes high-performance custom accelerators with full control flow and data access support. Cayman automates both candidate selection and hardware synthesis. Specifically, Cayman selects kernels to synthesize based on the whole-application program structure tree (wPST) representation, which captures program regions of rich control flows for hardware acceleration. Cayman introduces a dynamic programming-based algorithm with heuristic pruning and solution filtering for efficient and comprehensive selection exploration. To synthesize high-performance accelerators for selected kernels, Cayman proposes an accelerator model that considers specialized processor-accelerator data access interfaces: *coupled*, *decoupled*, and *scratchpad*. The model efficiently generates accelerator configurations comprising control flow optimization and data access interface application and conducts performance and area estimation. Moreover, Cayman proposes a novel accelerator merging mechanism that shares reconfigurable datapath units within a reusable accelerator to accelerate multiple program regions even with diverse control flows, effectively reducing area overhead.

In summary, this paper makes the following contributions:

- We introduce Cayman, an end-to-end framework to synthesize high-performance custom accelerator automatically.
- We propose a dynamic programming-based candidate selection algorithm with heuristic pruning, modeling processor-accelerator data access interfaces and control flows.
- We propose a novel accelerator merging mechanism to synthesize reusable accelerators.

For evaluation, we compare Cayman with two state-of-the-art custom accelerator synthesis frameworks on various applications. Experimental results show that Cayman outperforms NOVIA [21] and QsCores [23] by 14.4× and 8.0× with the same total area budget for the synthesized accelerators.

II. Background and Related Work

A. High-level Synthesis

High-level synthesis (HLS) [9] can synthesize hardware accelerators from software kernels. With a specified target clock period, HLS tools [15], [25], [26] schedule the operations to

* Corresponding author

TABLE I: Comparison between prior works and Cayman.

Methods	design entry	candidate selection	control flow	data access	hardware sharing
HLS[1]	kernel	manual	optimized	specified	/
CFU[2]	application	auto	/	scalar-only	restricted
OCA[3]	application	auto	sequential	slow	restricted
Cayman	**application**	**auto**	**optimized**	**specialized**	**flexible**

[1] [3], [11]–[13], [15], [17], [18], [24]–[26]; [2] [2], [5], [6], [10], [19], [21]; [3] [4], [22], [23], [31]

cycles within the kernel, subsequently crafting the accelerator design based on the scheduling outcome. HLS tools support various optimization techniques, such as loop pipelining and unrolling, which may transform the kernel's source code or direct the scheduler to refine the control logic of the accelerator, thereby enhancing performance. DSE frameworks [20], [27], [28] are proposed to explore the optimizations automatically.

Limitations: As shown in Table I, HLS tools' design entry is software kernels, requiring designers to extract and specify manually, rather than selecting them from applications automatically. As a result, HLS requires significant human interaction. The same problem applies to ASSIST [17], Longnail [18], and Bluespec Accelerate-HLS [3], all of which adopt HLS but require manual candidate selection. Besides, designers must choose data access interfaces for external memory operations in kernels, which impact scheduling and overall performance but are overlooked by existing DSE frameworks.

B. Prior Works on Custom Accelerator Synthesis

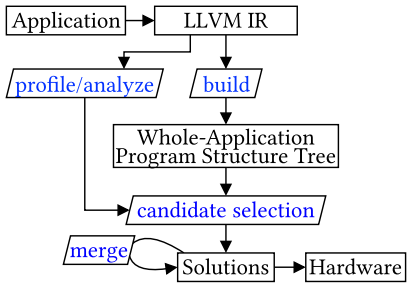
Based on the types of synthesized accelerators, we segregate prior custom acceleration synthesis works into two classes: custom functional unit (CFU) synthesis frameworks [2], [5], [6], [10], [19], [21] and off-core accelerator (OCA) synthesis frameworks [4], [22], [23], [31].

Limitations: As shown in Table I, CFU synthesis frameworks select candidates exclusively in the DFG form, precluding control flows. Their data access interfaces only take scalar operands and return results since they do not support other memory accesses. OCA synthesis frameworks support control flow and memory access. However, they only implement sequential control logic and show data access interfaces, such as the scan-chain interface characterized by high latency and low bandwidth in [22], [23], significantly circumscribing performance gains. For hardware sharing, some CFU synthesis frameworks [5], [21] merge candidates into a reusable CFU, while some OCA frameworks [4], [23] endorse sharing solely among almost identical loops or functions. In other words, they support restricted hardware sharing and cannot reuse one accelerator to accelerate multiple kernels with diverse control flows, missing area-saving opportunities.

III. Methodology

A. Overview

As overviewed in Fig. 1, Cayman ingests target application programs as input and automatically identifies the high-performance solutions, each comprising multiple accelerators. The framework compiles programs into LLVM IR and builds



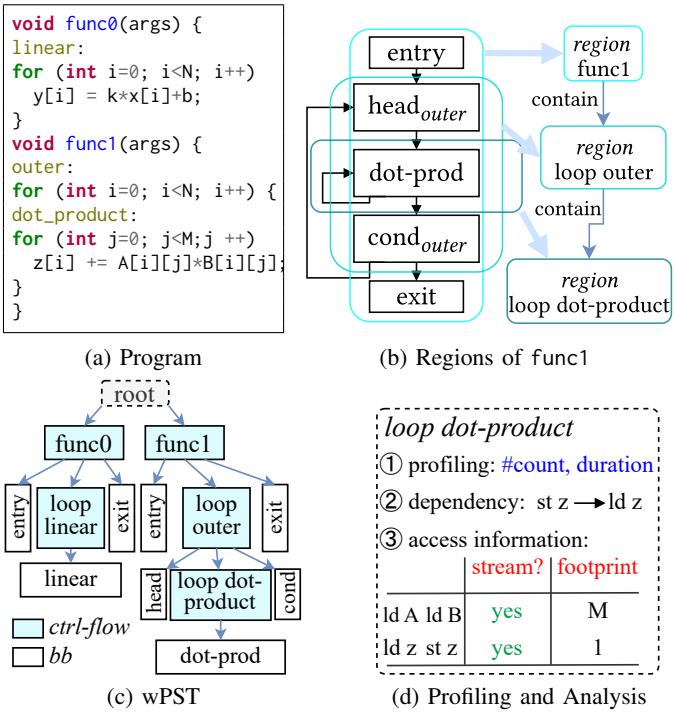


Fig. 1: Overview of the Cayman framework

(a) Program (b) Regions of func1

(c) wPST (d) Profiling and Analysis

Fig. 2: Example

the whole-application program structure tree (wPST) representation. The framework also runs profiling and program analysis through LLVM passes. The framework then leverages the profiling and analysis outcomes to conduct candidate selection on the wPST and produces solutions comprising selected kernels and accelerator configurations.

B. Representation, Profiling, and Analysis

Cayman introduces the whole-application program structure tree (wPST) representation for candidate selection. Traditional program structure tree (PST) [14] identifies single-entry-single-exit (SESE) *regions* inside a function as vertices and represents the containing relationships between regions as edges. The wPST extends PST with a *root* vertex representing the entire application and multiple function vertices representing every included function. We consider only SESE regions as legal acceleration candidates because the SESE property is necessary to guarantee that the candidate's execution can be completely isolated from the main processor through offloading and synchronization at their entry and exit points, respectively. The wPST captures all feasible acceleration candidates as its region vertices in a target application. Specifically, the

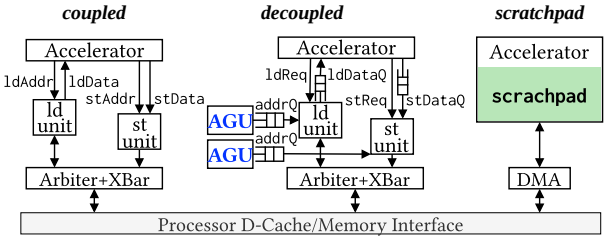

Fig. 3: CPU-accelerator data communication interfaces

wPST represents two region types: *bb* regions, corresponding to basic blocks, and *ctrl-flow* regions, corresponding to general control flow including loops and conditionals.

Cayman profiles application execution information including duration and execution count for every program region. The profiling results are essential for locating hotspot kernels and estimating performance gains. Besides, Cayman conducts program analysis to collect data access information, including memory dependencies, memory access patterns, and access footprints. Specifically, Cayman identifies loop-carried dependencies for every loop region, identifies *stream* access patterns whose access address sequence can be statically computed, and analyzes the access address range for every memory operation. The data access information is crucial for accelerator configuration decisions, including control flow optimizations and data access interface selections.

The program in Fig. 2a contains two functions, and Fig. 2c presents the corresponding wPST, showcasing *ctrl-flow* and *bb* regions as candidates for acceleration. Specifically, Fig. 2b shows the control-flow graph (CFG) of `func1` and illustrates three regions comprising control flows. Fig. 2d presents profiling ① and analysis ②③ results for the "loop dot-product" region. It includes one loop-carried dependency between the store and load operations to/from `z[i]`. Besides, all access operations have the *stream* access pattern, while `ld A` and `ld B` have the access footprint of `M` according to the induction variable `j` and `ld z` and `st z` have the access footprint of `1` due to the invariant `i` in the loop.

C. Accelerator Modeling

Data access interfaces between the processor and accelerators have nonnegligible impacts on the performance and area usage of the accelerators. However, it is overlooked by prior exploration works. Cayman systematically models three types of data access interfaces: *coupled*, *decoupled*, and *scratchpad*, as shown in Fig. 3:

- *Coupled* interface uses load/store units for access. A load-/store unit initiates data access to the memory system upon receiving requests with a target address from the accelerator, causing the accelerator to stall until the response arrives.
- *Decoupled* interface allocates dedicated address generation units (AGUs) for load/store units. The AGUs compute access addresses independently from the accelerator, which enables load units to start data access earlier than the accelerator's requests and enables store units to send out data later, both reducing the accelerator stall cycles. However, the *decoupled* interfaces pay extra area overhead for AGUs and data buffering FIFOs, and are only applicable to *stream*-pattern accesses for the requirements of independent address generation.
- *Scratchpad* interface reserves a dedicated buffer within the accelerator to cache a memory range. Data synchronization between the scratchpad and the memory system occurs before and after accelerator execution through a direct memory access (DMA) engine. It is beneficial when most positions in the cached memory range are accessed multiple times. However, the *scratchpad* interface incurs prominent area overhead for the scratchpad buffer and the DMA engine and requires statically analyzed footprints to determine the scratchpad size.

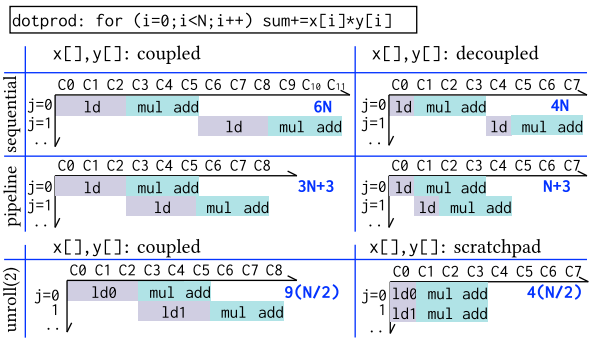

Fig. 4: Impacts of data communication interfaces.

Fig. 4 exemplifies data access interfaces' impacts on accelerator performance considering different control flow implementations. For sequential loop, the *coupled* interface leads to latency of 6N cycles, where N is the tripcount of the loop. The *decoupled* interface optimizes the latency to 4N cycles since it reduces the stall cycles associated with the loads by starting loads sooner before the accelerator requests. For loop pipelining, the *coupled* interface gives a pipeline initial interval (II) of 3 cycles, while the *decoupled* interface achieves an II of 1 cycle. For loop unrolling with the factor 2, the *coupled* interface leads to a latency of 9(N/2) cycles, and the *scratchpad* interface optimizes the latency to 4(N/2) cycles by enabling parallel access to the scratchpad without stalls. Cayman considers interface specialization for different access operations to achieve full data access acceleration.

Accelerator Configuration: Given the selected kernels for acceleration, Cayman can synthesize multiple accelerator configurations comprising control flow optimizations like loop unrolling and pipelining and data access interface strategies to achieve performance-area tradeoffs. Given the huge design space, Cayman adopts a fast exploration strategy. Specifically, it tries unrolling loops without loop-carried dependencies and pipelining the innermost loops after unrolling. Subsequently, Cayman determines data access interfaces heuristically for memory access operations: use *scratchpad* interface for operations with the total access count β times larger than the access footprint, indicating the necessity for caching; use *decoupled* interface for operations inside pipelined loops to achieve ideal II; and otherwise, use the *coupled* interface for area saving. Memory partitioning is configured for *scratchpad* interfaces inside unrolled loops to support parallel access. Consequently,

Algorithm 1: Candidate Selection

```
   Data: wPST T, profiling/analysis results R
   Result: Pareto-optimal selections
1  Function DP(vertex v):
2      if prune(v, R) then return ;
3      if v is bb then
4          F[v] ← filter(pareto(accel(v,R)));
5      else
6          F[v] ← ∅;
7          for u ∈ v.children do
8              DP(u);
9              F[v] ← filter(F[v] ⊗ F[u]);
10         if v is ctrl-flow then
11             F[v] ← filter(F[v] ∪ pareto(accel(v,R)));
12 DP(T.root);
13 return F[T.root];
```

Cayman efficiently generates candidate accelerator configurations with optimized control flow and data access.

Performance and Area Estimation: Cayman's accelerator model estimates performance gains and area usage for selected kernels with accelerator configurations without synthesizing complete hardware. The estimation comprises three steps: (1) apply loop unrolling to transform the kernels according to the configuration; (2) only synthesize pipelined loop regions P and sequential basic block regions B; and (3) estimate accelerators' latency and area through a bottom-up approach. Specifically, Cayman considers diverse interface-specific latencies and resource constraints when scheduling data access operations during synthesis. For every region in $P \cup B$, the cycle count is computed based on the scheduled latency and profiled execution count, and the area is retrieved from the synthesis report. For an outer region, the cycle count is calculated by summing the cycle counts of its child regions, and the area is estimated as the sum of its child regions' area plus extra control logic overhead. By doing so, the total cycle count of the accelerators is efficiently estimated as $Cycle_{cand}$. Given the profiled total duration of the accelerated kernels T_{cand} and the original execution duration of the entire program T_{all}, the overall performance gain is estimated as

$$Speedup = T_{all}/(T_{all} - T_{cand} + Cycle_{cand}/F) \quad (1)$$

where F is the target frequency of the synthesized accelerators.

D. Candidate Selection

Candidate selection determines a set of kernels corresponding to non-overlapping wPST subtrees for hardware acceleration to achieve the most performance gains under specific area budgets. Cayman models candidate selection as a knapsack problem: every wPST region, either *ctrl-flow* or *bb*, corresponds to a knapsack item, and the performance gain and area usage of the synthesized accelerator are the item's profit and weight, respectively. The knapsack problem has the constraint: if a vertex is selected, all its descendants cannot be selected, avoiding overlapping acceleration of kernels.

Cayman proposes a dynamic programming approach to solve the knapsack problem, as shown in Algorithm 1. The function DP(v) (line 1) solves the knapsack problem considering regions contained in the wPST subtree rooted at the vertex v. The function prune (line 2) terminates the search if the region v is identified as not a hotspot worth acceleration according to the profiling and analysis results R and a heuristic pruning strategy. We define $F[v]$ as the area-performance Pareto-optimal solution sequence accelerating kernels from v's subtree. Every solution $\phi \in F[v]$ comprises one or more non-overlapping kernels with accelerator configurations. Algorithm 1 builds $F[v]$ (line 3-11) according to the following recursion formula:

$$F[v] \leftarrow \begin{cases} \texttt{pareto(accel}(v,R)\texttt{)} & \text{if } v \text{ is } bb \\ \texttt{pareto(accel}(v,R)\texttt{)} \cup \bigotimes_{u \in v.children} F[u]) & \text{if } v \text{ is } ctrl\text{-}flow \\ \texttt{pareto}(\bigotimes_{u \in v.children} F[u]) & \text{otherwise} \end{cases}$$

where accel calls Cayman's accelerator model to generate configurations for selected kernels, producing accelerators with optimized control flow and data access and estimating performance and area as discussed in Section III-C, and pareto produces a Pareto-optimal sequence for the given solutions. Specifically, there are three cases for $F[v]$'s construction according to the type of vertex v. If v is a *bb* region, $F[v]$ gets accel(v, R) solutions accelerating v's dataflow subgraphs. If v is a *ctrl-flow* region, either the region v gets accelerated as an extracted kernel by a single accelerator, corresponding to accel(v, R) solutions, or its descendant regions get accelerated separately, applying the $\otimes$ operation to combine solutions from sibling subtrees rooted at v's children: $F[u_1] \otimes F[u_2]$=pareto$(\{\phi_1 \cup \phi_2 \mid \phi_1 \in F[u_1], \phi_2 \in F[u_2]\})$. Otherwise, v is the *root* vertex that cannot be selected directly, and $F[T.root]$ applies the $\otimes$ operation to combine solutions from different functions to form the overall selection solutions.

Algorithm 1 also features the filter function (line 4,9,11) that filters out unnecessary solutions that are too close to each other. Specifically, for a Pareto-optimal solution sequence $\{\ldots, \phi_i, \phi_{i+1}, \ldots, \phi_j, \ldots\}$ with increasing area $a_{i+1} > a_i$, suppose ϕ_j is the first solution whose area a_j is α times larger than that of ϕ_i. That is, $a_j > \alpha a_i$, filter removes solutions $\{\phi_{i+1}, \ldots, \phi_{j-1}\}$ from the sequence. After filtering, every neighboring solution pair (ϕ_i, ϕ_{i+1}) satisfies that $a_{i+1} > \alpha a_i$. For any knapsack with an area limit A, filter reduces the maximum possible number of solutions from A to $log_\alpha A$, greatly improving selection efficiency.

Algorithm Complexity: The complexity of Algorithm 1 is $O(N \log_\alpha^2 A + E)$, where N denotes the number of unpruned vertices in the wPST, A denotes the discretized area limit, and E denotes the total time complexity of the accelerator model. The term $N \log_\alpha^2 A$ arises from $F[v]$'s construction, where the $\otimes$ operation enumerates solution combinations from two F sequences, each of which contains at most $\log_\alpha A$ solutions.

E. Accelerator Merging

After the candidate selection, Cayman performs accelerator merging, enabling multiple program regions with distinct control flows to share a reusable accelerator. The core strategy is to merge basic blocks that share common operations by inserting multiplexers with reconfiguration bit registers, producing a reconfigurable datapath unit. Cayman then combines candidates that include the merged basic blocks into a reusable accelerator, each maintaining a standalone finite-state machine (FSM)

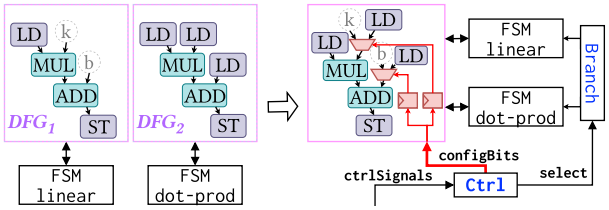

Fig. 5: Accelerator merging

for control. Upon triggering the reusable accelerator, a global control unit, named *Ctrl*, transmits configuration data to the datapath units and selects the appropriate control logic FSM to trigger. This merging strategy is based on the observation that basic blocks housing operations like floating-point arithmetic and data access contribute significantly to the accelerator area, while control logic FSMs demand much less area. Fig. 5 presents the example of merging the loop linear and loop dot-product candidates from Fig. 2. Cayman synthesizes a reusable accelerator containing a reconfigurable hardware unit merged from DFG_1 and DFG_2. The reusable accelerator accelerates both the loops with individual FSMs.

Cayman conducts accelerator merging in a heuristic manner for every Pareto-optimal selection solution that comprises multiple accelerators. It estimates the area savings for merging every pair of basic blocks contained in the solution, merges the basic block pair with the maximum estimated area savings into a reconfigurable datapath, and combines the two accelerators containing the merged basic blocks into a reusable accelerator. The merged datapaths and accelerators are also treated as normal basic blocks and accelerators, enabling further merging with others. The heuristic merging process is repeated until no area savings can be achieved.

F. Implementation

We implement Cayman based on LLVM 18 for candidate selection, accelerator merging, and hardware synthesis. We utilize the *RegionInfoAnalysis* pass to identify regions and build wPSTs. For profiling, we implement an instrumentation pass to insert execution count and timestamp recording instructions within regions; the modified bitcode is compiled and executed to gather profiling data. For program analysis, we employ the *MemoryDependenceAnalysis* pass to get memory dependencies, implement a custom pass to identify *stream* patterns, and run the *ScalarEvolution* pass to analyze footprints. Cayman's accelerator model retrieves delay and area of operations and data access interfaces by synthesizing them with OpenROAD [1] targeting Nangate45 PDK.

IV. Evaluation

A. Experiment Setup

All applications are compiled with the "-O3" flag. The target frequency of accelerators is set to 500 MHz. Speedup is calculated as per Equation 1. Area is retrieved from reports of synthesizing accelerators into complete hardware and is presented as ratios to that of a CVA6 RISC-V tile [32]. We compare Cayman to two state-of-the-art automated accelerator

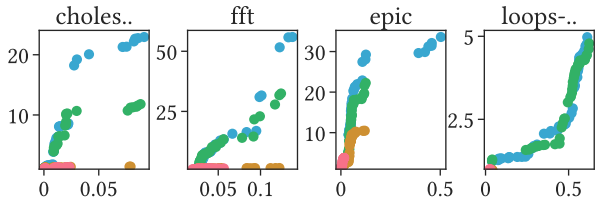

Fig. 6: Speedup (y-axis) and area (x-axis) of solutions: ● NOVIA, ● QsCores, ● *coupled*-only Cayman, and ● full Cayman.

synthesis frameworks, NOVIA [21] and QsCores [23]. We use diverse benchmarks from benchmark suites including PolyBench, MachSuite, MediaBench, and CoreMark-Pro for a comprehensive evaluation.

B. Result Analysis

We evaluate two different area budgets for the synthesized accelerators: small (25%) and large (65%). The area budgets are within the typical area range of custom accelerators [**?**], [7]. Table II presents experimental results. Cayman outperforms NOVIA and QsCores for all benchmarks. It achieves an average speedup of 14.4× and 8.0× over NOVIA and QsCores, respectively, under the budget 25%. The speedup increases to 27.2× and 15.0× when the budget is 65%, demonstrating the better acceleration potentials of Cayman. Cayman achieves superior performance because it optimizes control flow and adopts fast data access interfaces like *decoupled* and *scratchpad*. On the contrary, NOVIA fails to support control flow and memory accesses, and QsCores synthesizes sequential control flow and slow access interfaces, achieving much less performance improvement than Cayman.

Table II also presents kernel selection and accelerator configuration details of Cayman solutions. For applications with even-distributed hotspots, Cayman selects more kernels for acceleration when a larger area budget is available. One notable example is the loops-all-mid-10k-sp workload, where Cayman accelerates 13 sequential basic blocks and 1 pipelined region for the budget 25%, and accelerates 122 sequential basic blocks and 40 pipelined regions for the budget 65%. For applications with centralized hotspots, Cayman accelerates the performance-critical regions intently with more area. For example, Cayman synthesizes accelerators with the same #SB and #PR for two area budgets for 13 of 16 benchmarks from PolyBench in Table II, indicating consistent regions for acceleration. Cayman accelerates more access operations with a larger area budget: on average, it adopts 40 interfaces for the budget 25%, which is increased to 53 for the budget 65%. Besides, *decoupled* and *scratchpad* interfaces are widely adopted, occupying 83% and 81% on average for two budgets, respectively, demonstrating the significance of Cayman's interface specialization. Besides, more *scratchpad* interfaces are used when more area is available since the expensive *scratchpad* interface enables greater access parallelism.

Table II also shows that Cayman's accelerator merging mechanism effectively saves 36% and 35% area for two area budgets. Cayman widely synthesizes reusable accelerators, each of which accelerates 3 distinct program regions on average from the benchmarks. The area saving percentage goes up to

TABLE II: Results under two area budgets 25% and 65%. #SB and #PR denote the number of sequential basic blocks and pipelined regions from selected kernels. #C, #D, and #S denote the number of *coupled*, *decoupled*, and *scratchpad* interfaces in synthesized accelerators. The "Area saving" columns denote the area-saving percentage by accelerator merging.

74% and 70% for the 3mm benchmark, which includes 3 loops with identical basic blocks for merging. However, Cayman only saves 5% area for the doitgen benchmark since the benchmark only includes one hotspot region for acceleration and does not need accelerator merging. In practice, Cayman runs very fast, which only takes 70.8s on average.

Fig. 6 presents the speedup and area usage of Pareto-optimal solutions produced by the baselines and Cayman for four benchmarks from different suites. It shows that Cayman solutions achieve superior performance with different area usage for all the benchmarks. Specifically, NOVIA solutions are always located in the lower-left corner, indicating their limited speedup and low area overhead. Cayman also achieves comparable or better performance than NOVIA for low area budgets since Cayman explores a broader accelerator synthesis design space that fully covers NOVIA's. QsCores's performance speedup scales worse than Cayman when the area budget increases. Especially, QsCores cannot accelerate the loops-all-mid-10k-sp workload from CoreMark-Pro because it contains intensive control flow and memory access which cannot be accelerated by QsCores' sequential control and slow data access interface. Compared to full Cayman solutions, *coupled*-only ones achieve lower speedup for most benchmarks, demonstrating the significance of modeling and specializing processor-accelerator interfaces. The only exception is the loops-all-mid-10k-sp workload, where the difference between *coupled*-only and full Cayman solutions are minor. The reason is that loops in the workload commonly have loop-carried dependencies between floating-point operations, restricting the achievable pipeline II and circumventing the performance gains of adopting *decoupled* and *scratchpad* interfaces.

V. Conclusion

This paper proposes Cayman, an end-to-end framework for high-performance custom accelerator generation. Cayman models processor-accelerator data access interfaces and conducts efficient dynamic programming-based candidate selection, synthesizing accelerators with optimized control flow and data access. Cayman also introduces a novel accelerator merging mechanism to synthesize reusable accelerators. Experimental results on various benchmarks demonstrate that Cayman significantly outperforms the state-of-the-art frameworks.

***Abstract*—Multi-agent frameworks with Large Language Models (LLMs) have become promising tools for generating general-purpose programming languages using test-driven development, allowing developers to create more accurate and robust code. However, their potential has not been fully unleashed for domain-specific programming languages, where specific domain exhibits unique optimization opportunities for customized improvement. In this paper, we take the first step in exploring multi-agent code generation for quantum programs. By identifying the unique optimizations in quantum designs such as quantum error correction, we introduce a novel multi-agent framework tailored to generating accurate, fault-tolerant quantum code. Each agent in the framework focuses on distinct optimizations, iteratively refining the code using a semantic analyzer with multi-pass inference, alongside an error correction code decoder. We also examine the effectiveness of traditional techniques, like Chain-of-Thought (CoT) and Retrieval-Augmented Generation (RAG) in the context of quantum programming, uncovering observations that are different from general-purpose code generation. To evaluate our approach, we develop a test suite to measure the impact each optimization has on the accuracy of the generated code. Our findings indicate that techniques such as structured CoT significantly improve the generation of quantum algorithms by up to 50%. In contrast, we have also found that certain techniques such as RAG show limited improvement, yielding an accuracy increase of only 4%. Moreover, we showcase examples of AI-assisted quantum error prediction and correction, demonstrating the effectiveness of our multi-agent framework in reducing the errors of generated quantum programs.**

***Index Terms*—Machine Learning, Quantum Code Generation, Quantum Computing, Multi-agent Large Language Models**

I. Introduction

Recent advances in Large Language Models (LLMs) have revolutionized a wide range of AI applications, including natural language understanding, machine translation, and automated content generation [1]. Building on the exceptional natural language processing capabilities of LLMs, recent research has extended into the exploration of multi-agent frameworks, where each agent is driven by an LLM to facilitate complex interactions in complicated environments. These multi-agent frameworks form the foundation for embodied AI systems [2], paving the way for a future where AI plays a critical role in assisting and supporting daily human activities.

A key application of LLMs is in automatic software development, where AI can assist developers in generating increasingly high-quality code [3]. Various LLMs tailored for code generation, such as StarCoder [4] or CodeLlama [5], have been introduced to produce high-quality code and test suites. Furthermore, recent research has explored multi-agent frameworks, such as AgentCoder [6], to enhance collaborative code generation. However, most of these efforts have focused on general-purpose programming languages like C++ and Python, with relatively less emphasis on domain-specific programming languages.

As a pioneering force in quantum computing, IBM has advanced the application of LLMs for quantum program generation, demonstrating the potential of LLMs in producing domain-specific programs [7]. To facilitate the development of LLM in quantum computing, they introduce training datasets, a customized LLM and testbench for quantum program generation. While this work lays a solid foundation for leveraging LLMs in quantum computing, several key challenges remain in optimizing LLM-assisted quantum code generation:

- The rapid pace of quantum computing advancements requires frequent updates to code libraries, resulting in a lack of high-quality, up-to-date training data. Models trained on data that are only a few months old can quickly become obsolete due to the release of new libraries or algorithms.
- Quantum programs generated by LLMs, with only standard supervised fine-tuning, tend to be error-prone. It is essential to explore the role of advanced prompt engineering in improving the reliability of LLM-assisted quantum code generation.
- Prior approaches have applied traditional code generation techniques used for general-purpose programming languages to quantum computing without accounting for domain-specific optimizations, such as Quantum Error Correction (QEC). This results in suboptimal performance. For instance, to meet the stringent standards of quantum code generation, LLMs must be capable of producing fault-tolerant quantum code using QEC techniques.

To address the aforementioned challenges, this paper proposes a novel multi-agent quantum code generation framework that integrates iterative multi-pass optimization and automatic quantum error correction. Inspired by OpenAI's *GPT-o1* [1] which emphasizes inference time optimization over training

[1]https://openai.com/index/introducing-openai-o1-preview/

time effort, we demonstrate that multiple inference-time optimization techniques can effectively mitigate the issue introduced by limited training data. To enhance the efficiency of quantum code generation, we explore the impact of advanced prompt engineering techniques such as Chain of Thought (CoT) [8] and Retrieval-Augmented Generation (RAG) [9], providing different insights for optimizing LLM-assisted quantum code generation. Furthermore, by leveraging the domain-specific optimization potential in quantum programming, our framework incorporates a quantum error predictor to facilitate automatic quantum error correction, ensuring robust and fault-tolerant quantum code generation. Overall, this work makes the following contributions:

- We propose a novel multi-agent framework comprising three key agents: a code generation agent, a semantic analyzer, and a quantum error predictor. The framework employs a multi-pass inference strategy for iterative optimization (Section III).
- We investigate the effectiveness of different advanced prompt engineering techniques, presenting detailed experimental results that provide insights into optimizing LLM-assisted quantum code generation (Section IV).
- Our framework integrates automatic quantum error correction by leveraging Quantum Error Correction (QEC) decoders, significantly reducing noise in quantum environments (Section V-B).

II. Background and Related Work

A. LLMs and Multi-Agent Frameworks

Large Language Models (LLMs) are built upon the transformer model [10]. The most powerful and recent models, such as GPT-4 [11], are built upon the decoder-only transformer architecture, in which the output sequence is based on the previous tokens, rather than having separate encoders and decoders. Such models are used for a variety of Natural Language Processing (NLP) tasks, proving to be versatile tools that have the potential to have wide-ranging effects.

One developing area of LLM research is multi-agent frameworks. In this, multiple LLM agents are combined together to allow interaction between different LLMs, which could result in a more accurate response or allow users to use multiple input formats. [6] [12]. This has many potential uses, such as safeguarding text generation or a hierarchical chat.

B. Chain-of-Thought and Retrieval-Augmented Generation

Inference-time optimisation techniques have been shown to improve the quality of output generated by LLMs [13]. These techniques often either augment the prompt with additional information or get the model to think in different ways to better their understanding. Two promising methods are Retrieval-Augmented Generation (RAG) [9] and Chain-of-Thought prompting [8].

RAG involves collecting data or documents relevant to the generation task and building a vectorstore database. We then retrieve the appropriate chunks of data based on a ranking algorithm and augment the prompt with this additional data [9]. This gives the model more specific context from which to infer the answer, improving generation accuracy. Chain-of-Thought (CoT) prompting [8] encourages models to use logical reasoning when generating answers. Zero-shot CoT [14], in which the model is explicitly told to think "step by step", encourages the usage of logical reasoning. Another technique is manual CoT [8] in which a sample question and answer pair is provided to demonstrate the type of reasoning the model should use. Overall, both RAG and CoT have been shown to improve the accuracy of models at the inference stage by augmenting the context or eliciting the logical reasoning ability of the LLM.

C. Quantum Computing

Quantum computing is a rapidly growing field that shows profound potential. It uses quantum phenomena such as entanglement and superposition to allow information to be stored in an exponentially more dense manner using qubits. Whilst this information cannot be accessed in a one-to-one manner, it does allow access to unique phenomena such as interference and true parallelism, creating new algorithmic possibilities. The ability to exploit these phenomena has allowed quantum algorithms to be made for many problems that are NP or NP-complete in the classical environment. One example is Shor's algorithm for finding prime factors [15], which is a problem that is NP for classical computers. This algorithm uses superposition and interference to manipulate qubits in such a way as to find the factors in polynomial time. There are many more examples of algorithms in cryptography [16] and beyond, making quantum computing a field that has exciting possibilities.

One unique challenge posed by developing quantum algorithms is the presence of quantum noise. This is caused by factors such as thermal fluctuations and can result in qubit measurements being incorrect, meaning that experimental results often differ from theoretical results. Much work has been done in the field of quantum error correction (QEC), with many QEC codes being developed, such as the Steane code [17]. One common subset of QEC codes are surface codes [18], which encode one logical qubit onto a lattice of physical qubits. The nature of these codes means that they are topology-dependent, making it difficult to apply QEC codes in a practical development environment.

D. Related Work

LLM development is undergoing rapid improvement in the field of code generation [3], [19]. Models have shown promising ability to capture both the syntax and semantics of a language, with popular models such as CodeLlama [5] being able to produce high quality code. These models achieve consistently high scores on coding benchmarks like HumanEval [20], which is developed to evaluate models' ability to produce code to the same standard as a human software engineer. Multi-agent frameworks have also been utilized to create a fully-fledged code development environment, with a framework that can produce code and generate an appropriate test suite [6].

Writing code for quantum computers poses significant challenges, as quantum algorithms must be reversible and error tolerant, which demands developers to approach problems in a

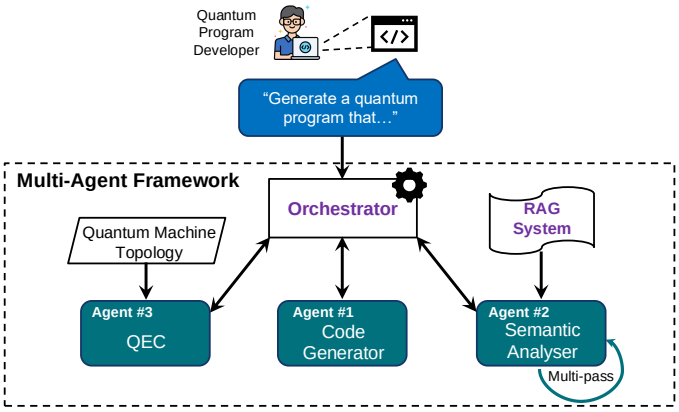

Fig. 1: Multi-Agent Framework for Quantum Code Generation.

different way. This creates a unique opportunity for LLMs to aid developers in code writing. Despite the accessibility of the Qiskit library [7], there is a steep learning curve for beginners to develop novel quantum algorithms. LLMs have the potential to enable developers to create accurate, fault-tolerant code without being experts in the field. IBM's Qiskit Code Assistant model [7] attempts to provide this by fine-tuning on a corpus of Qiskit programs. It achieves better accuracy on a HumanEval style benchmark [21] than traditional code generation models but still only achieves 46% accuracy, suggesting further development is needed. Furthermore, it does not take into account the presence of quantum noise in its code generation, so it will not produce fault-tolerant code.

III. Multi-Agent Framework and Training

A. Framework Overview

An overview of the proposed multi-agent framework is depicted in Figure 1. The framework mainly comprises three agents, each responsible for a specific task: code generation, semantic analysis, and quantum error correction.

- **Code Generation Agent**: We adopt Starcoder [4] as the base model for quantum code generation. To enhance the quality of the generated quantum program, we apply supervised fine-tuning on Starcoder using a custom dataset containing the latest open-source Qiskit [7] code. Additionally, we introduce several optimization techniques aimed to further improve the accuracy of the code generation agent, which will be detailed in Section IV.
- **Semantic Analysis Agent**: To enhance the quantum program generated by the initial model with better semantic accuracy, we design a dedicated agent for semantic analysis. This agent can help the code generation process to mitigate the lack of knowledge available in online sources about quantum algorithms, allowing users to incrementally improve the generated code to meet their requirements.
- **QEC Decoder Generation Agent**: Given the error-prone nature of quantum computing, primarily caused by quantum noise, it is essential to incorporate Quantum Error Correction (QEC) into our code generation process to enhance the reliability and robustness of the generated quantum programs. To achieve this, we adopt a QEC code decoder to predict and reduce quantum error, allowing our framework to generate fault-tolerant code.

By designing the multi-agent framework shown in Figure 1, we are able to address the three main challenges in optimizing quantum code generation. It allows us to not only generate syntactically and semantically valid quantum code, but also ensure that we can run the generated code in a stable environment, by the support of AI-generated Error Correction Codes (ECCs).

B. Training Dataset and Test Suite

We collected our training data by scraping Github repositories with an open-source license. Due to the fast-paced nature of quantum computing, we filtered the repositories to those updated after February 2024. We found that even filtering by a date this recent still resulted in out-of-date code, including code from official Qiskit Community repositories [22]. We further filtered the retrieved Python and Jupyter Notebook files based on whether they contained a Qiskit import statement. The notebooks were then split into code and markdown tiles based on sentinel tokens [7]. After filtering, our total number of tokens was 3M. Whilst this is a small dataset, it did not affect our approach to obtaining meaningful results, as we seek to compare the effectiveness of both fine-tuning techniques and a multi-agent structure. By demonstrating that these optimization techniques and our framework provide a meaningful improvement on the generated quantum code, we can justify working on creating a more accurate code generation agent by creating a larger dataset with higher data quality.

In order to perform our experiments, we created a set of prompt-answer pairs to be passed into our multi-agent system. These prompts cover a wide range of code-generation topics.

- **Basic**: These tests covers basic code generation for the Qiskit library, allowing us to test the basic syntactic requirements of our model. The tests include basic circuit generation and simulation on quantum devices, ensuring the model can generate and run code on real-world devices.
- **Intermediate**: These cover more complicated quantum circuits and algorithms, with a focus on well-known algorithms, such as Shor's [15] and Grover's [23] algorithms. This is intended to test advanced syntactic code generation, as well as allow for semantic testing on common applications.
- **Advanced**: This part covers more advanced topics specific to quantum computing. For example, this section contains prompts covering quantum teleportation [24], the quantum walk algorithm [25] and quantum annealing [26]. We expect the model to have little to no knowledge of these algorithms from the base training, so this section can be used to carry out advanced semantic testing.

Our test suite consists of 47% basic tests, 24% intermediate and 29% advanced. Compared to the Qiskit HumanEval benchmark [21], our test suite contains much more challenging prompts, asking the model to reason about complex quantum algorithms that the base model would have no knowledge of.

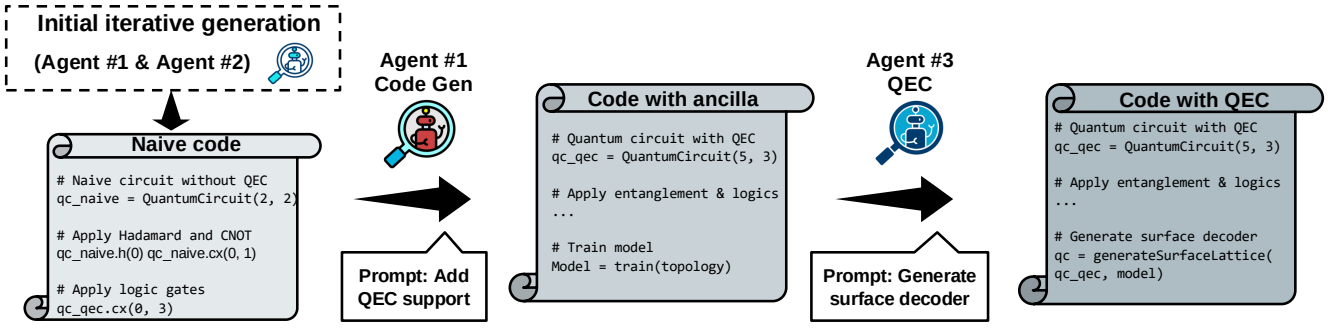

Fig. 2: Evolution of code during QEC generation.

IV. Optimization

A. Iterative Multi-Pass Optimization

Due to the limited availability of high-quality training data for quantum programming, the quantum programs generated by the fine-tuned LLM model remain error-prone. Inspired by recent advances in OpenAI's GPT-o1, we adopt an inference-time optimization approach to generate high-quality quantum programs. To this end, we implement an iterative multi-pass quantum code generation strategy. Specifically, we created a prompt template for multi-pass inference that includes the original prompt, as well as the generated code and error trace. This new prompt is then passed into the model in the hope of fixing the error generated on the previous pass.

By using a multi-pass structure and iterating upon the previous code, we are able to solve errors as they occur. Since we can pass the incorrect code back into the model multiple times, we can also account for multiple errors, allowing the model to focus on fixing a small, singular error, rather than regenerating the entire program.

B. Quantum Error Correction Enhancement

The quantum programs generated after passing through the code generation agents and semantic analyzer do not contain any form of quantum error correction. As a result, running these codes on a physical quantum computer would contain high levels of noise, which reduces the reliability of the generated quantum programs. Therefore, it is vital to incorporate the mechanism of error correction to mitigate the potential of quantum error.

To do this, we include a third agent in the framework, which generates a decoder for a Quantum Error Correction (QEC) surface code [18], [27]. As shown in Figure 2, this agent uses the topology of the quantum device and the number of logical qubits provided to generate a decoder that allows a surface error correction code to be used when running the algorithm. This is applied after the code has been generated and does not alter its semantics, but does add additional qubits in order to generate the appropriate surface code lattice. It maps the logical qubits required onto a subset of physical qubits, which allows us to take advantage of the topology of the device to implement a surface code. By applying this code, we extend the average qubit lifetime, which means we are less likely to see qubits affected by quantum noise. This, in turn, reduces the amount of error present in the results, improving their accuracy.

The main drawback of using a surface code is that they are topology-specific. This results in the model needing to be re-trained every time you want to run the code on a different device, which is extremely inefficient, so finding a way to make a QEC surface code that is topology-agnostic is vital to improving the framework's efficiency.

C. Prompt Engineering Optimisations

We adopted several techniques to mitigate the unique challenges posed by generating quantum code. The first was Retrieval-Augmented Generation (RAG) [9], to provide the model with knowledge of both the structure of quantum algorithms and the structure of the Qiskit library. We then implemented Chain of Thought (CoT) [8] and Structure Chain of Thought (SCoT) [28] prompting, as these have been shown to improve the accuracy of code generation. Our goal for these techniques was to improve the semantic accuracy of the code generated as we found that the lack of algorithmic knowledge available often led to syntactically correct but nonsensical code being generated. The final technique we implemented was multi-pass inference, which was intended to improve the syntactic accuracy of the code.

For our CoT and SCoT prompts, we manually created the first 5 prompts from our testing set using the same techniques demonstrated in previous code generation work [28]. For each subsequent prompt, we manually created a version in both CoT and SCoT and generated the same version using the GPT-4o model [11]. Figure 2 shows how generated CoT and SCoT prompts compare the original prompt that was provided to the model.

We collated two different RAG datasets. The first scraped the official Qiskit documentation repository on Github, taking the documentation for the latest Qiskit version, including Qiskit-adjacent libraries such as *qiskit-ibm-runtime*. The goal of this dataset is to improve the model's understanding of the library structure, reducing the amount of import errors due to deprecated features. The second consisted of a collection of guides and tutorials explaining the ideas behind and structures of a collection of quantum algorithms. The goal of this dataset is to improve the model's knowledge of algorithms, improving its

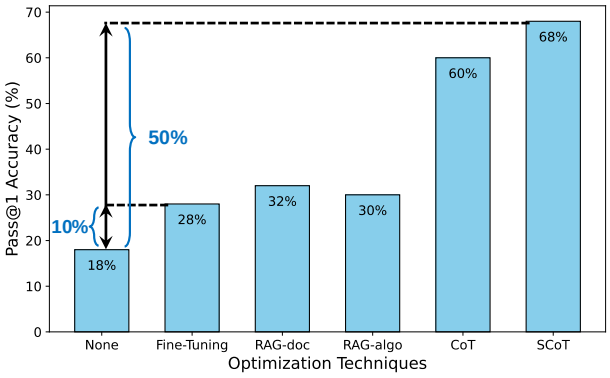

Fig. 3: The percentage of results that were semantically and syntactically valid for each technique.

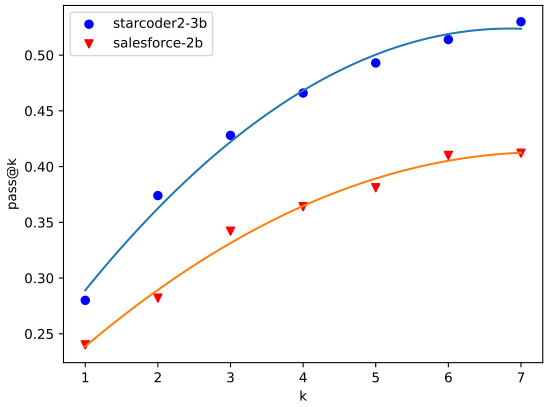

Fig. 4: pass@k values for fine-tuned models.

semantic accuracy. We used the langchain [29] and ragatouille [30] libraries to create the augmented prompts.

V. Experiments

A. Experimental Setup

We chose the StarCoder models [4] for fine-tuning since they were pre-trained on a wide corpus of languages and library files, making them suitable for adapting to new programming languages [31]. Furthermore, StarCoder models have demonstrated strong performance across a variety of coding tasks, showing their versatility and suitability for learning in new coding environments [3]. In our experiments, we selected StarCoder-3B as the main model for evaluation.

For fine-tuning, we used the *transformers* library [32] with LoRA adapter [33]. To facilitate the use of our custom dataset, we converted it into multiple chunked sets, with randomly applied Fill-in-the-Middle (FIM) transformations [34]. The chunk size was calculated upon training based on the amount of data provided. We found that the optimal FIM rate (the percentage of chunks to which a FIM transformation is applied) was 0.1. Training was conducted for 1400 steps with a batch size of 4. The learning rate was linearly increased from 0 to 3×10^{-4} over the first 100 warm-up steps and subsequently decayed using a cosine scheduler.

When testing our methods using our testing suite, each optimization method was evaluated independently. The CoT and SCoT prompts were passed directly into the model, upon which it generated the code. To further evaluate the accuracy of the fine-tuned model with no optimizations, we used the *transformers* library [32] to create a sample of results for each prompt and applied the pass@k metric [20] to obtain our results. Additionally, it was also our intention to compare our model with the recent IBM Qiskit Assistant [7] model. However, their model is paywall-locked, so it was not possible to get a comparison, despite multiple attempts of contacting the authors.

B. Overall Accuracy Results

Using our test suite, we were able to evaluate the accuracy of applying our multi-agent framework with the optimization techniques proposed. The overall results of the experiments are shown in Figure 3. The results provided are the percentage of prompts that are both syntactically and semantically correct. By training on the dataset of Qiskit repositories, we were able to increase the pass@1 metric by 10%, up to 28% overall. Figure 4 presents the accuracy of the model using the pass@k metric for k values ranging from 1 to 7, taken by generating a sample of prompts. The graph indicates that accuracy gains diminish as the sample size increases. Specifically, beyond 5 samples per prompt, we observe less improvement in the pass@k metric, indicating diminishing returns with additional samples. To investigate the effect of different model sizes on the model's pass@k accuracy, we also evaluate Salesforce-2B for comparison. As shown in Figure 4, the accuracy of Salesforce-2B model is consistently worse than that of StarCoder-3B across different k values. Therefore, the rest of the experiments adopt StarCoder-3B for evaluation.

C. Effects of RAG, CoT, and SCoT

As shown in Figure 4, applying RAG [9] optimization had negligible impact on the overall accuracy of the model. Whilst the algorithmic knowledge showed 4% improvement relative to the documentation knowledge, there is limited real-world benefit introduced by either method due to the negligible improvement.

The results for CoT [8] and SCoT [28] show remarkable increases, with CoT leading to an increase of 32% and SCoT an increase of 40% from the fine-tuned model. The majority of this increase came from a better semantic understanding of how the algorithms are structured, suggesting that the initial training dataset did not contain many good examples of such algorithms.

D. Effects of Multi-Pass Inference and QEC

We found that applying multi-pass inference into the semantic analyzer model can improve the accuracy to 34% using triple passes. However, additional inference passes, despite incurring higher computational costs, yielded limited benefit. The diminishing accuracy improvement is likely due to the nature of the error, which was mostly the misuse of imports or the use of deprecated code. If these issues were resolved,

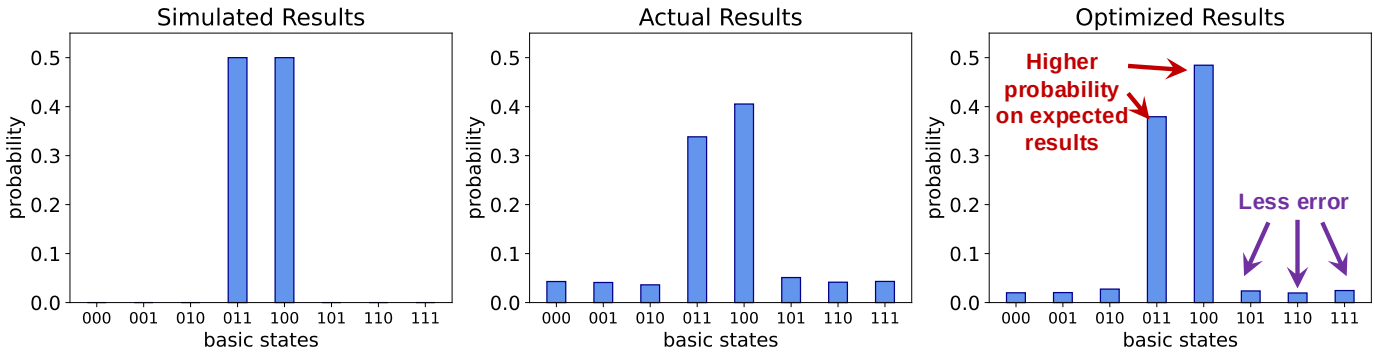

Fig. 5: Results for Grover's Algorithm Experiments.

the results did demonstrate evidence that multi-pass inference could be used to improve the model's ability to resolve other syntactic and semantic errors.

Leveraging our multi-agent framework with the support of quantum error prediction and correction, we were able to reduce the amount of quantum error in our experiment results. Figure 5 shows an example of Grover's Algorithm [23] under a quantum noise environment, with and without the use of our framework. Compared with the results without quantum error optimization, the optimized results demonstrate a general increase in the probability of the expected quantum states, as well as a decrease in observed errors across other quantum states throughout all experiments. Although this example with surface code applied is topology-dependent, it is sufficient to demonstrate the effectiveness of our framework in reducing quantum error.

E. Observation and Future Directions

Different from LLM-assisted code generation for general-purpose programming languages, our experimental results reveal that different optimization techniques have vastly distinct effects on quantum code generation. Applying RAG enhancement resulted in only a marginal increase in pass@1 accuracy. This technique aimed to enhance the model's understanding of the library structure and knowledge of algorithms. The limited accuracy increase is likely attributable to the fact that the documentation available for Qiskit is not up to date, preventing the effective mitigation of import errors. In contrast, other techniques such as Chain-of-Thought (CoT) reasoning introduced significant accuracy improvement. This improvement is attributed to the enhanced semantic knowledge provided to the model, allowing it to correctly structure the generated quantum program. This approach likely outperformed RAG, as it allowed us to more directly inform the model's decision-making process, rather than inferring how the algorithms work from the, rather limited, dataset we provided.

One limitation encountered during our experiments was the limited dataset sizes, which can be evidenced by both the poor increase in the fine-tuned models' pass@1 accuracy and the lack of improvement from applying the RAG technique. An important direction of our future work is to collect a larger and higher-quality dataset. This presents challenges due to the lack of data online and the rapidly changing nature of the field. One potential solution is to scrape other sites, such as the official Qiskit website and forums, while supplementing the dataset with hand-built examples. Other promising directions include the generation of synthetic data [35], federated learning [36], [37] and inference-time optimizations [38]–[40].

Moreover, a key area for future development is creating a topology-agnostic QEC decoder model. Currently, our work includes a model that is topology-specific, requiring retraining each time algorithms are adapted for different quantum computers. Whilst our work has shown that using a model like this can aid in producing fault-tolerant code, having a topology-specific model is not a scalable method. Developing a model capable of generating quantum error correction decoders for arbitrary topologies would significantly enhance the scalability of fault-tolerant quantum code generation.

VI. Conclusion

This paper proposes a novel multi-agent framework to provide an accurate, fault-tolerant quantum computing code generation LLM. We propose a three-agent system, with the first being a code generation based on LLM models. We investigate the effect of various conventional optimizations on our model, including Structured Chain of Thought. The second agent is a semantic analyser, which uses multi-pass inference and RAG to improve the accuracy of the generated code. The results observed during the code generation experiments suggest that a model with this purpose is necessary, as the code generation process lacks significant algorithmic knowledge. These techniques could be improved by collecting a larger dataset for RAG, which could also be combined with the multi-pass inference to improve the model's ability to understand why an error occurred. The third agent is a Quantum Error Correction model that predicts QEC surface code decoders. Our results showed a decrease in the average noise present in an experiment on IBM quantum computers. Overall, our framework makes a promising step forward in creating a tool to generate fault-tolerant quantum programs, which would greatly improve the accessibility of a complex field. In future work, we plan to extend our framework with advanced techniques such as test-time optimization and federated learning to further improve performance and scalability.

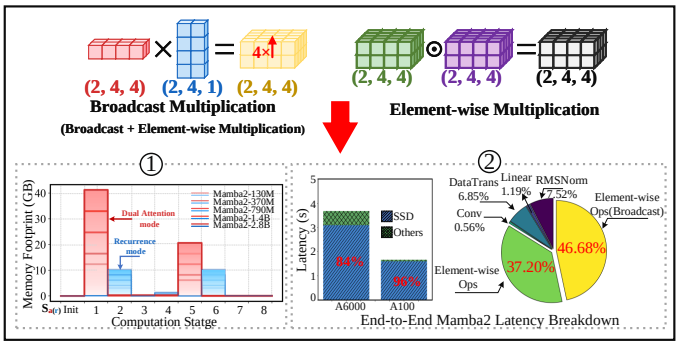
***Abstract*—State-space models (SSMs), such as Mamba, have emerged as a promising alternative to Transformers. However, the recently developed Mamba2, based on state space duality (SSD), is highly memory-bound and suffers from limited computation efficiency. This inefficiency arises from its irregular broadcast element-wise multiplications and structured sparse computations. In this work, we propose MambaOPU, an FPGA overlay processor, to accelerate SSD. First, to reduce memory overhead, we introduce a software-hardware co-optimized operator fusion framework. Specifically, operator merging combines adjacent broadcast multiplication and summation operations into a single descriptor, while operator backward shifting embeds segment multiplication into subsequent operations. Both techniques shorten the computation path and improve computation efficiency. Second, to enhance sparse computation efficiency, we skip zero-region computations using a tensor-reorder-and-group algorithm combined with a sparse-predefined data fetcher. Additionally, since Mamba integrates linear operations with SSD, we develop a reconfigurable systolic array to improve data reuse across different computation modes. Extensive experiment results demonstrate that MambaOPU achieves up to $1812\times$ and $880.79\times$ higher normalized throughput and up to $12908\times$ and $24.27\times$ higher energy efficiency over Intel Xeon Gold 6348 CPU and NVIDIA A100 GPU, respectively.**

I. Introduction

Large language model (LLM) based technology has a profound impact on daily life via applications such as smart assistants, content creation [1] and personalized recommendations [2]. The impact comes from the Transformer architecture [3]–[5], renowned for its self-attention mechanism, which excels in capturing long-range dependencies within sequences. However, Transformers face challenges in the quadratic time complexity and substantial memory demands, which severely limit inference performance, especially on edge computing platforms. A new architecture called Mamba [6] offers an efficient alternative inspired by state-space models. Mamba effectively captures complex dependencies in sequential data with near-linear computational scaling through parallel scanning and recurrent computation, making it a promising solution for resource-constrained environments.

To accelerate the inference of Transformer-based LLMs, most FPGA and ASIC accelerators have leveraged sparse-computing optimizations and memory-centric strategies to boost throughput and energy efficiency. The former identifies weak-relevant tokens and reduces redundant computations through pruning [7]–[16] and quantization [17]–[21], while the latter adopts techniques like model splitting, computation graph fusion and dataflow optimization [22]–[28] to balance memory load and computation efficiency. Despite their exceptional performances, these techniques cannot be directly applied to Mamba. The selective SSM mechanism necessitates recurrent computation [29] and element-wise operations, which are not well-suited for tensor-core performance. To resolve these issues, MARCA [30] proposes the first reconfigurable processing element (PE) array to optimize linear, element-wise operations and nonlinear computations, significantly improving energy efficiency and inference speed. On the other hand, Mamba2 [31] translates the SSM-recurrence computations into block semi-separable matrix multiplications through introducing SSD mechanism, thereby effectively leveraging GPU parallelism. However, accelerating Mamba2 still requires tailored hardware designs as most MARCA techniques do not apply.

Fig. 1 summarizes the challenges of developing Mamba2 accelerators: **(1) Large Memory Overhead Resulted from Tensor-Expansion**. Broadcast multiplications in SSD phase expand smaller tensors to larger ones for element-wise multiplications, significantly increasing memory footprint and traffic during inference. The element-wise operations between high-dimensional intermediate representations will also impose significant memory dependencies. Specifically, the peak memory usage reaches up to 41.55GB and 10.5GB for dual attention and recurrence modes, respectively. **(2) Limited Performance for Element-wise Multiplication on Existing Hardware**. Broadcast multiplications, *i.e.,* tensor expansion followed by element-wise multiplication, tend to have limited computation efficiency on existing hardware equipped with optimized units for tensor contraction, *e.g.,* tensor core [32] or systolic array [33], due to the mismatch of computation patterns. Profiling reveals that broadcast multiplications consume 46.68% of total inference time while element-wise operations dominate the SSD computation with 83.88% latency. **(3) Redundant Computation for SpMM and SDMM**. The inter-block sparse-sparse matrix multiplications (SpMM) resulting from zero-padded input sequences, along with sparse-dense matrix multiplications (SDMM) tied to the lower triangular causal matrix, introduce four classes of structural sparsity patterns. These sparsity patterns scale quadratically or linearly with the sequence length, leading to dynamic ineffective calculations. For instance, sparsity rates decrease from nearly 100% to zero as sequence length increases in Mamba2 computation phases S_{a1}, S_{a5}, and S_{a6}, while causal matrix multiplications maintain a sparsity close to 50% in phases S_{r4} and S_{r6} for long sequences (see Table. I for the phase definition).



To this end, we propose an FPGA overlay processor for Mamba2, named MambaOPU. It combines the merits of operator fusion and reconfigurable sparse computation architecture, to support efficient always-on-chip SSD computation. The four key contributions of this work are summarized as follows:

- A software-hardware co-optimized operator fusion framework through operator merging and backward shifting to alleviate the memory pressure induced by tensor expansion.
- A sparsity-predefined prediction engine combining tensor-reorder-and-group algorithm and data fetcher for sparse computation acceleration.
- A reconfigurable systolic array that can efficiently support four computation modes (i.e., GEMM, SpMM, element-wise operations and segment-mul).
- Extensive experiments on Mamba2 models consistently demonstrating the significant advantages of MambaOPU over CPUs and GPUs, in terms of end-to-end latency, normalized throughput and energy efficiency.

II. Background

State Space Duality. Mamba1 applies the selective thinking to modify LTI-SSM [34], allowing parameter matrices to vary with

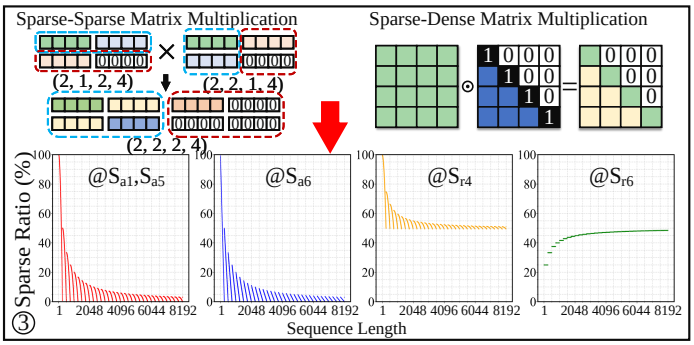

Fig. 1: Challenges in Mamba2 computation: ① Large memory overhead resulted from broadcast multiplication, ② Limited performance for element-wise multiplication on existing hardware, and ③ Redundant computation for SpMM and SDMM.

Note: The detailed definitions of the different computation stages (i.e., S_{ai} or S_{ri}) within SSD computation are provided in the Table I.

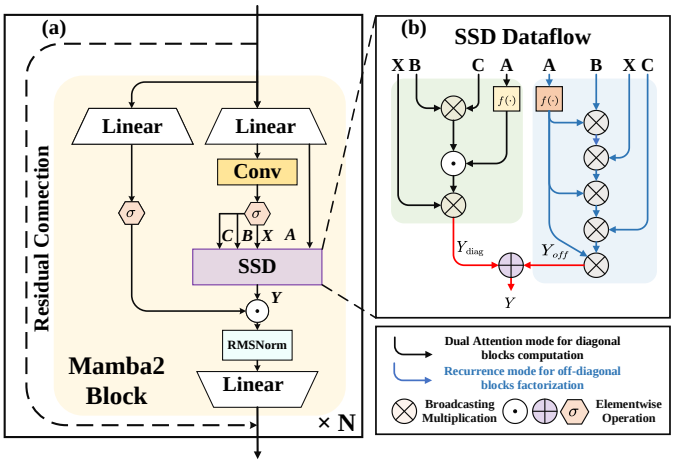

Fig. 2: The key components and SSD dataflow within Mamba2.

inputs and enhancing focus on more informative tokens. However, this recursive process is difficult to accelerate on GPUs, as it does not align with the parallel convolution paradigm of LTI systems. SSD is introduced in Mamba2 to unify selective SSMs with the attention mechanism, enhancing computational efficiency. Specifically, the selective SSMs are transformed into matrix multiplication as follows:

$$h_t = \sum_{s=0}^{t} A^{\times}_{t:s} B_s x_s = A_t \cdots A_1 B_0 x_0 + A_t \cdots A_2 B_1 x_1 + \cdots + B_t x_t$$
$$y_t = \sum_{s=0}^{t} C_t^T A^{\times}_{t:s} B_s x_s = Mx, M_{ji} := C_j^T A_j \cdots A_{i+1} B_i \quad (1)$$

where M denotes the causal matrix which is N-sequentially semi-separable [35] (NSS, N denotes the state dimension). For an arbitrary element M_{ji}, the vectors B_i, C_j and matrix A_j represent the input/output transformation and state transition matrix [36], respectively. Moreover, M can be reformulated in linear attention notation when A_j has reduced scalar-time structure (i.e., $A = aI$):

$$M = L \circ (CB^T) = \text{1SS}(a) \circ (CB^T), M_{ji} = A_{j:i} \cdot (C_j^T B_i) \quad (2)$$

where L denotes causal matrix with 1SS structure and the computation can be implemented using a *segment-sum* operator. Furthermore, M degenerates to a form dependent only on a, (i.e., $M = \text{1SS}(a)$) when C_j and B_i are scalars. Consequently, $y = Mx$ in Eq. 1 can be computed using the linear recurrence:

$$y_t = a_t(a_{t-1:0}x_0 + \cdots + a_{t-1:t-1}x_{t-1}) + a_{t:t}x_t = a_t y_{t-1} + x_t. \quad (3)$$

Mamba2 Workflow Mamba2 translates the SSD computation into a hybrid framework supporting linear recurrence and dual attention

TABLE I: Detailed phase description for Mamba2 algorithm

computation by leveraging the 1SS and NSS properties within M. The key components and flow of Mamba2 are shown in Fig. 2, where each block consists of layer normalization, linear projection, convolution, SSD block, and residual connection. Rather than interleaving Mamba2 blocks with feed-forward blocks, Mamba2 is built by stacking blocks with standard normalization and residual connections.

During SSD processing, the input feature is used to create a map from $[X, A, B, C]$ to Y through two computational branches. In Fig. 2, the path indicated by black solid lines denotes dual attention mode for diagonal block computation (Y_{diag}), while the path in blue solid lines indicates inter-chunk state transitions (Y_{off}) in linear recurrence mode. The full computation phases of Mamba2 are summarized in Table I, where S_a and S_r denote the core phases of dual attention and recurrence computation branches respectively, and S_o covers other operations within the SSD computation.

III. Software Stack

The software stack of MambaOPU shown in Fig. 3 (a) includes six key components: data-flow graph unrolling, operator fusion, data allocation, array mode selection, memory scheduling and event generation. Among them, the operator fusion and data allocation are crucial for reducing the memory load and enabling on-chip SSD computation. The software stack runs on a Host-CPU to compile the Mamba model, generating instructions and data, which are then transmitted to the MambaOPU via PCIe.

A. Operator Fusion

To reduce feature-induced memory access, an operator fusion framework is designed to merge operators and shift them backward.

Operator Merge: We merge the matrix broadcast multiplication and summation into a descriptor, thus unifying them with linear-based operations. As illustrated in Fig. 4, an arbitrary row-vector y_i within Y can be yielded via vector-matrix multiplication between x_i and the weight matrix W. Alternatively, y_i can be yielded by broadcast multiplication of x_i and the transpose of W, followed by column-direction summation. Each element of y_i can be expressed as follows:

$$y_{ij} = \underbrace{x_i W[:, j] = \sum_{k=1}^{K} x_{i,k} w_{k,j}}_{\text{(a) Linear-based Operations}} = \underbrace{x_{i,1}w_{1,j} + x_{i,2}w_{2,j} + \cdots + w_{i,K}w_{K,j}}_{\text{(b) Fused Operations}} \quad (4)$$

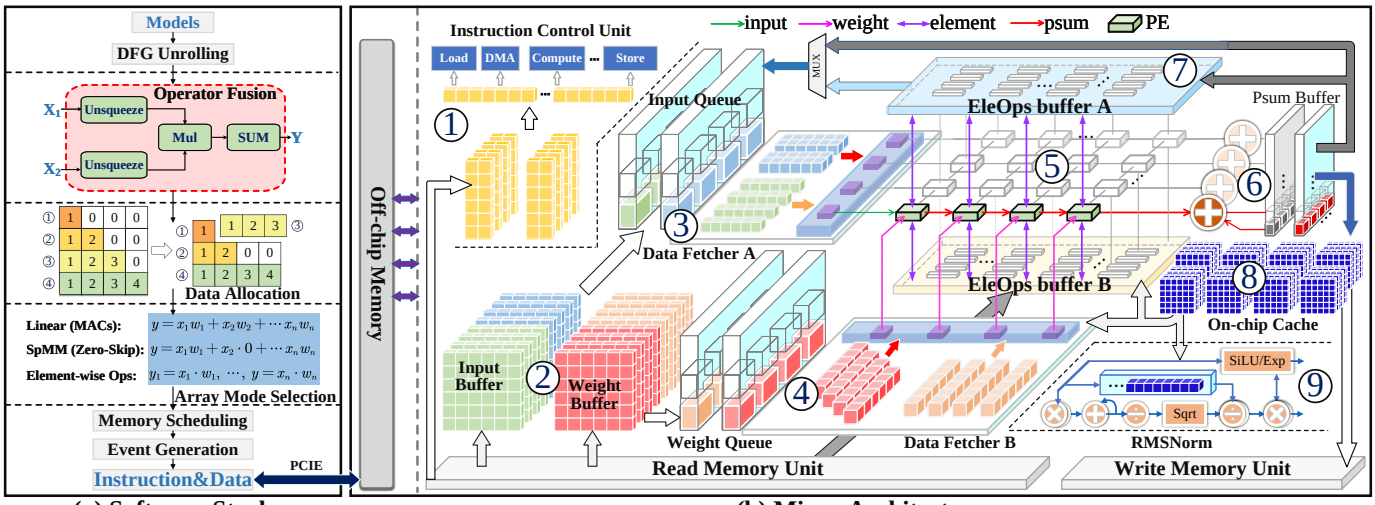

Fig. 3: Software stack and micro-architecture ① instruction control unit (ICU), ② input and weight buffer, ③④ data fetcher A and B, ⑤ reconfigurable systolic array, ⑥ psum buffer,⑦ element-wise buffer, ⑧on-chip cache and ⑨ special function unit (SFU).

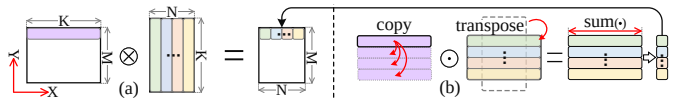

Fig. 4: Unifying (a) Linear-based operations with (b) broadcast multiply-and-accumulate.

Based on the **Operator Merge**, we can merge the operator pairs $\{S_{a1}, S_{a2}\}$, $\{S_{a3}, S_{a4}\}$, $\{S_{a5}, S_{a6}\}$, $\{S_{r2}, S_{r3}\}$, $\{S_{r4}, S_{r5}\}$ and $\{S_{r6}, S_{r7}\}$ into a one-phase operation.

Operator Backward Shift: The causal matrix M is first generated via *segment-mul* (containing *segment-sum* and *element-wise* exp), and then multiplied element-wise with the intermediate states H'_{state}. To shorten the computation path, we mask *segment-sum* by embedding *segment-mul* into element-wise multiplications between M and H'_{state}, based on the 1SS property $a^{\times}_{j:i} = a_{j-1} \cdot a^{\times}_{j-1:i}$, as expressed:

$$M_{ji} = m^{\times}_{ji} = \prod_{k=i}^{j-1} m_k = \exp(\sum_{k=i}^{j-1} a_k), m_k = \exp(a_k),$$
$$y_{ji} = M_{ji}h_{ji} = m^{\times}_{ji}h_{ji} = m^{\times}_{ji}h_j i = m_j \cdot m^{\times}_{j,i-1}h_{ji} = m_j y_{j,i-1}, \tag{5}$$

where a_k, h_{ji} are the corresponding elements within state transition matrix A and hidden state H'_{state}, respectively.

B. Data Allocation

We deploy two computation modes in each core of MambaOPU to support tile-granularity multiply-and-accumulate (MAC) operations, which are GEMM (yellow) and SpMM (green) shown in Algorithm 1. Each core can independently acquire the initial state, compute the transition state based on the input and return the output. For very long sequences with size of *Seqlen*, we partition the sentences into *ratio* chunks and distribute them across *Ncore* cores to achieve sequence parallelism, where *ratio* is defined:

$$\text{ratio} = (\text{Csize - Seqlen \% Csize} + \text{Seqlen})/\text{Csize}. \tag{6}$$

GEMM Mode can support linear layer computation and fused tensor broadcast MAC operations. To alleviate memory footprint, we can fetch the corresponding tiles for matrix multiplication and accumulation per cycle, based on the pre- and post-broadcast address mapping list. Once the tile data are prepared in a systolic-skew arrangement, vector-wise MAC is executed in the PE array.

Algorithm 1 Data Allocation and Mapping Algorithm

      end if
    end for
  end for
end for

SpMM Mode can eliminate ineffective computations and enhance the hardware efficiency by leveraging the sparsity within the output matrix. Specifically, zero-masking is applied to certain operand positions based on the triangular sparse prior within M. Then, more compact tensors can be obtained for matrix multiplication-and-accumulation through tensor-reorder-and-group transformation. For example, the optimized computation process for B and C can be unfolded as follows:

(1) B, C are broadcasted to achieve dimension matching.

(2) The broadcasted tensors B' and C' require the application of a lower triangular mask. The zero elements in either tile $B'[i]$ or $C'[i]$ will be filled with the non-zero elements from tile $B'[N-2-i]$ or $C'[N-2-i]$, where $i = 0, 1, 2, \cdots, \lfloor M/2 \rfloor$.

(3) The grouped tensor performs vector-wise MAC along a specified dimension to generate results, which are then reorganized into the final sparse output via *Recover*(·).

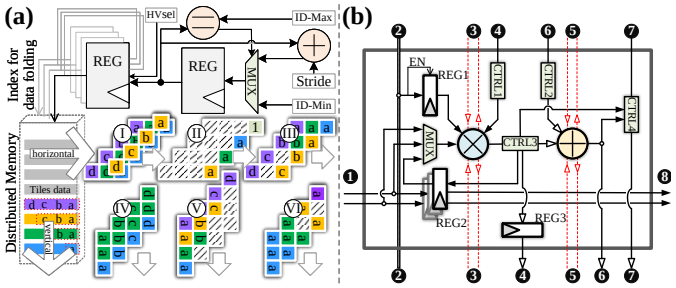

Fig. 5: (a) Sparse-predefined data fetcher supporting various computation modes (I/IV: S_{a1}, II/V: S_{a3}, III/VI: S_{a5}) and (b) PE with its in-out signals: ❶ CUR_IN, ❷ W_IN, ❸ ELE_MUL, ❹ CAS_MUL, ❺ ELE_ADD, ❻ CAS_MAC, ❼ BYPASS, ❽ NEXT_IN.

TABLE II: Computation modes of MambaOPU

Mode	Descriptions
Load/Store	Load data from DDR to on-chip buffer,Store data from on-chip buffer to DDR.
Fetch	Schedule data in a computation-friendly manner and correctly feed into the computing array.
GEMM	Support linear-based operations and broadcast multiplications: $C_{i,j} = \sum_{l=1}^{k} A_{i,l} \times B_{l,j}$
SpMM	sparse-sparse and sparse-dense: $C_{i,j} = \sum_{(i,l)\in \mathrm{NZ}(A)} A_{i,l} \times B_{l,j},\ \forall (i,j) \in \mathrm{NZ}(C)$
SegMul	Support causal matrix calculation $L(i,j) = \prod_{k=i}^{j} l_k$
EleOps	Support element-wise operations: $C_{i,j} = A_{i,j} \cdot B_{i,j}$ or $C_{i,j} = A_{i,j} + B_{i,j}$
SFU	RMSNorm(·), exp(·), SiLU(·), and other non-linear functions

C. Computation Mode Selection

We integrate high-level packaged instructions within the compiler to enhance support for various computation modes. This includes eight instructions listed in Table II. *Load* and *Store* denote data transfer between off-chip and on-chip memories, while *Fetch* configures the dataflows to align with the specific feeding requirements. *GEMM*, *SpMM*, and *EleOps* represent dense GEMM, optimized sparse SpMM, and element-wise operations, respectively. *SegMul* generates causal mask in the SSD phase, and *SFU* manages nonlinear computations such as RMSNorm(·), EXP(·), and SiLU(·).

IV. Hardware Micro-architecture

The micro-architecture of MambaOPU is shown in Fig 3 (b), which consists of eight key components: an instruction control unit (ICU), input and weight buffers, sparse-predefined data fetchers A/B, a reconfigurable systolic array, partial summation (psum) buffers, element-wise operation (EleOps) buffers A/B and a special function unit (SFU). Importantly, the reconfigurable systolic array and the data fetcher working together enable the implementation of different computational modes and achieve efficient end-to-end inference.

A. Sparse-predefined Data Fetcher

To support efficient reading of data streams and ensure compatibility across different computation modes, we design a sparse-aware data fetcher composed of an address sequence generator (ASG), a register group, and a distributed queue, as shown in Fig. 5 (a). Once the data fetcher receives the start signal from ICU, the ASG increments from *ID-min* by a step size of *Stride* until *ID-max*, where *Stride* can be configured by the ICU to generate various address sequences. During each cycle, the address index output from the ASG will pass through the register group to generate folded indexes, which will be sent to the input queue for reading data horizontally or vertically. Meanwhile, the corresponding PE control signals are generated and fed into the reconfigurable systolic array. In SSD computation, the sparse steps S_{a1}, S_{a3}, and S_{a5} correspond to I/IV, II/V, and III/VI indexing formats, respectively. Address IDs are generated according to the reordering rules to achieve compact tensor feeding. For sparse triangles, this compact stitching can reduce 49.80% of the redundant computations in a tensor of CSize × CSize.

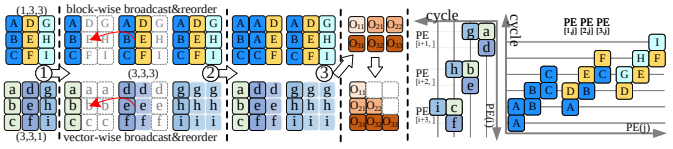

Fig. 6: Workflow of the systolic array for sparse computations.

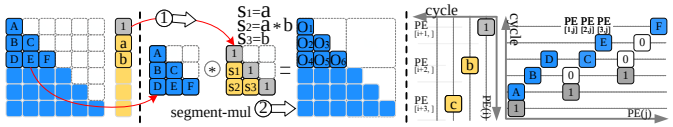

Fig. 7: Workflow of the systolic array for segment-mul primitive.

B. Reconfigurable Systolic Array

Following the computational requirements set by ICU, we design a reconfigurable systolic array that coordinates with the data fetcher to achieve four computational primitives: *GEMM*, *element-wise operations*, *SpMM*, and *segment-mul*. The systolic array consists of 32 × 32 cascaded processing elements (PEs) and incorporates with two EleOps buffers, with the details of PE shown in Fig. 5. Each PE is configured with a multiplexing switch, three registers (REG1∼REG3), four control signals (CTRL1∼ CTRL4), and eight data signals (❶ ∼ ❽).

• **GEMM**: We employ a classical systolic array to support GEMM within the software stack. For linear-based and merged broadcast MACs, feature embeddings and weights are fed into REG2 and REG1 via CUR_IN and W_IN, respectively. In the next cycle, the operands in REG1 and REG2 perform MAC, and outputs are passed through CAS_MAC to the next PE for post-accumulation. For one-dimensional convolutions, input data and weights are loaded onto REG1 and REG2, respectively. Once it completes, CTRL2 disconnects the cascading of adjacent PE rows, transferring the result to external buffers.

• **Element-wise Operations**: To enable computations attributed to EleOps to share the systolic array, we incorporate two dedicated EleOps buffers into the systolic array to support the high bandwidth demands of point-to-point computations. Specifically, the intermediate activations stored in dual buffers can be directly transferred to each cascaded PE for parallel point-granularity operations via the ELE_ADD or ELE_MUL. The results can be written back to buffer along the same routes, overwriting the values at the original locations.

• **SpMM**: To alleviate ineffective computations resulted from zero-padded input sequences and lower triangular causal mask, we employ CTRL2 and CTRL4 to disconnect the cascade between row-wise PEs for zero-skipping. Besides, we introduce additional input channels to prefill more input element c_{ij}, allowing each PE to coordinate with the sparse-predefined data fetcher for SpMM and SDMM. Fig. 6 illustrates the detailed SpMM for tensors $B \in \mathbb{R}^{1\times3\times3}$ and $C \in \mathbb{R}^{3\times3\times1}$. Each PE loads two elements into REG2 via CUR_IN and one element into REG1 via W_IN per cycle. Under MUX control, the current computation unit PE$[i,j]$ fetches a specific element from REG2 to perform a MAC with the loaded element b_{ij}. The resulting partial product is passed vertically to the next PE$[i+1,j]$ in the following cycles, while the input elements pre-stored in REG2 move horizontally to the right-side PE$[i,j+1]$. Each PE alternately performs calculations until all partial accumulations are complete, with the final results output by the last row of PEs.

• **Segment-mul**: To optimize computation resources for $\exp(\cdot)$ and segment-sum$(\cdot)$ operations during causal mask generation, we implement segment-mul (shown in Eq. 5) through the cooperation

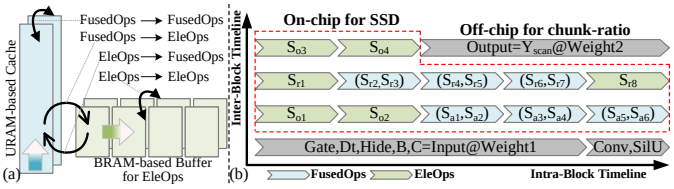

Fig. 8: Memory management and on-chip SSD

of datalines (CAS_MUL and BYPASS) and control signals (CTRL3 and CTRL4). The detailed process of segment-mul is shown in Fig. 7. Specifically, each PE loads an element of the exp-processed causal vector $\{1, \mathbf{a}_i\}$ onto REG2 via CUR_IN and the masked intermediate activations $\{\mathbf{b}\}$ into REG1 via W_IN for element-wise multiplications. The generated partial-product within PE$[i, j]$ is stored back either in REG2 or REG3. The result in REG2 is multiplied by element b_{ij} loaded on W_IN in the next cycle, while the result in REG3 is passed down through CAS_MUL to PE$[i+1, j]$ for cumulative multiplication with element $a_{i,j+1}$. Once each PE completes the computation for a specific position, the result is output to an external register via BYPASS by gating CTRL3 and CTRL4.

C. Always-on-chip SSD Computation

Mamba2 mainly consists of linear transformation and EleOps-centric SSD computations. The linear transformation has high weight reuse and low bandwidth, while the EleOps-centric SSD relies on high bandwidth due to the low data reuse potential. To leverage the on-chip BRAM's access rate of up to 5832 GB/s, we distribute data sequences across multi-cores and place CSize × CSize data blocks on chip for SSD. For linear and convolution operations, we instead use DDR memory with an access rate of 76.8GB/s for data communication. The complete inference process can be shown in Fig. 8. To support coherent on-chip inference, we employ a width-first buffer for EleOps and a depth-first cache for FusedOps operations. Additionally, we achieve a seamless interface between FusedOps and EleOps through memory management optimizations, which includes:

(1) FusedOps → FusedOps: Both input reading and result writing are implemented on the cache.

(2) FusedOps → EleOps: The result of FusedOps is written back to the EleOps buffer for the EleOps stage.

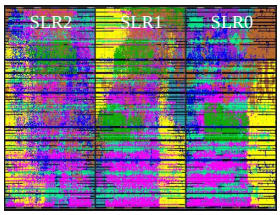
(3) EleOps → EleOps: The EleOps requires elements to be read from the buffer row by row, enabling the systolic array to perform parallel point-to-point multiplication or addition. The result is then written back to the EleOps buffers, overwriting the input operand for subsequent operations.

(4) EleOps → FusedOps: The results generated by EleOps are stored in EleOps buffer and read row by row for FusedOps.

D. Special Function Unit

We integrate other operations of Mamba2 into SFU, including SiLU(·) [37], EXP(·) and RMSNorm(·) [38], etc. For RMSNorm(·), the SFU reads vector-wise data $\{\mathbf{x}\}$ from the cache and processes it through a pipeline of square computation, accumulation, and reciprocal operations. Once the denominator $Var=\sqrt{\frac{1}{N}\sum_{i=1}^{N} x_i^2}$ is obtained, each element in FIFO [39] will be popped to calculate final normalized results x_i/Var.

V. Evaluation



A. Evaluation Methodology

We take five Mamba2 models (shown in Table III) as benchmarks, and generate MambaOPU instructions and data with FP16 [40], [41] using the proposed software optimization stack. The hardware of

Fig. 9: FPGA layout and resource utilization of MambaOPU-IV

MambaOPU is developed with Verilog, synthesized and implemented on Xilinx U200 FPGA with Vivado. To evaluate effectiveness, we compare the latency, normalized throughput (i.e., throughput per DSP is per GPU/CPU core for processing FP16 operations per cycle), and energy efficiency of MambaOPU with Intel Xeon Gold 6348 CPU, NVIDIA RTX A100 and A800. Power for GPU and CPU is measured with Nvidia-smi and PyRAPL, respectively, while MambaOPU is measured with the Xilinx Board Utility tool [42]. Latency for GPU and CPU is measured by CUDA Events and Python timers, respectively.

B. Experimental Results

We implement the single-core (MambaOPU-I) and four-core (MambaOPU-IV) versions, and the layout and resource utilization of MambaOPU-IV are shown in Fig. 9. On the U200 FPGA, the resource utilization is 74.03% of LUTs, 64.26% of FFs, 63.80% of DSPs, 92.70% of BRAMs, and 81.04% of URAMs. The speedup, normalized throughput and energy efficiency improvements for different sequence lengths are shown in Fig. 10.

V-B1 Speedup. By leveraging sequence parallelism, MambaOPU-IV achieves a 3.67× speedup over MambaOPU-I. This is because the long input sequence can be divided into proportional chunks that are processed in parallel across multiple cores. On the Mamba2-130M model, MambaOPU-IV delivers 1160× and 3.26× over the CPU and A100, respectively. This advantage comes from the operator fusion strategy and reconfigurable systolic array. For the Mamba2-2.8B model, MambaOPU-IV demonstrates a comparable latency to that of the A100. This is because the significant computational demands of linear layer transformations and multi-head SSD for large models or long texts exceed the resource limitations of U200.

V-B2 Throughput. In terms of normalized throughput, MambaOPU-I achieves 263.01×/880.79× improvement over A100 with a sequence length of 64, while MambaOPU-IV gains by 65.75×/220.20× with a sequence length of 8192, respectively. This is because MambaOPU optimizes the SSD computation, achieving comparable inference latency with fewer multiplication resources, leading to higher throughput. Compared to CPU, MambaOPU-I improves throughput by 1104×/1813× when running Mamba2-130M/2.8M with a sequence length of 64, while MambaOPU-IV reaches 794×/1014× with a sequence length of 8192. The results demonstrate that MambaOPU offers superior performance compared to the CPU, through careful optimization of both computation and storage.

V-B3 Energy Efficiency. For end-to-end energy efficiency, MambaOPU-I outperforms MambaOPU-IV in shorter sequence

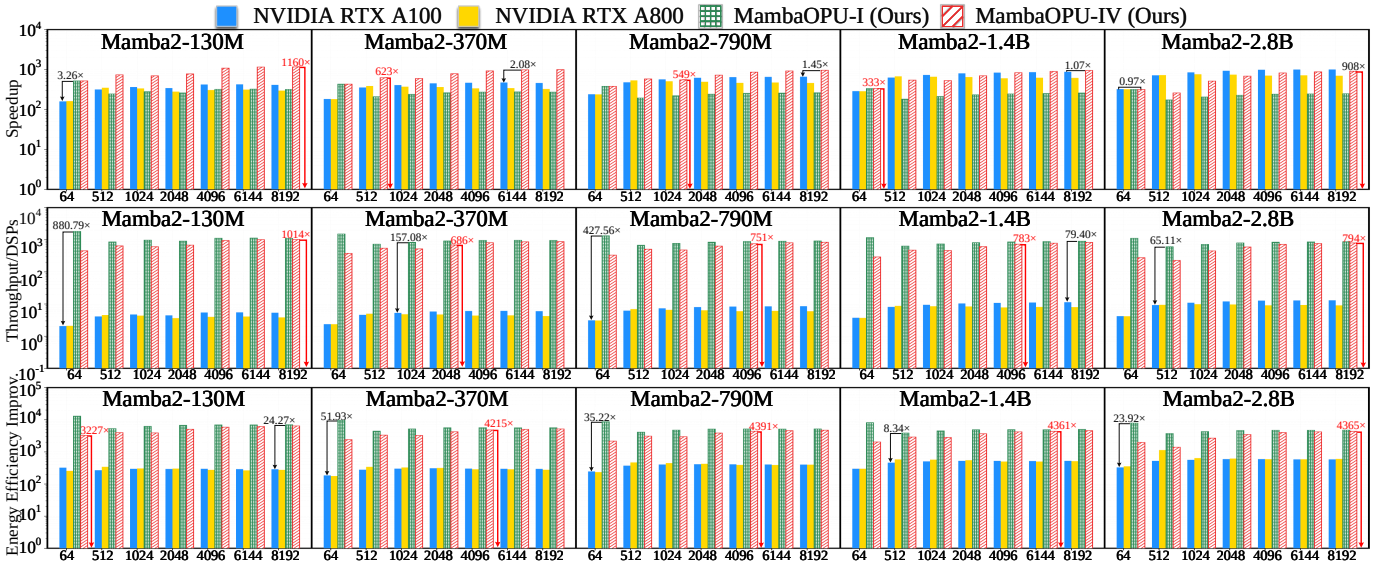

Fig. 10: Latency, throughput per DSP and energy efficiency comparison of MambaOPU and A100/A800 GPUs against Intel CPU (DSP normalized to 276,480 FP16 ops/cycle for A100/A800 and 3,583 FP16 ops/cycle for CPU) [43]. The horizontal axis represents sequence length.

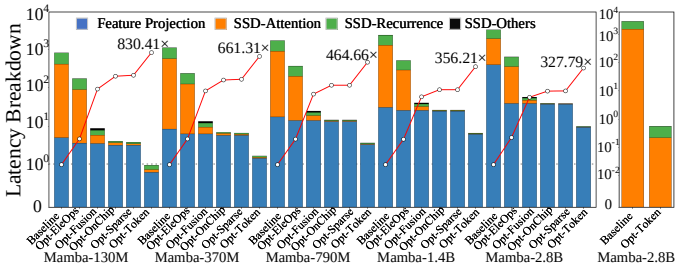

Fig. 11: Latency breakdown of MambaOPU with sequential optimization.

length, primarily due to reduced multi-core resource idling. On specific models such as Mamba2-2.8B and Mamba2-130M, MambaOPU-IV achieves energy efficiency gains of 4365×/6418× over the CPU, while MambaOPU-I achieves 7874×/12908×, respectively. For long text, MambaOPU-I improves energy efficiency by 8.14×/24.27× over A100 and A800, while MambaOPU-IV reaches 7.46×/22.25×. This demonstrates that the FPGA-based MambaOPU achieves excellent energy efficiency in power-constrained applications.

The superior throughput and energy efficiency improvements of MambaOPU come from optimized memory management and on-chip SSD computation that minimize off-chip memory communication. Also, the systolic array supports multiple computational modes, allowing for more efficient resource allocation.

C. Ablation Study

Fig. 11 presents the latency breakdown for five Mmaba2 models on MambaOPU-IV. Each model is accelerated through a sequence of optimization strategies, where each strategy builds on the previous one: element-wise operations(*Opt-EleOps*), operation fusion (*Opt-Fusion*), on-chip SSD computations (*Opt-OnChip*), causal mask sparse computations (*Opt-Sparse*) and sequence sparse computations(*Opt-Token*). Fig. 12 shows the access times and percentages for on-chip and off-chip memory using *Opt-Fusion* and *Opt-OnChip*.

Speedup of Optimization Strategies. The progressive optimization strategies introduce substantial enhancements in Mamba2's computational efficiency. Specifically, the *Opt-Token* accelerates by 327.79×/830.41× across different models compared to the baseline, though the linear layer for feature projection remains a primary

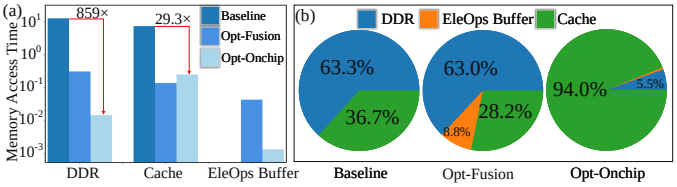

Fig. 12: Memory access time and its percentage for MambaOPU.

bottleneck. Examining individual strategies, *Opt-EleOps* effectively reduces the SSD computations latency by 4.74×, while *Opt-Fusion* further reduces latency for SSD-Attention and SSD-Recurrence by a remarkable 39.28×. These improvements stem from two key factors: first, the reconfigurable systolic array boosts point-to-point multiplication efficiency by introducing additional routes that work in tandem with EleOps buffers; second, operator fusion strategy reduces computation paths, thus enhancing the computation efficiency.

Building on the *Opt-Fusion* advancements, the *Opt-OnChip* strategy enables fully on-chip SSD computations, reducing the latency for attention and recurrence modes by 8× and 5.77×, respectively. Furthermore, *Opt-Sparse* and *Opt-Token* eliminate redundant computations and significantly improve SSD efficiency by a sparsity-predefined data fetcher.

Memory Access. Compared to the baseline, *Opt-OnChip* reduces off-chip memory access by 859×, allowing 94% of data access to be handled within the on-chip cache. This demonstrates that operator fusion and on-chip SSD effectively reduce communication overhead.

VI. Conclusion

We present MambaOPU, an overlay processor to accelerate Mamba2 models. Its compiler applies operator fusion and tensor-reorder-and-group to support efficient data allocation and reduce memory footprint of intermediate states. Its micro-architecture introduces a sparse-predefined data fetcher and a reconfigurable systolic array to optimize computational resource utilization and improve data reuse across various computation modes. Additionally, we design always-on-chip SSD computation. Our MambaOPU demonstrates superior throughput and energy efficiency, achieving 880.79× higher normalized throughput and 12908× greater energy efficiency than A100 GPU, respectively.

***Abstract*—IC3 and its variants are SAT-based model-checking methods that play a critical role in hardware verification. Efficient management of proof obligations, which track states that need to be proven unreachable, is essential for improving verification performance. This paper presents a novel approach that utilizes Critical Proof Obligations (CPOs) to improve proof obligation management. We propose two techniques, CPO-Driven UNSAT Core Generation and CPO-Driven Proof Obligation Propagation, to promote lemma propagation and frame refinement. Experimental results on HWMCC benchmarks demonstrate significant improvements in CPO discovery and lemma propagation, resulting in notable performance gains.**

***Index Terms*—model checking, IC3, critical proof obligation, assumption core consistency**

I. Introduction

Safety model checking (MC) automatically determines whether a transition system $S = \langle V, I, T \rangle$ satisfies a specified safety property P. MC is a fundamental software and hardware verification challenge with extensive theoretical and practical applications [9]. IC3 [8] (also known as PDR [10]) is a prominent symbolic MC algorithm that leverages high-performance incremental SAT solvers and sophisticated induction-based interpolation sequence refinement techniques. In recent years, IC3 and its variants [11, 15, 18] have gained significant attention due to their completeness and scalability compared to Bounded Model Checking (BMC) and Interpolation-based Model Checking (IMC).

IC3 maintains an over-approximation sequence known as *frames*, incrementally constructing and refining them to either generate a proof for the specified safety property or provide a counterexample. This refinement is achieved by recursively blocking bad cubes, which are counterexamples to induction (CTIs) capable of reaching the negation of the safety property. During this process, proof obligations (POs) are generated to track states that need to be proven unreachable. These POs are then generalized to produce lemmas, which are added to the frames and propagated to subsequent frames, reducing redundancy and accelerating convergence.

Lemma propagation plays a crucial role in the efficiency of IC3, as highlighted by several studies. [13] explore blocking states farther from the bad states to discover stronger inductive lemmas, enabling deeper generalization and enhancing lemma propagation in IC3. [22] directs induction generalization towards propagating i-good lemmas to accelerate convergence. [21] predicts a possible minimal lemma before dropping variables using the counterexample to propagation. These studies underscore the importance of effective lemma propagation in optimizing IC3 performance.

Proof obligation management, in turn, facilitates improved lemma propagation and contributes to the overall efficiency of IC3. [12] treats the negation of a discovered lemma as a may-proof-obligation to attempt possible lemma propagation and uses the reachable states that witness a failure of a may-proof-obligation to improve future lemma generalization. [20] presented a comprehensive study on proof obligation generalization techniques in IC3, including lifting, 01X-simulation, and justification-based generalization, highlighting the significant impact of different PO generalization methods on experimental performance.

Motivated by these insights, we introduce Critical Proof Obligations (CPOs), a novel concept aimed at improving the effectiveness of IC3 by prioritizing the handling of proof obligations that significantly influence the lemma propagation process. By identifying and focusing on these critical proof obligations, we streamline the verification process, boost lemma propagation, and improve the algorithm's convergence speed.

Contributions: This paper introduces the concept of CPO, which prioritizes highly impactful proof obligations to improve lemma propagation and frame refinement and presents two CPO-driven methods designed to enhance the IC3/PDR algorithm. The first method, CPO-Driven UNSAT Core Generation, optimizes UNSAT core generation by leveraging CPOs to prioritize relevant literals in SAT queries, effectively identifying CPOs that drive lemma propagation. The second method, CPO-Driven Proof Obligation Propagation, selectively propagates proof obligations based on their criticality, minimizing unnecessary lemma accumulation and promoting efficient verification.

We implemented our two novel CPO-driven methods in two well-performing IC3 safety model checkers: IC3ref [8] and modelchecker [3]. Additionally, we conducted experiments using HWMCC benchmarks to compare our solvers against three other state-of-the-art IC3/PDR algorithms. A comprehensive evaluation of the proposed methods demonstrates that identi-

*Corresponding author

fying CPOs boosts lemma propagation and proof efficiency, leading to substantial performance gains and validating the effectiveness of our approach.

Structure: Section II provides the necessary background information. Section III introduces the concept of CPO and two CPO-driven methods for optimizing proof obligation management. We evaluate the proposed methods in Section IV, discuss related work in Section V, and conclude the paper in Section VI.

II. Preliminaries

This paper focuses on bit-level symbolic model-checking methods. The following subsections introduce fundamental concepts relevant to propositional logic, finite-state transition systems, safety checking, SAT solving, and the IC3 algorithm.

A. Propositional Logic

Given a set of Boolean variables $V = \{v_1, \ldots, v_n\}$, a *literal* of a variable v is either the variable itself (v) or its negation ($\neg v$). We use $var(l)$ to denote the variable corresponding to a literal l.

A *clause* (resp. *cube*) is defined as the disjunction (resp. conjunction) of a set of literals. The negation of a cube forms a clause (also referred to as a *lemma*), and vice versa. If all literals of clause (resp. cube) d are included in clause (resp. cube) c, then d is called a sub-clause (resp. sub-cube) of c, denoted by $d \subseteq c$. The *conjunctive normal form* (CNF) represents a formula as a conjunction of clauses.

A full (resp. partial) *assignment* $\alpha : V \to \{false, true\}$ maps all (resp. some) variables to Boolean values and can be represented as a cube. We use $\alpha \models F$ (resp. $\alpha \not\models F$) to indicate that an assignment α satisfies (resp. falsifies) a formula F, making α a *model* of F. Additionally, $F \Rightarrow G$ implies that if F holds, G must also hold, meaning all models of F are also models of G.

B. Finite-state Transition System and Safety Checking

A *finite-state transition system* (FTS) is typically represented as a triple $S = \langle V, I, T \rangle$, where V is a set of Boolean variables, $I(V)$ is the initial state, and $T(V, V')$ is the transition relation describing the state transitions within the system. A state s of an FTS S is a cube composed of literals over V. We use the primed version s' to denote the next state of s according to $T(V, V')$. A state s is called an F-state if $s \models F$.

A *trace* of a finite-state transition system (FTS) S is a sequence of states $\gamma = s_0, s_1, s_2, \ldots$, which can be either finite or infinite. The initial state s_0 must satisfy the initial condition I, and for each state pair s_i, s_{i+1} in the trace γ, the transition relation $s_i, s'_{i+1} \models T$ must hold. A state s is said to be *reachable* if it appears in any trace of the system S.

In formal verification, safety properties of transition systems are commonly verified through *safety model checking*. A safety property $P(V)$ asserts that only those states satisfying P (referred to as P-states) are reachable. The property P is considered an *invariant* for the system S if all reachable states are P-states. If P is not invariant, there exists a finite counterexample trace $s_0, s_1, s_2, \ldots, s_k$ with $s_k \models \neg P$, where s_k is referred to as a *bad state*.

A lemma c is called *inductive* if it satisfies the following two conditions:

- *Initiation*: c holds for all initial states, i.e., $I \Rightarrow c$.
- *Consecution*: c is closed under the transition relation, i.e., $c \wedge T \Rightarrow c'$.

A lemma c is said to be *inductive relative* to F_i if $I \Rightarrow c$ and also ensures that $F_i \wedge c \wedge T \Rightarrow c'$. This can be verified by checking whether the formula $F_i \wedge c \wedge T \wedge \neg c'$ is unsatisfiable. An *inductive strengthening* of a safety property P is a formula F such that the conjunction $F \wedge P$ is inductive.

C. SAT Solving and Unsatisfiable Core

The propositional satisfiability (SAT) problem is a decision problem that determines whether a given propositional formula is satisfiable. SAT solvers are algorithms designed to solve this problem, typically taking inputs in *conjunctive normal form* (CNF).

Incremental SAT solvers are a specialized class of SAT solvers that can efficiently solve a sequence of related CNF formulas. One key feature of incremental SAT solvers is their ability to solve a formula while considering a set of *assumption* literals, which are frozen to true during the search process.

Given a CNF formula F and a set of assumptions A, if F is satisfiable, the solver returns "SAT" along with a satisfying assignment. If F is unsatisfiable, the solver returns "UNSAT" and a subset A_{core} of A, known as the UNSAT core, representing the reason for the formula's unsatisfiability.

For clarity in describing the following algorithms, we assume that the SAT solver used in this paper provides the following APIs for incremental SAT solving [16]:

- **is_SAT**(F, A): Checks the satisfiability of a propositional formula F under the assumption A. This can be expressed as is_SAT($\overline{F}$), where $\overline{F} = F \wedge A$.
- **get_model**(): If is_SAT(F, A) returns "SAT", this API returns a model for F under the assumption A. We use val(v) to denote the value of the variable v.
- **get_core**(). If is_SAT(F, A) returns "UNSAT", this function returns the UNSAT core A_{core} for F under the assumption A.

D. IC3 Algorithm Overview

The IC3 algorithm, also known as PDR, is an efficient model-checking technique designed to verify safety properties in finite-state transition systems. A high-level overview of IC3/PDR is presented in Alg. 1.

IC3 incrementally constructs an inductive proof of correctness using a sequence of frames, denoted as $F_0, F_1, F_2, \ldots$, where each frame F_i over-approximates the states reachable within i steps from the initial state. The algorithm starts with $F_0 = I$, representing the initial state set. It builds subsequent frames such that $F_i \Rightarrow F_{i+1}$ and $F_i \wedge T \Rightarrow F_{i+1}$, progressively strengthening them to ensure no bad states are reachable. The goal is to eventually obtain a frame F_k that is safe and

inductive, i.e., it contains no bad states and is closed under the transition relation, thereby proving the system's safety.

IC3 iteratively selects a cube s in F_k such that it transitions to a bad state in one step. Such an s is identified as a counterexample to induction (CTI), which starts from F_k and transitions to a bad state. IC3 attempts to block CTIs by maintaining a proof obligation (PO) queue and adding new lemmas to the frames. Each PO is a pair (s, i), where s is a CTI and i is a frame number, indicating that s must be proven inductively relative to F_i; otherwise, the property fails. If s is inductively relative to F_i, meaning it is unreachable within $i+1$ steps from the initial state, we say (s, i) is blocked.

The blocking process may involve the recursive generation of proof obligations, which are propagated backward through frames until reaching a safe resolution or the initial state. Once blocking ensures that F_k cannot reach a bad state, the propagation phase begins, pushing a lemma c in $F_i \setminus F_{i+1}$ to F_{i+1} if it is inductive relative to F_i. When two consecutive frames become identical ($F_i = F_{i+1}$), an inductive invariant is established, and the model's safety is proved.

III. Leveraging Critical Proof Obligations

In the IC3 algorithm, managing and effectively processing proof obligations (POs) is crucial for ensuring the system's safety, as it enables iterative refinement of frames to exclude bad states. In this section, we present our methodology for enhancing the IC3/PDR algorithm by evaluating and prioritizing proof obligations to promote effective lemma propagation during frame refinement. This will thereby accelerate convergence towards proving system safety.

A. Intuition behind Critical Proof Obligations

As discussed in the preliminaries, a proof obligation (PO) is defined as a pair (s, i), where s represents a counterexample to induction (CTI) leading to a bad state and should be proved inductive relative to F_i. In the IC3/PDR framework, blocking all possible states that may lead to a bad state within a frame is impractical due to the prohibitive computational cost. Instead, the primary objective is to ensure that each blocked counterexample contributes a useful lemma that facilitates lemma propagation and the construction of system invariants. Specifically, for a lemma $\neg c$ in $F_i \setminus F_{i+1}$, and a CTI s such that $c \subseteq s$, the successful processing of the PO (s, i)—i.e., showing that s is inductive relative to frame F_i and adding the lemma $\neg s$ to frame F_{i+1}—is crucial for propagating the lemma $\neg c$ from frame F_i to frame F_{i+1}. This motivates the formal definition of a critical proof obligation (CPO).

Definition 1 (Critical Proof Obligation)**.** *Let (s, i) be a proof obligation, where s represents a counterexample to induction (CTI) leading to a bad state, and i is a frame index. We define (s, i) as a Critical Proof Obligation if at least one lemma $\neg c$ exists in $F_i \setminus F_{i+1}$ such that $c \subseteq s$.*

Theorem 1. *Let $\neg c$ be a lemma in $F_i \setminus F_{i+1}$. The lemma $\neg c$ can be propagated to F_{i+1} if only all critical proof obligations (s, i) such that $c \subseteq s$ are blocked.*

```

Proof. Assume a proof obligation (s, i) exists such that $c \subseteq s$ is not blocked. Then, there exists a state t in F_i such that $t \wedge T \Rightarrow s'$. Since $\neg c$ is present in F_i, we have $t \wedge \neg c \wedge T \Rightarrow t \wedge T \Rightarrow s' \Rightarrow c'$. Therefore, there exists a state t in F_i such that $t \wedge \neg c \wedge T \Rightarrow c'$, implying that the lemma $\neg c$ is not inductive relative to F_i, and thus cannot be propagated to F_{i+1}.

This contradicts the original claim that $\neg c$ can be propagated to F_{i+1}. Therefore, our assumption is false, and all critical proof obligations (s, i) such that $c \subseteq s$ must be blocked for $\neg c$ to propagate. □

Critical Proof Obligations are crucial because they directly impact the propagation of lemmas across frames, which is fundamental to the success of the IC3 algorithm. Our approach aims to identify and leverage CPOs and prioritize their impact to effectively propagate lemmas, refine frames, and contribute to verification. The following subsections introduce two methods for leveraging and managing Critical Proof Obligations for optimal impact.

B. CPO-Driven UNSAT Core Generation

The branching strategy is a crucial feature of modern Conflict-Driven Clause Learning (CDCL) [16] SAT solvers. Traditional branching heuristics, like Variable State Independent Decaying Sum (VSIDS) [17], play an important role in prioritizing decision variables based on their involvement in conflicts, ensuring that frequently involved variables are selected to drive the solver towards resolution.

In our approach, we adopt a similar idea to influence the generation of UNSAT cores by ordering the assumption literals in SAT queries according to their scores (sort from high to small, see line 12 of Alg. 1). This score reflects how often each literal appears in recent Critical Proof Obligations. The key observation is that modern SAT solvers apply the assumption literals in the order provided by the user. Consequently, the UNSAT core produced when the formula is unsatisfiable depends heavily on this order, with literals that appear earlier being more likely to be included in the core.

Our goal is to ensure that each returned UNSAT core leads to the generation of a Critical Proof Obligation. To achieve this, we keep track of the UNSAT cores that successfully produce CPOs and heuristically adjust the input assumption order, aligning the variables in the assumption list with those frequently observed in successful CPO-generating cores. To facilitate this process, we introduce a metric called *Assumption Core Consistency* (ACC) to evaluate the consistency of variable occurrence in CPOs.

Definition 2 (Assumption Core Consistency)**.** *Let A be the set of assumptions, and let $O_A(a)$ denote the index of $var(a)$ in the default assumption ordering. Let $C_A = \{a_1, \ldots, a_n\} \subset A$ represent the UNSAT core obtained during the CTI search, and let $i \in \{1, \ldots, n\}$ denote the index of variable $var(a_i)$ in C_A. The rules governing UNSAT core generation hold that $i \leq O_A(var(a_i))$ for all variables in the core.*

The ACC score for a variable $v \in \{var(l) \mid l \in C_A\}$ is defined as the difference between its index in the UNSAT core and its original position in the assumption list:

$$acc(var(a_i)) = O_A(var(a_i)) - i$$

A higher ACC score indicates greater inconsistency in the ordering, suggesting a need for adjustment.

ACC serves as a basis for refining the assumption ordering to improve UNSAT core generation. The refinement process is outlined below (function *get_predecessor* of Alg. 1):

ACC-based Generalization Refinement: After identifying a predecessor state t of the CTI s in frame F_l, the SAT solver produces an UNSAT core *pre*, which serves as a generalized version of t and forms a new proof obligation $(pre, l-1)$. For each variable $v \in \{var(l) \mid l \in pre\}$, we calculate its ACC score $acc(v)$ and adjust its sorting score $sc(v)$ only if $(pre, l-1)$ is identified as a Critical Proof Obligation. This ensures that variable scores are updated exclusively when the associated proof obligation is crucial for lemma propagation across frames.

The score is updated as follows (line 16 of Alg. 1):

$$sc(v) := sc(v) + acc(v)$$

This adjustment improves UNSAT core generation by compacting the trail of assumptions to effectively refute the given assumptions and leveraging CPO historical data to identify better UNSAT cores and enhance lemma propagation.

C. CPO-Driven Proof Obligation Propagation

In the IC3/PDR algorithm, proof obligation propagation is critical in frame refinement by generating lemmas that block bad states. Traditionally, all proof obligations are propagated to the latest frame, which increases the chance of finding counterexample paths further from the current frame. However, several studies ([5, 12]) have indicated that unguided lemma learning can accumulate redundant lemmas. Similarly, indiscriminate proof obligation propagation can result in excessive lemmas generated from blocking distant counterexamples, which are unreachable in the current frame, making it more challenging to propagate all lemmas within the same frame to prove system safety.

Therefore, our approach leverages Critical Proof Obligations for a more efficient trade-off. Instead of propagating all proof obligations, we selectively push forward CPOs that are directly linked to learned lemmas in the corresponding frames. This targeted approach ensures that only the most impactful proof obligations contribute to lemma propagation, reducing the production of unnecessary lemmas while still facilitating the discovery of critical counterexample paths.

The implementation of CPO-Driven Proof Obligation Propagation (function *block_obligation* in Alg. 1) is straightforward, as it builds upon the existing IC3 framework with minimal changes to the core algorithm. When a proof obligation (s, i) is blocked, we first check for any lemma $\neg c$ in frame F_i such that $c \subseteq s$. If such a lemma exists, we identify (s, i) as

TABLE I: Tested tools and configurations in the experiments.

Tools	IC3ref	MCer	ABC	CAV23	DAC24
Available Flags	-uc -pr	-uc -pr	-pdr	-	-

a CPO, generalize s to F_l, and push the CPO to frame F_{l+1} (see line 23–31 of Alg. 1). If no such lemma is found, the PO is generalized and discarded. By selectively propagating CPOs, our method enhances lemma propagation efficiency and accelerates convergence, as shown in Section IV-C.

IV. Evaluation

A. Experimental Setup

We implemented our two proposed methods—CPO-Driven UNSAT Core Generation and CPO-Driven Proof Obligation Propagation—on two top-performing baseline solvers, using the flags "-uc" and "-pr" to enable each method, respectively:

- **IC3ref** [8]. Developed by the original inventor of IC3, this solver is competitive and commonly used as a baseline in recent studies [19, 21, 22].
- **modelchecker** [3]. This tool implements IC3 using the advanced incremental SAT solver CaDiCaL [7] and is referred to as MCer for brevity.

Additionally, we selected three state-of-the-art open-source IC3/PDR algorithms for comparison:

- **ABC** [1]. This tool includes the well-known implementation of the PDR algorithm.
- **IC3ref-CAV23** [22]. This version enhances IC3Ref by controlling lemma generalization to discover i-good lemmas and is referred to as "CAV23" for brevity.
- **IC3ref-DAC24** [21]. This version applies a generalization technique based on lemma prediction within IC3ref and is referred to as "DAC24" for brevity.

Table I lists the available configurations for the tools mentioned above.

We conducted our experiments using the AIGER format benchmarks from the Hardware Model Checking Competitions (HWMCC) of 2019, 2020, and 2024, totaling 786 instances. All benchmarks were converted to AIGER version 1.8 [6] using the "aigmove" command from the AIGER tool suite [2] to ensure compatibility with open-source model-checking tools, such as ABC, which have limitations in handling invariant constraints.

Since all solvers discussed in this paper are deterministic, each instance was run once on a dedicated CPU core, with a wall time limit of 5000 seconds and an 8 GB memory limit. Experiments were conducted on a cluster with two AMD EPYC 7763 CPUs (128 cores, 1024 GB RAM) running CentOS 7.7.1908. All solvers were implemented in C/C++ and compiled with GNU gcc/g++ 9.4.0. To ensure reproducibility, the source code for our optimized solvers is available at https://github.com/IC3Contributor/DAC25.

B. Experimental Results

The experimental results are summarized in Table II, Fig. 1, and Fig. 2, which present the overall performance, configuration comparisons, and runtime scatter plots of implementations with and without our proposed optimizations, respectively. By incorporating our optimizations, different implementations solved more cases than the original versions across various time limits, achieving higher efficiency in solving a more significant number of instances. Notably, IC3ref-uc-pr and MCer-uc-pr solved 18 and 15 additional instances, respectively, demonstrating significant gains.

Compared to three state-of-the-art IC3/PDR algorithms, our best configuration, IC3ref-uc-pr, solved 16, 5, and 15 more instances than ABC, CAV23, and DAC24, respectively. Specifically, for unsafe instances, IC3ref-uc performed on par with CAV23, solving most cases, while for safe instances, IC3ref-uc-pr achieved similar performance to the best competitors (ABC), with only one instance difference. IC3ref-uc-pr showed notable improvements in verifying both safe and unsafe instances, achieving better results with fewer losses compared to the baseline and competing solvers.

In conclusion, the performance summary table, Cumulative Distribution Function (CDF), and scatter plots consistently demonstrated runtime improvements with our methods. Both IC3ref-uc-pr and MCer-uc-pr achieved significant speedups across multiple instances, underscoring the effectiveness of our optimizations in enhancing IC3's performance and efficiency.

C. Further Analysis

To demonstrate the effectiveness of our methods, we computed two metrics for each instance: the CPO Identification Rate ($SR_{cpo} = N_{cpo}/N_{cti}$) and the Lemma Propagation Success Rate ($SR_{pr} = N_{sp}/N_{pr}$). Here, N_{cpo} is the number of CTIs identified as CPOs, N_{cti} is the total number of generated CTIs, N_{sp} is the number of successful lemma propagation attempts, and N_{pr} is the total number of lemma propagation attempts. The average SR_{cpo} for MCer, MCer-

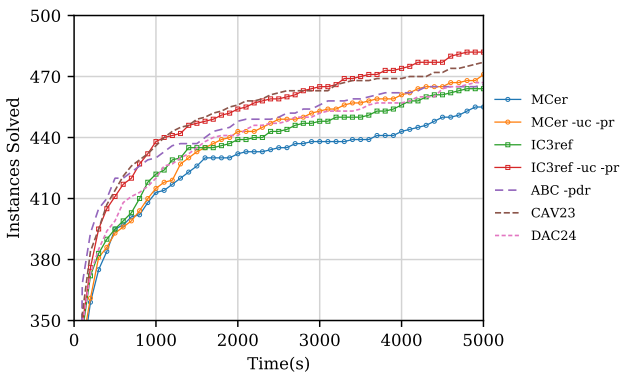

Fig. 1: Cumulative distribution function (CDF) comparing the performance of our improved solvers with state-of-the-art solvers (for clarity, results for single heuristic configurations are omitted).

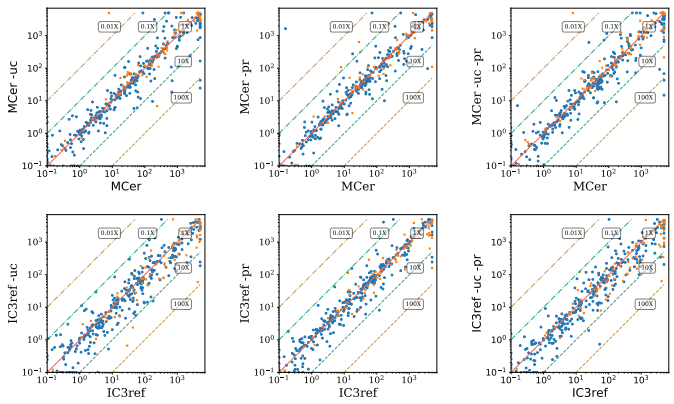

Fig. 2: Scatter plots comparing runtimes of MCer/IC3ref and their optimized versions. Points below the diagonal indicate better performance, with orange for unsafe instances and blue for safe instances.

uc-pr, IC3ref, and IC3ref-uc-pr were 0.4962, 0.5378, 0.2657, and 0.3152, respectively, indicating that our optimizations consistently improved CPO identification. Likewise, the average SR_{pr} for these solvers were 0.7052, 0.7259, 0.6585, and 0.7056, showing enhanced lemma propagation efficiency and accelerated convergence.

Fig. 3 visualizes the impact of our methods through a scatter plot, comparing the deviation in SR_{cpo} (y-axis) with the deviation in verification time (x-axis) for MCer/IC3ref with and without our optimizations. For each instance, let t and t' represent the verification times for MCer/IC3ref and MCer-uc-pr/IC3ref-uc-pr, respectively, and sr and sr', denote their corresponding CPO Identification Rates. Each point on the plot is defined by $t - t'$ on the x-axis and $sr' - sr$ on the y-axis. More points in the first quadrant provide more substantial evidence for the effectiveness of our method, as they indicate higher CPO identification rates and shorter verification times. The results in Fig. 3 for both MCer and IC3ref clearly demonstrate that identifying CPOs contributes to improved model-checking performance by reducing verification time.

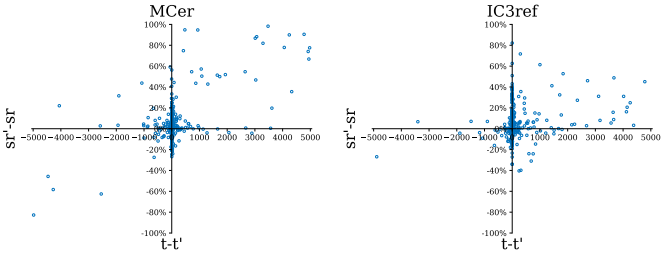

Fig. 3: Scatter plot illustrating the impact of our optimizations on verification time and CPO Identification Rate.

V. Related Works

SAT-based model-checking algorithms are fundamental in hardware verification, driving the development of various IC3 [8] and PDR [10] variants to improve efficiency and applicability. For example, [18] proposed a forward/backward hybrid version of PDR, and [4] introduced IC3 integrated with a specialized SAT solver called "SAT Modulo SAT". Additionally, kAvy [14] combined IC3 with k-induction to enhance its capabilities.

Lemma propagation involves propagating learned lemmas through different frames to block invalid states and accelerate convergence towards proving safety. [13] introduced counterexamples to generalization to enhance blocking bad states and lemma propagation; [21] refined failed pushed parent lemmas as predictions to avoid dropping variables. Our approach differs from these works by introducing Critical Proof Obligations (CPOs) to optimize proof obligation management, thereby enhancing lemma propagation and frame refinement.

Another related work is QUIP [12], which treats the negation of a discovered lemma c as a may-proof-obligation, attempting to push it to the next frame to propagate more lemmas. While both QUIP and our method focus on proof obligation management and selective lemma propagation, our approach evaluates and prioritizes existing proof obligations that directly impact lemma propagation across frames rather than introducing new ones.

VI. Conclusions and Future Works

This work enhances the IC3 algorithm's efficiency through Critical Proof Obligations and two CPO-driven methods that optimize proof obligation handling and lemma propagation. Extensive experiments demonstrated that our methods significantly improved the identification of impactful proof obligations and increased the success rate of lemma propagation, highlighting their effectiveness in enhancing overall performance. In the future, we plan to design IC3 algorithms that tightly cooperate with SAT solvers, extend our techniques to word-level IC3 tools, and adapt CPO-driven methods for broader application in other model-checking algorithms.

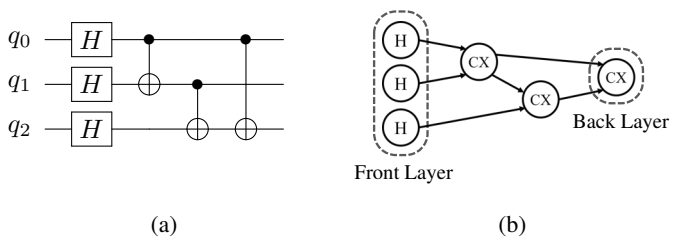
***Abstract*—In the Noisy Intermediate-Scale Quantum (NISQ) era, the topological constraints present in many of the currently available quantum devices pose a physical limit on the feasible interactions between qubits. To comply with such limitations, the compilation of quantum circuits requires solving the Qubit Routing Problem (QRP), by inserting `SWAP` operations among qubits. The State of the Art provides heuristic algorithms addressing this task, yet the depth of the output circuits is often incompatible with the current limits of quantum hardware. Therefore, we propose DDRoute, a novel heuristic algorithm to solve QRP, designed to reduce the depth overhead introduced by the routing process in the compiled circuits. Our experimental evaluation proves the efficiency of our approach, with a depth reduction of up to 70% with respect to the state-of-the-art routing procedures.**

***Index Terms*—Quantum Computing, Qubit Mapping, Qubit Routing, Quantum Circuit, Depth Minimization.**

I. Introduction

Quantum computing has raised particular interest in the last decades due to its potential in different relevant applications. Quantum algorithms are able to solve important problems with remarkable speedups over their classical counterparts, such as integer factorization [1] and unstructured database search [2]. The availability of quantum computing devices has by now become a reality, with IBM [3], Rigetti [4], and Google [5], among others, releasing powerful quantum processors. Current devices offer hundreds of quantum bits (qubits), but their computational capabilities are limited due to the connectivity constraints between qubits in the Quantum Processing Unit (QPU) [6]. Moreover, further technological issues lie between the development of quantum software and its implementation on quantum hardware, such as the limited fidelity of the operations and the restricted coherence time of each qubit, which introduce errors in the computation and limit the maximum allowed execution time [7].



To ease development, current software toolchains allow engineers to represent quantum algorithms as abstract circuits, based on a high-level instruction set (referred to as *gates* of the circuit) and *logical* qubits with unlimited connectivity. This abstraction layer does not consider hardware limitations, and relies on compilation to produce hardware-compliant quantum assembly. Such a process resembles classical Electronic Design Automation, since it requires Place & Route algorithms to *map* high-level logical qubits to the *physical* qubits belonging to the machine, and to *route* such qubits, to overcome their connectivity issues and implement multi-qubit operations.

More specifically, the Qubit Routing Problem (QRP) considers the connectivity constraints among qubits. To execute a two-qubit operation between two unconnected physical qubits, it is necessary to modify their mapping, by inserting `SWAP` (or equivalent) gates along the circuit. Such a process may increment both the number of two-qubit operations and the depth of the final circuit, thus limiting reliability and support from current NISQ architectures. In particular, the insertion of `SWAP` operations decreases the fidelity of the circuit, due to the high error rates of physical implementations of gates. Furthermore, the increase in depth due to the addition of `SWAP`s may also produce circuits that are incompatible with the coherence time of the physical qubits. Algorithms addressing QRP should, therefore, minimize both the number of `SWAP` operations and the overall circuit depth. Unfortunately, these two objectives represent NP-complete tasks [8], [9], and the State of the Art provides heuristics [10]–[14], which often trade-off optimality for compilation runtime. As a consequence, output circuits are often excessively deep, thus exceeding the allowed limits to maintain coherence.

In this work, we propose DDRoute[1], a depth-driven *routing* algorithm with a heuristic approach that aims to reduce the overhead in circuit depth introduced by the routing process. We employ a custom min-path procedure, which exploits a *generalized distance function* between qubits to schedule `SWAP` gates efficiently, allowing several quantum operations to be executed in parallel, in order to reduce the final depth of the output quantum circuits. Finally, we introduce DDPlace, a qubit *mapping* technique which provides convenient initial conditions for DDRoute.

Our work aims to provide *flexibility* with respect to the specific topology of the QPU; *scalability*, to maintain reduced compile time even in presence of hundreds of logical qubits; and *gate length awareness*, meaning that the instruction scheduling is sensitive to the duration of the supported gates on the QPU. We theoretically evaluate the computational complexity of DDRoute, and we provide experimental validation, demonstrating that we achieve up to 70% reduction in depth with respect to state-of-the-art routing algorithms.

II. Preliminaries

In this Section, we provide an introduction to quantum computing and QRP. We specifically refer to the gate-based model of quantum information.

A. Gate-based Model of Quantum Computing

Quantum computing is a paradigm of computation based on the laws of quantum mechanics. Its unit of information is the *qubit*. While classical bits can lie in one of two states, 0 and 1, qubits are described as a *superposition* of two basis states, $|0\rangle$ and $|1\rangle$. The state of a qubit can be represented as a linear combination of the two basis states: $|\Psi\rangle = \alpha|0\rangle + \beta|1\rangle$, where α and β are complex coefficients, and $|\alpha|^2 + |\beta|^2 = 1$ [15]. We can modify a quantum state by applying reversible operations, called *gates*. Current physical implementations of gates support either one operand (single-qubit gate) or two operands (two-qubit gate). Among the most employed single-qubit gates are the Pauli X gate (equivalent to a classical NOT operation) and the Hadamard H gate, often used to create uniform superpositions of basis states; among the most common two-qubit operations are the Controlled-X (CX or CNOT), which takes as input a control qubit and a target qubit and bit-flips the latter if the former is set to $|1\rangle$, and the SWAP operation, employed for swapping the state of two qubits. One SWAP gate can be implemented using three CNOTs, and more generally any n-qubit quantum gate can be decomposed in a set of single-qubit gates and CNOTs [16].

A common representation of quantum algorithms is the *quantum circuit*, where qubits are represented as wires and gates as blocks acting along the wires of their operands. An example of quantum circuit is given in Figure 1a. For circuit compilation, a more convenient representation is the Directed Acyclic Graph (DAG), where nodes represent gates, and edges represent dependencies between gates. We define the front layer F of a DAG as the set of nodes without incoming arcs, corresponding to the operations that can be executed without waiting for previous dependencies. The back layer B, instead, is the set of nodes without outgoing arcs. An example of DAG for the circuit in Figure 1a is shown in Figure 1b.

We now introduce three distinct concepts of *depth*, acting at different levels of the quantum algorithm. The *gate depth* of a node in a DAG is the length of the longest path between any of the nodes in the front layer F and the given node. As an example, the first CX from the left in Figure 1b has a gate depth equal to 1, since both its operands belong to F. The *qubit depth* of a given qubit, instead, is $1 +$ the length of the longest path between any of the nodes in F and the node corresponding to the last operation applied to that qubit. This can be interpreted as the number of *time steps* required to execute all the operations on a specific qubit, assuming that independent operations are performed in parallel, when possible. In Figure 1a, q_0 and q_2 have qubit depth equal to 4, while q_1 has qubit depth equal to 3. Finally, the *circuit depth* of a given circuit is defined as the maximum among the qubit depths of all the qubits belonging to that circuit. This can be interpreted as the number of time steps required to completely execute the given circuit. For the circuit in Figure 1b, the overall circuit depth is equal to $\max\{4, 3, 4\} = 4$.

B. The Qubit Routing Problem

Current NISQ devices mainly support only single-qubit and two-qubit operations, with limited gate set and connectivity. Therefore, in order to compile a generic n-qubit gate to a specific device backend, this operation is decomposed in single-qubit and two-qubit gates which are directly supported by the platform. After gate decomposition, the n logical qubits are associated with physical qubits on the device (*mapping* or *placement*), and operations are scheduled accordingly [17]. This mapping can be mathematically described by a function $\pi : q \mapsto \widetilde{q}$, mapping a logical qubit q to a physical qubit $\widetilde{q}$.

Whilst single-qubit gates can be directly applied onto their operands $\widetilde{q}$, two-qubit gates require that their operands are directly connected in the quantum processor. For example, if the two-qubit gate G is applied to logical qubits q_1 and q_2, then the corresponding physical qubits $\widetilde{q_1}$ and $\widetilde{q_2}$ must be directly connected. Such topological constraints can be visualized as a 2D *coupling map*, where nodes are physical qubits and edges represent supported interconnections for two-qubit operations [6]. In case such constraints are not respected by the initial mapping π, qubit routing must be performed to modify the physical mapping of q_1 and q_2, such that their newer mapping $\widetilde{q_1}$ and $\widetilde{q_2}$ are interconnected.

Assuming that we need to change the physical location of a logical qubit q from $\widetilde{q_a}$ to $\widetilde{q_b}$, two possible cases arise: if $\widetilde{q_a}$ and $\widetilde{q_b}$ are directly connected in the coupling map, a SWAP operation between $\widetilde{q_a}$ and $\widetilde{q_b}$ will be sufficient; alternatively, if $\widetilde{q_a}$ and $\widetilde{q_b}$ are not directly connected, the routing algorithm must find a path between $\widetilde{q_a}$ and $\widetilde{q_b}$ in the coupling graph, and schedule SWAP operations accordingly. Identifying a convenient selection of qubits to swap in order to minimize the overall circuit depth corresponds to solving the QRP.

C. Related Works

The literature provides a theoretical analysis of the QRP, showing that both the minimization of the number of SWAP gates [8], useful to improve fidelity, and the minimization of

the circuit depth [9] are NP-complete problems. Therefore, based on the complexity of the instances and the requirements of the users, current approaches to address QRP may prefer reduced execution time or higher accuracy. Thus, two families of algorithms were developed, having different objectives. The first family tackles the problem by formulating all the topological constraints and the quantum operations by means of mathematical constraints or clauses, to be resolved by a SAT solver or other exact procedures [17]–[22]. These algorithms provide accurate solutions, but their exponential time complexity makes their use unfeasible for large circuits. For instance, the exact solution introduced in [17] requires $\mathcal{O}((n!)^2 \cdot n \cdot g)$ steps to solve the QRP on a circuit with n qubits and g two-qubit gates, and other similar approaches only tackle quantum circuits with few qubits and hundreds of operations. The second family, currently in use in modern quantum computing frameworks, follows a heuristic approach, effectively reducing execution time and providing good solutions, but without guaranteeing optimality [10]–[14]. As an example, the approach employed in t|ket⟩ [12] and Cirq [13] is to discard single-qubit gates and divide the circuit into independent sets of two-qubit gates called *timesteps* or *layers*. Then, the QRP is solved on each timestep, employing a heuristic cost function to select the `SWAP`s to be inserted. A similar approach is followed by QMAP [14], which employs an A*-search-based procedure to find the best `SWAP`s, and StochasticSwap [11], which uses a randomized approach to select an efficient permutation to be applied to logical qubits. Following a different direction, the algorithm SABRE [10] does not act on independent timesteps, but performs routing incrementally using a similar heuristic cost function, with a worst-case time complexity of $\mathcal{O}(gn^{2.5})$.

The primary objective of these algorithms is to reduce the number of additional gates, yet *not* to minimize the final depth of the given circuit. Their final solutions often present excessive depth, which is inconvenient for the satisfaction of the coherence time constraints. Moreover, their heuristics often exclude solutions where the addition of further `SWAP`s may result in a circuit with reduced depth, due to parallelization of operations. We deem that this feature is pivotal for NISQ devices, whose supported circuit depth is still limited [23]. Therefore, DDRoute follows a *depth-driven* approach.

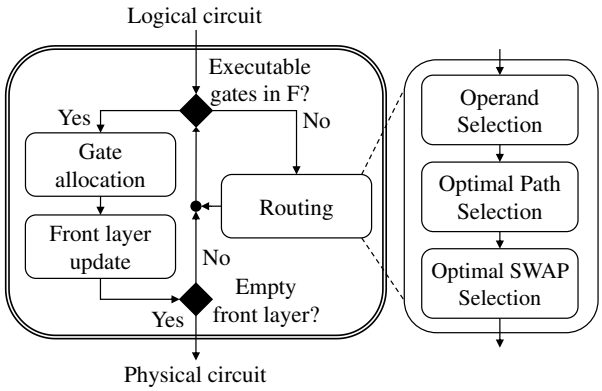
III. Our Proposed Algorithm

This Section introduces DDRoute, DDPlace, and an analysis of the computational complexity of both components.

A. DDRoute: Algorithm Overview

Given a logical circuit C_l, the goal of DDRoute is to compute an equivalent physical circuit C_p where all the two-qubit gates comply with the coupling map of the device. To do so, logical operations from C_l are sequentially evaluated and added to C_p, along with the necessary `SWAP` gates.

The setting conditions of DDRoute, i.e., the initial mapping $\pi(\cdot)$, are provided by DDPlace (Section III-B), and are tailored to reduce the number of `SWAP`s needed to route the first instructions of C_l. After this initialization, DDRoute begins



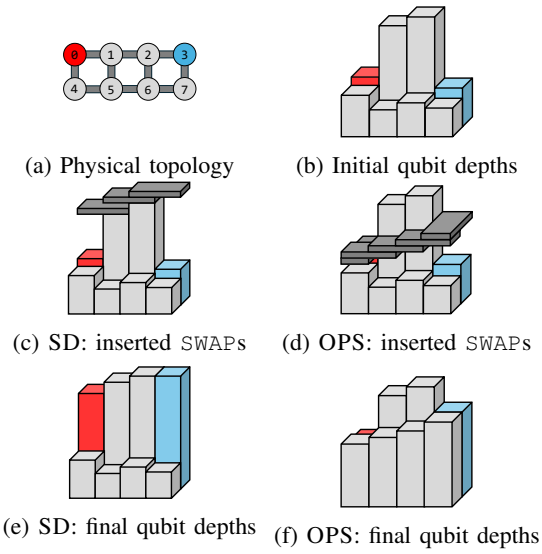


Fig. 2: Overview of DDRoute. The procedure explores F and performs routing when necessary. At every iteration, two-qubit gates are allocated in the physical circuit and F is updated.

by inspecting F, as shown in Figure 2. If one of the gates in F is directly executable, i.e., its operands are mapped to adjacent physical qubits, it can be added to C_p. Afterwards, such a gate is removed from the DAG, and F is updated accordingly. If none of the gates in F can be executed due to topological constraints, it means that the circuit contains two-qubit gates whose operands are not interconnected on the coupling graph. Therefore, `SWAP` operations have to be scheduled to allow those two-qubit gates to be executed. The criterion for choosing which `SWAP` operations to perform is pivotal, since it defines the depth of the final circuit. Our `SWAP` allocation process is based on three main heuristic components: OperandSelection, OptimalPathSelection, and OptimalSWAPSelection. DDRoute iteratively exploits such components until all the gates in C_l have been correctly routed.

1) Operand Selection: The OperandSelection procedure is responsible for choosing the *operands* of the `SWAP` gates, i.e., two qubits that need to be routed. The first one is the input of a gate in F whose mapping needs to be modified. The choice of a specific qubit aims to minimize the schedule time of the inserted `SWAP`s, to reduce the overall circuit depth. To do so, we select the logical operand whose corresponding physical qubit (according to the current mapping) has a low *qubit depth*. Since the depth of a possible `SWAP` applied to the selected qubit is determined by the qubit depth of both its operands, we improve this metric by also considering the qubit depth of the neighbors of the physical qubit. The one which minimizes these factors is selected as the current operand to be routed. We refer to the selected logical qubit as q_{curr}, to the corresponding gate in F as g_{curr}, and to the other operand as q_{oth}.

2) Optimal Path Selection: The OptimalPathSelection routine is employed to compute a path in the topology graph that connects the physical qubits corresponding to the operands selected in the previous step. Inserting `SWAP`s along this path would route the selected logical qubit in a position adjacent to its corresponding operand, making the

(c) SD: inserted SWAPs (d) OPS: inserted SWAPs

(e) SD: final qubit depths (f) OPS: final qubit depths

Fig. 3: Shortest Distance (SD) and OPTIMALPATHSELECTION (OPS) on a routing problem between qubit 0 and 3.

operation feasible on hardware. Most algorithms employ a simple shortest-path approach, while the goal of OPTIMALPATHSELECTION is to exploit the same efficient shortest-path procedures, yet with a tailored, depth-driven distance metric. To do so, we define a *generalized distance function* $\delta(\widetilde{p})$, able to reduce the depth of each operation along the path and, most importantly, the depth of the final circuit.

More specifically, given a physical source qubit $\widetilde{q}$, another physical qubit $\widetilde{p}$ in the coupling map, and a path ρ from $\widetilde{q}$ to $\widetilde{p}$, we define $\delta_{depth}(\widetilde{p})$ as the depth of the last SWAP gate along the path ρ; $\delta_{swap}(\widetilde{p})$ as the number of SWAP required to reach $\widetilde{p}$; and $\delta_{next}(\widetilde{p})$, that is a score depending on the quality of the mapping resulting after applying the SWAP gates required by ρ. In particular, for each of the gates immediately after g_{curr} in the logical circuit, a positive penalty is assigned to SWAP gates that bring its operands further apart and a negative discount is assigned to SWAP gates that bring its operands closer.

Thus, we combine such scores and define the generalized distance $\delta(\widetilde{p})$ from $\widetilde{q}$ to $\widetilde{p}$ as:

$$\delta(\widetilde{p}) = \delta_{depth}(\widetilde{p}) + \delta_{swap}(\widetilde{p}) + \delta_{next}(\widetilde{p})$$

This definition allows the distance function to be efficiently computed using Dijkstra's algorithm, with the same computational complexity as a simple shortest-path computation. The algorithm visits one physical qubit at a time, selecting at each step the nearest one not yet visited and updating the shortest path to its neighbors. The procedure terminates when the visited node is the routing destination.

Figure 3 provides an example with a physical topology of eight qubits (3a). We assume that a certain number of gates has already been allocated in C_p, with the qubit depths represented by the height of the corresponding columns (3b). Notice that the *circuit depth* equals to the highest column. The goal is to modify the mapping of an operand from qubit 0 to qubit 3 by means of SWAPs (represented as darker blocks). The simple shortest distance (SD) approach solves the problem by inserting three SWAPs (3c), with an unnecessary increase in the circuit depth (3e). The OPTIMALPATHSELECTION (OPS), instead, follows a seemingly longer path (3d), yet reaching the destination qubit at a lower depth without increasing the overall circuit depth thanks to $\delta(\widetilde{p})$ (3f).

3) Optimal SWAP Selection: During the OPTIMALPATHSELECTION, the routing algorithm obtains a path ρ between the physical operands $\widetilde{q} = \pi(q_{curr})$ and $\widetilde{p} = \pi(q_{oth})$. Placing *all* the SWAPs along the path ρ is not, however, the best strategy, since it does not take into account the possible SWAPs that can be performed by other operands in parallel. A simple yet effective strategy to exploit parallelism, employed by the OPTIMALSWAPSELECTION, is to allocate just the first operation along the path, updating the mapping of q_{curr} accordingly. If $\pi(q_{curr})$ and $\pi(q_{oth})$ are now adjacent, meaning that the end of ρ has been reached, then the corresponding gate g_{curr} can be inserted in C_p and removed from F. If $\pi(q_{curr})$ and $\pi(q_{oth})$ are not adjacent, then, instead of inserting the remaining SWAPs, the routing process is restarted from the OPERANDSELECTION step. Then, if the selected operand is still q_{curr}, the optimal path computation is not required, as the best operation to be inserted is the next SWAP in the previously computed path ρ. If the selected operand is different, instead, the previous optimal path is discarded and OPTIMALPATHSELECTION is performed again. This assures that all the SWAPs added to C_p are associated with the current best operand, thus reducing the schedule time of all the inserted SWAPs. Once all the gates in C_l have been inserted in C_p, causing F to be empty, the routing process can terminate and C_p can be executed on the QPU.

Finally, a key aspect is the allocation of single-qubit gates. Most routing algorithms ignore the presence of single-qubit operations as they are not subject to topological constraints, inserting them in the circuit after the routing procedure. To reduce their depth contribution, DDRoute postpones their allocation until a two-qubit gate, i.e., an operation from C_l or a routing SWAP, has to be inserted. In the first case, it has no choice but to insert all the postponed single-qubit gates right before the new operation. In the case of a SWAP, instead, it can exploit the fact that the SWAP gate depth depends on the highest qubit depth among its operands. If the physical operand with the lowest qubit depth corresponds to the physical mapping of a logical qubit, then the routing procedure inserts single-qubit gates acting on that logical qubit before the new SWAP, until it fills the difference in qubit depth between the two qubits or it meets a two-qubit gate or the end of the circuit. Using this strategy, the algorithm can minimize the contribution of single-qubit gates to the final circuit depth.

B. DDPlace

DDPlace is our depth-driven procedure to compute the initial mapping $\pi(\cdot)$ for DDRoute. It begins by sorting all the two-qubit gates in C_l by depth. Then, it selects two random physical qubits and maps the operands of the first two-qubit

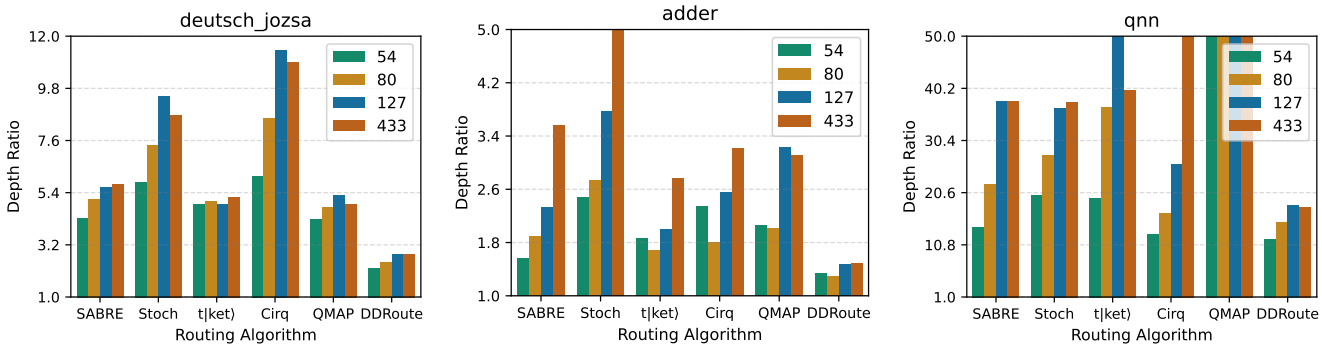

Fig. 4: Depth ratio comparison on DEUTSCH_JOSZA, ADDER, and QNN circuits, targeting the 54-qubit Google Sycamore, 80-qubit Rigetti Aspen, 127-qubit IBM Eagle, and 433-qubit IBM Osprey topologies.

gate onto them. The procedure then iterates over the remaining two-qubit gates, ordered by depth, mapping their remaining operands. If both the operands have not been mapped yet, they are assigned to two physical qubits which are the closest to the last assigned physical qubit. If one of the two operands has not been mapped yet, it is associated with the *free* physical qubit closest to the one assigned to the other operand. Finally, if some logical qubits have not been mapped, they are assigned to the physical qubits closest to the last assigned physical qubit.

C. Computational Complexity

The computational complexity of DDPlace is $\mathcal{O}(g \log n)$, where g and n are the number of two-qubit gates and the number of logical qubits in the circuit, respectively. Indeed, computing the depth of all the two-qubit gates in the graph requires $\mathcal{O}(g)$ operations. Then, F is continuously updated using a binary min-heap. Since the number of two-qubit gates in F at each step is at most $\lfloor \frac{n}{2} \rfloor$, removing the gate with the lowest depth and updating F requires $\mathcal{O}(\log n)$ operations. In the worst case, when the whole circuit traversal is necessary, DDPlace requires $\mathcal{O}(g \log n)$ operations.

The computational complexity of DDRoute is $\mathcal{O}(gn^{1.5} \log n)$. Indeed, on a 2D coupling map, the average number of `SWAP`s required to map two operands of a gate onto adjacent physical qubits is $\mathcal{O}(\sqrt{n})$, resulting in a total of $\mathcal{O}(g\sqrt{n})$ `SWAP` insertions. In the worst case, the selected operand q_{curr} is changed for each `SWAP`, causing the recomputation of the optimal path ρ, where $\mathcal{O}(n \log n)$ steps are required by the OPTIMALPATHSELECTION procedure. Therefore, the complexity of the whole algorithm is $\mathcal{O}(g\sqrt{n}(n \log n)) = \mathcal{O}(gn^{1.5} \log n)$.

IV. EXPERIMENTAL RESULTS

In this Section, we experimentally evaluate DDRoute, and its DDPlace initialization, comparing its performance against other state-of-the-art algorithms. We consider multiple benchmark suites and target superconducting architectures.

A. Experimental Setup

Our evaluations aim to compare the performance of DDRoute, initialized by DDPlace, against other state-of-the-art procedures. The algorithms we use for comparison are SABRE [10] with Qiskit v1.2.0, t|ket⟩ [12] v1.31.0, Google Cirq [13] v1.4.1, and MQT QMAP [14] v2.6.0, initialized by their default mapping technique; and StochasticSwap [11], with Qiskit DenseLayout [24] as a mapping procedure. We consider state-of-the-art benchmark suites: the Munich Quantum Toolkit Benchmark [25], QASMBench [26] v1.4, VeriQBench [27], and Qiskit Circuit Library [28], and target the following QPUs: Google Sycamore [29] (54 qubits), Rigetti Aspen [30] (80 qubits), IBM Eagle [31] (127 qubits), IBM Osprey [32] (433 qubits), and IBM Condor [33] (1121 qubits). All our experiments were executed on a 32-core Intel Xeon E5-2680 CPU with 32GB of memory and the Ubuntu 24.04 LTS operating system, setting a compile time limit of 3 hours. We perform three classes of testing: a depth analysis, a scaling analysis, and an analysis on gate length awareness.

B. Depth Analysis on Benchmark Circuits

This class of experiments compares DDRoute against the State of the Art, targeting medium-sized circuits and QPUs, with a focus on the depth overhead introduced by the routing. To provide more accurate results, we run all stochastic algorithms 30 times, and we average depth and compile time values. We define the *depth ratio* of circuit c as:

$$\text{DepthRatio[c]} = \frac{\text{FinalDepth[c]}}{\text{InitialDepth[c]}}$$

which quantifies the overhead of the routing process on the final depth. Indeed, the addition of `SWAP` gates produces outputs with increased depth with respect to the input circuit. The more the routing procedure is efficient, the closer the depth ratio to 1. Additionally, we define the improvement in depth of DDRoute with respect to a generic algorithm ALG for circuit c as:

$$\text{Improvement[c]} = \frac{\text{FinalDepth}_{\text{ALG}}[c] - \text{FinalDepth}_{\text{DDRoute}}[c]}{\text{FinalDepth}_{\text{ALG}}[c]}$$

The results of our experiments, such as the ones presented in Figure 4, show a consistent reduction in circuit depth. DDRoute is able to outperform all the algorithms employed in the current quantum computing frameworks, both in depth

TABLE I: Improvement of DDRoute with respect to the State of the Art, targeting the 80-qubit Rigetti Aspen, the 127-qubit IBM Eagle, and the 433-qubit IBM Osprey topology.

#Qubits	Improvement (%) of DDRoute w.r.t.				
	SABRE	Stochastic	t|ket⟩	Cirq	QMAP
54	25.52	46.98	39.13	26.14	51.62
80	34.93	47.17	41.51	29.05	55.10
127	36.06	53.87	47.41	45.27	70.86
433	47.97	58.28	47.53	60.68	71.15
Average	**36.88**	**52.02**	**43.02**	**40.92**	**62.56**

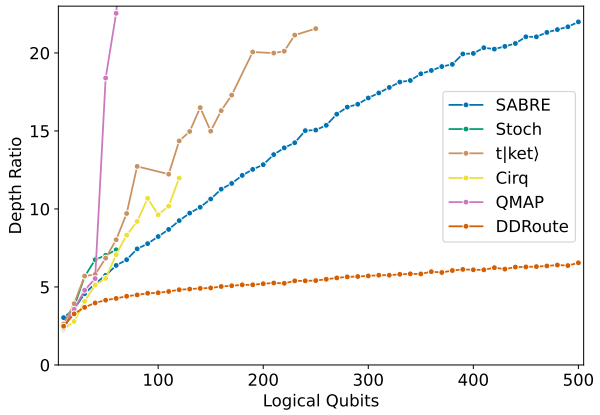

Fig. 5: Depth ratio comparison on circuits generated with Qiskit Circuit Library , targeting the 1121-qubit IBM Condor.

and compile time, with an average depth improvement of over 36.8% and a geomean average speedup of 92.8× over all experiments. We point out that the achieved speedup in compilation time also depends on the execution runtime of the algorithms, which is based on Python and C++ for DDRoute, and mainly on Python for the State of the Art. Regarding the SWAP count of the output circuits, we note that DDRoute is outperformed by algorithms like SABRE and QMAP, where the minimization of the number of added operations is the main target objective, rather than circuit depth. Table I shows a detailed comparison of DDRoute with the six algorithms on circuits and topologies with different sizes. We highlight that the increase in circuit size and physical qubits produces up to 71.15% improvement.

C. Scalability Analysis & Awareness of Gate Length

To further quantify the scalability trend, we performed another set of experiments targeting the 1121-qubit IBM Condor topology. We generated input circuits combining several components of the Qiskit Circuit Library [28], from 10 to 500 qubits. The results of these experiments are shown in Figure 5. Out of the six compared algorithms, only DDRoute and SABRE were able to complete routing for all circuits without exceeding the time limit of 3 hours. As it can be seen, DDRoute outperforms SABRE, with an average depth ratio of 6.51 against 21.99 for the largest test case, reducing the circuit depth by 70.4%. Regarding the count of SWAPs, which is *not* the main target of DDRoute, SABRE only achieves 38.7% improvement over DDRoute in the largest test case. Therefore, DDRoute proves to provide an important reduction in circuit depth with only a limited increase in SWAPs.

TABLE II: Depth comparison with different metrics between SABRE and DDRoute, on circuits generated with Qiskit Circuit Library, targeting the 1121-qubit IBM Condor.

	1/0-11-33	6183399	1761279	71.52

As a final class of experiments, we aim to evaluate the awareness of gate length, i.e., the ability of the routing procedure to take into account $\tau(g)$, corresponding to the duration of each gate g, and minimize the circuit depth accordingly. To perform such evaluation, we repeated the experiments on the largest available topology, IBM Condor, varying the metric over which the circuit depth is computed. We employed three different metrics for $\tau(g)$: **1-1-3**, where the depth of single-qubit gates, CXs, and SWAPs are 1, 1, and 3, respectively; **1-2-6**, where the depth of single-qubit gates, CXs, and SWAPs are 1, 2, and 6 [34]; and **1/0-11-33**, where X and SX gates have a depth of 1, RZs have a depth of 0, CXs of 11, and SWAP operations of 33. The latter is proportional to the average gate execution time on IBM devices [35], [36]. Table II shows a comparison for some of the test cases between SABRE and DDRoute, highlighting that DDRoute achieves significant improvements in the final depth for all three metrics, with the ones reflecting different gate durations having an even more important reduction, up to 71.52%. For further flexibility, we also provide the possibility of specifying different $\tau(g, \widetilde{q_1}, \widetilde{q_2})$ for different operands of the same gate.

V. Conclusion

In this paper, we proposed DDRoute, a depth-driven approach to the QRP, which compiles logical quantum circuits into physical ones, while reducing the overall depth overhead. We devised a generalized distance function, able to quantify the impact of SWAP insertions on the final circuit depth. We also introduced DDPlace, a depth-driven mapping procedure to generate convenient initial conditions for the routing algorithm. Experimental results show that our approach is able to effectively reduce the depth of the routed circuits, achieving up to 70% improvement over state-of-the-art solutions.

As the next steps, we aim to tune the definition of the generalized distance function to keep into consideration additional factors, such as the hardware-specific tradeoff between SWAP fidelity and coherence time.

***Abstract*—Large language models (LLMs) have gained significant attention recently. However, executing LLM is memory-bound due to the extensive memory accesses. Process-in-memory (PIM) emerges as an energy-efficient solution for LLMs, delivering high memory bandwidth and compute parallelism. Nevertheless, the trend towards larger LLMs introduces escalating memory footprint challenges for monolithic PIM chips. This paper proposes McPAL, which tackles this challenge by emphasizing unstructured sparse compute within PIM and hierarchical multi-chiplet scaling. McPAL decomposes arbitrary sparse weight matrix into multiple irregular sparse vectors. The non-skipped computations in each vector are then routed via an in-memory butterfly network to the standard PIM array, enhancing the PIM utilization. In addition, we scale McPAL vertically by strategically organizing the 3D-HBM hierarchy to minimize the internal long-distance data travel. Meanwhile, a 2.5D IO chiplet scales McPAL horizontally, reducing die-to-die (D2D) data transfer and ensuring sparse workload balance. We conducted extensive experiments from Llama-7B to Llama-70B. The results show that McPAL achieves 1.57× to 3.12× speedup and 10.43× to 35.66× energy efficiency over Nvidia A100 GPU. Compared to SOTAs, McPAL also achieves 1.08× to 2.15× speedup and 1.65× to 5.14× energy efficiency.**

***Index Terms*—HBM, Chiplet, Large Language Model, Unstructured Sparsity, Processing-in-Memory**

I. Introduction

LLMs exhibit superior capability to learn long-range contextual dependencies and remarkable scalability as parameters grow, from GPT-2 1.5 billion [1] to GPT-4 1.76 trillion [2] in just 5 years. As LLMs continue to expand, a simultaneous need arises to scale up compute throughput, memory capacity, and inter-chip bandwidth. Conventional architectures like GPUs typically store all parameters in an external memory chip (e.g. DRAM) and perform LLMs on another separate processor chip, moving large-scale weights back and forth. Unfortunately, CMOS compute logic scales much faster than inter-chip links and memory capacity [4]. As a result, the performance of GPU-DRAM systems is often constrained by the limited bandwidth between memory and processor chips.

PIM is a promising solution for memory-intensive LLMs. It features ultra-tight coupling between compute and storage cells, avoiding the performance bottleneck limited by the memory-processor bandwidth. PIM pioneers leverage dataflow optimization [10]–[12] and attention sparsity [13]–[15] to accelerate self-attention in LLMs, but leave linear layers unexplored. These linear layers frequently become bottlenecks during LLM inference. For example, the Llama-7B model [3] with 4K tokens requires 6.47 billion weights for its linear layers, compared to just 1.07 billion for self-attention's key-value caching. The extensive weight parameters take up 85.8% of model storage, placing significant memory demands on LLM systems.

Sparsification Techniques [16]–[18] are widely adopted to reduce the memory footprint of linear layers. However, the irregular memory access and compute pattern of sparse weight matrices are inherently incompatible with the regular PIM structure. Consequently, previous PIM designs primarily support structured sparsity, where weights are pruned in block-wise [21], [22] or channel-wise [23] patterns. However, SparseGPT [6] proves that structured sparsity could lead to performance degradation in LLMs. In addition, ***Multi-Chiplet Integration*** emerges as another approach to manage memory footprint, breaking the monolithic limitation of a single PIM chip. Heterogeneous integration enables the creation of a virtual "*super-die*" by dividing it into multiple chiplets. Thanks to the flexibility and scalability, various chiplet architectures [24], [25] were proposed for high-performance computing. However, these works primarily optimize compute-bound tasks, such as matrix multiplication, but lack specific optimizations tailored for memory-bound LLMs, resulting in redundant storage and inefficient data transfer [19].

In summary, efficient LLM execution in PIM requires satisfying the following requirements: (1) The overall architecture should support the full scope of LLM operations, including not only self-attention but also linear layers and other components. (2) The PIM chiplet should accommodate unstructured weight sparsity to minimize the memory overhead without compromising LLM accuracy and hardware utilization. (3) The PIM-chiplet system meticulously optimizes LLM workflows, maximizing compute/storage utilization while minimizing inter-chiplet communication. This paper proposes McAPL to address these challenges through the following contributions,

- McPAL explores unstructured sparsity in HBM-PIM through a novel matrix decomposition algorithm. It decomposes arbitrary sparse weight matrices into irregular sparse vectors, which are then routed through an in-memory butterfly network for regular vector products in PIM. This method delivers nearly 2× speedup at 50% sparsity, significantly reducing memory footprint without compromising LLM accuracy or hardware utilization.
- McPAL introduces a hierarchical multi-chiplet scaling topology. We first scale McPAL vertically by strategically organizing the 3D-HBM hierarchy to minimize HBM's internal long-distance data travel by through-silicon vias (TSVs). A dedicated 2.5D IO chiplet furthers scales McPAL vertically to reduce D2D data synchronization and enables sparse workload balance.
- We conduct extensive experiments to test McPAL scalability from Llama-7B to Llama-70B models. The results show that McPAL achieves 1.57× to 3.12× speedup and 10.43× to 35.66× energy efficiency over Nvidia A100 GPU. Compared to SOTA accelerators, McPAL also achieves 1.08× to 2.15× speedup and 1.65× to 5.14× energy efficiency.

II. Background and Motivation

A. LLM Preliminaries

Fig. 1 illustrates the LLM structure, comprising an embedding layer, a stack of transformer layers and a language model (LM) head. The embedding converts discrete tokens into feature vectors, while

* Chixiao Chen is the corresponding author, cxchen@fudan.edu.cn.

This work was supported by the National Key Research and Development Program of China under Grant No. 2023YFB4404402 and the National Natural Science Foundation of China under Grant No. 62495101.

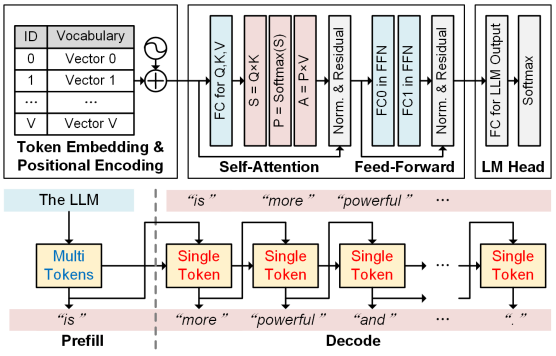

Fig. 1. LLM and transformer topology.

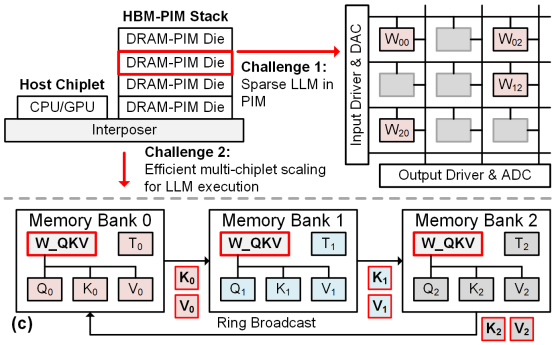

Fig. 2. Challenges for HBM-PIM chiplet architecture.

the LM head predicts the next token based on the transformer output. Between these lies the transformer layer, which is the core component of LLMs. It consists of two consecutive blocks: self-attention and feed-forward. The self-attention first projects input vectors into three intermediate features: Query (Q), Key (K) and Value (V). The Q×K yields attention scores (S), then normalized by a softmax to produce attention probabilities (P). Next, the P×V yields attention outputs. These outputs are fed into the feed-forward network, which comprises several linear layers separated by non-linear activation functions.

Most LLMs are pretrained for causal modelling, essentially as the next-token predictors. As shown in Fig. 1, LLMs typically contain two distinct phases. The prefill phase processes the input prompt in a single inference to generate the first new token. Since all tokens in the prompt are predetermined, LLMs perform matrix-matrix multiplication, making the prefill compute-bound. In contrast, the decode phase aggressively generates a single token per inference, serving as the input in the next iteration. The KV vectors of the input prompt and the generated tokens are stored to construct the "*KV Cache*", which is reused in the subsequent decode inference. The decode phase involves vector-matrix multiplication and is memory-bound. According to S3 [28], A100 GPU utilization reaches 68.4% during GPT-J model inference with a batch size of 512 (compute-bound), but drops to 0.4% with a single batch (memory-bound). It indicates that bandwidth limitation is the main bottleneck in LLM acceleration. Therefore, the PIM, offering high memory bandwidth, is a promising solution for accelerating memory-bound LLMs.

B. Motivations for HBM-PIM-Chiplet Architecture

The chiplet architecture integrates multiple smaller dies through 2.5D/3D advanced packaging technologies. This modular approach offers several advantages, including improved yield, reduced development time, and enhanced customization. Combining large-capacity HBMs, the HBM-PIM-chiplet architecture is developed. While HBM-PIM [19] and chiplet [24] are individually prevalent, their integration into a multi-chiplet HBM-PIM architecture raises new challenges:

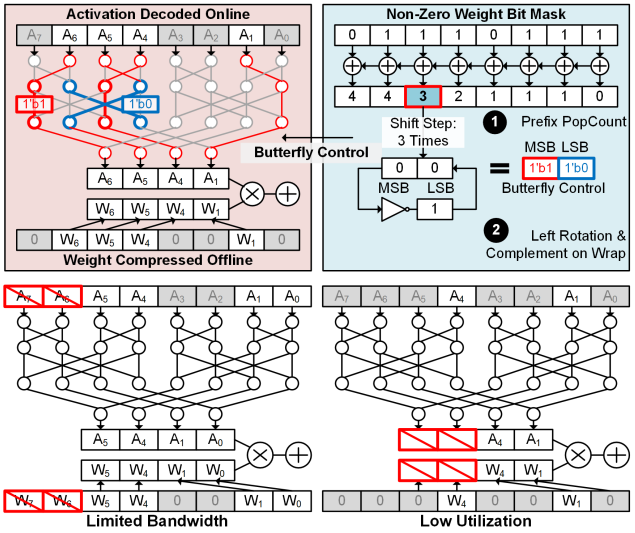

Fig. 3. (a) BFLY network to map M:N sparsity in PIM. and (b) The challenge of mapping unstructured sparsity in PIM using BFLY.

❶ **Efficient LLM storage in HBM-PIM.** The billions of parameters in LLMs create substantial memory demands, far exceeding the photolithographic limitation of a single HBM chiplet. While sparsification can minimize LLM size, most HBM-PIM designs struggle with under-utilization when mapping sparse weight matrices. Given the PIM crossbar in Fig. 2, the randomly distributed sparsity patterns lead to DRAM cells filled with zeros, resulting in low utilization. Consequently, most PIM designs only support block-wise [21], [22] or channel-wise [23] structured sparsity. SparseGPT [6] proves that structured sparsity could degrade LLM performance. Therefore, a PIM design that supports unstructured sparsity is necessary, distinguishing our work from other HBM-PIM works. ❷ **Efficient multi-chiplet scaling for LLM execution.** TransPIM [19] is the first PIM design to explore LLM scaling by distributing the input prompt across multiple HBM banks. As shown in Fig. 2, it duplicates all weight parameters in bank groups to enable parallel computing, which is impractical for larger LLMs. Moreover, it ring-broadcasts and synchronizes the KV cache for each input token. Since the KV cache size scales with the number of tokens, TransPIM incurs massive data transfers, rendering it inefficient for handling long input sequences, such as those with 4K tokens. Finally, TransPIM optimizes matrix multiplication within the HBM-PIM die, but overlooks auxiliary operations such as normalization, embedding, etc. In practical LLM applications, these remaining operations necessitate an additional master, which diminishes PIM efficiency by introducing substantial long-distance data travel within HBM or even inter-chip communication. To mitigate this issue, an efficient multi-chiplet scaling scheme tailored for LLMs is essential, setting McPAL apart from other chiplet-based architectures.

III. Sparsity-Aware McPAL PIM Design

A. Local Bank-Balance M:N Sparsity in PIM

Mapping unstructured sparsity to PIM is the knob to reduce memory footprint without sacrificing LLM performance. We first review the local-balanced M:N sparsity [8], [9], which lays the foundation for the subsequent exploration of the fully unstructured sparsity in McPAL HBM-PIM. In M:N sparsity, the weight matrix typically reserves ***M*** non-zero weights (NZWs) out of ***N*** elements within each weight vector. The sparse vector is then compressed and encoded by a bitmask. Guided by the bitmask, the activations

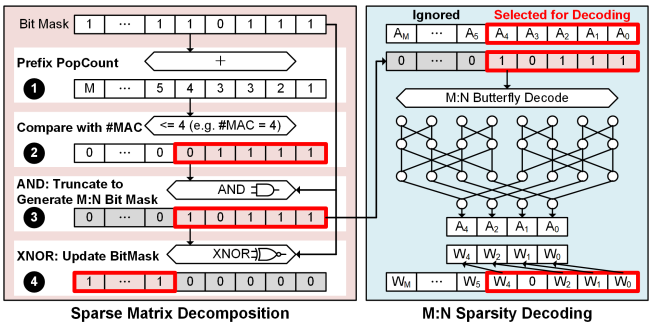

Fig. 4. Decompose sparse weight matrix to avoid limited bandwidth in BFLY.

associated with the NZWs are routed from the original inputs. The product between the compressed NZWs and the extracted activations effectively converts the M:N sparsity into regular vector products, which is well-supported in many PIM designs.

Fig. 3 depicts the M:N sparse compute flow and the butterfly network (BFLY) to route the non-skipped activations to NZWs [9]. The BFLY decoder contains two primary operations: prefix popcount and left-rotation complement-on-wrap (LRCW). The popcount performs cumulative sum on the given bitmask. The count of bit-1 indicates the number of NZWs up to a certain position. LRCW is a standard left rotation except that the MSB is complemented whenever it wraps around. Fig. 3 shows how to generate the control bits for two BFLY switches in stage 2. The two LSBs of the popcount result, PP[5], are used as the rotation step to execute LRCW on two zeros ('00'), which yields control bits '10'. Other switches follow a similar decoding method just with different popcount results. BFLY accurately directs the activations to the paired NZWs in M:N sparsity. However, due to the random distribution of NZWs in arbitrary unstructured sparsity, BFLY may cause limited bandwidth or low utilization. As shown in Fig. 3, the limited bandwidth arises when the number of NZWs exceeds BFLY's output bandwidth, preventing simultaneous extraction of all required activations. Conversely, low utilization happens when the weight vector is highly sparse, resulting in insufficient workloads to fully utilize the downstream MACs.

B. Unstructured Sparsity in McPAL PIM

McPAL leverages an algorithm-architecture co-design to enable arbitrary unstructured sparsity in PIM. ❶ Sparse weight matrix decomposition (SMD) and ❷ double-buffering BFLY (DB^{2}FLY) address the limited bandwidth and low utilization issues, respectively.

*1) **Sparse Weight Matrix Decomposition**:* The essence of SMD is to break down any sparse weight matrix into multiple M:N sparse vectors, which are then decoded as described in Sec. III-A. As shown in Fig. 4, SMD includes four steps to align the excess NZWs with both BFLY bandwidth and the downstream MACs (#MAC). ❶ Perform prefix popcount on the input bitmask to count the number of NZWs up to each position. ❷ Compare the popcount result with #MAC. The resulting bit-1s define the range of the first #MAC NZWs. ❸ Perform element-wise AND operation between the original bitmask and the comparison result. It truncates the bitmask for the first #MAC NZWs and sets the remaining to zero for the excess NZWs. The truncated bitmask is then forwarded to the standard BFLY decoder. With the bitmask for the excess NZWs set to zero, BFLY will only route the first #MAC NZWs. ❹ Finally, perform element-wise XNOR operation between the truncated bitmask and the original bitmask. It updates the bitmask for the next SMD iteration. In summary, the four-step SMD decomposes arbitrary sparse weight matrix to multiple M:N sparse vectors, enabling effective PIM mapping using the BFLY decoding logic.

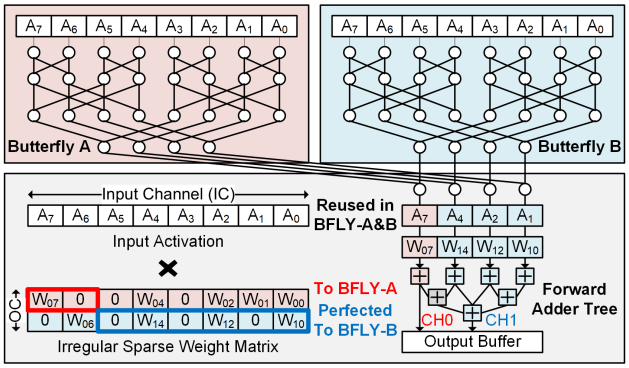

Fig. 5. Double-buffering BFLY to address low utilization issue.

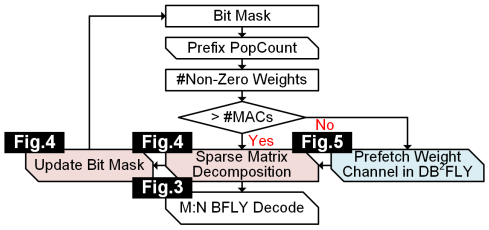

Fig. 6. The overall workflow of McPAL to map unstructured sparsity in PIM.

*2) **Double Buffering Butterfly Network**:* McPAL uses DB^{2}LFY to tackle the low utilization when handling highly sparse weight matrices. As shown in Fig. 5, the DB^{2}FLY comprises two independent regular BFLYs. If the sparse weight vector has enough NZWs to fill all MACs, only one BFLY is activated to reduce dynamic power. Otherwise, DB^{2}FLY activates both BFLYs to allocate adequate workload from a boarder region. Take the sparse weight matrix in Fig. 5 as an example. At the first cycle, McPAL employs SMD to produce M:N sparse compute for the first four NZWs, W_{00} to W_{04}. As a result, the remaining weight vector contains only one NZW, W_{07}, leading to insufficient data to fully utilize all MACs in the next iteration. To prevent low utilization, the DB^{2}FLY prefetches and then routes the NZWs from two consecutive output channels. Each BFLY handles M:N sparsity for its respective channel. In addition, both BFLYs reuse the same input activations, thereby reducing the input bandwidth requirement. The partial sums from these two channels cannot be accumulated directly. To resolve this issue, we leverage the forwarding adder tree in Sigma [17] for parallel accumulations within a single adder tree.

The integration of SMD and DB^{2}FLY enables McPAL to deal with unstructured sparsity in PIM. Fig. 6 summarizes the overall flow of the unstructured sparse computing. First, McPAL conducts prefix popcount on the input bitmask to calculate the number of NZWs and compares it with #MAC. As long as the NZWs can fill all MACs, SMD is then executed. Otherwise, the DB^{2}FLY prefetches the next weight channel to mitigate the low utilization. McPAL supports prefetching only two consecutive channels. That's because more channels would require a larger BFLY, forwarding adder tree and additional memory for partial sum storage, resulting in a higher hardware overhead. Although NZWs in these two channels may still fail to fully utilize the downstream MACs, the experimental results in Sec.V demonstrate that DB^{2}FLY is enough to achieve nearly a 2× latency reduction at 50% weight sparsity.

IV. Multi-Chiplet McPAL Scaling

A. 3D Vertical McPAL Scaling with Hierarchical HBM-PIM

To overcome the monolithic limitations of a single PIM chip, we first realize the sparsity-aware McPAL PIM and scale it vertically

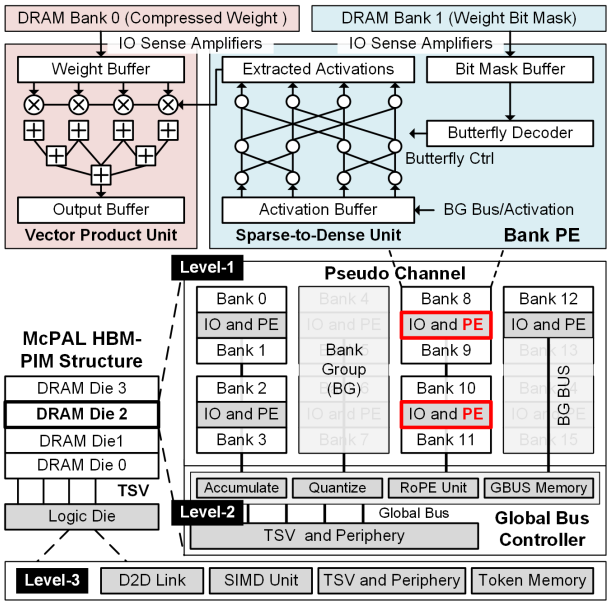

Fig. 7. 3D vertical McPAL scaling with hierarchical HBM-PIM.

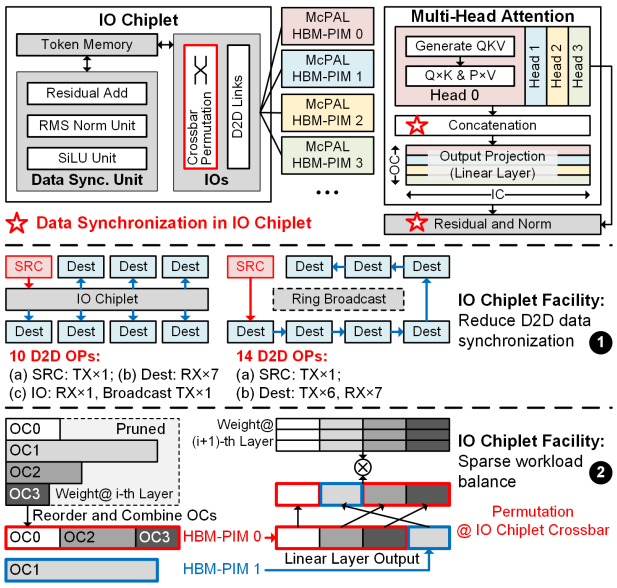

Fig. 8. 2.5D horizontal McPAL scaling with IO chiplet.

using 3D HBM technology. Fig. 7 gives the integration of the McPAL process engine (PE) into the HBM architecture. McPAL includes four DRAM dies and a logic die, all 3D stacked via TSVs. Each DRAM die contains four pseudo channels (pCH) that operate independently, with each pCH comprising four bank groups (BGs). BG is further divided into four banks and every two banks share one McPAL PE. Each McPAL PE can execute 32 INT-8 MACs in parallel, leveraging the 256-bit local bank I/O. Once McPAL issues a sparse PIM operation, the PE reads 32 NZWs and a 128-bit bitmask from two adjacent banks via I/O sense amplifiers, while activations are delivered from the logic die through TSVs, global bus and BG bus. The bitmask is decoded to control a 128×2-input-32-output DB^{2}FLY, which dispatches the required activations to NZWs. For circuit implementation, the embedded MACs and transmission-gate-based BFLY switches are derived from IMPERA [9].

FGDRAM [27] reveals that data transfer from BGs to the logic die via TSVs accounts for 56.6% of the HBM power consumption. To minimize long-distance travel via TSVs, we strategically organize the hardware hierarchy within HBMs to align with the distinct operational characteristics in LLMs. Besides the bank-level PEs, McPAL has two other hierarchical hardwares in the global bus controller (GBUS CTRL) of the DRAM die and the logic die. For linear layers, the activations from the logic die are broadcast to multiple BGs, which then process different weight output channels in parallel. For self-attention, the KV cache is stored in DRAM dies. Different BGs reuse the same Q to calculate Q×K or P×V for various KV vectors. This approach enables McPAL to fully leverage the abundant internal BGs of HBMs for vector-matrix multiplication, maximizing PIM utilization during the LLM decode phase. As shown in Fig. 7, the partial sums are accumulated and quantized in the GBUS CTRL per BG before writing back to the logic die through TSVs. It consumes less power as partial sums travel a shorter distance. The GBUS CTRL also includes a memory to buffer activations from the logic die and a RoPE unit for positional embedding. The activations are reused locally to avoid direct access to token memory in the logic die, while the RoPE unit locally embeds the positional information into the QK vectors. Then the prepared KV vectors are directly written back to the DRAM banks. Therefore, the GBUS CRTL further minimizes the data transfer through TSVs, improving the power efficiency of McPAL HBM. Finally, we place a 128-way SIMD in the logic die to compute softmax, where the exponential and division are approximated by Taylor expansion. That's because the softmax collects Q×K results from all BGs. Placing softmax at the GBUS or bank level would involve complex transfers among pCHs. Compared to HAIMA-like [11] HBM-PIM, which assigns matrix multiplication to the bank-level PE and allocates all other operations in the host logic die, the hierarchical McPAL reduces the power consumption by 34.3%.

B. 2.5D Horizontal McPAL Scaling with IO Chiplet

We further scale McPAL HBM-PIM horizontally to fit larger LLMs using an IO chiplet. The IO chiplet minimizes D2D communication during data synchronization and ensures balanced sparse workload across various McPAL devices. As shown in Fig. 8, the IO chiplet comprises a token memory, a synchronization unit and abundant IO functionalities. The token memory stores input tokens which are then dispatched to McPAL HBM-PIMs. The synchronization unit receives results from HBM-PIMs, and concurrently performs auxiliary operations in LLMs such as residual addition, RMS normalization or SiLU. Similarly, the non-linear functions are approximated by Taylor expansion. Following tensor parallel [20], McPAL divides self-attention by heads and linear layers by output channels across multiple McPAL HBM-PIMs. Each device independently processes the designated workload segment, contributing to a portion of the entire output. Therefore, output synchronization is essential for subsequent operations. For instance, the attention results from different heads must be concatenated before proceeding to the output projection. The synchronization is also required after each linear layer.

In contrast to ring broadcast [19], [20], the IO chiplet can minimize the D2D communication during data synchronization. Take 8 McPAL HBM-PIMs in Fig. 8 as an example. To move data from one source to the others, HBM-PIMs issue one transmission (TX from source) and 7 receptions (RX to destinations), while the IO chiplet receives data from the source and broadcasts it to the destinations. Consequently, the IO chiplet employs 7 distinct RX channels, which encompass the physical layer, D2D adapter and protocol layer, while reusing a single TX channel. Therefore, a total of 10 D2D transmissions are required. In contrast, the ring broadcast necessitates 7 TX and 7 RX transmissions, 1.4× higher than McPAL. In addition, the IO chiplet enables workload balance across different McPAL HBM-PIMs. Due

to the unstructured sparsity within McPAL, directly distributing the linear layers to various McPAL devices could result in unbalanced workloads. The HBM-PIM, which is assigned the heaviest workload, dominates the total latency, leading to low utilization of both PIM logic and D2D bandwidth. To address this issue, as shown in Fig. 8, we combine several highly sparse output channels and assign them to McPAL-0, while a single dense channel is assigned to McPAL-1. Note that the reordered outputs are misaligned and thus cannot directly multiply with the weight in the next layer. The IO chiplet utilizes a crossbar that permutes the output during data synchronization, ensuring correct LLM execution.

V. EXPERIMENTAL RESULTS

We developed a McPAL prototype using 28nm technology. The 8GB HBM used in McPAL follows the standard HBM2 protocol. Its hardware characteristic is drawn from FGDRAM [27] and summarized in Table. I. The embedded multiplier and transmission-gate BFLY switches are derived from IMPERA [9], and redesigned with Cadence Virtuoso. The digital modules in McPAL PE and logic die are synthesized using Synopsys Design Compiler and then placed and routed with Synopsys IC Compiler. The post layout provides area and power estimations. Similar to TransPIM [19], we consider the process difference between the CMOS logic and DRAM, where the DRAM process incurs about 50% area overhead to the logic process. We evaluate McPAL across various Llama models (7B, 33B and 70B). To facilitate McPAL execution, these models are pruned to 50% sparsity by Wanda [5] and quantized to INT-8 by SmoothQuant [7]. The perplexities on the WikiText dataset are 7.45, 5.86 and 4.07, respectively, resulting in perplexity losses of 1.77, 1.09 and 0.95 compared to the original models. We run Llama models on Nvidia A100 40GB GPU, serving as the baseline and compare with McPAL. To fit the entire parameters on McPAL, we utilize 1, 4 and 8 McPAL HBM-PIMs to run Llmam-7B, 33B and 70B models, respectively. Finally, **McPAL-S** enables sparse compute, whereas **McPAL-D** stands for the dense counterpart without sparsity.

A. McPAL Performance and Design Space Exploration

*1) **Power, Area and Latency Breakdown**:* Table II reports McPAL specification. To match the column access time of HBM ($t_{CCD} = 2ns$), McPAL PEs and other digital modules run at 500MHz frequency and 1.0V power supply. As described in Sec. IV, every

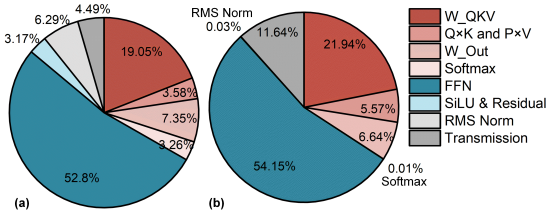

Fig. 9. (a) Latency and (b) Energy breakdown of McPAL with 8 McPAL HBM-PIMs on Llama-70B model.

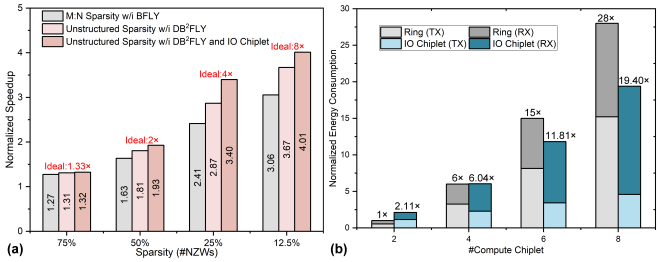

Fig. 10. Design space exploration: (a) The impact of unstructured weight sparsity on McPAL performance, and (b) Transmission energy reduction in IO-chiplet-based McPAL compared to ring broadcast.

two DRAM banks share a single 32-MAC McPAL PE. Therefore, the total of 32 PEs and the GBUS CTRL occupy a 3.64mm^2 area, incurring 6.8% overhead to the original HBM die (53.15mm^2) [19]. As shown in Table I, each pCH provides a 64-bit data bus to transfer 16-bit partial sums. To avoid congestion, only half of the McPAL PEs are activated at the same time. As a result, a single McPAL HBM-PIM yields a peak throughput of 2.048TOPs. Both the logic die and IO chiplet contain a 16MB token memory, capable of storing up to 2K input tokens for the Llama-70B model. Finally, the D2D link adheres to the standard UCIe protocol [26], providing a total transmission speed of 256Gb/s with 16 lanes. Fig. 9 gives the latency and energy breakdown of running the Llama-70B model on 8 McPAL HBM-PIMs with sparsity enabled. The model processes an input sequence of 2K input tokens and sequentially generates an additional 2K tokens. The matrix multiplication in HBM-PIM dominates the inference, accounting for 82.78% latency and 88.31% energy cost. Consequently, the average throughput is 13.56TOPS (82.78%×2.048TOPS×8 McPAL HBM-PIMs). The IO chiplet orchestration reduces D2D communication, which only contributes to 4.49% latency and 11.64% energy consumption. The remainder is for the non-linear functions.

*2) **McPAL Speedup with Sparsity**:* Fig. 10(a) shows the impact of unstructured weight sparsity on McPAL performance, with comparison between BFLY and DB^{2}FLY. In this experiment, we exclusively compute the feed-forward network of the Llama-70B model. With a lower sparsity where 75% of NZWs are reserved, the BFLY and DB^{2}FLY shows similar speedup. At a higher sparsity of 50%, BFLY fails to fully exploit the sparsity benefit, resulting in only 1.63× speedup. In contrast, DB^{2}FLY reduces the data congestion during sparsity decoding and achieves 1.81× speedup. The IO chiplet further enables sparse workload balance across various McPAL HBM-PIMs. As a result, the ultimate McPAL achieves 1.93× speedup, approaching the 2× speedup upper bound. It even achieves 3.40× speedup with only 25% of NZWs preserved. Finally, McPAL struggles to maintain utilization at higher sparsity. Nevertheless, McPAL well supports 50% sparsity, which is the highest compression ratio attainable by the prevalent sparsification algorithms [5], [6] without compromising LLM accuracy.

*3) **IO Chiplet Efficiency**:* We evaluate the efficiency of the IO chiplet for data synchronization and compare it with a baseline,

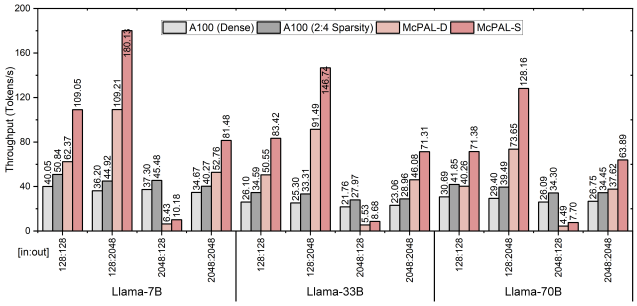

Fig. 11. McPAL throughput improvement over Nvidia A100 GPU.

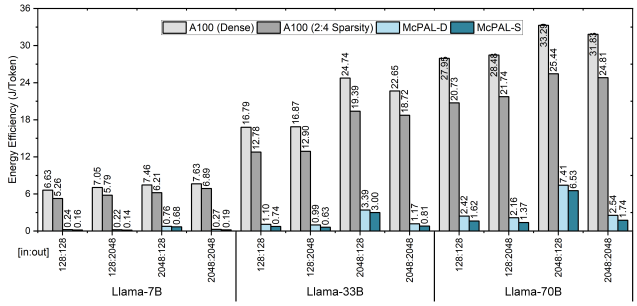

Fig. 12. McPAL energy efficiency improvement over Nvidia A100 GPU.

where McPAL HBM-PIMs are organized as a ring [20]. To fit all parameters on fewer McPAL devices, a smaller Llama-7B model is used to generate 2K tokens with another 2K input tokens. Fig. 10(b) reports the normalized energy cost of D2D communication. The ring topology exhibits better energy efficiency when configured with 2 or 4 McPAL HBM-PIMs. It indicates that direct communication among HBM-PIMs is more efficient in such cases. Nevertheless, the IO chiplet proves to be more efficient for coordinating more McPAL HBM-PIMs, making it more compatible with LLM evolution towards large model sizes. Specifically, the IO chiplet consumes 1.27× less energy to coordinate 6 McPAL HBM-PIMs and 1.44× less energy for 8 McPAL HBM-PIMs. As described in Sec. IV-B, the I/O chiplet broadcasts data to all destinations simultaneously, thereby reducing TX transmission requirement with a minimal RX transmission overhead.

B. Comparison to Baseline

1) ***Comparison to Nvidia A100 GPU****:* We first compare McPAL with the Nvidia A100 GPU. To accommodate the entire model on devices, we use 1, 4 and 8 8GB HBM-PIMs to run Llama-7B, 33B and 70B models, respectively, while utilizing 1, 2 and 4 A100 GPUs to run the same models. Even using fewer GPUs, the peak TOPS of a single A100 GPU remains 76.2× higher than that of 8 McPAL HBM-PIMs. Fig. 11 and Fig. 12 show McPAL's improvements in throughput and energy efficiency across various prefill and decode sequence lengths, [in:out]. For throughput comparison, the latency of both prefill and decode phases are considered and divided by the number of output tokens. The approach to calculate energy efficiency is similar. Compared to the A100 GPU, McPAL-D shows an average speedup of 1.57×, 1.95× and 1.35× on Llama-7B, 33B and 70B models, respectively. It also achieves 24.50×, 14.75× and 10.43× energy efficiency. Besides the inherent advantages of HBM-PIM, the proposed hierarchical multi-chiplet scaling method ensures >80% utilization under various workloads, while the A100 GPU achieves only about 3.2% utilization under the same scenarios. By pruning the weights to 50% sparsity, McPAL-S results in further speedup of 2.58×, 3.12× and 2.34×, along with energy efficiency improvements of 35.66×, 21.50× and 15.34×. For a fair comparison, we also

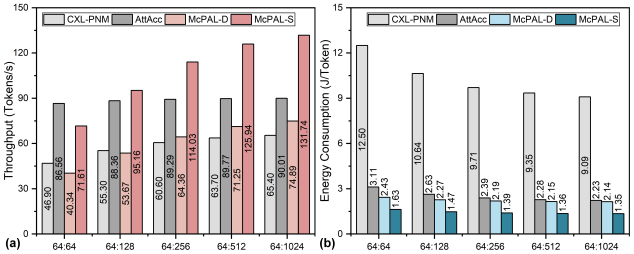

Fig. 13. Comparison with CXL-PNM and AttAcc: (a) Throughput and (b) Energy Consumption. McPAL and AttAcc run Llama-70B model and CXL-PNM runs OPT-65B model.

explore 2:4 sparsity (described in Sec. III-A) on A100 GPUs, which is inherently supported by Nvidia sparse tensor core. Nevertheless, McPAL-S still achieves 2.10×, 2.39× and 1.76× average speedup, and 29.86×, 16.90× and 11.69× energy efficiency at the same sparsity. Finally, McPAL shows better performance with longer input sequences, but worse performance with fewer input tokens. Take Llama-70B model as an example. Compared to A100 GPU, McPAL-S achieves 3.24× speedup and 15.88× energy efficiency when [in:out] is [128:2048]. That's because the memory-bound decode stage exacerbates the overhead caused by the back-and-forth weight movement in GPUs. In contrast, McPAL-S demonstrates only 0.21× throughput and 3.89× energy efficiency with [2048:128] workload, where the compute-bound prefill phase saturates GPU utilization.

2) ***Comparison to SOTA LLM Accelerators****:* We also compare McPAL with SOTAs LLM accelerators. CXL-PNM [29] is a near-memory architecture based on LPDDR5, utilizing 8 devices to run the OPT-65B model. Each device delivers the same peak throughput as one McPAL HBM-PIM. AttAcc [30] is a hybrid attention accelerator for the Llama-70B model, where A100 GPU handles the linear layer and HBM-PIM processes the self-attention. Fig. 13 compares the performance of McPAL HBM-PIM with CXL-PNM and AttAcc. AttAcc's results are obtained from its open-sourced simulator, while CXL-PNM provides explicit performance. McPAL-D achieves a similar throughput as CXL-PNM, but delivers 4.25× to 5.14× energy efficiency. In addition, McPAL-S further achieves 1.53× to 2.01× speedup and 6.75× to 7.68× energy efficiency. AttAcc demonstrates a speedup of 1.20× to 2.15× over McPAL-D across all workloads, and even a speedup of 1.21× over McPAL-S under [64:64] workload. That's because AttAcc allocates more compute resources, using A100 GPUs and 40 HBM3-PIMs to process LLMs. Nevertheless, McPAL-S still achieves 1.08× to 1.46× speedup with very few compute logic, alongside energy efficiency improvements of 1.65× to 1.91×. The data communication of self-attention between A100 GPU and HBM-PIM negatively impacts the energy efficiency of AttAcc, accounting for about 43.3% of energy consumption. In contrast, McPAL eliminates the need for inter-chip transfer for the KV cache by the three-level hierarchical HBM-PIM design.

VI. Conclusion

The paper introduces McPAL, a novel HBM-PIM-chiplet architecture that enhances sparse compute and multi-chiplet scalability for LLM inference. The sparse matrix decomposition enables unstructured sparse compute in PIM without compromising LLM accuracy or hardware utilization. Further, the chiplet scaling reduces D2D data transferor and enables sparse workload balance. The experimental results show that McPAL achieves 1.57× to 3.12× speedup and 10.43× to 35.66× energy efficiency over Nvidia A100 GPU. Compared to SOTA accelerators, McPAL also achieves 1.08× to 2.15× speedup and 1.65× to 5.14× energy efficiency.

***Abstract*—Emerging multimodal LLMs (MLLMs) exhibit strong cross-modality perception and reasoning capabilities and hold great potential for various applications at edge. However, MLLMs typically consist of a compute-intensive modality encoder and a memory-bound LLM decoder, leading to distinct bottlenecks for hardware designs. In this work, we present a multi-core CPU solution with heterogeneous AI extensions, which are based on either the compute-centric systolic array or memory-centric digital compute-in-memory (CIM) coprocessors. In addition, dynamic activation-aware weight pruning and bandwidth management are developed to enhance bandwidth efficiency and core utilization, improving overall performance. We implemented our solution using commercial 22nm technology. For representative MLLMs, our evaluations show EdgeMM can achieve 2.84× performance speedup compared to laptop 3060 GPU.**

***Index Terms*—Multimodal Large Language Model, Multi-Core CPU, Heterogeneous Architecture, CPU Extension.**

I. Introduction

Multimodal large language models (MLLMs) exhibit strong perception, reasoning, and planning abilities, with promising applications in autonomous driving [1], embodied AI [2], mobile [3], and AR/VR. As shown in Fig. 1 (a), MLLMs take in various modalities of input, such as image, audio, and LiDAR, which are processed by modality encoder to generate token representations. Following LLM and post-processing are performed for tasks such as comprehension, object segmentation [4], or trajectory planning [5]. Due to the application demands for privacy and real-time responses, deploying MLLMs on edge devices is highly desired.

Achieving low-latency inference of MLLMs at edge is challenging. First, the hardware resource is quite constrained at edge. Second, different phases in MLLMs exhibit opposite characteristics and performance bottlenecks. For instance, the encoder network is compute-intensive, while the LLM-decoding phase is bounded by the memory bandwidth. Such workload behaviors limit performance improvements of certain accelerators tailored for particular Transformers [6], [7]. Meanwhile, the prior optimization techniques for long-context

*Corresponding author.

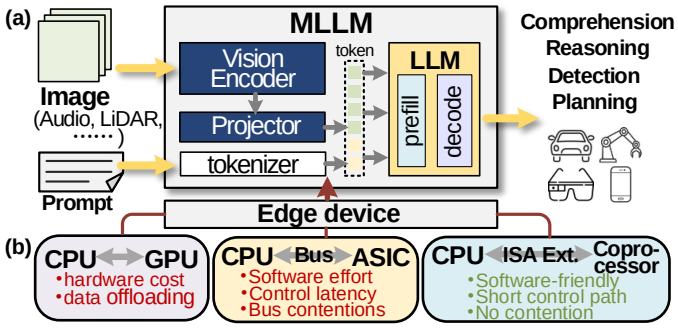

Fig. 1. MLLMs and hardware architecture design choices.

LLMs are not suitable for edge MLLMs, which process short token sequences with streaming inputs.

There are multiple hardware architecture choices for edge devices, as shown in Fig. 1(b). CPU remains the most common hardware in edge devices, while it has limited parallelism for AI tasks. The use of GPU on edge devices is severely limited by cost, and data offloading from CPU to GPU may become a system bottleneck [8]. ASIC accelerator is also a popular solution [9], which is connected to host CPU through memory-mapped interface. However, ASIC accelerators require corresponding compiler development, adding huge engineering effort for software developers. They also introduce bus access with increased control latency and bus contention [10].

In recent years, AI-target ISA extension with in-CPU coprocessors has emerged as a promising solution for AI tasks. For example, Intel introduced its advanced matrix extensions (AMX) [11] in the Xeon processors [12], [13]. Arm developed scalable matrix extension (SME) in Armv9-A [14]. T-head proposed open-source RISC-V matrix extension [15]. At architecture level, the host CPU cores decode and dispatch these extended instructions to coprocessors for execution via direct-linked interfaces. Compared to conventional bus-attached accelerators, coprocessors have a shorter control path and avoid bus contention. Moreover, this architecture can be merged into existing CPU ISA and inherit the compiler stack [13].

In this work, we explore a multi-core CPU solution for

TABLE I

edge MLLMs with heterogeneous AI-extension. For compute-intensive general matrix multiplication (GEMM), systolic array is utilized as the coprocessor. Alongside, for memory-bound matrix-vector multiplication (GEMV), which dominates LLM-decoding phase, area- and power-efficient digital compute-in-memory (CIM) macros are adopted. These coprocessors have different dataflows and resource distributions, coupled with RISC-V ISA and programming model for easy deployment. Furthermore, a dynamic activation-aware weight pruning is developed along with hardware support to alleviate memory bandwidth pressure. At the system level, the DRAM bandwidth can be dynamically managed to fully utilize heterogeneous cores for diverse sequence lengths.

The contributions of this paper are summarized as follows:

- We analyze the attributes of edge MLLMs, revealing that different phases encounter distinct bottlenecks in computation and memory access.
- We develop the heterogeneous extension for multi-core CPU, employing the systolic array and CIM macro tailored for GEMM and GEMV.
- We present an activation-aware weight pruning and bandwidth management, leveraging the limited bandwidth and heterogeneous cores to accelerate edge MLLM.
- EdgeMM is implemented and evaluated at 22nm, achieving a 0.217 token/J efficiency and 138 tokens/s throughput, which is 2.84× better than RTX 3060 GPU.

II. BACKGROUND AND MOTIVATIONS

A. Multimodal Large Language Models

MLLM builds on standard LLM by incorporating multimodal data for input and output. In recent two years, leading MLLMs such as Gemini [32], GPT-V [33], LLaVA [18], InstructBLIP [34] have emerged, impacting both industry and academia. Combining LLMs' reasoning with multimodal perception, they exhibit remarkable performance.

Fig. 1(a) illustrates the typical backbone architecture of MLLM, which is composed of modality encoder, projector, and LLM. Take visual modality as an example. The features are extracted from input images by Transformer-based vision encoder, e.g. CLIP [19], DINOv2 [26] and then aligned with language model via a projector, e.g. MLP, Q-former [23], to generate vision tokens. The vision tokens and text tokens from the prompt are jointly fed into the LLM. The inference of LLM consists of two phases, i.e. prefill and decoding. In the prefill phase, attention is applied between all tokens, generating the first output token and key-value (KV) cache. In the decoding phase, only the last token is taken as input, autoregressively generating the next token and updating the KV cache. The

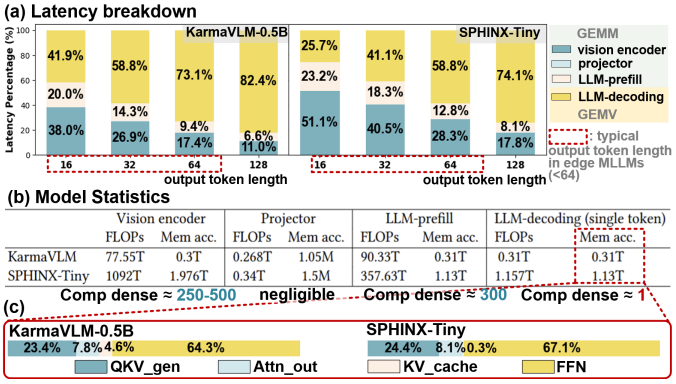

Fig. 2. Workload analysis of two MLLMs: (a) latency breakdown, (b) model statistics, (c) memory accesses.

generated tokens can be converted into language as output or further processed by downstream tasks, e.g. AD [1].

Tab. I lists a few representative open-source MLLMs and their model architectures. MLLMs [16], [18] often adopt LLMs with parameter amounts surpassing 7B. Meanwhile, there is also a model development trend for lightweight MLLMs to assist the deployment at edge. These edge MLLMs adopt compressed LLMs with less than 3B parameters, such as Phi2-2.7B [24], TinyLlama-1.1B [27], Qwen1.5-0.5B [31]. It is also worth pointing out that these edge MLLMs also demonstrate comparable performance compared to large-scale MLLMs in many benchmarks [35]–[38].

B. Model Profiling and Analysis

To better understand the workload characteristics, we conduct profiling on two representative MLLMs: SPHINX-Tiny [25] and Karmavlm [30]. The input token length is about 300, primarily made up of vision tokens. The inference latency breakdown on Nvidia 3060 GPU with varying output token lengths is shown in Fig. 2(a). An increase in output tokens leads to more LLM-decoding iterations, enlarging the proportion of this phase in overall latency. Alongside, the vision encoder and LLM-prefill also contribute to the overall latency notably in edge applications with short token lengths. The latency of the projector is negligible.

Fig. 2(b) also indicates the computing and memory attributes differ significantly during different phases. In vision encoder and LLM-prefill, multiple token embedding vectors share weight matrices forming computation-intensive GEMM. Meanwhile, LLM-decoding performs the operations between the entire weight matrix and a single embedding vector, resulting in low-computational-density GEMV. The LLM-decoding employs the same model parameters as LLM-prefill but involves two orders of magnitude fewer FLOPs, revealing an obvious memory-bound bottleneck. As shown in Fig. 2(c), weight matrices dominate the memory access, with FFN consuming the largest portion as the channel dimension is typically several times larger than the model dimension [39]. The KV cache only contributes a small portion of memory access due to the short token length in edge MLLMs.

Since the majority of DRAM access is occupied by FFN weight matrices, we further analyze the characteristics of this

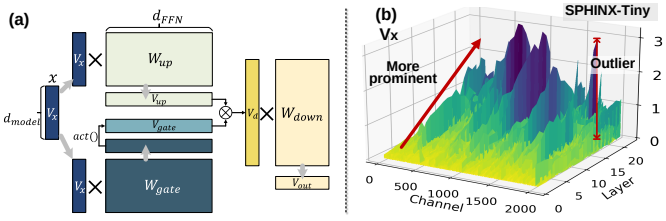

Fig. 3. Gated-MLP and the activation vector sparsity in FFN.

portion, e.g. sparsity. Currently the mainstream LLMs, e.g. Llama series [40], Mistral [41], Qwen [31], use the gated-MLP as FFN. Fig 3 (a) shows the detailed process, which contains three GEMV, and the calculation formula is as follows:

$$FFN(V_x) = ((V_x * W_{up}) \circ (act(V_x * W_{gate}))) * W_{down} \quad (1)$$

where V_x is the input vector, W_{up}, W_{gate} are $d_{FFN} \times d_{model}$ weight matrices. $Act()$ is the activation function. In fact, the activation vectors (V_x, V_d) in GEMV exhibit notable sparsity across channels. Fig. 3(b) shows profiled magnitudes of V_x during a token generation in SPHINX-Tiny [25]. The x, y, and z axes denote the decoder layer index, vector channels, and absolute magnitudes. As presented, these activation vectors exhibit notable sparsity for most channels, with a few outlier channels that can be easily masked out. Moreover, as the layer index increases, these outliers become more prominent.

The above analysis guides us to rethink the optimal architecture for edge MLLMs with the following design insights. **Insight 1: Heterogeneous coprocessors for GEMM and GEMV are desired.** The performance of compute-bound GEMM can be enhanced by increasing computing resources, while memory-bound GEMV requires addressing bandwidth. **Insight 2: Activation-aware weights pruning is promising.** Many prior work focuses on long-context KV cache optimization [42]. For short-context edge MLLMs, the weight matrices of FFN are key constraints, while the sparsity in most activation channels offers great potential for optimization. **Insight 3: Scheduling for output token lengths is needed.** Since the workload proportion varies with the output token length, dynamic scheduling is also strongly desired to maintain the balanced workload latency of heterogeneous cores.

III. EdgeMM Architecture Design

A. Architecture Overview

To accommodate the mentioned characteristics of edge MLLMs, we present a multi-core CPU architecture, i.e. EdgeMM, with heterogeneous AI extensions, as shown in Fig. 4. EdgeMM adopts a hierarchical multi-core architecture based on the open-source Snitch_cluster [43]. Two types of accelerator architecture are incorporated as coprocessors for compute-centric (CC) cores and memory-centric (MC) cores. Specifically, CC-cores utilize compute-dense systolic array (SA)-based coprocessors for GEMM. While MC-cores utilize memory-abundant digital CIM, which integrates the compute units within SRAM banks, as coprocessors for GEMV.

For CC-cores, cores in a cluster share the instruction memory and data memory. In contrast, the data memory and

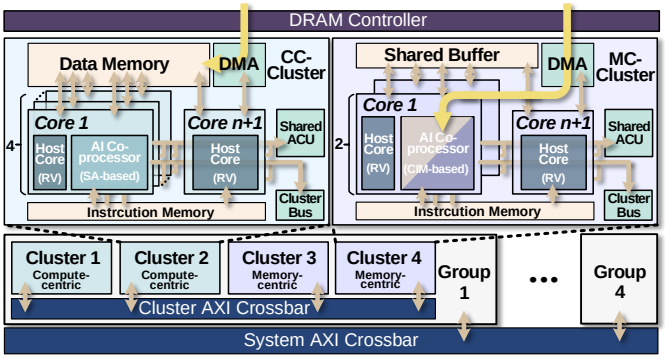

Fig. 4. Architecture overview of EdgeMM design.

compute array in MC-cores are integrated as a CIM macro in each core, and a small shared buffer is equipped for inter-core data transfer. Every cluster has a distributed DMA module, all of which are linked to the DRAM controller for data transfer to on-chip data memory. Auxiliary compute units (ACU), e.g. 32-bit multiplier and divider, are also shared among cores in a cluster for uncommon calculations.

The entire chip contains 4 groups, each consisting of 2 CC-clusters and 2 MC-clusters. Each CC-cluster and MC-cluster contains 4 CC-cores and 2 MC-cores respectively. These cores integrate an area-efficient RISC-V host core [43] for control and an extended coprocessor for AI computing. Each cluster also has a dedicated host core to control the DMA module. The groups and clusters are connected by the hierarchical AXI crossbars. The hardware architecture can also be scaled by changing architecture parameters.

B. CPU Extension for AI Acceleration

Fig. 5 and Fig. 6 illustrate the design details of CC and MC cores. Both core types consist of a host core and a coprocessor. The extended instructions are decoded by host core and dispatched to coprocessor via direct-linked interface.

Compute-Centric core: As shown in Fig. 5, the bulk of compute-centric GEMM coprocessor is a systolic array, which contains $R \times C$ multiply-accumulate processing elements (PE). For GEMM operations, the weights stored in the PE array remain stationary, while the input activations are sent into the array in a systolic manner. Four $R \times C$ matrix registers are equipped to store operands. The vector units are employed to execute vector instructions for element-wise computations. Vector instructions share the matrix registers and have an element width of C, enabling parallel operation on a row of a matrix register by one instruction. The coprocessor has an independent load/store unit for matrix registers, avoiding the data bottleneck caused by the narrow port of the host core. For multiplication between a $R \times C$ and an $M \times R$ matrix, the cycles of loading and computing equals:

$$L_{SA} = R + (R-1) + (C+M-1) - 1 = 2R + C + M - 3 \quad (2)$$

Systolic dataflow enables data transfer solely between neighboring PEs, reducing wiring overhead. However, there is only one column of activation (circled in red in Fig. 5) in GEMV, causing PEs idleness and inefficiency.

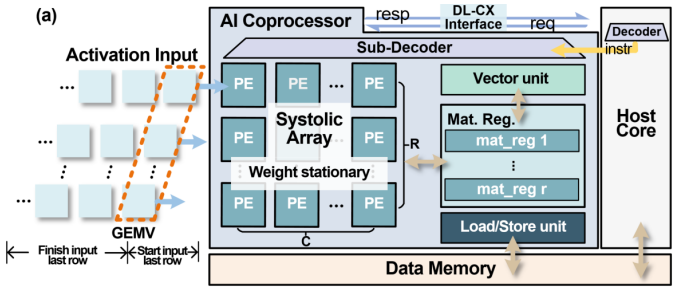

Fig. 5. Compute-centric core with Systolic Array.

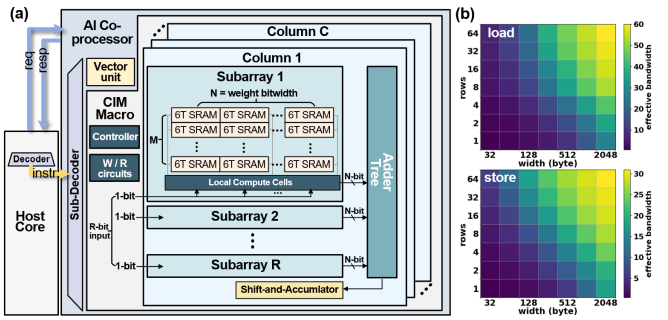

Fig. 6. Mem-centric core with CIM macro design.

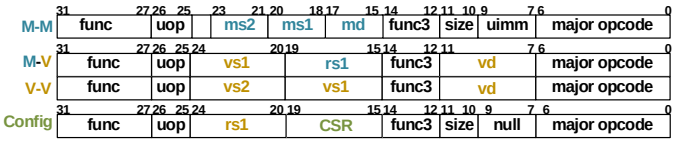

Fig. 7. Instruction format of the extended instructions.

Memory-Centric core: As shown in Fig. 6, the main feature of an MC-core is utilizing digital CIM for the coprocessor, which integrates compute cells within SRAM macro to avoid reg-to-SRAM load/store. A CIM macro consists of a controller, wordline decoder, write-and-read circuits, and C columns. Each column contains R subarrays, an adder tree, and a shift-and-accumulator. Each subarray consists of $M \times N$ 6T SRAM bit-cells. Here N equals to the bit-width of a weight data. During GEMV, the W-bit activation data is broadcasted into the columns in bit-serial. One of the weights in each subarray is read out and multiplied with 1-bit activation every cycle. Adder tree sums the R product and sends the result to shift-and-accumulator, in which the sum is shifted and accumulated to finish the entire W-bit multiplication. The broadcast dataflow fully utilizes the compute cells for GEMV, which is completed in $W+1$ cycles. The cycle number of a M rows GEMM is:

$$L_{CIM} = M * W + 1 \tag{3}$$

Compared to SA, CIM requires fewer cycles for GEMV, i.e. $M = 1$ in (2)(3). But for GEMM, CIM is less efficient due to the bit-width factor W. Moreover, MC-clusters have significantly larger data memory than CC-clusters, which allows larger matrix block to be transferred at once. We assess the effective bandwidth (data amount/cycles) for transferring matrices with various sizes. Fig. 6 (b) shows that the effective bandwidth drops notably for small matrices, but nears the ideal bandwidth as matrix size increases. This indicates the ample on-chip memory in MC-cluster can alleviate the bandwidth pressure and enhance DMA and DRAM efficiency.

C. ISA Extension and Programming Model

We adopt RISC-V as our main ISA and extend instructions for AI acceleration as shown in Fig 7. The first row illustrates the matrix instruction (i.e. mm_mul for GEMM) supported by CC-core. The matrix instructions differ from scalar instructions by employing matrix registers for both the source and destination operands. The CIM-based MC-core supports matrix-vector instructions, in which the *vs1* and *vd* are vector registers that store source and destination operands, and the *rs1* store the base address of matrix operand. The vector units in all cores support a subset of RISC-V vector instructions for activation functions and data precision conversion. Configure instructions can modify the control and status registers (CSR), storing the runtime parameters such as vector/matrix sizes.

The programming model of our EdgeMM is similar to snich_cluster [43]. The computing tasks, e.g. GEMM/GEMV, are allocated across cores with tensor partitioning. Specifically, each core and cluster contains read-only CSRs that store its index and type, allowing cores to calculate address offsets to access the allocated tensor shards. The core synchronization function is also supported. For ISA extension, the extended instructions can be utilized by customized kernel functions, enabling the use of the RISC-V toolchain without the internal modification of the compiler.

IV. Bandwidth Optimizations

To effectively utilize the limited bandwidth, we optimize memory access reduction by activation-aware weight pruning and perform token-length-driven bandwidth management.

A. Activation-aware Weight Pruning for GEMV

As Sec. II-B mentioned, the FFN weight matrices dominate DRAM access, and the activation vectors exhibit significant sparsity and outliers across channels. This motivates us to perform channel-wise activation-aware pruning. As shown in Fig. 8, GEMV can be performed by selecting the Top-k outliers and pruning the rest channels with corresponding rows in weight matrices. Recent works [44], [45] adopt the similar concept, but they all regard k as a fixed empirical input. In fact, k can vary along different decoder layers for better pruning. For example, early decoder layers should retain most weights to avoid errors accumulating and the latter layers have more distinct outliers, allowing for more efficient pruning.

As shown in Alg. 1, a layer-wise dynamic Top-k pruning scheme is presented. The update of k is based on straightforward yet effective principles: a channel that is t times smaller than the max channel can be considered negligible, where t is a fixed parameter set to 16 in our design. Moreover, k should decrease progressively with layer depth. If the number of retained channels n is less than k, it indicates that the current k is too large. Thus, k is set to n.

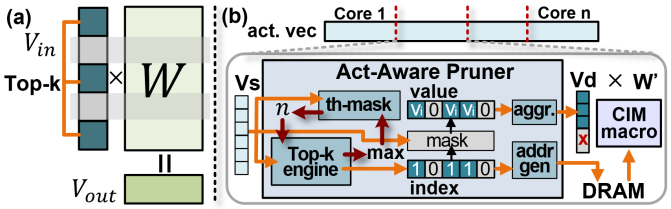

Fig. 8. Activation-aware weight pruning and hardware pruner.

Algorithm 1: Layer-wise Dynamic Top-k Pruning

input : Threshold t, Vector dim d
for *layers* in model **do**
  if $layer_index == 1$ **then**
    $k = d$; // no pruning
  $V_x^{'}$ = top-k(V_x, k) ; // select channels
  $W^{'}$ = pruning(W, index($V_x^{'}$)); // pruning
  GEMV($W^{'}$, $V_x^{'}$)
  n = count($V_x[i]$ ¿ $\frac{max(V_x[i])}{t}$)
  if $n < k$ **then**
    $k = n$; // update k
  /* remaining computation */
generate an output token

The hardware pruner in the MC-core facilitates the execution of GEMV with Alg. 1, as shown in Fig 8 (b). In practice, the activation vector is allocated to cores by channels. Each core focuses on its assigned local channels, avoiding complex global Top-*k* selections. The core first loads a slice of the activation vector into the vector register *vs*, then calls the hardware Act-Aware pruner for processing via specific instruction. In pruner, the Top-*k* engine finds the *max* value in *vs* and marks the selected elements with 1 in the index register. The th-mask receives the *max* value and *vs*, generating *n* in Alg. 1 for *k* update. The index is fed into the address generator, which calculates the address of the non-pruned weight rows for DRAM read requests. Following that, the *vs* is masked by the index and aggregated, and then output to *vd* register. Then the CIM macro computes the GEMV between *vd* and stored weights. The above process reduces DRAM access without wasting on-chip computation or memory resources.

B. Token-Length-Driven Bandwidth Management

The heterogeneity of EdgeMM complicates workload distribution. For MLLMs, it is optimal to run modality encoder and LLM-prefill on CC-clusters, with LLM-decoding on MC-clusters. In real-time applications (e.g. AD, robot, AR/VR), continuous streaming input enables pipelined execution. But the latency of LLM-decoding increases with the output token length, which can result in an unbalanced pipeline.

To maintain a balanced pipeline for various token lengths *l*, a throttling-based dynamic bandwidth allocation is adopted. For a model with default equal bandwidth sharing among clusters, an expected token length l_e can balance the latency of CC and MC clusters. As shown in Fig. 9(a), if l exceeds

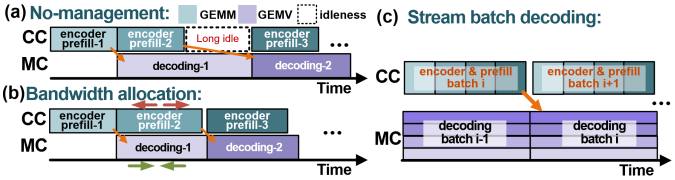

Fig. 9. Pipeline of bandwidth and workload management.

(a)

	CC-cluster	MC-cluster
Cores	4	2
Array(R,C)	(16,16)	(32,16)
OPs/s	2T	0.25T
Data Mem	32kB	128kB
DMA width	512bit	512bit
Crossbar width	1024bit	512bit
Area	$0.619mm^2$	$0.652mm^2$
Clusters in a group	2	2

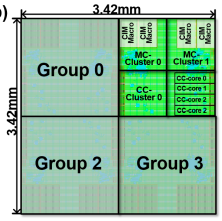

Fig. 10. Design configurations and the 22nm layout of EdgeMM.

l_e, CC-cluster will enter waiting idle. In such scenarios in Fig. 9(b), limiting CC-cluster bandwidth and reallocating it to MC-clusters can accelerate LLM-decoding, reducing overall latency. To implement bandwidth allocation, each cluster is assigned a memory access budget *B*. Within an interval *T*, the performance monitoring counter (PMC) in DMA accumulates the memory access usage d of each cluster. If $d > B$, subsequent DMA requests from this cluster are blocked until T elapses and PMCs are reset. We adjust the cluster budget B_c and B_m to enable dynamic bandwidth allocation.

Note the bandwidth allocation can only balance the pipeline with l in a certain range. For larger l, stream-based batch processing can be employed. As shown in Fig 9 (c), CC-clusters can encode and prefill a batch of streaming input without waiting for LLM-decoding. The MC cluster performs decoding concurrently on this batch. Larger batch multiplies the latency of CC-clusters, while decoding latency of MC-clusters increases slightly for the weight reuse. Hence the overall throughput can be boosted with minimal latency loss.

V. Evaluations

A. Implementation and Evaluation Setup

We leverage open-source Snitch_cluster [43] as the foundation platform for our EdgeMM development. The CC-cluster and MC-cluster are implemented using RTL flow and in-house 22nm digital CIM macro IP. We utilize Cadence Genus and Cadence Innovus for synthesis and physical implementation at 1GHz using TSMC 22nm technology. Fig. 10 demonstrates the layout view and design configurations of EdgeMM. The chip power is 112mW according to post-P&R report. The SA-based coprocessor occupies 62% area of a CC-core, and the CIM macro occupies 81% area of an MC-core. The performance is evaluated by RTL simulation and the in-house simulator with a dedicated mapping explorer.

B. Benefits of Heterogeneous Extensions

To evaluate the benefits of our heterogeneous AI-extensions, we compare our heterogeneous EdgeMM with homogeneous cluster designs: homo-CC and homo-MC, which consist solely of CC-clusters and MC-clusters. The original snitch_cluster

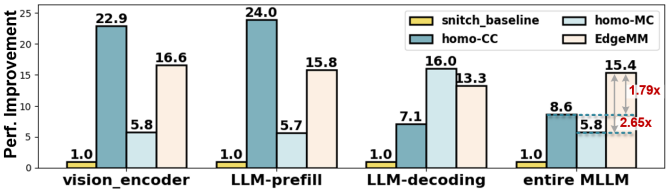

Fig. 11. Perf. improvements of homo. and hetero. designs

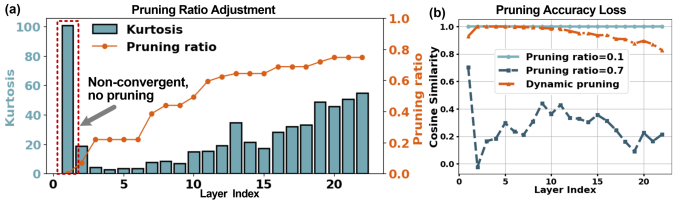

Fig. 12. Evaluation of activation-aware dynamic Top-k weight pruning.

[43] including SIMD cores is set as the baseline. The SPHINX-Tiny [25] MLLM and its inner phases with averaged input and output token length are used as the workload.

As shown in Fig. 11, all extended designs have significant performance boosts compared to the baseline since matrix extensions and coprocessors enhance computing power and reduce redundant load/store. Homo-CC and homo-MC perform the peak speedup in their adapted phases: a CC-cluster shows 4.3× better GEMM performance than an MC-cluster, whereas an MC-cluster is 2.42× faster in GEMV due to more efficient memory access. However, homo-CC and homo-MC encounter bottlenecks in non-adapted phases due to hardware mismatch. For the entire MLLM, the heterogeneous EdgeMM outperforms them by 1.79× and 2.65× respectively.

C. Benefits of Bandwidth Optimizations

Fig. 12 (a) presents the evaluation results for activation-aware dynamic TOP-k weight pruning during a token generation, where *Kurtosis* is a mathematical metric to represent channel-wise data distribution. Higher *Kurtosis* indicates more distinct outliers, i.e. more channels can be pruned. Results show that with *Kurtosis* increasing with layer depth, with pruning ratio of a randomly chosen core increases dynamically, proving the activation-awareness of dynamic TOP-k mechanism. Note that although the first layer exhibits a high *Kurtosis*, its data distribution remains unstable. Our experiment reveals that pruning this layer leads to significant accuracy degradation. Thus Alg. 1 skips the first layer.

To validate the accuracy of dynamic TOP-k pruning, we assess the cosine similarity between pruned and unpruned output vectors in FFN as depicted in Fig.12 (b). It is observed that dynamic pruning achieves comparable accuracy as a mild fixed pruning ratio of 0.1 while fixing pruning ratio at 0.7 causes irreversible accuracy loss in the shallow layers. Overall, our activation-aware pruning reduces the LLM-decoding latency of SPHINX-Tiny by 42% on average, with minimal score reduction in VQA [35].

Our dynamic bandwidth allocation can harness the heterogeneous cores under varying output token lengths l. As described in Fig. 13, when $l < l_e = 36$, bandwidth is not the critical

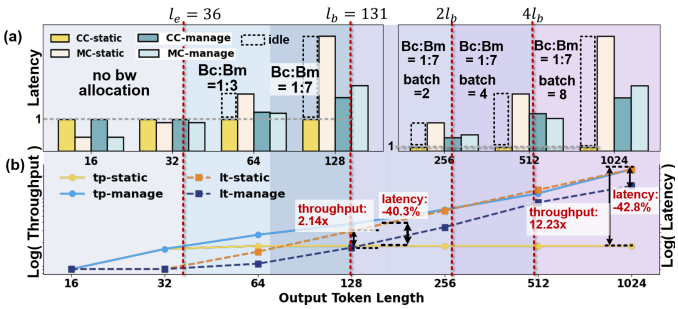

Fig. 13. (a) Latency and (b) throughput gains by bandwidth management.

bottleneck as the latency of CC-cores is large. As l rises, the extended duration of LLM-decoding slows down the pipeline. Thus the bandwidth budget of CC-cores B_c is reduced progressively, reallocating bandwidth to MC-cores. The B_c:B_m ratio ranges to 1:3 or even 1:7, accelerating MC-cores with tolerable latency increment of CC-cores. This optimization reduces latency by 40.3% and improves throughput 2.14× at l=128. When l increases to $l_b = 131$, bandwidth allocation nears its limit, where batch decoding is introduced to balance the pipeline. While batch decoding increases latency by 42% at $l = 1024$, it boosts throughput by 13.98×, compensating for the latency overhead.

We further compare EdgeMM with existing mobile GPU, as shown in Table II. Although SM cores in GPU provide massive parallelism, they often remain underutilized and not as effective as SA and CIM extensions in EdgeMM. Compared to laptop RTX 3060 GPU, EdgeMM achieves 2.15× performance for better resource utilization driven by heterogeneity. With our activation-aware weight pruning, the performance gain can be enhanced to 2.84×, reaching 138 tokens/s throughput. Overall, EdgeMM achieves a 0.28 token/J energy efficiency.

TABLE II
COMPARISON OF EDGEMM AND MOBILE GPU

	Compute Power	Bandwidth	MLLM perf.
RTX 3060 Laptop	13TFLOP/s (FP32)	GDDR6 336GB/s	1×
EdgeMM	18TFLOP/s (BF16)		2.15×
EdgeMM+Weight pruning	18TFLOP/s (BF16)		2.84×

VI. CONCLUSION

We present EdgeMM, a multi-core CPU with heterogeneous AI-extension for edge MLLM. To accommodate phases with diverse attributes in MLLM, coprocessors based on systolic arrays and digital CIM macros are integrated for GEMM and GEMV. To leverage limited bandwidth, activation-aware dynamic weight pruning is proposed with hardware support. Token-length-driven bandwidth allocation is employed to fully utilize heterogeneous cores. Overall, EdgeMM achieves 2.84× performance improvement compared to RTX 3060 GPU.

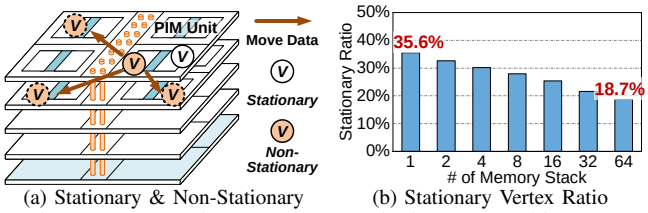
***Abstract*—Substantial data movement caused by irregular graph topologies hinders the efficient processing of graph neural networks (GNNs). Although the emerging near-bank processing-in-memory (PIM) architecture offers a promising solution to reduce data transfer between memory and computing units, cross-bank communication remains a critical challenge, limiting the benefits of PIM architectures. Our findings indicate that only 35.6% of the data can stay stationary within PIM units on average, with the rest requiring movement due to graph dependencies. This situation worsens as the number of PIM units increases, reducing the ratio to 18.7%.**



In this paper, we argue that to fully leverage PIM architectures, systems must *maximize stationary data and minimize the movement of non-stationary data*. Following this principle, we propose *Anchor*, a scalable PIM architecture that exploits stationary data for GNNs through a hardware-software co-design approach. To maximize stationary data, we introduce the graph partitioning algorithm Mastav, which carefully allocates vertices and edges to preserve data locality. To minimize the movement of non-stationary data, we employ a two-step strategy. First, a customized dataflow ensures that non-stationary data is accessed and distributed exactly once. Second, an optimized communication mechanism reduces redundant data transfers through critical paths. Our extensive experiments demonstrate that Anchor significantly reduces processing latency and data movement compared to representative schemes.

***Index Terms*—GNN, Processing-in-Memory, Stationary Data**

I. Introduction

Graph neural networks (GNNs) have emerged as a powerful learning paradigm for graph-structured data [11], [14], [23]. Computational efficiency is a primary concern in such deep learning systems, where vast numbers of nodes and edges have to be simultaneously processed. GNNs mainly consist of two time-consuming phases: (i) *combination* and (ii) *aggregation*. The sparse and uncertain topology of the input graph results in significant data movement, posing a severe challenge to the efficient processing of GNNs. The emerging 3D-stacked processing-in-memory (PIM) architecture [15], [22] allows computing units to be integrated near memory banks. The PIM architecture has proven to be an effective approach for addressing the data movement issue in GNNs [6], [7]. While PIM-based accelerators are already in place, the data movement problem still persists, leading to performance degradation. We observe that an unsolved key challenge is how to minimize unnecessary data movement across different PIM units.

Fig. 1 illustrates two types of vertices: *stationary* and *non-stationary*. Stationary vertices stay within their local processing units (PIM units) during aggregation, while non-stationary vertices have to migrate to remote PIM units due to graph dependencies. From the preliminary test results, only 35.6% of vertices are stationary vertices. Over 60% of the vertices are migrated to other PIM units. As the number of PIM units increases, the amount of stationary data drops quickly, indicating significant opportunities for optimization. To address this issue, we propose the ***Max-Min principle****: a PIM system must maximize stationary data and minimize the movement of non-stationary data.*

(a) Stationary & Non-Stationary (b) Stationary Vertex Ratio

Fig. 1: Low stationary vertex ratio in PIM architectures.

Many domain-specific architectures [20], [25], [30] have been proposed to address the challenges faced by GNNs. Some works capture the memory access patterns of GNNs and alleviate irregular data access by employing dedicated buffers [12], [16], [24]. Other works focus on reducing redundant memory accesses through algorithmic and architecture co-optimization [5], [10], [29]. Existing works only partially solve the issue by reducing memory accesses. Considerable efforts on architectural and system-software support are required to reduce the significant data movement.

This paper presents *Anchor*, a scalable PIM architecture harnessing stationary data to efficiently process GNNs. Anchor follows the proposed Max-Min principle using a hardware-software co-design approach. The objective is to fully exploit the PIM architecture and reduce data movement. At the software level, we introduce the graph partitioning algorithm *Mastav*, which maximizes stationary data by strategically allocating vertices and edges to maintain data locality. At the hardware level, we design a customized PIM architecture with a two-step optimization to minimize the movement of non-stationary data. A hybrid dataflow ensures that each non-stationary vertex is distributed only once, while an optimized communication mechanism further minimizes redundant data transfers through critical paths. We evaluate the proposed Anchor using a set of extensive experiments. The experimental results show that Anchor can significantly reduce latency and

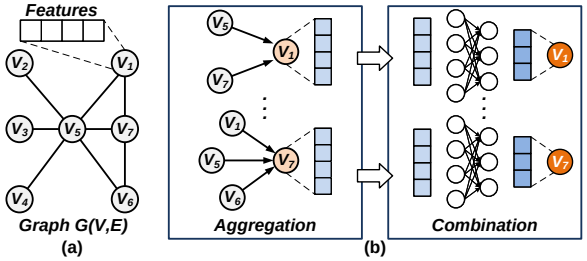


Fig. 2: (a) An input graph. (b) Illustration of a GNN model.

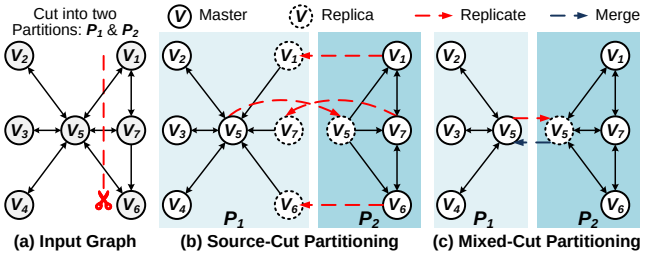

Fig. 3: Source-cut partitioning and mixed-cut partitioning.

data movement compared with representative schemes.

The main contributions of this work include:

- *Principle*: we propose the Max-Min principle to maximize stationary data and minimize the movement of non-stationary data.
- *Algorithm*: A novel graph partitioning algorithm *Mastav* is proposed to maximize stationary data within PIM units.
- *Dataflow*: A hybrid dataflow and an optimized communication mechanism are introduced to reduce redundant data movement.
- *Architecture*: A scalable PIM architecture with dedicated compute and control logic is carefully designed to implement the Max-Min principle.

II. Background

A. Graph Neural Networks (GNNs)

A GNN model generally consists of multiple GNN layers [11], [14], each with two main phases: aggregation and combination. As shown in Fig. 2(a), GNN models take a graph $G(V, E)$ as input, where V and E denote vertices and edges, respectively, and each vertex is represented by a feature vector. In the aggregation phase, each vertex aggregates features from neighboring vertices using an *aggregate* function, such as the mean function. In the combination phase, each aggregated feature vector is further transformed via a *combine* function, typically implemented as a multi-layer perceptron (MLP). Fig. 2(b) illustrates a typical GNN inference workflow. Vertex V_1 aggregates features from neighbors V_5 and V_7, generating a four-dimension feature vector. An MLP then transforms it into three dimensions. The k-th GNN layer is defined as:

$$X^{k+1} = \sigma(AX^kW^k) \tag{1}$$

Here, σ denotes the non-linear activation function, A is the sparse matrix derived from E, and X^k and W^k represent the feature and weight matrices for the k-th layer, respectively. The execution order of the combination and aggregation phases can be interchanged, and we adopt a combination-first approach to reduce computations, as suggested in prior work [9], [16].

B. Graph Partitioning for GNNs

Source-cut and mixed-cut are two typical edge partitioning methods. Source-cut partitioning [26] assigns a vertex and all its incoming edges to the same partition, making it suited for GNNs since they aggregate vertices using incoming edges. Fig. 3(b) presents an example for the source-cut partitioning. During the aggregation phase, V_5 pulls remote vertices V_1, V_6, and V_7 from P_2, creating their replicas in P_1. This allows V_5 to perform aggregation operations locally in P_1. Similarly, V_7 pulls V_5 from P_1 to P_2. Mixed-cut partitioning [27] allocates edges to the vertex with a lower degree, allowing low-degree vertices to remain stationary and reducing replicas. This approach requires an additional *merging* phase to gather updated replicas since incoming edges of a vertex may span multiple partitions. As shown in Fig. 3(c), V_5 creates a replica in P_2, with edges (V_1, V_5), (V_6, V_5), and (V_7, V_5) assigned to vertices in P_2 due to their lower degrees. Partial aggregation of V_5 occurs in P_2, and the replica is merged back to P_1. Mixed-cut partitioning requires only two communications, compared to four for source-cut partitioning.

C. Processing-in-Memory (PIM) Architecture

As shown in Fig. 4(a), a typical PIM system consists of multiple memory stacks connected via external links, with a dragonfly-based network widely adopted for its simple topology and high performance [8]. This network topology includes multiple interconnected groups, with each group fully connected internally and fully interconnected with other groups. Each stack is managed using a memory controller (MC). Fig. 4(b) illustrates a PIM architecture enabled by 3D-stacking technology. Multiple DRAM dies are stacked on a base die and interconnected by through-silicon vias (TSVs). Each DRAM die is organized into channels, with each channel comprising bank groups and each bank group comprising individual banks. To reduce off-chip data movement, many PIM systems [18] integrate compute logic directly on the base die. The emerging PIM architectures [3], [15], [19] further integrate compute and control logic near memory banks, forming a PIM unit, as depicted in Fig. 4(c).

D. Motivation: Rethinking Graph Partitioning for PIM

Graph partitioning for PIM architecture requires careful design to reduce data movement. Since data movement is

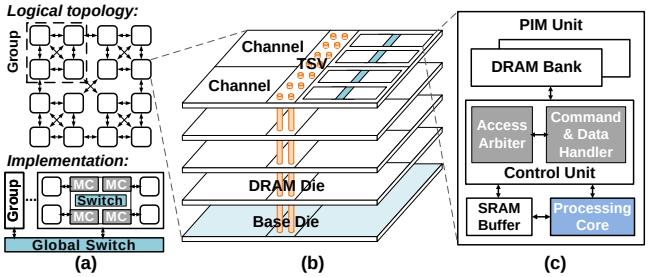

Fig. 4: A PIM system. (a) Dragonfly-based topology. (b) 3D-stacked PIM architecture. (c) PIM-enabled bank group.

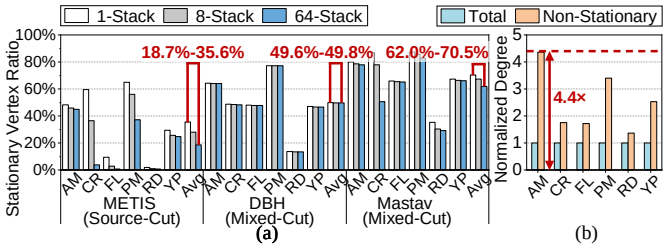

Fig. 5: (a) Ratio of stationary vertices. (b) Normalized average degrees of total and non-stationary vertices.

primarily caused by non-stationary data, maintaining data stationary within local PIM units can prevent data from traveling to remote PIM units. Therefore, we argue that maximizing stationary data is a promising direction to fully exploit the potential of PIM architecture. To validate our idea, we conduct a series of preliminary experiments. Fig. 5(a) presents the ratio of stationary vertices using different partitioning methods. The source-cut-based partitioning method METIS [13] demonstrates an unsteady ratio as the number of PIM stacks increases, declining from 35.6% to 18.7%. In contrast, the mixed-cut-based method DBH [21] maintains a steady ratio, ranging between 49.6% and 49.8%. There is still significant potential to increase stationary vertices. Our proposed Mastav achieves higher ratios, ranging from 62.0% to 70.5%.

Data movement can be further reduced by optimizing the distribution of non-stationary vertices. Fig. 5(b) presents the normalized average degrees of all vertices and non-stationary vertices using our Mastav algorithm. The degrees of non-stationary vertices are notably higher, ranging from 1.3× to 4.4× the average. This indicates that non-stationary vertices tend to have more connections. These vertices often need to move data repeatedly, requiring further optimization. Based on these observations, we are motivated to design a new PIM architecture for GNNs through a hardware-software co-design approach, following the Max-Min principle.

III. Anchor: A Scalable PIM Architecture Harnessing Stationary Data for GNNs

The proposed Anchor is built based on the Max-Min principle for efficiently processing GNNs via a hardware-software co-design approach. The objective is to take advantage of the near-bank PIM architectures and minimize data movement. The overview of Anchor is presented in Fig. 6. At the software level, a graph partitioning algorithm, *Mastav*, is proposed maximize stationary data by exploiting locality. At the hardware level, a novel architecture with two-step optimization, including *hybrid dataflow* and *optimized communication*, is implemented to minimize data movement through critical paths. As shown in Fig.6, the PIM unit is redesigned to support hybrid dataflow, while additional base die logic is integrated to support optimized communication.

A. Mastav: Maximizing Stationary Vertices

To maximize stationary vertices, the graph partitioning algorithm Mastav is proposed to optimize for both edges and vertices allocation. For edge allocation, Mastav employs mixed-cut partitioning to enhance vertex stationarity, as discussed in

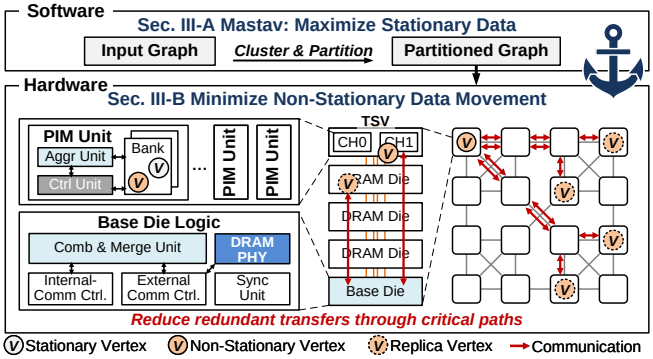

Fig. 6: Overview of Anchor.

Section II-D. For vertex allocation, Mastav uses modularity-based vertex clustering to group vertices with strong localities within the same PIM units, thereby minimizing data movement across PIM units.

$$\Delta Q(c,t) = 2\left\{\frac{w_{ct}}{2|E|} - \frac{\text{Degree}(c)\cdot\text{Degree}(t)}{(2|E|)^2}\right\} \tag{2}$$

As illustrated in Algorithm 1, the Mastav algorithm consists of two main stages: edge partitioning and vertex allocation. It begins with mixed-cut edge partitioning, where each edge is assigned to the vertex with the lower degree (Lines 1-6). Then, vertex clustering is performed. Mastav initializes individual clusters for each vertex and sorts these clusters by vertex degrees (Line 7). For each cluster c, a target vertex t among its neighbors is selected to maximize the modularity increment ΔQ (Line 9), as defined in Equation (2) [4]. Here, E is the edge set, and w_{ct} is the weight of edges between clusters. A higher ΔQ indicates a stronger connection between clusters. If joining c with t results in a positive modularity gain and the combined edge count remains below the threshold T_e, the clusters are joined (Lines 10-11). The edge threshold balances edge allocation to fully exploit the parallelism provided by PIM. The joining process repeats until no further beneficial joining operations can be performed, and the output cluster set C is obtained. The time complexities of Mastav is $O(|E|)$. The edge partitioning traverses all edges to allocate them based

on vertex degrees, and it has a time complexity of $O(|E|)$. The vertex clustering calculates the maximum modularity increment by traversing the neighbors of each vertex, also resulting in a time complexity of $O(|E|)$.

B. Minimizing Non-Stationary Data Movement

Non-stationary vertices are often required by multiple PIM units, incurring repeated data transfers. To minimize data movement, Anchor introduces a two-step optimization with hardware support. A hybrid dataflow ensures each non-stationary vertex is distributed only once, and optimized communication reduces redundant movement during distribution.

*1) **Hybrid Dataflow with Hardware Support**:*

Hybrid Dataflow. Anchor employs a hybrid dataflow for aggregation, combining push-based and pull-based approaches. The push-based dataflow broadcasts features from local vertices to their neighbors along outgoing edges, as shown in Fig. 7(a), where vertex V_5 broadcasts to V_1, V_6, and V_7 in P_2 and to V_2, V_3, and V_4 in P_1. This ensures that features of non-stationary vertex V_5 are distributed once, minimizing redundant accesses and transfers. The push-based dataflow processes edges in column order, and thus a compressed sparse row (CSR) format is used for edges of local vertices. Processing remote vertices with a push-based dataflow can exhaust memory due to the need to store all intermediates during aggregation. Therefore, the pull-based dataflow is adopted to handle remote vertices. As shown in Fig. 7(b), remote vertex V_5 in P_2 pulls features from neighbors, V_1, V_6, and V_7, along incoming edges. The pull-based dataflow processes edges in row order using a compressed sparse column (CSC) format.

Hardware Support. As shown in Fig. 8, the PIM unit is redesigned with an aggregation unit, an aggregation queue, and a vertex locator to support the proposed hybrid dataflow. The aggregation unit includes MAC arrays and dedicated SRAM buffers for aggregation. The vertex locator manages the allocation of space and the search for vertices addresses, and the aggregation queue stores vertex IDs prepared for aggregation. Similar to previous works [19], the access arbiter manages memory access within and outside the PIM unit, and the handlers process external instructions to enable cross PIM unit communication.

Anchor organizes the bank space into three distinct zones: edge data zone, local vertex zone, and remote vertex zone,

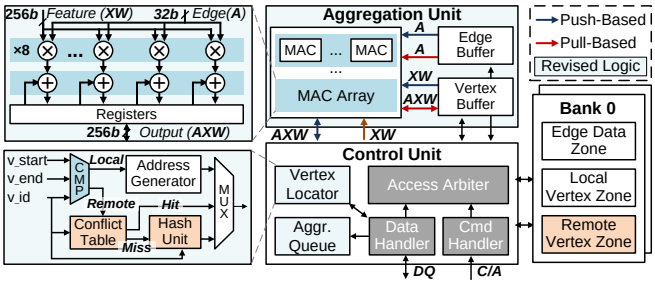

Fig. 8: Architecture design of the PIM unit.

to support the hybrid dataflow. The edge data zone stores the weights of edges assigned to the PIM unit. The local vertex zone holds the features of the vertices allocated to the PIM unit. The remote vertex zone temporarily caches features of non-stationary vertices from other PIM units, utilizing huge DRAM space to prevent blocking of remote vertex delivery. Anchor employs a hash unit and a conflict table to manage the space allocation of the remote vertex zone.

The aggregation unit supports both push-based and pull-based dataflows, as shown in Fig. 8. Local vertices are aggregated using the push-based dataflow. First, a portion of edge weights (A) is read from the edge data zone into the edge buffer. Second, IDs of prepared vertices are fetched from the head of the aggregation queue, and their features (XW) are retrieved from the banks to the vertex buffer. Third, the MAC arrays then perform matrix multiplication with edges and vertex features, accumulating the resulting output (AXW) back into the local vertex zone. Remote vertices are aggregated using the pull-based dataflow, following a similar process.

Anchor defines three types of extended instructions for GNNs, using standard DRAM commands with reserved DRAM rows and columns [15], [19]. The `Sync` instruction inserts vertex IDs into the aggregation queue, `Replic` stores remote vertex features to banks, and `Merge` fetches aggregated replicas from banks to the base die. The data and command handlers decode these instructions.

*2) **Optimized Communication with Hardware Support**:*

Optimized Communication. The proposed customized dataflow enables simultaneous processing of each non-stationary vertex, facilitating communication optimization. As shown in Fig. 9(a), Anchor uses a broadcast mechanism to optimize replicating operations during the aggregation phase. Local broadcast is used to reduce intra-stack data movement, where vertices updated after the combination operation are directly broadcast from the base die to PIM units via TSVs. To optimize inter-stack communication, Anchor utilizes the hierarchical structure of the dragonfly network [26], employing a tree-based global broadcast to minimize redundant data movement through critical paths. As illustrated in Fig. 9(a), the repeated access paths (S00, S01), (S00, S02), (S02, S08), and (S01, S04) are reduced from two accesses each to a single access. Similarly, a tree-based reduction is adopted for the merging phase, as depicted in Fig. 9(b). This phase conducts both local and global reduction. Local reduction pulls local replicas to the base die for merging, while global reduction

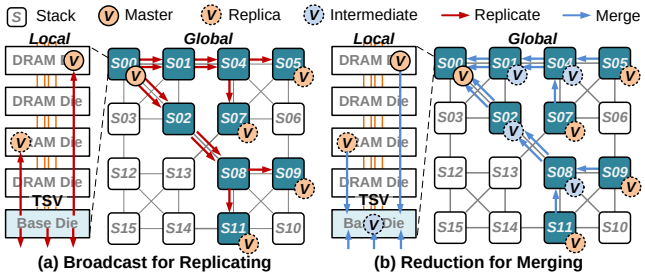

Fig. 9: Communication optimization mechanisms.

merges replicas from child nodes in the reduction tree.

Hardware support. Fig. 10 illustrates the architecture design of the base die logic. A combination and merging unit (MCU) is added for the combination and merging phase. An internal communication (IC), an external communication (EC) controller, and a synchronization unit are designed to support the proposed communication optimization. The IC controller generates commands and instructions to interact with PIM units, while the EC controller packets and delivers data to other stacks. To manage the delivery of vertices, a sliding window approach is adopted [28]. The synchronization unit distributes vertex IDs prepared for aggregation to local PIM units.

During the combination phase, the MCU uses a pull-based dataflow to perform matrix multiplication similar to the aggregation phase. After the combination phase, each updated vertex is delivered by the IC and EC controllers to different PIM units. Stationary vertices are directly returned to their allocated PIM units via the IC controller using the `Replic` instruction. Non-stationary vertices are broadcast by both the IC and EC controllers. Vertices that complete `Replic` instructions are sent to the synchronization unit, which then broadcasts `Sync` instructions to the PIM units for further aggregation. During the merging phase, the IC controller issues `Merge` instructions to PIM units, pulling aggregated replicas to the base die for local reduction. Once a vertex completes local reduction, its intermediate result (*Mid*) is delivered by the EC controller for global reduction. Finally, vertices that have completed merging are returned to their allocated PIM units.

IV. Evaluation

A. Experimental setup

Models and Datasets. To evaluate our scheme, we employ a set of representative GNN models, including GCN [14], GIN [23], and GraphSage [11]. Each GNN model consists of

TABLE II: System configurations and power-area models.

	Configuration
PIM System	16 stacks × 16 channels × (1 bank group + 3 PIM bank groups) × 4 banks, 8GB per stack, 48 PIM units per stack, 16GB/s intra-stack bandwidth per channel, 64GB/s inter-stack bandwidth per bidirectional link.
PIM unit	4×8 MACs @ 125MHz, 1KB conflict table, 2KB edge buffer, 2KB vertex buffer, Power=42.66mW, Area=0.18mm^2 (4.9 % of a bank group)
Base Die Logic	32×16 MACs @ 1MHz, 64KB sparse buffer, 32KB feature buffer, 1MB dense buffer, 8KB address buffer (FIFO), 8KB address table (CAM), Power=2719.68mW, Area=9.48mm^2(10.6% of the base die)

two layers with a hidden size of 64. As listed in Table I, we utilize six commonly used graph datasets [2] for evaluation.

Implementation and Configuration. We modify and extend DRAMSim3 [17], a cycle-accurate simulator, to support in-memory operations for GNNs. The area and power consumption of the processing units are obtained by implementing Anchor in Verilog and synthesizing the RTL using the Synopsys Design Compiler with a 32nm standard library. We employ CACTI [1] to estimate the SRAM buffer, interconnect components, and the DRAM stack. Detailed configurations, power models, and area models are listed in Table II.

Baselines. At the hardware level, we compare Anchor with state-of-the-art architectures, including HyGCN [24], GROW [12], GCIM [6], and Lift [7]. HyGCN and GROW are typical GNN accelerators, whereas GCIM and Lift are near-bank PIM architectures for GNNs. At the software level, we compare the proposed Mastav with graph partitioning methods, including METIS [13], DBH [21], and Lift [7].

B. Overall Performance

1) Speedup: Fig. 11 illustrates the performance speedup across various benchmarks, with Anchor outperforming all baselines. Specifically, Anchor achieves average speedups of 13.01×, 3.57×, 10.12×, and 3.15× over HyGCN, GROW, GCIM, and Lift, respectively. This performance gain is primarily driven by PIM architectures, which offer substantial processing bandwidth and minimize data movement. Additionally, Anchor further reduces data movement across PIM

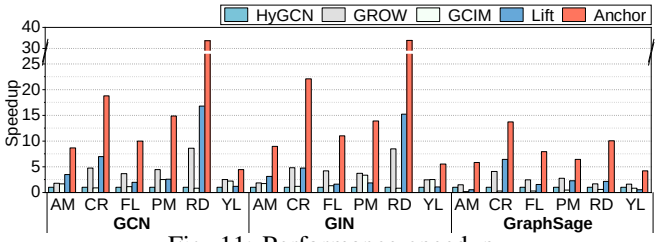

Fig. 11: Performance speedup.

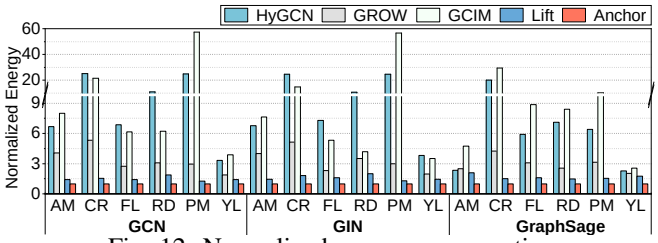

Fig. 12: Normalized energy consumption.

units by efficiently leveraging stationary data, enabling it to outperform other PIM architectures, including GCIM and Lift.

2) Energy Consumption: Fig. 12 presents the normalized energy consumption across various benchmarks, demonstrating that Anchor achieves the lowest average energy consumption. Anchor achieves energy savings of 11.10×, 3.19×, 14.40×, and 1.58× compared to HyGCN, GROW, GCIM, and Lift, respectively. This reduction is attributed to the hybrid dataflow, which minimizes unnecessary memory accesses, and optimized communication mechanisms that reduce redundant data movement.

C. Comparison of Graph Partitioning Algorithms

1) Performance and Scalability: Fig. 13 shows the speedups for different graph partitioning algorithms as the number of stacks increases. It can be observed that Mastav achieves the highest speedup among the baseline algorithms. As the stack number increases from 4 to 16 and 64, Mastav improves performance by an average of 3.22× and 7.16×.

2) Data Movement: Fig. 14(a) presents the data movement for different graph partitioning algorithms. Compared to Lift and DBH, Mastav reduces data movement by 40.55% and 38.44%, respectively. For the AM, CR, and PM graphs, METIS incurs less data movement than Mastav by prioritizing the minimization of cross-partition edges, often at the cost of workload balance. In contrast, Mastav effectively reduces data movement while maintaining balanced workloads.

3) Energy Breakdown: Fig. 14 (b) illustrates the normalized energy breakdown for various graph partitioning algorithms, where 'M', 'L', 'D', and 'A' denote METIS, Lift, DBH, and Mastav, respectively. Mastav achieves the lowest energy consumption, reducing energy usage by 28.15%, 26.30%, and 35.07% compared to METIS, Lift, and DBH, respectively. This reduction is attributed to Mastav's ability to minimize data movement, thereby lowering energy consumption.

4) Stationary Vertex Ratio: Fig. 15 shows the ratio of stationary vertices for different graph partitioning algorithms as the number of stacks increases. Both METIS [13] and Lift [7], which utilize source-cut edge partitioning, experience

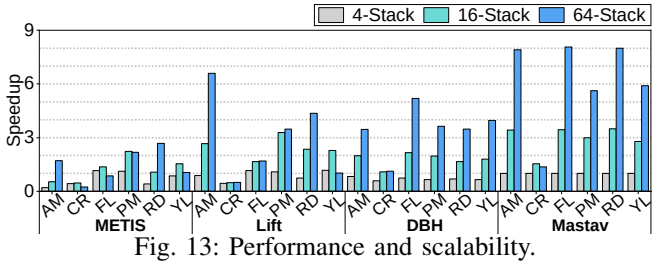

Fig. 13: Performance and scalability.

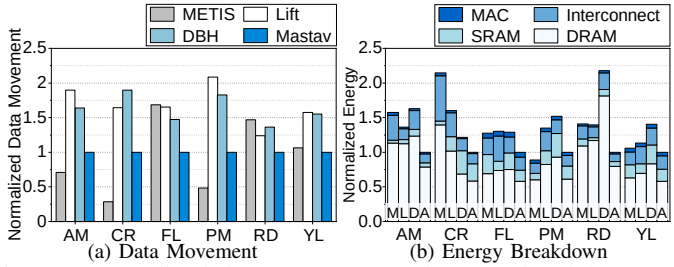

Fig. 14: Normalized data movement and energy breakdown.

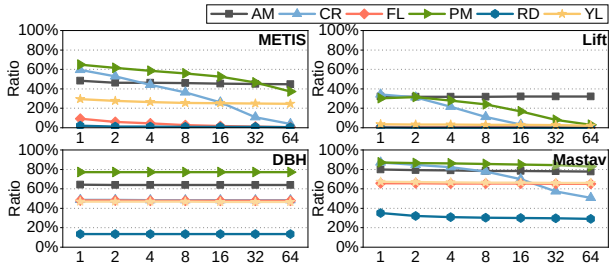

Fig. 15: Ratios of stationary vertices for different graph partitioning algorithms as the number of stacks increases.

a sharp decline in stationary vertex ratios as the stack count increases, dropping from 35.6% to 18.7% for METIS and from 16.9% to 6.3% for Lift. In contrast, DBH and Mastav, employing mixed-cut partitioning, maintain a stable stationary vertex ratio as the stack count increases. Compared to DBH, Mastav leverages clustering to optimize locality, achieving the highest stationary ratios, ranging from 62.0% to 70.5%.

V. Conclusion

This paper presents Anchor, a scalable PIM architecture for GNNs through a hardware-software co-design approach. Following the Max-Min principle, we focus on maximizing stationary data and minimizing the movement overhead of non-stationary data. A graph partitioning algorithm, Mastav, is proposed to maintain data in place. Furthermore, an optimized dataflow and a communication mechanism are introduced to reduce memory access and data movement. Experimental results demonstrated that Anchor significantly reduces latency and data movement compared to existing schemes. In the future, we plan to explore more architectural characteristics of PIM architecture to handle dynamic and more complex graph workloads.

***Abstract*—Intel SGX is susceptible to intra-enclave software vulnerabilities. Existing automated bug-finding methods primarily focus on fuzzing enclave boundaries for SGX applications in simulated, rather than *actual* hardware-protected enclaves. This limits the ability to identify potential security violations originating from within SGX application code. This paper presents INTRAFUZZ, the first system that enables efficient fuzzing of SGX applications inside *actual* hardware enclaves. We evaluated INTRAFUZZ with 21 real-world SGX applications, running on Intel Xeon scalable processors with up to 256 GB of enclave page cache. INTRAFUZZ successfully detected all vulnerabilities in SGX application code previously identified by the state-of-the-art tool EnclaveFuzz, as well as 6 previously undiscovered vulnerabilities. These results highlight the importance of hardware-based fuzzing in securing SGX applications.**

I. INTRODUCTION

Today's commercial processors natively support trusted execution environments (TEEs) to safeguard data in use from unauthorized access [1]–[3]. A prime example is Intel's Software Guard eXtensions (SGX) [4]–[7], which establishes a hardware-isolated environment, called *enclave*, specifically designed to be non-introspectable to prevent data leaks.

Despite hardware-enforced protections, SGX applications remain vulnerable to software flaws that can undermine system security [8]–[10]. Many are written in C/C++ languages, which are prone to memory vulnerabilities like buffer overflow and use-after-free. For instance, a heap or stack overflow in mbedTLS-SGX can be exploited to leak the entire enclave memory by manipulating untrusted inputs [10]. Even seemingly minor issues like null pointer dereference can become critical in SGX environments, as the untrusted OS controls the zero address [11]. Moreover, SGX-specific malware poses additional threats, such as stealing RSA keys from other enclaves [12] or encrypting sensitive data to restrict access [13].

The fundamental cause of these vulnerabilities often stems from developer-introduced flaws, either intentional or unintentional, and untrusted third-party libraries. For example, developers unfamiliar with SGX requirements may inadvertently introduce vulnerabilities into SGX applications [14]–[17]. On the other hand, legacy code is frequently ported into SGX enclaves [18]–[23] with limited validation, which inherits existing security flaws (e.g., OpenSSL library) or introduces new enclave-specific risks. These issues highlight the need for efficient detection mechanisms tailored to SGX applications.

Recent studies have introduced several tools to detect vulnerabilities in SGX applications [10], [11], [24]–[33]. Among them, fuzzing is more effective for vulnerability detection, as it automatically generates diverse inputs to rigorously test applications. Nevertheless, existing SGX fuzzing tools still exhibit notable limitations: 1) Lack of *actual* hardware fuzzing. Existing approaches like SGXFuzz [24] and EnclaveFuzz [11] perform fuzzing exclusively in simulated enclave environments, which lack essential SGX-specific protections and features, such as remote attestation and sealing/unsealing. This limits detection accuracy and scope. Further, SEnFuzzer [26] runs programs within actual SGX enclaves but collects only selective runtime data, which leads to insufficient analysis and potential false positives. 2) Incomplete application behavior analysis. Current methods focus primarily on enclave boundary interfaces (e.g., ECALLs or/and OCALLs) [10], [11], [24] and often overlook internal application bugs. For performance and security purposes [9], [34], SGX applications are often designed to use a single ECALL-OCALL pair to ensure that execution completes without intermediate exits or re-entries. As a result, the absence of runtime context information makes analyzing the application code challenging. 3) High overhead of crash detection on SGX. Exception handling in SGX enclaves is resource-intensive, which complicates efficient crash detection in hardware-based fuzzing. Current tools avoid this issue, as they typically run in simulated environments without SGX exception handling costs. This affects the detection speed and accuracy on actual hardware.

In this paper, we introduce INTRAFUZZ, an automated framework for full-process fuzzing of SGX applications directly within actual hardware enclaves. We adapt a coverage-guided fuzzing framework for SGX, which leverages a modified library OS as the runtime. This runtime transparently manages interactions between the target application and the fuzzing engine. INTRAFUZZ employs an intra-enclave tracer to monitor each fuzzing process and iteratively generates refined inputs through seed mutation. This process updates the corpus with high-quality seeds to enable efficient crash detection and vulnerability identification during program execution. Further, it incorporates an efficient process management mechanism based on in-enclave shared memory, which allows rapid runtime information exchange across processes. To handle hardware exceptions caused by program crashes, we set up a signal handling trampoline to promptly capture crashes and analyze them by parsing enclave stack memory traces.

We evaluate INTRAFUZZ on 21 real-world SGX applications running on Intel Xeon scalable processors, with up to 256 GB of enclave page cache. INTRAFUZZ successfully detected all vulnerabilities in SGX application code previously reported by the state-of-the-art tool EnclaveFuzz, along with 6 previously undiscovered vulnerabilities.

Detection Scope. This work focuses on fuzzing SGX application code within actual enclaves, rather than the host-enclave

*Corresponding author: Jiliang Zhang

boundary in simulated environments, which prior studies have extensively explored. Thus, it departs from existing methods and complements efforts to secure hardware enclaves.

Our contributions are summarized as follows:

- We conduct a systematic analysis of differences and challenges between simulated and *actual* hardware enclaves.
- We propose the first full-process intra-enclave fuzzing framework for SGX applications, called INTRAFUZZ, which enables internal tracers to monitor security violations in target application code.
- We evaluate INTRAFUZZ with 21 open-source projects configured to run with up to 256 GB of enclave page cache, and uncover 9 vulnerabilities in them, including 6 previously undiscovered ones.

II. BACKGROUND

A. Hardware-enforced Enclaves with Intel SGX

Intel Software Guard eXtensions (SGX) [35] is a set of secure instructions integrated into Intel x86 processors. It protects sensitive data and code within an isolated execution environment, known as an enclave, from the rest of the system.

Enclave Entry/Exits. SGX introduces specialized instructions to control the interaction between the enclave and non-enclave code. In particular, the `EENTER` instruction manages entry into the enclave (ECALLs), while `EEXIT` controls the exit (OCALLs). The processor validates the ECALL by checking that it points to an authorized entry located in the enclave's metadata. A predefined wrapper function is used to handle the OCALL request and securely return to the enclave. However, note that for performance and security consideration [9], [34], developers often utilize a single ECALL-OCALL pair for SGX applications to guarantee that execution completes without extra exits or re-entries.

Exception Handling in SGX Enclaves. When an exception occurs within an enclave, the hardware first triggers an Asynchronous Enclave Exit (AEX) to hand over control to the OS. After the OS receives the exception, it sends the corresponding signal to the host process. The host process re-enters the enclave via `EENTER`, and the exception handler within the enclave reads the CPU state in the Saved State Area (SSA) and executes the default or user-defined handling code. Once completed, the enclave exits via `EEXIT`, and the host process then resumes normal execution of the enclave via `ERESUME`. This mechanism ensures the secure saving and restoring of the enclave's state during exception handling.

B. Coverage-guided Fuzzing

Fuzzing is an automated technique for identifying software vulnerabilities by repeatedly executing the target program with diverse inputs [36]. Coverage-guided fuzzing refines this process by utilizing coverage feedback to select inputs that explore more new execution paths. Tools like Honggfuzz [37] compute coverage based on metrics such as executed instructions, branches, and unique basic blocks and retain test cases that uncover new code as good seeds. Prior SGX fuzzing methods [11], [24]–[26] primarily perform in non-SGX environments, where feedback is collected outside the enclave. This often misses critical runtime states within enclaves and hence causes overlooked vulnerabilities and false positives. Moreover, these methods mainly focus on testing enclave boundaries, such as ECALLs, OCALLs, and system calls. In contrast, our work emphasizes identifying vulnerabilities within the security-critical application code inside enclaves. This complements existing methods, collectively offering a more comprehensive strategy for securing SGX enclaves.

III. ANALYSIS OF SGX ENCLAVE FUZZING

A. Simulated vs. Actual Hardware Enclaves

Intel offers a software simulation environment that enables SGX functionality on machines without native SGX hardware support [38]. In simulation mode, SGX instructions are fully emulated through software. Since fuzzing depends on executing target programs and monitoring their runtime behavior to uncover vulnerabilities, the discrepancies between simulated and actual hardware environments can substantially diminish the reliability and effectiveness of fuzzing results.

D1. Security Gaps. Unlike actual hardware-based SGX, which provides strong security guarantees, simulated enclaves lack these protections that leaves them vulnerable to attacks. As a result, attackers can bypass software-based protections through various methods to steal sensitive data. This means fuzzing SGX applications in actual hardware enclaves can more accurately evaluate their security, as simulated environments fail to replicate real-world threats and risks.

D2. Library Discrepancies. Simulated and real hardware environments differ significantly in implementation. In hardware mode, SGX APIs interact with hardware features through dedicated libraries, such as `sgx_trts.lib`. In contrast, simulation mode relies on alternative libraries, such as `sgx_trts.lib_sim`, to emulate this functionality. Similarly, `sgx_tcrypto_opt.lib`, a hardware-optimized cryptographic library, provides enhanced performance on actual SGX hardware, while `sgx_tcrypto.lib` is a basic library intended for simulation environments.

D3. Functional Gaps. Certain operations, such as remote attestation, require hardware support and are unavailable in simulation mode. As a result, fuzzing conducted in a simulated environment produces less accurate results and may fail to fully reflect the effectiveness of tests on actual hardware. In contrast, hardware-based fuzzing provides more reliable and representative outcomes. While SEnFuzzer [26] introduces an on-device fuzzing framework, it still relies on extracting ECALL and OCALL data to construct a fuzzing harness, without running the application throughout SGX enclaves.

Consequently, we emphasize that fuzzing SGX applications on actual hardware is essential for uncovering vulnerabilities that may not manifest in simulated environments and for accurately reflecting real-world attack surfaces.

B. Challenges of Fuzzing on Actual Intel SGX CPUs

C1. Constraints on Intra-enclave Multi-process Fuzzing. Intel SGX imposes strict limits on the size of protected memory, typically 128 MB or 256 MB [4]. As such, the number of enclaves that can be instantiated simultaneously on a single platform is constrained by the memory footprint of each enclave. In addition, fuzzing, which typically employs a multi-process model for efficiency, demands real-time execution and monitoring across multiple processes. However, hardware enclaves lack native support for multitasking within a single

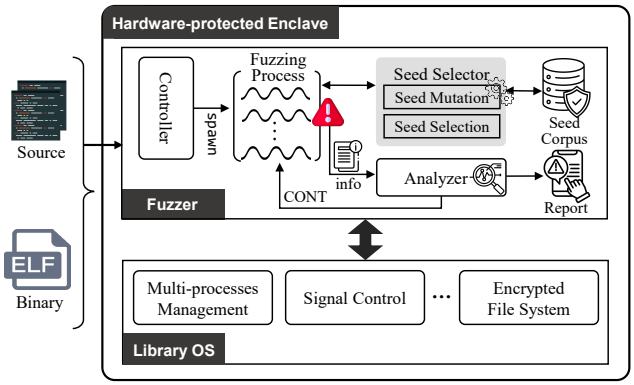

Fig. 1: INTRAFUZZ Overview

enclave. Running multiple enclaves for parallel fuzzing processes drastically reduces efficiency due to the high overhead of inter-enclave communication.

C2. Obstacles to Intra-enclave Monitoring. The security design of Intel SGX ensures that enclaves are isolated from one another and non-introspectable to the outside world. Consequently, conventional monitoring tools cannot directly access or inspect an enclave's internal operations. This inherent opacity poses significant challenges for detecting program crashes, tracking coverage information, and applying other fuzzing techniques within the SGX ecosystem.

C3. Costly Enclave I/O Operations. Communication across enclave boundaries is limited to the interfaces defined in an EDL file, namely ECALLs and OCALLs. This increases complexity and delays input mutation and output reporting during fuzzing. Further, since the enclave cannot directly access the file system, all file operations must be carried out through OCALLs. This affects the overall performance of the tests, particularly when frequent file reads and writes are required during fuzzing.

IV. INTRAFUZZ APPROACH

A. Overview

As illustrated in Figure 1, INTRAFUZZ enables intra-enclave fuzzing of SGX applications within actual SGX environments. The process starts with preparing the instrumented source code or binary file and initial seeds. At the beginning of fuzzing, the *seed selector* mutates the initial seed. The *controller* `clones` worker threads and `spawns` enclave processes to execute the target application with mutated inputs. When a crash occurs, the *analyzer* parses the crashed stack and generates a detailed report. During each iteration, the seed selector updates a seed corpus with high-quality inputs that either trigger vulnerabilities or explore new code paths. The *library OS* provides basic services, such as system call interfaces and an encrypted file system, to facilitate intra-enclave fuzzing. It employs in-enclave shared memory for process management, which enables precise control over the target program's execution state and efficient delivery of runtime information. INTRAFUZZ further integrates an exception-based monitoring mechanism to detect unexpected program behaviors and utilizes enclave stack traces for crash diagnostics.

To overcome the three challenges outlined in Section III-B, we 1) harness an SGX library OS to enable multi-process fuzzing inside a single enclave on SGX v2 with up to 256 GB of enclave private memory, which effectively supports an unlimited number of concurrent enclaves; 2) propose an intra-enclave multi-process management module to monitor program behaviors and gather runtime information; 3) incorporate an encrypted file system into SGX enclaves to enable secure and efficient seed file access during fuzzing.

B. Efficient Multi-process Management

Since the fuzzer process requires control over the target process and the collection of its runtime information, communication between the processes is essential. However, the fuzzer and target processes are isolated from each other due to the enforcement of multi-domain Software Fault Isolation (SFI) technology [39]. To address this limitation, we design a shared memory mechanism between the processes. Each block of shared memory is 2048 bytes in size and divided into three fields: `exec` (256 bytes), `info` (80 bytes), and `stack` (the left space). The `exec` field records execution status, the `info` captures details about abnormal signals and the `stack` stores information for stack backtracking.

As shown in Figure 2, the target process communicates its runtime state to the fuzzer process via shared memory. During initialization, the fuzzer creates N shared memory blocks, where N is the number of parallel processes specified by the user. To be specific, the main fuzzing process first clones N worker threads. Each worker thread then creates a child process using `spawn` to execute the target program. To organize this setup, the parent worker thread and its child process are grouped into a `workgroup`, with the parent thread's *TID* indexing the corresponding memory block to obtain runtime information. This design adheres to SGX's memory constraints while ensuring that each process operates securely within actual enclaves.

C. Enclave Crash Monitoring

When a crash occurs in the SGX application code, INTRAFUZZ must interpose the target process to collect runtime context information for detailed analysis. However, since each crash causes the current process to exit the SGX enclave—triggering an asynchronous enclave exit (AEX) exception—it is essential to restore control flow to the target process. To address this, we propose a signal handling based implementation, as shown in Figure 3. During the instrumentation of target program, a custom signal handler is registered (❶). When an exception occurs, this handler is invoked to collect crash details and store runtime context information into shared memory (❷). The analyzer subsequently reads this information, identifies the type of crash, and determines whether it represents a previously unseen issue (❸). If a new crash is detected, the analyzer generates a report and saves the seed (❹).

After completing the analysis, the analyzer writes `cont` signal to the `exec` field in shared memory to inform the target program to continue execution (❺). The target program then resumes from the point of the crash, which will trigger the same signal (e.g., SIGSEGV) and eventually exiting due to the unhandled exception. At the end of each iteration, the controller spawns a new child process to start the next iteration. This loop continues until a termination condition is reached, at which point the fuzzing process ends.

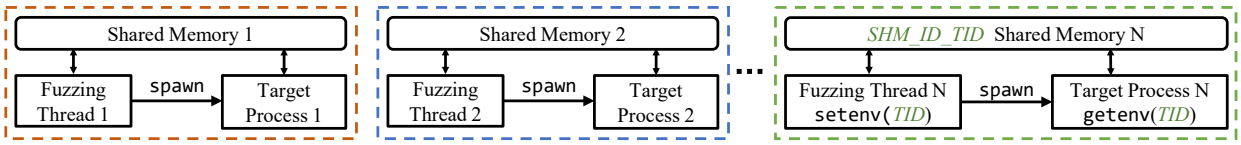

Fig. 2: Efficient Process Management via Shared Memory

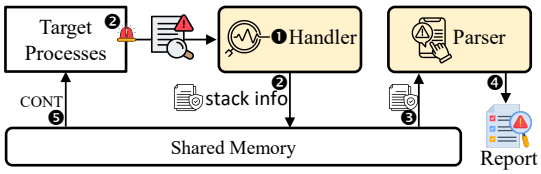

Fig. 3: Exception-based Monitoring Workflow

D. Enclave Crash Analyzing

When the target process crashes, gathering program details is necessary for analysis. However, pinpointing the root cause of a crash can be challenging. To address this, we introduce an adaptive enclave stack memory parsing mechanism within the analyzer. Upon receiving a signal, it dynamically analyzes runtime information using memory mappings, call stack traces, and instruction disassembly. Specifically, it extracts essential details from the signal structure (`siginfo_t`) and the program counter (`PC`) , which are stored in the `info` field of shared memory. It then leverages the `libunwind` library to trace the call stack and parses the `/proc/[pid]/maps` file to retrieve memory mapping details. Finally, we leverage Capstone engine to disassemble instructions in memory. Based on these above, IntraFuzz delivers real-time, detailed insights into the execution path and instruction-level information.

Spawn-based process creation introduces the challenge of identical instruction addresses mapping to different memory addresses, which makes the address alone insufficient to uniquely identify crashes. Despite each child process operating in a separate virtual space, the layout of code segments within the virtual address space is consistent across processes. Thus, crashes at the same instruction exhibit identical lower 12 bits (in-page offset) of the virtual address, which reflects the instruction's position in the code segment. Based on this, we define crash uniqueness using four key attributes: (i) the signal type, (ii) the lower 12 bits of the instruction address, (iii) the current instruction, and (iv) a hash value of the call stack.

V. Implementation

We implemented IntraFuzz prototype by extending honggfuzz [37], a lightweight, feedback-driven fuzzer, to work within advanced SGX runtime systems such as Occlum [18]. IntraFuzz retains the core components of honggfuzz, including the mutation algorithm, and test case scheduling. To enable intra-enclave fuzzing, we developed several key modules, such as multi-process management, signal control and enclave stack memory parsing. Due to SGX's isolation constraints, the `fork` system calls in honggfuzz are not supported within a single enclave. To resolve this, we modified the controller to use `spawn` for creating enclave processes. Moreover, the target program and initial seed are stored in the encrypted file system to facilitate the fuzzing.

VI. Evaluation

In this section, we evaluated IntraFuzz on real-world SGX applications to demonstrate its effectiveness in detecting vulnerabilities. We also compare IntraFuzz with existing state-of-the-art SGX vulnerability detection techniques and analyze their methodologies. Finally, we highlight the vulnerabilities newly uncovered in the target SGX applications.

A. Evaluation Settings

Experiment Setup. The evaluation was conducted on a server equipped with four Intel Xeon Platinum 8444H CPUs, 512 GB of RAM, and 256 GB of enclave page cache, running Ubuntu 20.04 with the 5.15.0-124-generic kernel. Each project was fuzzed for over 24 hours.

Tested SGX Applications. We selected 20 widely recognized open-source projects with notable star ratings on GitHub. Table I presents the fuzzing results for these SGX applications, including the size, coverage, and verified bugs. The specific versions of these applications were adapted to be compatible with IntraFuzz.

B. Vulnerability Detection

IntraFuzz detected hundreds of crashes across 7 applications during fuzzing. Since a single bug can lead to multiple crashes, deduplication is required. We applied an intra-enclave adaptive stack trace parsing mechanism to identify unique crashes, followed by manual analysis. This process revealed 9 distinct and verified bugs, as shown in Table I.

Detail of Reports. Table II shows a detailed summary of the bugs identified by IntraFuzz and other works. Two buffer overflow vulnerabilities were discovered in SGXCryptoFile and cave, both caused by input file sizes exceeding expected limits. These vulnerabilities were uniquely detected by our approach, as previous methods failed to preserve the original semantics of the applications, which is essential for effective fuzzing. In sgx-wallet, a double-free vulnerability was found. In webassemblyEnclave, a logic error was identified, where incorrect control flow leads to unintended execution branches. In sgx-kmeans, an out-of-bound access error was observed due to insufficient validation before data allocation. Detailed explanations of these vulnerabilities are provided in Section VI-D. For clarity, Table II excludes crash counts associated with boundary interface issues for SGXFuzz and EnclaveFuzz.

To validate the effectiveness of detecting vulnerabilities in the remote attestation process, which is not supported in simulated enclaves, we introduced a fault into a confidential function in the program. Experimental results demonstrated that IntraFuzz successfully identified the vulnerability.

Coverage. Table I shows that IntraFuzz achieves comparable coverage to EnclaveFuzz. While EnclaveFuzz analyzes the source code without considering contextual semantics, IntraFuzz, by fully preserving the context of SGX applications, results in improved coverage. Specifically, EnclaveFuzz achieves 14.8% coverage, whereas IntraFuzz reaches 17.7%.

TABLE I: Fuzzing Results of IntraFuzz and EnclaveFuzz

SGX Application	Version	Size	Coverage		Verified Bugs

EnclaveFuzz [11]	Fuzzing	ECALLs & OCALLs	✗
Emilia [27]	Fuzzing	System Calls	✗
IntraFuzz (this work)	Fuzzing	SGX Application Code	✓

✗ indicates fuzzing conducted entirely within simulated enclave environments. ✘ means that SGX applications run inside actual enclaves, while the fuzzing process is performed outside the enclave. ✓ refers to fuzzing conducted entirely within actual, hardware-protected enclaves.

Responsible Disclosure. When a bug is detected and manually verified, we adhere to a 90-day disclosure timeline and notify the affected vendor via email or repository issue.

C. Comparison with State-of-the-art Works

We compare advanced SGX vulnerability detection tools with IntraFuzz based on their detection targets and fuzzing environments, as summarized in Table III. Unlike existing tools that primarily focus on boundary interfaces such as ECALLs, OCALLs and syscalls, IntraFuzz targets intra-enclave application code. This focus enables it to uncover vulnerabilities that prior methods might overlook and expose critical code segments previously unexamined. IntraFuzz is the first to implement full-process fuzzing directly on SGX hardware. This offers comprehensive monitoring of the actual runtime behavior within hardware enclaves. In reproducing EnclaveFuzz, we observed that it requires manual source code modifications for instrumentation. In contrast, IntraFuzz automates this process.

D. Case Study

We showcase representative examples of each bug type identified by IntraFuzz.

```
1  int decryptFile(const char* input, const char* output)
2  {
3    ...
4    size_t decMessageLen = fsize - (SGX_AESGCM_MAC_SIZE +
5    SGX_AESGCM_IV_SIZE);
6    unsigned char *decMessage = (unsigned char *) malloc
7    ((decMessageLen+1)*sizeof(unsigned char));
8    sgxDecryptFile(message,fsize,decMessage,decMessageLen);
9    decMessage[decMessageLen] = '\0';
10   fwrite(decMessage, decMessageLen, 1, ofp);
11 }
```

Listing 1: Stack Overflow in CryptoFile

Stack Overflow. Several crashes caused by buffer overflow were found, with SGXCryptoFile as a notable example. As shown in Listing 1, if the input size (`fsize`) is smaller than `SGX_AESGCM_MAC_SIZE+SGX_AESGCM_IV_SIZE`, the calculation of `decMessageLen` results in an underflow (line 4) and produces an unexpected large value `decMessageLen`. This value is then passed to `malloc` (line 6), which causes excessive memory allocation. If the allocation succeeds, operations like writing to `decMessage` (line 10) will exceed the allocated buffer. This leads to memory corruption and hence may overwrite critical memory areas. More severely, this vulnerability may enable attackers to perform arbitrary writes, which compromise the confidentiality and integrity of the enclave.

```
1  cell eval(cell x, environment * env)
2  {
3    if (x.type == Symbol)
4      return env->find(x.val)[x.val];
5    ...
6  }
```

Listing 2: Logical Execution Vulnerability in CAVE

Logical Execution. Listing 2 illustrates a logical execution vulnerability in cave. The behavior of `eval`, which includes

multiple branches, can be directly influenced by the input data. This vulnerability allows attackers to manipulate the input and alter the program's execution flow within the enclave.

```
1  int* k_means(float** data, int n, int m, int k, float t,
       float** centroids)
2  {
3    ...
4    for (h = i = 0; i < k; h += n / k, i++) {
5      if (!centroids) {
6        c[i] = (float * ) calloc(m, sizeof(float));
7      }
8      /* pick k points as initial centroids */
9      for (j = m; j-- > 0; c[i][j] = data[h][j]);
10   }
11   ...
12   for (i = 0; i < k; i++) {
13     float distance = 0;
14     for (j = m; j-- > 0; distance += pow(data[h][j] -
15         c[i][j], 2));
16     ...
17   }
18 }
```

Listing 3: Out-of-bound Access in SGX-KMEANS

Out-of-bound Access. Out-of-bound access occurs when a program accesses data outside its intended boundaries, which may lead to memory corruption, crashes, or unpredictable behavior. In Listing 3, the issue arises when `data[h][j]` is inadequate for assignment to `c[i][j]`. The operation $\texttt{pow}(\texttt{data}[\texttt{h}][\texttt{j}] - \texttt{c}[\texttt{i}][\texttt{j}], 2)$ may fail due to the improper assignment. Specifically, if `data[h][j]` is not properly validated before the assignment, it may result in out-of-bound access when subtracting `c[i][j]`. This mis-assignment causes the program to access memory beyond the allocated bounds, which finally triggers undefined behavior or memory corruption.

VII. Discussion

IntraFuzz automatically detects memory corruption vulnerabilities in Intel SGX applications. However, some memory vulnerabilities may not cause crashes. For example, a missing bounds check in the handling of the TLS heartbeat [59] extension leads to an out-of-bound read across the enclave boundary, which ultimately reveals up to 64 KB of memory data to a connected client or server without triggering a crash. While sanitizers [60], [61] can address these issues, implementing them within the SGX environment requires much engineering effort, which we leave for future work. Moreover, several solutions for SGX compatibility have been proposed [18], [19], but we cannot perform vulnerability detection on these toolchains, as our work primarily focuses on discovering vulnerabilities in SGX application code itself. For such toolchains, fuzzing would likely require the generation of specialized fuzzing harnesses.

VIII. Related Work

A. Fuzzing for SGX Applications

SGXFuzz [24] simulates key SGX execution conditions and uses the kAFL fuzzer along with the Nyx snapshot-based fuzzing engine to recreate critical enclave contexts outside the SGX environment. FuzzSGX [25] is a fuzzer based on input and program mutations. It applies static analysis and symbolic execution to construct the host application and modifies both the application and seed inputs iteratively to evaluate the enclave program. SEnFuzzer [26] extracts ECALL and OCALL information from the EDL files to create specialized fuzzing drivers. Despite executing the enclave program within an actual SGX environment, the fuzzer runs outside the enclave and only focuses on the ECALL and OCALL interfaces. EnclaveFuzz [11] presents a multi-dimensional structure-aware fuzzing framework that extracts input structures from enclave source code and analyzes their inter-dependencies to generate fuzz harnesses. Emilia [27] intercepts system call return values to reproduce potential Iago attacks [34] through fuzzing. However, it operates outside actual SGX environments and is limited to the return values, which results in reduced coverage. In summary, existing SGX fuzzing methods analyze the enclave boundaries. However, none of them perform full-process fuzzing within actual SGX enclaves, leaving real vulnerabilities undetected, as demonstrated by IntraFuzz.

B. Symbolic Execution for SGX Applications

TEERex [28] takes a binary file as input, identifies ECALLs through static analysis, and then uses symbolic exploration to detect vulnerabilities during execution. COIN [10] identifies security vulnerabilities in enclave interfaces (ECALLs/OCALLs) and performs symbolic execution on binary files by parsing interface information from EDL files. SymGX [30] introduces a global transformation graph and context-sensitive analysis model, GSTG-CAP, for simulating SGX applications. It records execution behaviors and drives symbolic execution for vulnerability detection. Pandora [31] uses the angr framework with SGX-specific semantic augmentation. It extracts the enclave's internal state to guide symbolic execution, with plugins designed to detect different vulnerabilities.

C. Others Techniques for Shielding SGX Enclaves

SgxMonitor [32] introduces a security tracking mechanism akin to Intel PT, which implements provenance analysis on SGX. It monitors the target enclave's operating status to ensure it aligns with expectations and identifies any discrepancies. SGXRacer [33] detects controlled data races in enclave code by analyzing shared variables and thread interleavings to ensure proper synchronization. It employs a two-phase approach: identifying shared and lock variables, followed by reentrancy-aware, lockset-based data race detection.

IX. Conclusion

We introduce IntraFuzz, a new system for efficiently fuzzing SGX applications within actual hardware-protected enclaves. Using an internal tracer, IntraFuzz monitors intra-enclave processes to detect security violations with mutated inputs. Our results show IntraFuzz identified 9 vulnerabilities across 21 real-world SGX applications on actual Intel SGX processors, including 6 vulnerabilities missed by simulation-based tools like EnclaveFuzz. These findings highlight the importance of actual hardware-based fuzzing for comprehensive security analysis of SGX applications.

***Abstract*—Diffusion models have demonstrated superior performance in image generation tasks, thus becoming the mainstream model for generative visual tasks. Diffusion models need to execute multiple timesteps sequentially, resulting in a dramatic increase in workload. Existing accelerators leverage the data similarity between adjacent timesteps and perform mixed-precision differential quantization to accelerate diffusion models. However, merging differential values with raw inputs in each layer of each timestep to ensure computational correctness requires significant memory access for loading raw inputs, which creates a heavy memory burden. Moreover, mixed-precision computations may lead to low hardware utilization if not well designed. Unlike these works, we propose MHDiff, a tailored framework that identifies the focal pixels at the first layer and finetunes them to fit all layers, then represents focal pixels with high-precision while using low-precision for others, thereby accelerating diffusion models while minimizing memory burden. To improve hardware utilization, MHDiff employs a packing module that merges low-precision values into high-precision values to create full high-precision matrices and designs a processing element (PE) array to efficiently process the packed matrices. Extensive experiment results demonstrate that MHDiff can achieve satisfactory performance with negligible quality loss.**

I. Introduction

Currently, diffusion models have demonstrated superior performance in generative vision tasks. In the field of image generation, diffusion models such as Stable Diffusion [1], DALL-E 2 [2], and Midjourney [3] have achieved remarkable results in various tasks (e.g., image generation [4]–[7], image super-resolution [8]–[10], and image inpainting [11], [12]). Due to their powerful generative capabilities, diffusion models are increasingly becoming the mainstream model for generative visual tasks. The fundamental characteristic of diffusion models is the iterative generation process, which requires the entire model to execute multiple timesteps sequentially. While this characteristic helps produce higher-quality images, it comes at the cost of a dramatic increase in workload, hindering their further application.

To eliminate these problems, researchers have designed various accelerators to accelerate the generation process of diffusion models, such as Cambricon-D [13] and HCDiff [14]. Cambricon-D leverages the data similarity between adjacent timesteps in diffusion models by applying outlier-aware differential quantization to accelerate the generation process. As illustrated in Fig. 1(a), at each layer of every timestep, Cambricon-D retrieves the input data of the previous timestep $T-1$ from DRAM (indicated by the purple arrow) and computes the differentials by subtracting it from the current input data. As a result, the differential data can be computed using mixed-precision. Afterwards, the current result is added by the previous result of timestep $T-1$ (indicated by the purple arrow) to obtain the final result of the current timestep T. Next, it writes the resultant data back to DRAM (indicated by the orange arrow), awaiting for the differential data generation during the next timestep $T+1$. In summary, Cambricon-D faces two limitations: 1) It requires two read operations and one write operation to DRAM at each layer of each timestep, which **creates a heavy memory burden**; 2) It uses different processing elements (PEs) to process high-precision and low-precision differentials separately, which **results in low hardware utilization** since the distribution of high- and low-precision differentials is unpredictable and irregular.

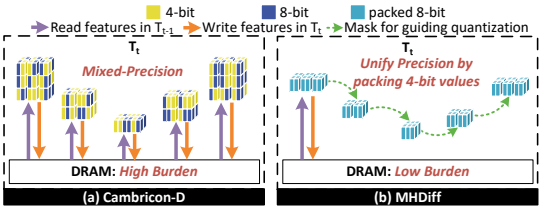

Fig. 1. Comparison of MHDiff and traditional method.

Different from Cambricon-D, our goal is to accelerate diffusion models in a memory-efficient and hardware-efficient manner. In this paper, we observe that the focal pixels to be generated at each timestep play a critical role in image quality, where the focal pixels are defined as the features that change significantly within a timestep. To excavate the acceleration opportunity brought by focal pixels, our study addresses two key challenges: 1) How to identify focal pixels of each timestep in a memory-efficient manner? Given that the focal pixels are consistent across all layers, just like an artist focuses on painting a special area on the canvas for a period of time, we propose a first-predict-then-finetune method. It predicts focal pixels at the beginning of each timestep and then refines them according to the specific operation of each

* Zhuoran Song and Jun Wang are the corresponding authors.
This work is partly supported by the National Natural Science Foundation of China (Grand No. 62202288).

layer, enabling the identified focal pixels to be effectively utilized across all subsequent layers. As shown in Fig. 1(b), compared to Cambricon-D, since we only fetch previous data for prediction at the first layer (indicated by the purple arrow), our approach avoids $n-1$ reads and writes for each timestep given n layers, significantly alleviating the burden on memory. 2) How to accelerate diffusion models based on focal pixels in a hardware-efficient manner? We propose to use high- and low-precision quantization for focal pixels and others respectively, thereby achieving acceleration. Building upon this, we design a specialized packing module that reorganizes the quantized data to pack them into full high-precision matrices. Specifically, based on the principle of avoiding conflicts between high-precision values, the packing module selectively packs adjacent low-precision values into high-precision values as much as possible, thus unifying precision. Therefore, our PE array can process the condensed high-precision matrices at the same speed, resulting in higher hardware utilization.

The main contributions of this paper are listed as follows:

1) On the algorithm level, we propose a MHDiff algorithm, which can identify the focal pixels for each timestep, finetune them according to the specific operation of each layer, and apply high- and low-precision quantization for focal pixels others respectively, thereby achieving acceleration.
2) On the hardware level, we design a MHDiff architecture to support the proposed algorithm. Specifically, MHDiff architecture employs a packing module to pack mixed-precision matrices into full high-precision matrices and use a PE array to process the condensed high-precision data through minor modifications to the PE units.
3) Extensive experiments and in-depth research across various diffusion models consistently validate the advantages of our proposed MHDiff framework, leading to 3.1x, 6.2x, and 38.4x speedup over state-of-the-art diffusion accelerator Cambricon-D, GPU, and CPU while maintaining image quality.

II. Background

A. Diffusion Models

Diffusion models are a new class of machine learning algorithms that have excellent performance in generative vision tasks such as image generation, super-resolution, and image inpainting. Essentially, a diffusion model functions as a denoising model, taking an image composed of Gaussian noise as input and producing a visual image through successive denoising steps. Each denoising step, called a timestep, uses the output from the previous step as input, applying a U-Net model to generate an image with reduced noise. This progressive generation process enables diffusion models to achieve superior image quality compared to previous models. However, this advantage comes at the cost of significantly increased computation and latency, as the model must execute many steps sequentially to produce the final image.

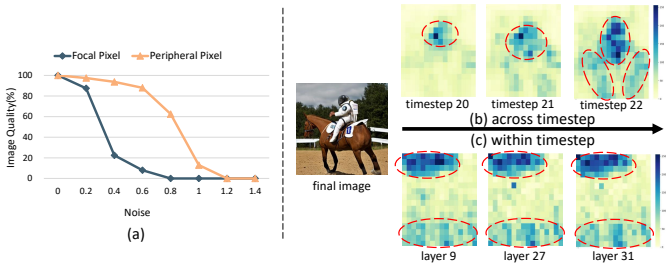

Fig. 2. Explore focal pixels: image quality bearing different noise patterns (a) and the visual focal pixels (marked with red dashed boxes) of different timesteps (b) and different layers (c).

B. Related Work

To address the limitations of diffusion models, researchers have done some work to optimize them from different perspectives, but *they all lack exploration of the relationships between timesteps and the characteristics within each timestep*. On the algorithmic side, DPM-Solver++ [15] introduces a new high-order sampling solver that reduces the number of timesteps required to generate images. Q-Diffusion [16] focuses on model quantization, proposing a timestep-aware post-training quantization method that reduces the activation of diffusion models to 8 bits, thereby accelerating the generation process.

On the hardware side, both Cambricon-D [13] and HCDiff [14] exploit the data similarity between adjacent timesteps in diffusion models by computing the differentials and using outlier-aware quantization to quantize them to a low bitwidth, thus accelerating the inference of diffusion models. Cambricon-D features an outlier-aware PE array to support mixed-precision computations, while HCDiff separates the quantized results into dense normal value matrices and sparse outlier value matrices for separate computation. However, both methods ignore the characteristics within each timestep, thus requiring computing differentials for each layer, which severely increases memory burden. Moreover, they all use different PEs to process high-precision and low-precision differentials separately, which results in low hardware utilization.

III. Motivation

While existing works have achieved notable acceleration, they overlook the existence of focal pixels in diffusion models. To study the impact of focal pixels on image quality, we add different levels of noise to focal pixels and other pixels respectively and measure image quality. As shown in Fig. 2(a), the curve "Focal Pixel" and the curve "Peripheral Pixel" indicate that noise is added to the focus pixels and the same number of other pixels, respectively. We can find that focal pixels are more sensitive to noise. Therefore, we propose a pixel-adaptive quantization method to apply high-precision representation for focal pixels and low-precision representation for others, thereby achieving acceleration while ensuring image quality.

Furthermore, we find that the focal pixels in diffusion models differ across timesteps. To validate this, we compare the change levels of pixels in different timesteps of Stable Diffusion and visualize them using heatmaps. As shown in Fig. 2(b), darker colors represent greater changes, while lighter colors represent smaller changes. We can find that

the number of focal pixels and their corresponding locations across different timesteps vary greatly. Therefore, we propose a prediction method to identify focal pixels for each timestep before applying pixel-adaptive quantization.

Lastly, we discover focal pixels across different layers within the same timestep exhibit consistency. As shown in Fig. 2(c), the focal regions across different layers within the same timestep align closely, indicating the consistency of these regions. Therefore, we propose a prediction finetuning method that performs prediction only once at the first layer and then finetunes the prediction results to efficiently predict focal pixels in subsequent layers, thus minimizing memory burden.

IV. MHDiff Algorithm

A. Focal Pixel Prediction

To identify the focal pixels at each timestep, we propose the focal pixel prediction operation. Given a $H \times W \times C$ input feature map, it identifies whether a $1 \times C$ vector (pixel P) is a focal pixel based on its change level. Specifically, we compute the L_1 distance between the pixel P_{ij}^t at the current timestep t and the corresponding pixel P_{ij}^{t-1} from $t-1$. As shown in Eqn. 1, where i denotes the row coordinate of the pixel, and j denotes the column coordinate. After calculating the L_1 distance, we compare it with a predefined threshold $Bias$. If the L_1 distance exceeds $Bias$, we think this pixel changes significantly and is a focal pixel; otherwise, we think it is a peripheral pixel. In this way, we divide these pixels into two categories: focal pixels and peripheral pixels, and generate a Bitmask B to record their locations.

$$L_1[i][j] = \sum_{k=1}^{C} abs(P_{ij}^t[k] - P_{ij}^{t-1}[k]) \quad (1)$$

B. Pixel-adaptive Quantization

To accelerate diffusion models based on focal pixels, we propose the pixel-adaptive quantization method, which applies different precisions to different pixels based on the Bitmask from the focal pixel prediction operation. Specifically, we use high-precision quantization for focal pixels as they require detailed generation in current timestep, thus necessitating a large bitwidth to ensure accuracy. In contrast, peripheral pixels exhibit minimal change, allowing us to apply low-precision quantization. Fig. 3 illustrates the process of the pixel-adaptive quantization. We first extract focal and peripheral pixels from input feature map based on the Bitmask, followed by applying uniform high-precision ($int8$) quantization to focal pixels and outlier-aware mixed-precision ($int4 + int8$) quantization to peripheral pixels. Subsequently, we merge the quantized results back into a complete feature map. The input feature map becomes a mixed-precision feature map after quantization, which results in low hardware utilization. Therefore, we design a packing module in Section 5.2 to address this problem.

C. Prediction Finetuning

To identify focal pixels for each layer within a timestep in a memory-efficient manner, we propose the prediction finetuning operation that performs the same calculation process on Bitmasks as on each layer so that Bitmasks can match the focal

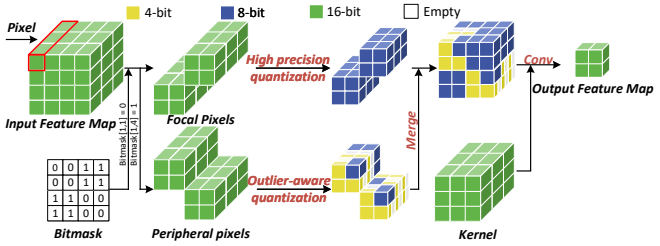

Fig. 3. The process of the pixel-adaptive quantization method.

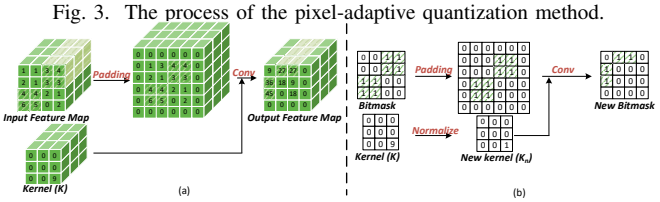

Fig. 4. An example of the prediction finetuning operation.

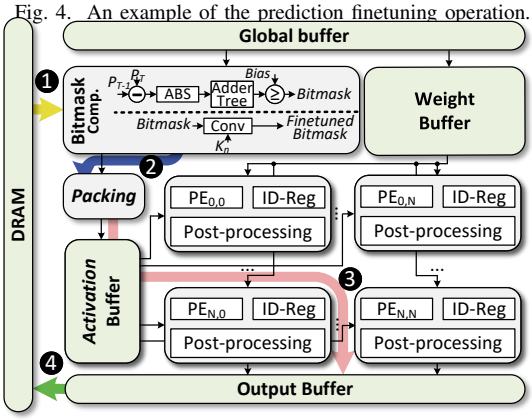

Fig. 5. Overview of the MHDiff architecture.

pixels of each layer. The necessity of the prediction finetuning operation is that the window-based sliding processing of each layer will cause a slight shift in the positions of focal pixels, which makes the Bitmask obtained in the first layer no longer valid in subsequent layers.

Specifically, as depicted in Fig. 4(a), we use a $3 \times 3 \times 3$ convolution kernel K and a $4 \times 4 \times 3$ input feature map as an example. For simplicity, we only show the calculation on one channel. We can find that since the weights are concentrated in the bottom right corner, when K is used to perform convolution on the input feature map, the focal pixels (the shaded area in Fig. 4(a)) will be shifted to the upper left corner. Therefore, current Bitmask is no longer valid for the next layer. To solve this problem, as shown in Fig. 4(b), we finetune this Bitmask according to the calculation process of convolution operation. We first normalize K to generate a new kernel K_n. Then we use K_n to perform convolution on the original Bitmask to obtain a new one, where the distribution of "1" perfectly matches the distribution of focal pixels in the output feature map. Through this method, we achieve finetuning Bitmasks, allowing Bitmasks to effectively guide the quantization for subsequent layers with minimal overhead.

V. MHDiff Architecture

A. Overview

Fig. 5 presents an overview of the MHDiff architecture, which consists of a Bitmask computation module, a packing

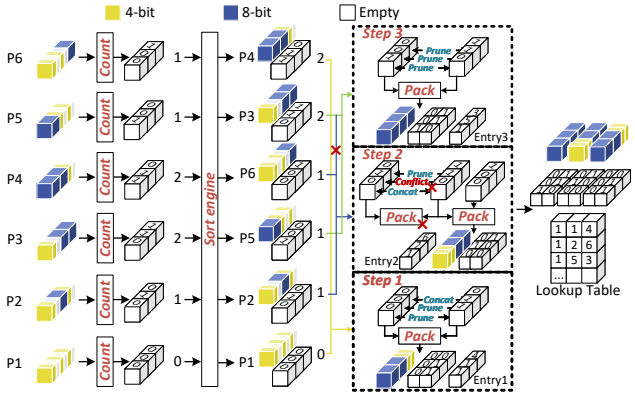

Fig. 6. The process of packing.

module, a PE array, and four buffers. The Bitmask computation module performs focal pixel prediction and prediction finetuning operations. The packing module packs mixed-precision feature maps into high-precision feature maps to facilitate efficient processing of the PE array. The PE array executes tensor multiplication operations. The on-chip buffers store activations, weights, outputs, and intermediate data generated by these modules, respectively.

The dataflow of the MHDiff architecture is also depicted in Fig. 5. In step 1, the Bitmask computation module first determines whether it is currently at the first layer of a timestep. If so, it reads the feature map of the previous timestep from DRAM and performs the focal pixel prediction operation to generate a Bitmask for the current timestep. Otherwise, it performs the prediction finetuning operation on the existing Bitmask to generate a new one for current layer. In step 2, the packing module extracts peripheral pixels from feature maps based on the Bitmask. Then they are packed into high-precision pixels. In step 3, the PE array reads the packed feature maps composed of focal pixels and packed peripheral pixels from activation buffer and the weight vectors from weight buffer for computation and writes the results to the output buffer. Finally, in step 4, the results in the output buffer is requantized and written back to DRAM.

B. Packing Module

To support mixed-precision ($int4 + int8$) computation, the PE units in the PE array need to be able to perform int4 or int8 calculations. However, PE units that perform $int4$ computation will complete faster and need to wait for that perform $int8$ computation, which results in low hardware utilization due to frequent synchronization. Therefore, we propose to pack two $int4$ values to form a $int8$ value, resulting in PE units running in the same speed. As a result, we are able to avoid synchronization, enabling higher hardware utilization.

Since only the peripheral pixels are mixed-precision, we need to pack these pixels to condense into full high-precision pixels. As the positions of $int8$ values in the quantized peripheral pixels are unpredictable, there are three possible cases during packing: (1) packing two $int4$ values, (2) packing a $int4$ value with a $int8$ value, and (3) packing two $int8$ values. For case 1, we can directly pack them into a $int8$ value that is called $int4+int4$ format. For case 2, considering

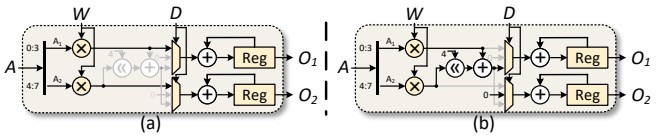

Fig. 7. The structure of PE unit.

that $int4$ values have little impact on model accuracy, we can directly discard the $int4$ value and only save the $int8$ value, which is called $int8+0$ format. For case 3, since $int8$ values are critical to model accuracy, we can't discard any of them. Therefore, we need to avoid this case. To this end, we design a packing module based on the greedy algorithm that attempts to avoid two $int8$ values conflicts.

The packing module consists of multiple count units, a sort engine, and a merge unit, which are responsible for recording the number of $int8$ values and their positions, sorting peripheral pixels, and merging them, respectively. The dataflow of the packing module is shown in Fig. 6. Upon receiving peripheral pixels, each count unit will count the number of $int8$ values and generate an identifier vector to record their positions. Then the sort engine will sort these pixels based on their number of $int8$ values. Afterwards, the merge unit will pack the pixel with the most $int8$ values and that with the least $int8$ values. In the example of Fig. 6, the packing module needs to pack 6 pixels ($P1-P6$). In step 1, it tries to pack $P4$ with $P1$. To avoid packing two $int8$ values, it first performs a logical AND operation on their identifier vectors and finds the result contains no "1", which means that these pixels don't have $int8$ values at the same position, so they can be packed together. It then packs these two pixels and their identifier vectors, and creates an entry to record the positions of these two pixels before packing. In step 2, the packing module attempts to pack $P3$ with $P2$, but finds they have two $int8$ values at position 2. Therefore, they cannot be packed together. It then attempts to pack $P2$ with $P6$. Finally, these two pixels are successfully packed together. In step 3, the packing module packs the remaining two pixels ($P5$ and $P3$), whose packing process is the same as step 1. In this way, we successfully pack the mixed-precision peripheral pixels into high-precision pixels and use the packed identifier vectors to record the type of each packed high-precision value. At the same time, we form a lookup table with the generated entries to facilitate the PE array to write results back to the correct buffer addresses.

C. PE Unit

In this section, we design a new PE unit to process the packed high-precision ($int8$) values. The specific structure of this PE unit is shown in Fig. 7. To support the $int4 + int4$ format, as shown in Fig. 7(a), the PE unit reads an activation ($int8$) and a weight ($int16$) from ports A and W, respectively. It then splits the high and low parts of the activation into two $int4$ values, A_1 and A_2. Then A_1 and A_2 are multiplied with the weight, and the results are accumulated into two registers. To support the $int8+0$ format, as shown in Fig. 7(b), after A_1 and A_2 are multiplied with the weight, the result of A_2 is left-shifted by 4 bits and then added to the result of A_1 to complete high-precision calculation. This result is then accumulated into

one of the registers. In this way, the PE unit efficiently supports the packed high-precision values.

Since this PE unit needs to support two different data formats, a key issue is how it can identify the format of the activation. To solve this problem, we add an additional port D, which reads a 2-bit identifier generated by the packing module. If the identifier is "00", it indicates the activation is formed by packing two $int4$ values. In this case, the PE unit will be configured as shown in Fig. 7(a). If the identifier is "10" or "01", it indicates the activation is originally a $int8$ value. In this case, the PE unit will be configured as shown in Fig. 7(b) and the identifier will control the multiplexer to write the result into the upper or lower register.

D. PE array

Building upon such PE units, we design a PE array to perform computations on the packed high-precision feature maps. Since the packing module disrupts the locations of pixels in the original feature map, it introduces two challenges. The first challenge is how to find the corresponding weights for each feature. The second challenge is how to write results back to the correct buffer addresses after computation.

For the first challenge, although the packing module disrupts the locations of pixels along the H (height) and W (width) dimensions, the locations along the C (input channel) dimension remain unaffected. Therefore, we propose to prioritize convolution calculations in the C dimension rather than in the H and W dimensions. Based on this, we design a PE array where PE units share a broadcast weight vector ($1 \times C$) but receive different activation vectors ($1 \times C$) for dot-product computations.

To address the second challenge, we equip each PE unit with a post-processing module that uses the lookup table generated by packing module to correctly write the results back to the output buffer. The lookup table we established is shown in Fig. 6. The i_{th} row of the table stores the information about the i_{th} pixel in the packed feature map, with three values indicating whether the vector is a packed vector and the positions of the two packed vectors in the original feature map. For example, in Fig. 6, the first row of the lookup table stores the information about the first pixel in the packed feature map. After a PE unit completes the calculation of this pixel, its post-processing module will read the first value of this row and find the value is "1", indicating that this pixel is a packed pixel. Then, according to the last two values, the post-processing module will read the two results from the O_1 and O_2 ports of the PE unit and write them to address "1" and "4" in the output buffer, respectively.

E. Bitmask Computation Module

The Bitmask computation module consists of multiple L_1 distance computation units and a convolution unit, which are responsible for performing the focal pixel prediction operation and the prediction finetuning operation. The L_1 distance computation unit reads a pixel at the current timestep and the corresponding pixel at the previous timestep. The two pixels undergo element-wise subtraction, followed by the absolute function, resulting in an absolute value vector. This vector is then passed into an adder tree for accumulation. Finally, the output from the adder tree is compared with a preset threshold to generate an element of the Bitmask. When the prediction finetuning operation is to be executed, the Bitmask computation module will perform convolution on the Bitmask, and generate the new Bitmask to guide the next layer.

VI. EVALUATION

A. Evaluation Methodology

Software implementation To verify the effectiveness of the MHDiff algorithm, we select Stable Diffusion [1], Latent Diffusion [4], and Guided Diffusion [17] as benchmarks. Stable Diffusion is assessed on the Conceptual Captions dataset (at 512×512 resolution) [18]. Latent Diffusion is tested on LSUN datasets (bedroom and church-outdoor, both at 256x256 resolution) [19]. Guided Diffusion is tested on ImageNet datasets (at resolutions of 128x128 and 512x512) [20].

Hardware implementation We implement the proposed MHDiff architecture in Verilog and synthesize it by Synopsys Design Compiler to get the area and power consumption under 28nm technology, with a design frequency of 500MHz. For SRAM-based on-chip buffers, we use CACTI 7 [21] to model their area and power consumption. We then rescale the area and power data to 28nm technology using DeepScaleTool [22]. Table I provides the detailed design parameters, area, and power breakdown for the MHDiff.

Platforms for comparison We compare MHDiff with widely used hardware platforms, including a server CPU (Intel Xeon Gold 6226R) and a GPU (Nvidia A100). We also compare a state-of-the-art Diffusion accelerator Cambricon-D [13] on the same area budget.

B. Experiment Result

1) Precision: We measure the image quality of each workload using precision, which is a widely used evaluation metric [13], [17]. As illustrated in Table II, compared to the

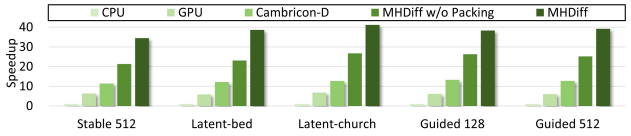

Fig. 8. Speedup of MHDiff.

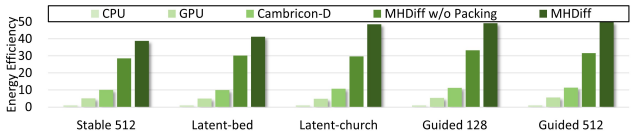

Fig. 9. Energy efficiency of MHDiff.

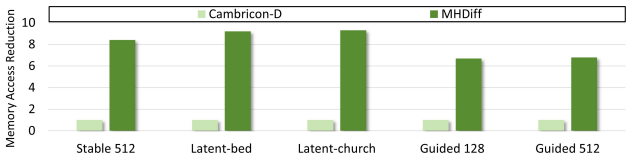

Fig. 10. Memory traffic of MHDiff compared with Cambricon-D.

baseline and $int8$ quantization, the precision of the MHDiff algorithm drops by less than 1% on average, which indicates that the MHDiff algorithm can maintain image quality well. Moreover, the MHDiff algorithm creates 83% $int4$ values and 17% $int8$ values on average, which greatly reduces computation compared to $int8$ quantization.

2) Speedup: Fig. 8 shows the speedup of the MHDiff over CPU, GPU, and Cambricon-D. MHDiff outperforms CPU, GPU, and Cambricon-D by 38.4×, 6.2×, and 3.1×, respectively. Compared to CPU and GPU, the speedup mainly comes from the proposed pixel-adaptive quantization algorithm that discards redundancy in diffusion models. Compared to Cambricon-D, the speedup originates from two aspects. First, Cambricon-D's high memory burden increases memory access latency, which drags down its acceleration gains. As we can see in Fig. 10, compared to Cambricon-D, we reduce memory traffic by 8.1x, which proves that MHDiff reduces the memory burden very well. Second, Cambricon-D has low hardware utilization. For example, as shown in Fig. 11, the PE array in Cambricon-D is idle nearly 50% of the time, while the idle time of the PE array in MHDiff is close to 0%. Therefore, MHDiff can make full use of its computing resources and achieve better acceleration.

In order to discuss the acceleration gained by the packing module, we implement a MHDiff accelerator without the packing module (labeled as MHDiff w/o Packing). As we can see in Fig. 8, MHDiff outperforms MHDiff w/o Packing by 1.6x. This is mainly because the packing module unifies precision, thus eliminating synchronization overhead and improving hardware utilization.

3) Energy Efficiency: As shown in Fig. 9, the energy efficiency of MHDiff is 45.2×, 8.3×, and 4.4× over CPU, GPU, and Cambricon-D. Compared to CPU and GPU, MHDiff uses fewer bits to represent data and perform calculations, which reduces the energy consumed by the computing units and memory. Compared to Cambricon-D, energy savings can be attributed to the following factors: 1) since MHDiff reduces memory accesses, the energy consumption caused by memory

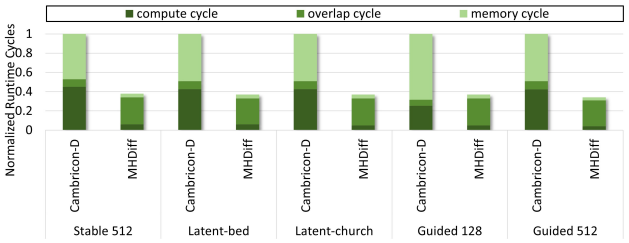

Fig. 11. Runtime breakdown of MHDiff compared with Cambricon-D.

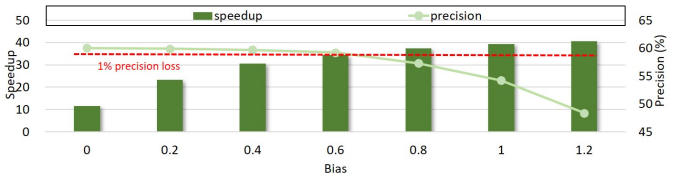

Fig. 12. Exploration on predefined threshold Bias.

is reduced; 2) the packing module improves hardware utilization, allowing MHDiff to save more computation energy.

4) Runtime Breakdown: Fig. 11 shows the runtime breakdown of MHDiff compared to the Cambricon-D, where the compute cycle, memory cycle, and overlap cycle refer to the computation time, memory access time, and the time they can run in parallel. We observe that MHDiff has less computation time than Cambricon-D because MHDiff has higher hardware utilization. Moreover, we find that the overlap cycle of MHDiff accounts for a large proportion, while that of Cambricon-D accounts for a small proportion. This is because Cambricon-D's heavy memory burden makes its PE array often idle due to lack of input data, resulting in serial execution of computation and memory access. In contrast, our memory traffic is relatively light, allowing computation and memory access to be performed in parallel. This is the main reason why the runtime of MHDiff can be significantly reduced.

5) Design Space Exploration: The goal of the MHDiff algorithm is to achieve a balance between optimizing efficiency and maintaining image quality by identifying focal pixels, in which the threshold $Bias$ plays an important role. Specifically, a larger $Bias$ means that fewer pixels are identified as focus pixels, which results in higher speedup but lower image quality. To explore the impact of $Bias$, we vary $Bias$ from 0 to 1.2 and see the precision and speedup of Stable Diffusion model on Conceptual Captions dataset. As illustrated in Fig. 12, when $Bias$ increases from 0 to 0.6, fewer pixels are identified as focus pixels, leading to higher speedup. But when we keep increasing $Bias$, the precision drops severely. As a result, we set $Bias$ as 0.6 to ensure both precision and performance.

VII. Conclusion

This paper proposes MHDiff, a framework for accelerating diffusion models. On the algorithm side, MHDiff identifies focal pixels for each timestep and applies different precision representations for different pixels, thereby achieving acceleration. On the architecture side, MHDiff transforms mixed-precision matrices into high-precision matrices and designs a specialized PE array through minor modifications to PE units. Experiments show that MHDiff can achieve satisfactory performance while maintaining image quality.

***Abstract*—*Adaptive Radix Tree* (ART) is a widely used tree index structure prevalent in various domains such as databases and key-value stores. Despite many solutions have been proposed to improve the performance of ART, they still suffer from significant redundant tree traversals and serious synchronization cost when concurrently performing the operations (e.g., read/write) over ART. In this work, we observe that most operations of real-world workloads tend to target a small subset of ART nodes frequently, exhibiting strong temporal and spatial similarities among the operations. Based on this observation, we propose a data-centric hardware accelerator, called *DCART*, to efficiently support the operations over ART. Specifically, DCART proposes a novel data-centric processing model into the accelerator design to coalesce the operations associated with the same ART nodes and adaptively cache the frequently traversed ART nodes and their search results, thereby fully exploiting the similarities among the operations for lower tree traversal and synchronization overhead. We implemented DCART on the Xilinx Alveo U280 FPGA card and compared it with the cutting-edge solutions, DCART achieves 21.1×-44.2× speedups and 71.1×-148.9× energy savings.**

I. Introduction

Adaptive Radix Tree (ART) [6], [8], [9], [17], [19], [27] is an efficient tree index structure, which plays a crucial role in numerous applications like large-scale database systems [7], [11] and key-value stores [12], [31]. With the wide application of ART, many optimizations (such as DART [28], Heart [17], and SMART [11]) are designed to improve the performance of the operation (e.g., read or write a key-value item) over ART. However, when concurrently performing the operations over ART, these solutions still suffer from significant redundant tree traversals and serious synchronization cost on general-purpose processors due to the following two problems.

First, different operations usually traverse the same nodes of ART individually, which incurs significant *redundant tree traversal overhead*. Moreover, the irregular and unpredictable tree traversal cause massive random data accesses, resulting in poor data locality. It eventually causes most proportion (up to 90.1%) of the fetched nodes in the on-chip memory to be redundant, underutilizing the memory bandwidth significantly. Second, the same node of ART may be handled by different operations concurrently, which brings serious *synchronization cost*. This is because existing ART design applies a lock-based algorithm [8], [9] for concurrency control and the real-world workloads typically perform the operations frequently over a few common nodes of ART. As a result, the synchronization cost wastes much execution time (up to 53.6%).

Through analyzing the operation distribution of the real-world workloads, we have two findings. First, the same nodes of ART may be frequently handled by different operations within a short time interval, which shows temporal similarity. This motivates us to coalesce the processing of the operations targeting the same nodes to achieve lower synchronization and tree traversal cost. Second, many operations get involved with only a small subset of ART nodes, which exhibits spatial similarity. This suggests that these frequently traversed nodes and their search results can be cached in the on-chip memory to further reduce off-chip communications.

Based on the observations, this paper proposes an efficient **data-centric** hardware accelerator *DCART*, which leverages a novel data-centric *Combine-Traverse-Trigger* processing model to effectively handle the operations over ART by fully exploiting the similarities among them. Specifically, DCART features specialized hardware pipelines to dynamically *combine* the operations targeting the same nodes of ART and then *traverse* the nodes of ART associated with these combined operations so as to *trigger* their processing together. Moreover, DCART dynamically maintains the search results (i.e., which are essentially the shortcuts) for the frequently traversed nodes of ART, enabling multiple operations to reuse these shortcuts to quickly search their target nodes. In this way, the redundant tree traversals and synchronization overhead can be effectively alleviated, ensuring higher utilization of the processing unit and fewer off-chip communications. To achieve better data locality, DCART further specializes the memory subsystem to preferentially resident the frequently traversed nodes of ART in the on-chip memory for multiple operations.

We have implemented DCART on a Xilinx Alveo U280 FPGA card. Experimental results show DCART outperforms the cutting-edge ART implementations (i.e., SMART [11] and

CuART [6]) running on Intel Xeon CPU and NVIDIA A100 GPU by 35.9×-44.2× and 21.1×-31.2× with 92.7×-148.9× and 71.1×-126.2× energy savings, respectively.

II. Background and Motivation

A. Adaptive Radix Tree

Adaptive Radix Tree (ART) [7]–[9], [11], [17], [19], [27], [28] standing out as a widely used tree index structure crafted to enhance the memory efficiency of traditional radix tree. As depicted in Figure 1(a) and (b), both the traditional radix tree and ART organize the segmented keys within the top-down search path of the tree. Specifically, in traditional radix tree, each internal node contains an array of child pointers, where each pointer corresponds to a *partial key* (i.e., a segment of bits of the whole key). Note that an internal node in the traditional radix tree typically reserves space for all 256 potential partial keys. However, due to the sparse distribution of actual keys [8], [11], [17], many of these pointers remain empty, resulting in inefficient memory usage. To resolve this issue, as shown in Figure 1(b), ART [8], [9] optimizes the traditional radix tree by reducing tree height with path compression and introducing four well-designed internal node structures (i.e., `N4`, `N16`, `N48`, and `N256` as shown in Figure 1(c)), where each accommodating a distinct number of pointers (4, 16, 48, and 256, respectively). For better memory efficiency, ART dynamically selects the most suitable internal node structure according to the actual data distribution.

For each operation (e.g., read or write a key-value item) over an ART, it needs to traverse the internal nodes of this ART by performing top-down partial key matching so as to locate the target node of this operation. When concurrently performing the operations over ART, a lock-based algorithm (i.e., the *Read-Optimized Write EXclusionn* (ROWEX) protocol [9]) is used to achieve concurrency control of ART. In detail, it adopts the node-level write locks (e.g., `node_C` must be locked when an operation related to `Key2` needs to modify it), and any read or write is executed atomically. Note that if the operation causes a change in the type of node (e.g., `N4` split into `N16` when `N4` is full), its parent node also needs to be locked.

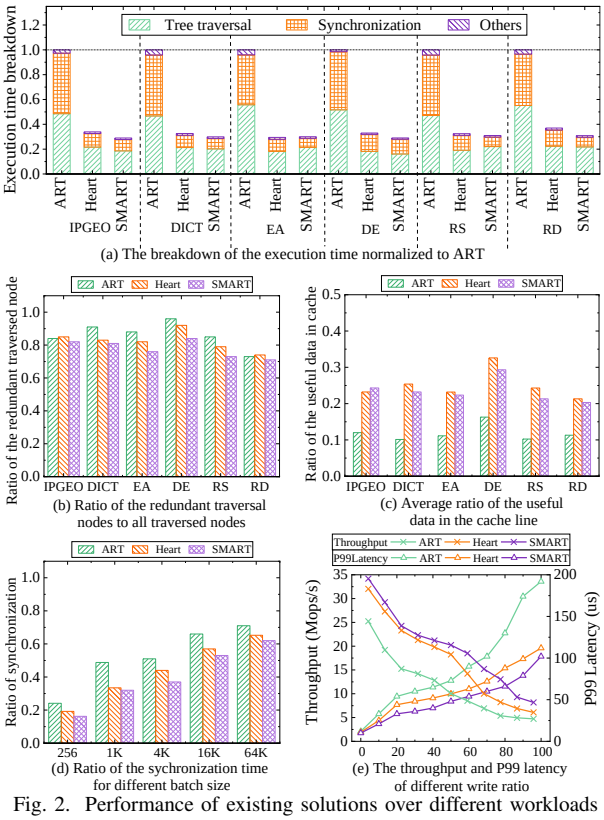

Fig. 2. Performance of existing solutions over different workloads

B. Challenges of Existing Solutions

Although many solutions [6]–[9], [11], [17], [19], [27], [28] have been developed to enhance the performance of the operations (e.g., read or write a key-value item) over ART, they still suffer from significant redundant tree traversal and serious synchronization overhead when concurrently processing the operations over ART. These unique challenges lead to inefficient utilization of the cores and memory bandwidth of the general-purpose processors. To demonstrate these problems, we evaluated three state-of-the-art ART implementations (i.e., ART [9], Heart [17], and SMART [11]) running on Intel Xeon CPU. Note that the details of the platform and benchmarks used in this evaluation are described in Section IV-A. Figure 2(a) shows that, although SMART outperforms other under all circumstances, the majority of execution time for the processing of operations on SMART (more than 95.82%) is still consumed by tree traversal and synchronization. We illustrate the reasons for the above inefficiency as follows.

Challenge 1: Massive redundant tree traversal cost incurs the underutilization of memory bandwidth. Different operations may need to individually traverse the same nodes of ART, incurring significant redundant tree traversal cost. As depicted in Figure 1(b), when processing two operations associated with `Key2` and `Key3`, respectively, each operation needs to individually conduct partial key matching along the nodes `node_A`→`node_B`→`node_C`. Such duplicate tree traversal incurs many redundant off-chip communications (e.g., the accesses to `node_A`, `node_B`, and `node_C`). As shown in Figure 2(b), more than 77.8% of traversed nodes are redundant when handling the operations over SMART, while this ratio

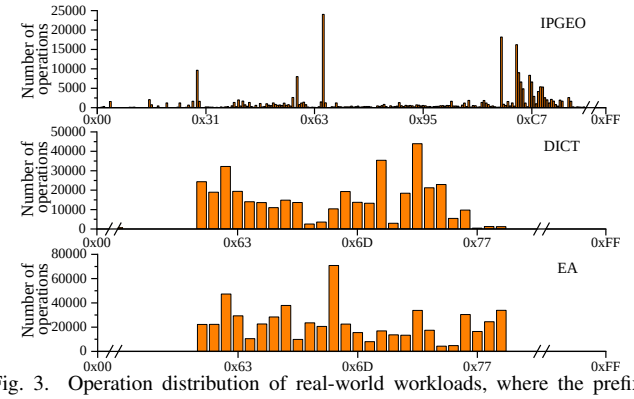

Fig. 3. Operation distribution of real-world workloads, where the prefixes (ranging from 0x00 to 0xFF) of the keys are listed along the horizontal axis and the number of operations led by different prefixes are shown vertically

can be even as high as 86.1% and 82.5% for ART and Heart, respectively. Besides, massive irregular and unpredictable data accesses during the tree traversal cause significant random data accesses, incurring poor data locality. Note that the partial key and child pointer are typically sized of 1 and 8 bytes, respectively, significantly smaller than the 64-byte cachelines of general-purpose processors. Thus, only a small portion of the data loaded into the cache line (20.2% on average in Figure 2(c)) is useful. This eventually results in many superfluous fragmented off-chip communications, underutilizing the on-chip memory and memory bandwidth significantly.

Challenge 2: The concurrency control of ART suffers from serious synchronization overhead. Existing ART implementations typically use lock-based algorithms [6]–[9], [19], [27], [28] to achieve concurrency control, which incurs serious synchronization overhead among different operations over ART. As depicted in Figure 1(b), when the operation associated with Key2 has acquired a lock for the node (e.g., node_C) of ART, the operation associated with Key3 can be conducted only when the operation associated with Key2 has been completed and released the lock. Although several works (e.g., Heart [17] and SMART [11]) endeavor to alleviate the node-level lock contention using the atomic primitive *Compare-And-Switch* (CAS), atomic operations are still very inefficient. This is because the operations over ART suffer from poor data locality, which leads to frequent cache misses, whereas a CAS operation on an Intel processor experiences a slowdown of more than 15 times when data resides in RAM compared to when it resides in L1 cache [21]. As shown in Figure 2(d), when the number of operations increases in the real-world workload *IPGEO*, the ratio of the execution time associated with concurrency control to the total execution time increases from 16.2% to 62.1% over Heart and SMART, while this ratio increases from 24.1% to 71.3% over ART. In addition, from Figure 2(e), we can observe that the performance deteriorates rapidly when the ratio of write operations increases in *IPGEO* (i.e., more lock acquirement and release are required).

C. Similarities among the Operations over ART

Figure 3 describes the statistical studies on the operation distribution of three real-world workloads. We observe that there are strong spatial and temporal similarities among the operations over ART. It provides opportunities to address the limitations of existing architectures and enhance the performance of the operations over ART.

Observation 1: The same nodes of ART may be frequently handed by different operations within a short period of time, which exhibits the temporal similarity. Figure 3 shows that the nodes corresponding to the keys with the prefix 0x67 are traversed and handled by over 24,000 operations for *IPGEO*. This motivates us to propose a novel ***data-centric*** *Combine-Traverse-Trigger* (CTT) processing model to efficiently coalesce the operations over ART by fully exploiting the temporal similarity. This model first *combines* the operations targeting the same nodes of ART according to the prefixes of their keys. It then *traverses* the nodes of ART to search the target nodes of these combined operations and finally *triggers* the processing of these operations together. Thus, each node of ART needs to be traversed only once to drive the processing of multiple operations, and the concurrent operations associated with this node can be serialized to naturally alleviate synchronization overhead. This is fundamentally different from the ***operation-centric*** processing model used in existing solutions [6]–[9], [11], [17], [19], [27], [28] that launch each operation to individually perform the tree traversal over ART to retrieve and atomically handle its target nodes. Take Figure 1(b) as an example, our proposed CTT processing model first combines the operations associated with Key2 and Key3 because their keys have same prefix, and then traverses the nodes of ART through conducting the partial key matching along node_A→node_B→ node_C. After that, the combined operations will be triggered to perform together without the synchronization of node_C when these operations need to modify node_C. Besides, the duplicate partial key matching from node_A to node_C can be eliminated by coalescing the same tree traversals, achieving lower tree traversal overhead.

Observation 2: Many operations involve only a small fraction of nodes within ART, which exhibits the spatial similarity. Figure 3 shows that more than 96.65% of tree traversals is responsible for accessing only 5% of the nodes in ART. The results depict that the node traversal distribution is usually skewed. This prompts us to enhance the performance of our proposed data-centric CTT processing model via the following aspects. First, the frequently traversed nodes (denoted as the high-value nodes) can be preferentially resident in the on-chip memory, efficiently exploiting the spatial similarity among the operations for fewer off-chip communications. Second, the partial key matching results associated with these nodes (e.g., the prefix of the key and the address of the corresponding node such as <0x000842, address of node_C> in Figure 1(b), which is essentially a *shortcut*) can be cached to be directly reused by other operations that need to handle them (i.e., the operations that need to handle node_C), further reducing the tree traversal overhead.

Challenges: Although our proposed data-centric CTT processing model ensures much lower synchronization cost and fewer tree traversals, its software-only implementation suffers from high runtime overhead (see Section IV-B) due to the

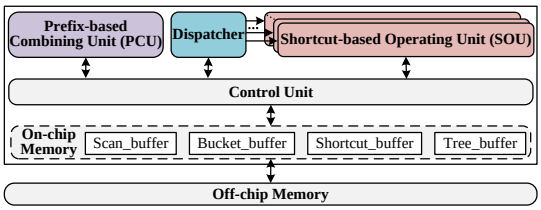

Fig. 4. Architecture of DCART

following reasons. First, it requires expensive runtime cost to dynamically coalesce the operations and maintain the shortcuts on the fly, which may impede the performance improvement brought by exploiting the similarities among the operations over ART. Second, the tree traversal involves data-dependent branches, which induces low instruction-level parallelism. To overcome these challenges, we present a data-centric hardware accelerator *DCART*, which customizes specialized hardware designs to efficiently handle the operations over ART.

III. DCART Architecture

A. DCART Overview

Figure 4 depicts the architecture of DCART, which contains three key hardware units (i..e, *Prefix-based Combining Unit* (PCU), *Dispatcher*, and *Shortcut-based Operating Unit* (SOU)) and on-chip buffers. Specifically, the PCU is employed to combine the operations targeting the same ART nodes by assigning the operations into disjoint buckets based on the prefixes of their keys. The *Dispatcher* is used to dispatch these buckets to different SOUs for parallel processing, in which the operations targeting the same nodes are only handled by a single SOU, alleviating synchronization overhead. Each SOU is employed to efficiently handle the combined operations in each bucket and also maintain the shortcuts to eliminate the duplicate tree traversal cost. On-chip memory is composed of several buffers to cache different types of data and also isolate the accesses to these different data (e.g., tree structure and operations), efficiently reducing off-chip communications. To fully exploit the spatial similarity of the operations over the ART, it also adaptively caches the frequently handled nodes for multiple operations, avoiding the data thrashing of them.

B. Prefix-based Operation Combining

To alleviate the lock contention among the concurrent operations over ART, the PCU sequentially scans the keys of the operations and dynamically assigns them into different disjoint buckets according to the prefixes of these keys. As shown in Figure 5, the PCU performs three stages as a pipeline to efficiently achieve the operation combining. Note that sixteen tables are created in the off-chip memory to store the combined operations for different buckets, where each table (e.g., *Bucket_Table*$_i$) is specified to a particular bucket (i.e., the i^{th} bucket) using a label (defined by the prefix). When the concurrent operations are arrived, at the *Scan_Operation* stage, it sequentially obtains the key of each operation. Then, the *Get_Prefix* stage calculates the specified prefix (e.g., *Prefix*$_i$) of this key, where the first 8 bits of the key are used as the specified prefix by default. After that, at the *Combine_Operation* stage, it assigns this operation into the corresponding *Bucket_Table* by matching *Prefix*$_i$ with

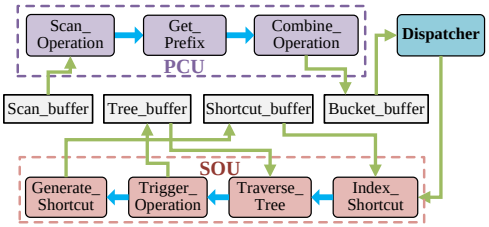

Fig. 5. Microarchitecture of DCART, where blue solid lines and green solid lines denote data flow and on-chip memory transfers, respectively

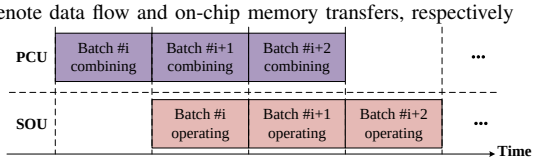

Fig. 6. The overlap between PCU and SOU

the labels of *Bucket_Tables* and then sets this operation as combined. In this way, the operations that target the same nodes are combined into the same bucket. It enables the *Dispatcher* to dispatch the operations that target the same node to be handled by only a single SOU, avoiding the acquirement of locks to perform synchronization for concurrent control.

C. Shortcut-based Operating

When a SOU is dispatched with a bucket of operations, this SOU sequentially retrieves an operation from this bucket and searches the target node of this operation by traversing the tree or using the shortcuts (to be introduced later), efficiently conducting the operations that target the same node together with lower tree search overhead. Note that a hash table, i.e., *Shortcut_Table*, is created in the off-chip memory to store the partial key matching results to be reused by multiple operations, avoiding significant redundant tree traversal overhead. Each entry of *Shortcut_Table* is the form of <`Key_ID`, `Address_Target_Node`, `Address_Parent_Node`>.

Specifically, as shown in Figure 5, each SOU contains four stages, which are conducted as a pipeline. At the *Index_Shortcut* stage, the SOU pops an operation from the assigned bucket and obtains the key (e.g., `Key`$_x$) of this operation. Then, it uses the `Key`$_x$ to obtain the addresses of the target node (e.g., `Node_X`) and its parent node (e.g., `Node_Y`) according to the *Shortcut_Table*. If the corresponding addresses can be obtained from the *Shortcut_Table* (e.g., `Node_X` has been handled by another operation previously), the *Traverse_Tree* stage will directly use these addresses to fetch `Node_X` and `Node_Y` from the tree structure (i.e., the ART), avoiding the tree traversal. Otherwise, the *Traverse_Tree* stage will use `Key`$_x$ to obtain `Node_X` and `Node_Y` through performing top-down partial key matching over the tree. At the *Trigger_Operation* stage, the SOU triggers all retrieved operation (e.g., read or write) on the target node to be performed together. If `Node_X` and `Node_Y` are obtained by traversing the tree, the *Generate_Shortcut* stage will generate a shortcut associated with `Key`$_x$, i.e., creating an entry (i.e., <`Key`$_x$, `Address_Node_X`, `Address_Node_Y`>) in *Shortcut_Table*. Note that the corresponding entry in *Shortcut_Table* needs to be updated when this operation causes a change in the type of `Node_X`. As the operations that target the same node being coalesced, the SOU typically obtains the

target nodes of the operations directly based on the maintained shortcuts and also achieves better data locality.

D. Overlap of Combining and Operating

The combining of the operations needs to assign them into different disjoint buckets on the fly, which introduces extra runtime cost. Fortunately, the interleaving between combining and operating for each operation batch provides the potential opportunity to hide the operation combining overhead. Thus, we can sequentially divide the arrived operations into a series of batches. As shown in Figure 6, when the i^{th} batch of operations has been handled by PCU, the Dispatcher will assign the combined operations associated with the i^{th} batch to be handled by SOUs. In the meantime, the PCU starts combining the operations of the $(i+1)^{th}$ batch. By such means, the overheads of the operation combining can be usually hidden for better performance.

E. Value-aware Memory Hierarchy

To efficiently access the ART nodes, arrived operations, *Bucket_Tables*, and *Shortcut_Table*, as shown in Figure 4, four on-chip buffers, i.e., *Tree_buffer*, *Scan_buffer*, *Bucket_buffer*, and *Shortcut_buffer*, are employed to cache these data, respectively. However, the high-value nodes (introduced in Section II-C) may be evicted from the *Shortcut_buffer* due to the irregular tree traversal over ART. The access to the tree structure typically accounts for the most portion of all data accesses. Therefore, we design a value-aware data management strategy to efficiently manage the *Tree_buffer*, while DCART uses LRU [4] to manage the other buffers by default. In detail, for the management of the *Tree_buffer*, DCART uses the values of the nodes to determine the victims. Note that a node (e.g., `Node_X`) will be handed more times when the corresponding bucket owns more operations, thus we use the number of the operations in the corresponding bucket to approximate the value of this node (i.e., $Value_x$), which can be obtained after the operation coalescing. When a node `Node_X` is requested, if the *Tree_buffer* is not full, `Node_X` will be directly cached in the *Tree_buffer*. Otherwise, DCART will evict the node with the lowest value (i.e., $Value_{low}$) from the *Tree_buffer* and cache `Node_X` in the *Tree_buffer* when $Value_x$ is greater than $Value_{low}$. In this way, DCART can effectively prevent cache thrashing for high-value nodes (i.e., frequently traversed nodes), ensuring better data locality.

IV. Evaluation

A. Experiment Setup

DCART Settings. We implement DCART on the Xilinx Alveo U280 FPGA card, which is equipped with the XCU280 FPGA chip. The FPGA provides 1.3 M LUTs, 2.6 M Registers, 9 M BRAM resources, and 8 GB HBM. DCART has 16 SOUs, and we implement the on-chip memory of DCART using the BRAM resources. More parameter details of DCART are depicted in Table I. We use Xilinx Vivado 2019.1 to obtain the clock rate for DCART and conservatively use 230MHz in our experiments. Besides, we also implement our data-centric CTT processing model on a machine equipped with two 48-core Intel Xeon Platinum 8468 processors and 1024 GB DRAM.

TABLE I
Parameter details of DCART

Compute	1×PCU, 1×Dispatcher, 16×SOUs
On-chip memory	*Scan_buffer* (512 KB), *Bucket_buffer* (2 MB), *Shortcut_buffer* (128 KB), *Tree_buffer* (4 MB)

The CPU version (i.e., the software-only implementation of our processing model) is called *DCART-C*.

Workloads. We use three real-world workloads (i.e., *IP address record by GeoLite2-Country* (IPGEO)[1], DICT[2], and *E-mail Addresses* (EA)[3]) and three synthesized workloads [9] with 50M dense 8-byte integer keys (DE), 50M random sparse 8-byte integers keys (RS), and 50M random dense 8-byte integers keys (RD), respectively. For each workload, the operations consist of 50% read and 50% write by default.

Baselines. We compare DCART with two cutting-edge CPU-based tree indexes (i.e., ART [9] and SMART [11]) and a state-of-the-art GPU-based tree index (i.e., CuART [6]), where ART and SMART are used as the CPU baselines and CuART is used as the GPU baseline. Note that SMART is designed for disaggregated memory, thus we port them to shared-memory by re-implementing them from scratch. All experiments run on a machine configured with two 48-core Intel Xeon Platinum 8468 processors, 1024 GB DRAM, an NVIDIA A100 GPU, and a Xilinx Alveo U280 FPGA. Like existing solutions [1], [3], [22], [26], we employ CPU Energy Meter [15], nvidia-smi [18], and xbutil [25] to measure the energy consumption of the CPU-based solutions (i.e., ART [9], SMART [11], and DCART-C), the GPU-based solution (i.e., CuART [6]), and the FPGA-based solution (i.e., DCART), respectively.

B. Overall Performance

Lock Contentions. Figure 7 evaluates the number of lock contentions induced by different solutions. It shows that the lock contentions induced by DCART-C and DCART are only 3.2%-19.7% of that by other solutions. This is because our data-centric CTT processing model only needs to acquire a single lock for multiple operations that need to handle the same node by efficiently coalescing these operations, alleviating massive lock contentions for lower synchronization overhead.

Partial Key Matches. Figure 8 shows the number of partial key matches performed by different solutions. It depicts that the number of partial key matches of DCART-C and DCART are only 3.2%-5.7%, 6.5%-14.3%, and 8.8%-15.9%, of ART, SMART, and CuART, respectively. The reasons are twofold. First, different operations can share the common tree traversals through combining these operations according to their prefixes. Second, the shortcuts of the frequently traversed nodes can be reused by multiple operations to directly search their target nodes, further reducing the tree traversal overhead.

Performance. Figure 9 evaluates the execution time of different solutions. We can find that DCART-C only slightly outperforms ART, SMART, and CuART, although our processing model can efficiently reduce redundant tree traversals

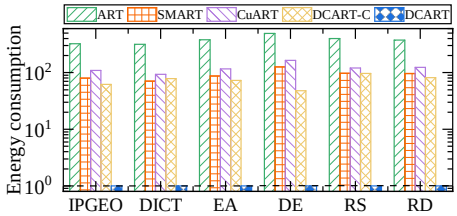

Fig. 11. Normalized energy consumption

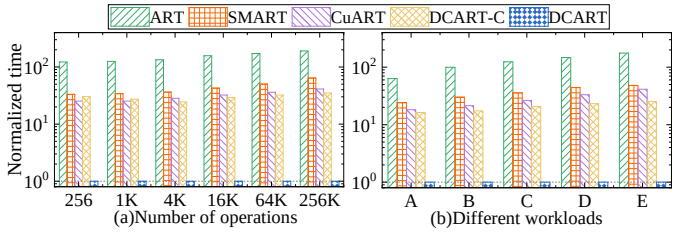

Fig. 12. Sensitivity studies

and synchronization overhead when handling the operations over ART. This is because DCART-C requires high runtime overhead to dynamically combine the operations, maintain the shortcuts, and irregularly traverse the tree structure on the fly. This impedes the overall efficiency of our processing model. Different from DCART-C, DCART can achieve 123.8×-151.7×, 35.9×-44.2×, and 21.1×-31.2× performance improvements compared with ART, SMART, and CuART, respectively. The reasons are manifold. First, DCART can reduce the runtime cost arising from our processing model because of its sophisticated hardware designs. Second, DCART can preferentially resident the frequently traversed ART nodes on the on-chip memory, achieving better data locality. Figure 10 evaluates the throughput-latency curves of different solutions with three real-world workloads, using various numbers of the operations. It shows that DCART achieves lower P99 latency and higher throughput in comparison with other solutions.

Energy Savings. Figure 11 shows that DCART reduces the energy consumption of ART, SMART, CuART, and DCART-C by 315.1×-493.5×, 92.7×-148.9×, 71.1×-126.2×, and 48.1×-97.6×, respectively.

C. Sensitivity Studies

Figure 12(a) evaluates the performance of different solutions when handling *IPGEO* with different number of concurrent operations. It shows that DCART achieves better performance as the number of operations increases. This is because DCART can efficiently coalesce the operations to alleviate more lock contention and tree traversal cost. Figure 12(b) evaluates the performance of different solutions with various workloads of *IPGEO*, where the workloads contain A (100% read), B (75% read, 25% write), C (50% read, 50% write), D (25% read, 75% write), and E (100% write). The results show that better performance improvement can be obtained as the ratio of write increases (which means more lock contention).

V. Related Work

Two categories of index structures (i.e., hash indexes and tree-based indexes) are most widely used today for databases.

Hash Indexes. Hash indexes [2], [14], [16], [32] are flat data structures that are able to support fast point access within constant lookup time complexity, i.e., O(1). However, because hash tables scatter the keys randomly, they are unable to support range queries efficiently.

Tree-based Indexes. Tree-based indexes [10], [20], [29], [30] are critical for many applications requiring range queries, and most previous databases typically apply the variants of B+tree [5], [13], [23], [24] to build range indexes. However, B+tree suffers from write amplification. In comparison with it, ART [8], [9] has smaller write amplification because it does not hold the entire keys in its internal nodes. Recently, many optimizations [7], [12], [19], [27], [31] have been proposed for ART. DART [28] introduces a triplet-based search mechanism to guarantee its scalability. Heart [17] proposes a PM-friendly node structure and a CAS-based concurrency control method to reduce the high PM overhead and improve scalability. SMART [11] is proposed to achieve efficient ART for disaggregated memory. To further improve the performance of ART, CuART [6] offloads the read and write operations onto GPUs. However, these solutions still suffer from serious redundant tree traversals and synchronization cost when concurrently performing the operations over ART. In contrast, DCART can effectively overcome these challenges by fully exploiting the temporal and spatial similarities among these operations.

VI. Conclusion

This paper proposes a novel data-centric hardware accelerator DCART to enhance the efficiency of operations over ART. By coalescing the operations targeting the same ART nodes and adaptively caching the frequently traversed ART nodes and their search results, DCART significantly reduces the synchronization cost and off-chip communications, achieving high energy efficiency. Compared to the state-of-the-art solutions, i.e., SMART [11] and CuART [6], DCART gains 21.1×-44.2× speedups with 71.1×-148.9× energy savings.

***Abstract*—High-level synthesis (HLS) tools streamline FPGA design by enabling engineers to implement hardware using C/C++ languages. However, while clock management serves as a critical stage in the FPGA EDA flow that affects system-level performance, area, and especially power consumption, existing commercial HLS tools lack comprehensive solutions for clock management. Specifically, the diversity of clock resources creates a vast design space for finding the optimal configuration, and the insufficient analysis of multiple clock domain scenarios hinders effective clock-oriented optimizations in HLS. This work introduces AutoClock, an open-source integrated clock management framework that complements AMD Vitis HLS. AutoClock allocates resources for clock generation, assigns modules to appropriate clock domains, addresses metastability and time division multiplexing (TDM) malfunctioning introduced by multi-clock domain architectures, and hierarchically gates the clock of modules in a design. Experimental results demonstrate that AutoClock can fully utilize clock resources on FPGAs and help reduce dynamic power consumption by up to 74.38%.**

***Index Terms*—High-level synthesis, clock management, clock domain crossing, clock gating, clock multiplexer.**

I. Introduction

Field-programmable gate array (FPGA) is widely used in various fields, such as autonomous driving [1]–[3], data center [4]–[6], and deep learning algorithm acceleration [7]–[9], owing to its reconfigurable nature with low latency. As applications become increasingly complex, the requisite time for their implementation on FPGA has increased exponentially. To address this problem, *high-level synthesis (HLS)* has gained significant traction as a methodology that enables engineers with limited hardware design expertise to use high-level programming languages for application implementation, largely bypassing the demand for learning specific low-level hardware minutiae.

Despite the popularity of HLS for FPGA, few commercial or academic tools have placed a focus on clock resource management, although the clock is one of the most essential components of an FPGA design. On the one hand, the use of clock resources is highly related to *performance, power, and area (PPA)* metrics of FPGA designs, particularly the power consumption [10], [11]. On the other hand, when serving as an *application-specific integrated circuit (ASIC)* prototyping platform, FPGA should maintain the same clock behaviors as on ASIC. The inherent disparities in clock resources between FPGAs and ASICs have historically necessitated manual reconstruction of clock topology for FPGA-based prototypes, which involves a time-consuming process. Consequently, empowering HLS to manage clock resources automatically would not only mitigate the power dissipation of FPGA designs but also enable HLS to support more complex applications while accelerating the overall development cycle for engineers.

Clock resources available in AMD FPGAs include clock buffers such as BUFGMUX and BUFGCE, as well as clock management tiles containing *phase-locked loop (PLL)* and *mixed-mode clock manager (MMCM)* [12]. Though previous works have explored various approaches for managing clock resources in FPGA designs, their efforts addressed only a limited spectrum of obstacles. Some challenges remain when seeking to fully leverage these resources from the HLS level:

- Existing studies have largely focused on PLLs for clock generation [13] or conceptualized digital clock management modules without delving into the practicalities of resource selection [10]. However, modern FPGAs, such as those from AMD, offer a diverse array of clock resources with similar functionalities but distinct power profiles. This diversity, coupled with the finite availability of these resources, presents a considerable challenge in optimizing power consumption while meeting design specifications.
- Besides, prior works have predominantly address specific *clock domain crossing (CDC)* scenarios, such as memory sharing across two clock domains and handshake mechanisms [13], or double buffering [14]. Various types of multi-clock domain designs present a challenge in automatically handling all types of CDC cases appropriately.
- Additionally, the limited number of clock gates in FPGAs demands a strategic allocation methodology. Nevertheless, existing HLS-based clock gating insertion work [15] has primarily dealt with small benchmarks and has not addressed the limitation of resources.
- Finally, while previous research [15] has explored clock gating in streaming modules using buffer status for back-pressure, real-world FPGA applications often encompass a broader range of modules, necessitating more versatile clock gating methods that can accommodate the diverse module interactions.

To address these challenges, this paper proposes the first integrated, automatic clock resource management framework, named AutoClock, aimed at presenting power optimization of HLS designs on the AMD Vitis flow. AutoClock leverages

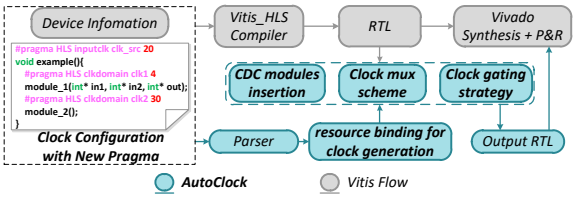

Fig. 1. Overview architecture of AutoClock.

clock buffers and clock management tiles while considering a broader range of CDC and clock gating scenarios. Additionally, the quantity and power consumption of these resources are considered to minimize overall power cost. Our contributions are highlighted as follows:

- We develop an open-source clock resource management framework that addresses a significant gap in current HLS tools. The open-source repository is available at: https://github.com/MasLiang/AutoClock.
- By formulating the resource binding of clock generation as an *integer linear programming (ILP)* problem featuring iterative constraint refinement, and coupling it with a greedy hierarchical clock gating strategy, AutoClock minimizes the overall power consumption of FPGA designs.
- AutoClock provides adaptive automatic CDC modules insertion for various interfaces and signals, as well as a clock multiplexer-based scheme to handle diverse multiple clock domain scenarios.

II. AutoClock Framework Design

The overall flow of the proposed clock management framework is illustrated in Fig. 1. Firstly, a pair of new pragmas are introduced that allow users to configure clock domains within an HLS design, accompanied by a dedicated parser to process these pragmas. Based on the parsing result, AutoClock generates a *clock reset generator (CRG)* for clock generation and reset synchronization while binding modules and related signals to different clock domains. Subsequently, AutoClock inserts clock gates into various types of modules in each clock domain using a greedy, hierarchical strategy to significantly minimize dynamic power consumption. Afterward, issues introduced by multiple clock domains are solved by inserting appropriate CDC modules automatically for various types of signals, including async-FIFO, async-BRAM, level- and pulse-synchronizer, to ensure reliable data transfer between clock domains, and applying clock multiplexer scheme to handle TDM modules invoked by multiple clock domains. Finally, the modified RTL code with clock management is fed into Vivado for further implementation.

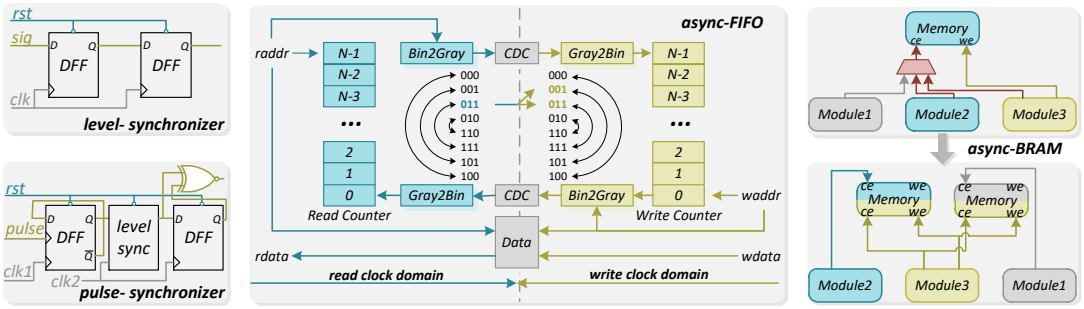
A. Clock Configuration with New Pragmas

For compatible with Vitis HLS with supporting multiple clock domains configuration, a pair of new custom pragmas is proposed as listed in Table I. With these pragmas, users can easily configure the clock domain and target frequency of each HLS function. The parser processes these pragmas, using naming conventions to associate configurations with corresponding RTL modules. The pragmas are then removed from the project to ensure compatibility with Vitis HLS, while the extracted clock domain information is used in subsequent steps of the AutoClock framework.

TABLE I
AutoClock-specific Pragmas: Templates and Descriptions.

Coding Template	Description
`#pragma HLS inputclk <name> <frequency>`	Used before the top module to define clock frequency of the input clock.
`#pragma HLS clkdomain <name> <frequency>`	Used before a module to define the clock domain of this module.

B. Resource Binding for Clock generation



Given the clock frequencies specified in the user configuration, multiple types of clock resources can be leveraged for generating them, namely BUFGCE_DIV and clock management tiles, including MMCM and PLL, in which MMCM can support the most complex functionality while BUFGCE_DIV costs the least power. Our purpose is to find the optimal binding of these resources that can satisfy the design requirements and consume minimum power. The problem is formulated as:

Problem. *Given the input system clock frequency f_{in}, the list of clock frequencies needing to generate $\boldsymbol{F} = \{f_i\} \in \mathbb{R}$, and the set of available clock resources $\boldsymbol{S}$. The goal of resource binding for clock generation is to identify a set of clock resources S_f that fulfill $\boldsymbol{F} = g(f_{in}; \boldsymbol{S}_f)$ while minimizing the power consumption under the constraints of resource quantity and design performance.*

Given the large number of clock resources and broad exploration space, the problem is formulated as an ILP problem featuring iterative constraint refinement for speedup. To simplify the problem, we first traverse all the frequency values to find the ones that BUFGCE_DIV can generate under the constraint of resource number. Subsequently, the remaining part of the problem can be solved as an ILP problem:

$$\begin{aligned} & min(n_{PLL} \times p_{PLL} + n_{MMCM} \times p_{MMCM}) \\ & s.t.\ n_{PLL} \le N_{PLL} \\ & \quad n_{MMCM} \le N_{MMCM} \\ & \quad Nf_{PLL}^{max} \times n_{PLL} + Nf_{MMCM}^{max} \times n_{MMCM} \ge n_{freq} \\ & \quad n_{PLL} \in \mathbb{Z} \\ & \quad n_{MMCM} \in \mathbb{Z} \end{aligned} \tag{1}$$

where n_s and p_s mean the number and power consumption of clock resource of type s, respectively, N_s is the upper limit of each type of resource, Nf_s^{max} represents the maximum number of frequency that a type of resource can generate. After obtaining the solution, the feasibility of it is validated by considering additional physical constraints. Frequencies in $\mathbf{F}$ are grouped into subsets based on the solution above, namely $\{\mathbf{F}_i^{MMCM}, \mathbf{F}_j^{PLL}\}$ representing clock frequencies bound to an MMCM or a PLL. Each subset must satisfy the requirement of its corresponding resource. Take a subset of clock frequency

(a) (b) (c)

Fig. 2. CDC modules. (a) single-bit synchronizers for level- and pulse- signals. (b) async-FIFO. (c) async-BRAM.

bound to an MMCM as an example. MMCM contains a global multiplier, a global divider, and some specific dividers for each output clock. Input frequency is processed by the global multiplier and divider to produce an intermediate value, which is then divided by specific dividers to generate output frequencies. Therefore, there are certain constraints associated with the MMCM:

$$\begin{aligned} &\exists \alpha, \beta \in \mathbb{R} \\ s.t. &\frac{\alpha}{f_{in}} \in \textbf{factor}_{mult_g} \\ &\frac{\alpha}{\beta} \in \textbf{factor}_{div_g} \\ &\frac{\beta}{f_k} \in \textbf{factor}_{div_k} \end{aligned} \tag{2}$$

in which α and β represent results of the global multiplier and divider, $\textbf{factor}_{mult_g}$, $\textbf{factor}_{div_g}$, and $\textbf{factor}_{div_k}$ denotes the valid factors of the global multiplier, the global divider, and divider for $k-$th output clock in an MMCM, respectively. PLL has a similar constraint. It should be noted that there are many combinations when grouping these clock frequencies, and a solution is feasible as long as there is a combination that meets the requirements. If a solution is infeasible, a new constraint is introduced to exclude it from the solution space:

$$s.t.\ n_{PLL} \times p_{PLL} + n_{MMCM} \times p_{MMCM} > P_{solution} \tag{3}$$

where the $P_{solution}$ is the power consumption of the failed solution. Then the ILP solver will be exerted again with the new constraint. This process is iterated until a feasible solution is found.

C. CDC Modules Insertion

Since different clock domains have varying features, such as frequency and phase, signals crossing clock domains must be synchronized to prevent metastable states from being sampled and propagating, which leads to incorrect circuit behavior. To satisfy this requirement, a series of CDC modules, including single-bit synchronizers, namely synchronizers for pulse- and level-signals, as well as multi-bit synchronizers, i.e., *asynchronous first-in first-out (async-FIFO)* and *asynchronous block random access memory (async-BRAM)*, are tailored to deal with a different type of signals.

1) Single-bit synchronizer: There are two types of single-bit signals: level signals and pulse signals, between which level signals are the most common in digital circuits. The top part of Fig. 2a shows a two-flip-flop synchronizer for single-bit level signals. Since it is used as a part of the handshake mechanism in [13], there is no need to care about the relationship between the frequency of two clock domains. However, this synchronizer has limitations when being applied independently. As illustrated in Fig. 3a, the width of the signal in the faster clock domain might be narrower than the period of the slower clock domain, leading to the risk of missing sampling. To mitigate this risk, AutoClock expands those level signals crossing the clock domain as Fig. 3b so that they can always be properly sampled in the slower clock domain.

Pulse signals are commonly used in control circuits. When this type of signal crosses clock domains, the two-flip-flop synchronizer can not fulfill the requirement. For instance, a pulse from the slower clock domain that sustains longer than twice the period of the faster clock domain will be sampled twice, generating a level signal after synchronizing. Therefore, a dedicated pulse-synchronizer is employed, shown in the bottom part of Fig. 2a. In this synchronizer, the input pulse serves as an enable signal to control the conversion of a level signal, which will cross the clock domain boundary relying on the level-synchronizer. In the destination clock domain, the edge of the synchronized level signal triggers the generation of a pulse signal. Fig. 3d gives the timing diagram for this process. Due to the constraint of level-synchronizer, the width of the level signal, i.e., the interval between two pulses T_{pulse}, must exceed the period of the target clock.

In addition to regular signals, the reset signal is another significantly important type of signal. Similar to regular signals needing to satisfy setup and hold time constraints, reset signals must satisfy the requirement of the recovery and removal time constraint as Fig. 3c, or metastable state might propagate. As a result, reset signals must also be synchronized for each clock domain when de-assertion. The reset-synchronizer shares the same module with the level-synchronizer depicted in the top part of Fig. 2a with the input signal set as constant 0.

2) multi-bit synchronizer: CDC for multi-bit signals introduces more complexity. Although the reliability of two-flip-flop based level-signal synchronizer has been proven in [13]

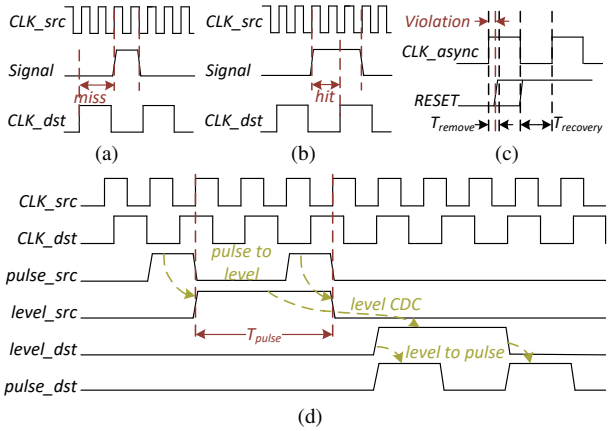


Fig. 3. Timing analysis of synchronizers. (a) Miss of signal sampling. (b) After expanding, the signal is sampled by the slower clock. (c) A violation example of removal time. (d) The timing of the pulse synchronizer.

to have an enormous *mean time before failure (MTBF)*, the MTBF of n parallel level-synchronizers for multi-bit signals will decrease by n times [16]. To address this problem, async-FIFO and async-BRAM are applied. While there are some other types of CDC modules, such as synchronizers based on handshake mechanism [16], they can be viewed as variations of previous basic synchronizers and will not be analyzed in detail here.

Async-FIFO is used when sequential multi-bit signal transfers. As illustrated in Fig. 2b, an async-FIFO includes shared data storage space and two address pointers binding to two clock domains. Pointers are converted to Gray Code before being synchronized because only a single bit changes in Gray Code when the address value increases. In this way, the MTBF is equal to a single-bit synchronizer. Moreover, there are only two conditions when Gray Code crosses clock domains: 1) successfully sampling and 2) failing to sample the changed bit that the value remains unchanged. For instance, in Fig. 2b, when the original *r-address* changes from 001 to 011, the synchronized *r-address* will either change to 011 successfully or remain at 001. If it remains, the state of the *r-pointer* in the write clock domain does not change. Thus, async-FIFO can guarantee the correctness of reading and writing.

BRAM is widely used as a shared data storage space among modules for transferring data. When a BRAM is shared by two clock domains, two BRAM ports are bound to different clock domains [13]. However, BRAM might be scheduled with time division multiplexing to be accessed by multiple modules for minimizing resource cost, e.g., as shown in the top part of Fig. 2c, $module3$ writes data to the BRAM while $module1, 2$ from different clock domains read data via a multiplexer. In this case, the BRAM will be copied for each read clock domain and memory accessing via multiplexer is separated to multiple independent accessing.

D. Clock multiplexer scheme

To limit resource allocation in the implemented design and reduce resource utilization, Vitit-HLS supports TDM for

Pseudo-Algorithm 1. Hierarchical greedy clock gating strategy

Input: the number of BUFGCEs g_n
the number of level L
the number of modules at l-th level N_l
the number of gated module $N_g = 0$
input design with a set of modules $M = \{m_0^0, ...m_{n-1}^{L-1}\}$

Output: Set of gated module M_g

```
for l = 0 to L do
    for n = 0 to N_l do
        calculate power that can be saved using Equation. 6
    sort modules by saved power
    for n = 0 to N_l do
        if father module is dataflow module do
            skip this module
        else do
            insert BUFGCE for clock gating
            N_g += 1
            if N_g == g_n do
                break
     if N_g == g_n do
        break
```

modules. However, multi-clock domains strategy makes it malfunctioning because a module is confined to a single clock domain. Thus, invoking the same module in multiple clock domains requires creating copies for each clock domain. It will introduce additional resource utilization as well as static power cost. To address this issue, a clock multiplexer scheme is proposed. For modules utilized across multiple clock domains, a new clock domain is created that incorporates multiple clocks with different frequencies corresponding to clock domains initiating these modules. In the protocol from Xilinx official document [17], an *finite state machine (FSM)* is implemented to control status of each kernel. A selection signal is then generated based on the FSM states to indicate which clock domain is invoking the module. With this signal, a BUFGMUX is instantiated to select the specific clock frequency. By implementing this scheme, the module can still function as a TDM module. Additionally, to mitigate potential signal instability because of frequency conversion, redundant idle states are inserted to the FSM. This remains sufficient time for the clock multiplexing process to ensure stable operation.

E. Clock Gating Strategy

Dynamic power dissipation, as described by Eq. 4, is closely related to active ratio. When signals remain, clock-related transistors still guzzle energy since their active ratio is 100%, including logic elements like LUT and DFF, as well as buffers and programmable switches on the route of the clock tree. To save such unnecessary power consumption, BUFGCEs are inserted into specific modules as clock gates in the clock tree to disable clock signals when their associated functions are idle. Due to the limited number of BUFGCEs on a given FPGA, a hierarchical greedy clock gating strategy, as illustrated in Pseudo-Algorithm 1, is advised for efficiently binding these BUFGCEs to maximize power saving.

$$\begin{aligned} P_{total} &= P_{static} + P_{dynamic} \\ &= Vdd \times I_{leakage} + \sum_{w \in W} \alpha_w C_w Vdd^2 f \end{aligned} \tag{4}$$

Firstly, there are two kinds of modules, i.e., dataflow modules whose sub-modules run continuously in the pipeline and non-dataflow modules where sub-modules exert in sequence. Due to the continuous working of sub-modules in a well-optimized dataflow module throughout the entire module execution, independent clock gating for them is unnecessary. For non-dataflow modules, some of their sub-modules might remain inactive when they are exerting. Thus, clock signals can be gated during the idle of these sub-modules to reduce power consumption. Previous works [11], [15] only care about dataflow modules and formulate them as an actor controlled through FIFO interface for inserting gates. When expanding to non-dataflow modules, the FIFO interface is not enough to cover all cases. Thus, the state of FSM in each module is used. Namely, when the FSM is in idle state, the clock is disabled.

Based on Xilinx documents [17], there are three block-level control protocols: *ap_ctrl_chain*, *ap_ctrl_hs*, and *ap_ctrl_none*. To generate an FSM for a block, *ap_ctrl_none* protocol is prohibited from use. In other protocols, the two signals, *ap_start* and *ap_done*, indicate the states of the FSM, thus are used to assert and de-assert the enable signals of clock gates. It is worth noting that the clock driving the FSM should always be on. Otherwise, deadlock will occur: if the clock is disabled, the state of the FSM will never change, and the clock will not be enabled. Additionally, the synchronous reset strategy is widely used in FPGA design, so the clock should be enabled when synchronous reset signals are asserted.

Besides, when a BUFGCE is inserted into a module, it influences circuits within this module and its sub-modules. Consequently, gating higher-level modules can save power more effectively than gating lower-level modules. Based on this, clock gates are inserted into modules from higher to lower levels. At the same level, all modules are sorted by power saving, which is closely related to two factors. First, the amount of saved power is linearly related to gated time. Second, modules with more transistors will result in more power saving in the same number of gated cycles. In a conclusion, the power that can be saved in a module is represented by:

$$P_{saved} = \frac{C_{idle}}{C_{total}} \times \sum_{t \in T} P_t \tag{5}$$

Where C is the number of cycles extracted from Vitis HLS reports, T is the set of basic elements in FPGA related to clock signals, including buffers in clock tree, LUTs, registers, DSP, and BRAM, and P_t is the power of an electronic element t in a cycle, obtained from AMD Xilinx Power Estimator. Since the idle time of a module overlaps with its higher-level modules, the clock gating time will also be calculated repeatedly. As a result, those time slots that have already been gated by clock gates in higher-level modules should be excluded when comparing with other modules. Thus, the Eq. 5 becomes:

$$P_{saved} = \frac{C^l_{idle} - \sum_{k=0}^{l-1} C^k_{idle}}{C_{total}} \times \sum_{t \in T} P_t \tag{6}$$

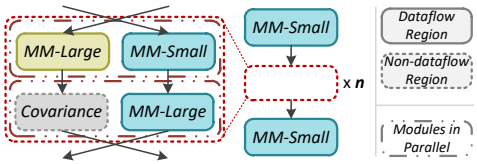

Fig. 4. Topology of of benchmarks PnMC. Different **background** color represent different clock domains.

in which C^l_{idle} and C^k_{idle} are the number of idle cycles of module at level l and its higher level modules, respectively. Subsequently, modules are sorted by the amount of saved power, and clock gates are allocated to those modules that have greater power savings.

III. Experiment

A. Experimental Setup and Benchmarks

The proposed AutoClock is implemented in Python with the Pyverilog tool [18] to parse and generate RTL code. All experiments are conducted on the AMD Alveo U280 FPGA based on Vitis 2023.2. *Xilinx Run Time (XRT)* is applied to measure power consumption, with power counter readings taken at *1ms* intervals. Each benchmark is executed 10,000 times successively to obtain a reasonable average power cost. Each experiment is repeated 20 times to eliminate random errors. For normalization, the system clock frequency of all benchmarks is set to *100MHz*.

To effectively evaluate AutoClock, a series of benchmarks are designed. Since the Vitis flow lacks clock management features, conventional HLS design benchmark suites such as Vitis Libraries [19] and Rosetta [20] are developed with a single clock domain, thus not clearly presenting the advantages of AutoClock. Similar to [21], we generate two dataflow kernels using AutoSA [22], namely *MM-Large* and *MM-Small* with the same matrix multiplication function but different latency, and a non-dataflow kernel *Covariance* from PolyBench [23]. We combine these to create composite large designs for generality in non-dataflow protocol. As these kernels have different latencies, they can be bound to different clock domains when working in parallel. Fig. 4 illustrates the structure of benchmarks used in this section, where PnMC represents cascading n parallel blocks. The background colors represent the clock domains to which these kernels belong. In the parallel block, two pairs of kernels work in parallel for multi-clock domain strategy analysis. They are also designed to demonstrate the effectiveness of the clock multiplexer scheme, as *MM-Large* works across different clock domains.

B. Clock Gating Evaluation

To thoroughly evaluate the impact of clock gating, we limited the number of BUFGCEs to 10 to address corner cases. Table II presents the comparison results. As benchmarks expand from P1MC to P3MC, the power reduction ratio consistently remains high, demonstrating the effectiveness of the clock gating method regardless of design scale. Additionally, since static power consumption is clock-independent, we focus on dynamic power. The results indicate that dynamic

P2MC_cdc_cg	0.81 (-47.01%)	0.25 (-74.38%)	341640 (+0.01%)	452915 (+0.28%)	1357 (+1.54%)
P3MC_cdc_cg	0.97 (-50.41%)	0.42 (-70.16%)	426533 (+0.03%)	565599 (+0.36%)	1792 (+2.31%)

power consumption can be reduced by up to 62.35%, similar to results from manually inserting clock gates at the RTL level [24], and greater than HLS-based work [15], which achieved a 53.7% reduction and focused solely on small dataflow designs.

Furthermore, to demonstrate the advantage of the proposed BUFGCE allocation strategy, random selection, *breadth-first search (BFS)*, and *depth-first search (DFS)* strategies were applied to P3MC to allocate a limited number of BUFGCEs. For random selection, conducted three times with different seeds, power cost increases in corner cases because the additional logic from clock gating consumes more power than it saves. The results demonstrate that our strategy achieves more significant power cost reduction. Resource utilization is also reported; although enabling signals introduces extra logic, the increases in LUT and FF usage are minimal.

C. Multi-Clock Domains Strategy Evaluation

The advantages of the multi-clock domains strategy are shown in Table II. In the baseline design, all modules within a parallel block run at the same clock frequency but exhibit varying latencies, causing faster modules to idle while waiting for slower ones. In such cases, modules with lower latency can be assigned a lower clock frequency. For example, the latency of *MM-Large* is 1/4 of *MM-Small*, corresponding to a clock frequency of *100MHz* $\times$ 1/4. As recorded in Table II, total and dynamic power can be reduced by up to 19.14% and 26.64%, respectively. Additionally, since BRAMs are used between kernels, extra BRAMs are required for CDC. However, only 2.31% of BRAMs for CDC are used in the corner case P3MC, which is acceptable. Given that BRAM is more likely to be the bottleneck than LUT, our benchmarks consist of numerical kernels, so async-FIFO and async-BRAM are widely used for CDC, helping explore the upper limit of BRAM usage. In designs with less data transfer and more control signals, the additional BRAM cost will be lower, while LUT consumption will be higher.

TABLE III
POWER AND AREA EVALUATION FOR CLOCK MULTIPLEXER SCHEME.

Flow	Total power(W)	Dynamic power(W)	LUT	DFF	BRAM
Vitis	0.75	0.29	230326	305926	762.5
AutoClock	0.67	0.21	230451	306992	799.5

We report the power consumption for these benchmarks using both methods. Clock gating proves to be more effective in saving power by disabling clock signals, while the multi-clock domain strategy only lowers frequency, even when modules are idle. These two methods are relatively independent and can be used simultaneously for greater power savings. In our benchmarks, dynamic power savings of up to 74.38% are achieved. Notably, although P3MC shows higher absolute dynamic power reduction, P2MC outperforms P3MC in power reduction ratio due to having fewer kernels and lower dynamic power. Subsequently, the TDM optimization strategy is applied to P1MC, limiting the *MM-Large* kernel in the RTL design to one instance. As shown in Table III, AutoClock still achieves a 25.58% reduction in power dissipation without compromising the effectiveness of the TDM optimization strategy and maintaining resource utilization.

IV. CONCLUSION

This paper introduces AutoClock, an open-source automatic clock management framework for HLS designs using the Vitis flow. AutoClock assists engineers in efficiently utilizing FPGA clock resources and reducing the power consumption of HLS designs. Our experiments demonstrate the effectiveness of AutoClock, achieving dynamic power savings of up to 74.38%.

***Abstract*—Circuit representation learning has shown promise in advancing Electronic Design Automation (EDA) by capturing structural and functional circuit properties for various tasks. Existing pre-trained solutions rely on graph learning with complex functional supervision, such as truth table simulation. However, they only handle simple and-inverter graphs (AIGs), struggling to fully encode other complex gate functionalities. While large language models (LLMs) excel at functional understanding, they lack the structural awareness for flattened netlists. To advance netlist representation learning, we present NetTAG, a netlist foundation model that fuses gate semantics with graph structure, handling diverse gate types and supporting a variety of functional and physical tasks. Moving beyond existing graph-only methods, NetTAG formulates netlists as text-attributed graphs, with gates annotated by symbolic logic expressions and physical characteristics as text attributes. Its multimodal architecture combines an LLM-based text encoder for gate semantics and a graph transformer for global structure. Pre-trained with gate and graph self-supervised objectives and aligned with RTL and layout stages, NetTAG captures comprehensive circuit intrinsics. Experimental results show that NetTAG consistently outperforms each task-specific method on four largely different functional and physical tasks and surpasses state-of-the-art AIG encoders, demonstrating its versatility.**

I. Introduction

Machine learning (ML) techniques have demonstrated remarkable achievements in electronic design automation (EDA). Existing ML methods are mostly tailored to specific tasks such as predicting physical metrics (e.g, timing [1], [2], [3], area [4], [5], [6], power [7], [8], [9], and routability [10], [11], [12]) or the reasoning of circuit functionalities [13], [14], [15], [16]. These methods are typically developed by supervised training, requiring extensive label collection and model customization for each task. Despite obvious effectiveness, they are time-consuming to develop and lack generalizability, often capturing only task-specific patterns rather than a generalizable understanding of circuits.

Recent circuit representation learning methods (i.e., encoders) generate informative embeddings for circuits and are able to support a range of downstream tasks [17], [18]. Existing methods mainly focus on VLSI circuit netlists, and some works also explore RTL circuits [19], analog circuits [20], and FPGAs [21]. We provide a detailed summary of the netlist encoders in TABLE I. All these netlist encoders capture circuit functionality through graph structure leveraging graph learning models, such as Graph Neural Networks (GNNs) or Graph Transformers (GTs). They either directly infer functionality with graph topology [22], [23], [24], or employ functional information to pre-train the models [25], [26], [27], [28], [29], [30], [31].

However, we argue that existing graph-only netlist encoders lack sufficient expressiveness to capture complex circuits. **These methods rely on graph models that inherently prioritize *structural* information over *semantics* (i.e., functionality).** Their limitations include: *(1) Limited to and-inverter graph (AIG).* Most methods target only simple AIG-based netlists, representing a narrow subset of standard cell libraries, and cannot handle post-mapping netlists with diverse gate types. *(2) Dependence on complex functional supervision.* Representative methods like the DeepGate family [25], [26], [27], [30] and FGNN [28], [29] incorporate truth table simulation to capture AIG functionality. However, truth tables suffer from exponential state expansion when applied to post-synthesis netlists with multi-input complex gates (e.g., full adders, multiplexers), limiting their applicability. *(3) Lack of physical information.* None of these methods consider physical characteristics, focusing solely on logic functionality. Consequently, these encoders are limited to AIG-based tasks (e.g., equivalence checking, SAT solving) and struggle with tasks for post-mapping netlists [2], [3], [7], [10], [11], [12], [14], [15], especially those evaluating physical design quality.

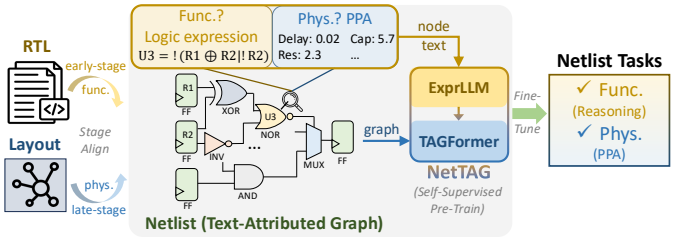

Fig. 1: Overvew of NetTAG. Netlists are formulated as text-attributed graphs, with functional and physical text attributes extracted for each gate. Within NetTAG, gate attributes are initially encoded by ExprLLM, then refined with global netlist graph structures using TAGFormer. NetTAG is pre-trained with self-supervised objectives and aligned with RTL and layout embeddings, enabling versatile support for both functional and physical tasks after fine-tuning.

Recently, large language models (LLMs) have demonstrated remarkable expressiveness in circuit-related generative tasks [32], [33], [34]. **However, LLMs inherently capture circuit textual *semantics* rather than *structure*.** Limited work has explored LLMs for general-purpose circuit representation learning, with key limitations summarized as follows: *(1) Struggle with netlists.* Although LLMs can interpret circuit functionality from RTL code, the gate-level netlists are more flattened and lack informative context, making functional understanding more challenging. *(2) Lack of structural encoding.* LLMs struggle to capture the circuit structures, limiting their utility for netlist representation learning.

In this work, we present **`NetTAG`**, a foundation model[1] for netlists that captures functional and physical properties across diverse gate types. Unlike previous circuit encoders and LLM solutions focusing on single circuit modality, NetTAG fuses gate text *semantics* with global graph *structures* to achieve *functional* and *physical* understanding. Serving as a foundation model, the pre-trained NetTAG generates versatile embeddings for logic gates, register cones, and full circuits. The embeddings can be easily fine-tuned for various downstream tasks, supporting largely different netlist-stage functional and physical tasks across these circuit granularities. As shown in Fig. 1, we propose the following innovative strategies in NetTAG:

- **Preprocess: formulating netlists as text-attributed graphs.** This paper is the first to represent netlists in text-attributed graphs (TAGs) format. In the netlist graph, we annotate each gate with functional symbolic logic expressions and physical characteristics as node-level text attributes. Our TAG format combines gate textual attributes with graph topology, moving beyond existing graph-only circuit representation learning.

[1]The code and pre-trained NetTAG model are available at https://github.com/hkust-zhiyao/NetTAG. The pre-trained model enables users to easily generate and fine-tune embeddings for their own netlist tasks.

TABLE I: Comparision of state-of-the-art netlist representation learning methods.

Method	Target Circuit		Encoding Methodology				Downstream Tasks	
	Cell Type	Circuit Type	Modality	ML Model	Pre-Train Target	Cross-Stage Align	Target	Type

- **Multimodal architecture: fusing semantic and structure.** Leveraging TAGs, NetTAG introduces an innovative multimodal architecture that combines an LLM-based text encoder (i.e., ExprLLM) with a graph transformer (i.e., TAGFormer). ExprLLM first encodes *fine-grained* gate text attributes into semantic-rich node embeddings, then TAGFormer refines them with *overall* graph structure, generating final individual gate and overall graph embeddings.
- **Aligned pre-training: self-supervised and cross-stage-aware.** We introduce four circuit-specific self-supervised objectives to pre-train NetTAG across circuit granularities, enhancing Boolean logic understanding and fusing gate semantics with the global graph structure. Moreover, we align netlist embeddings with those from RTL and layout stages to strengthen cross-stage functional and physical awareness.

We evaluate NetTAG on four largely different EDA tasks, covering both functional reasoning and physical design quality predictions at different circuit granularities. NetTAG consistently outperforms all state-of-the-art (SOTA) task-specific models, achieving 14% and 13% higher accuracy in logic gate and register function identification, respectively, and reducing errors by 2% for register slack, and 7% for both circuit area and power predictions. NetTAG demonstrates strong generalization across these representative tasks. Finally, we evaluate the scalability of NetTAG by scaling up model size and dataset volume. The results indicate a huge potential for improvement by scaling up either model or circuit datasets in future work.

II. Methodology

A. Overview

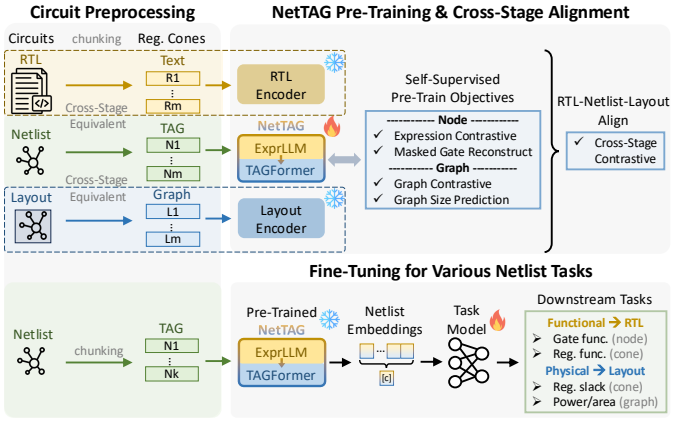
Fig. 2 outlines the NetTAG workflow. First, netlist data is converted into TAG format, detailed in Section II-B. NetTAG's multimodal architecture, which combines fine-grained gate text and overall circuit graph refinement, is illustrated in Section II-C. Step 1 enhances Boolean logic comprehension for ExprLLM (Section II-D), and Step 2 fuses gate semantics with circuit structure in TAGFormer, incorporating cross-stage alignment to strengthen both functional and physical understanding (Section II-E). Finally, Section II-F demonstrates the fine-tuning strategy that leverages the pre-trained NetTAG for various downstream tasks.

B. Circuit Data Preprocessing

Conventional graph methods like GNNs and GTs mainly capture structural information but fall short when the semantic context is also needed. TAG representation learning bridges this gap by encoding nodes as text and leveraging graph connections [35], [36], effectively improving node classification performance. *Intuitively, netlists, with their graph structure and detailed gate logic functions, are ideally suited for formulation as TAGs.*

Formulating netlist as TAG. Given a gate-level netlist $\mathcal{N}$, we represent it as a text-attributed graph $\mathcal{G}_{\mathcal{N}} = \{\mathcal{T}, \mathcal{E}\}$, where each gate in the netlist is a node in the graph. Here, $\mathcal{T} = \{t_1, \ldots, t_m\}$ is a set of gate text attributes, where m representing the total gate count. Each attribute t_i contains functional and physical properties of the i^{th} gate, as shown in Fig. 3(b), and consists of a sequence of tokens t_i. $\mathcal{E}$ is the set of edges connecting the gates.

Specifically, for functionality, we extract the symbolic logic expression for each gate based on its k-hop fan-in cone. These expressions are constructed using a formal verification toolkit [37], providing formal definitions for gate functionality. An example is demonstrated



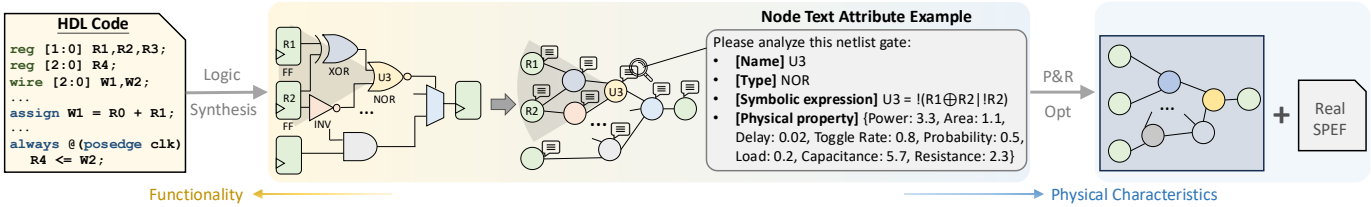


Fig. 2: NetTAG Workflow. Sequential netlists are chunked into combinational register cones and converted into TAGs. During pre-training, NetTAG is trained with node-level and graph-level self-supervised objectives, and it is aligned with RTL and layout embeddings. The pre-trained NetTAG then generates netlist embeddings, which are fine-tuned with netlist-stage task labels.

in Fig. 3(b), the 2-hop expression for this NOR gate with the symbolic name "U3" is derived from the Boolean functions of nodes within its 2-hop fan-in cone. The expression for "U3" is represented as: "U3 = !((R1 ⊕ R2)|!R2)". Each expression includes symbolic names for input gates and the Boolean operations. We summarize the key advantages of exploiting the symbolic expression for functional encoding:

1) **Versatile gate support:** Our symbolic expressions use Boolean formulas to represent any gate type, including complex gates like AOI and full adders. This enables NetTAG to support diverse gate types in netlists, beyond the limitations of AIG formats.
2) **Direct functional encoding:** In contrast to pre-trained circuit encoders that rely on graph-based learning with truth table supervision [29], [27], symbolic expressions enable straightforward static analysis, covering all input conditions without exponential growth problems by exhaustive truth table simulation.
3) **Structure independence:** Unlike structure-based methods that infer functionality with graph topology [23], [24], our approach derives gate expressions from Boolean formulas. It easily recognizes the same functionality across varying structures and distinguishes different functions in similar topologies.
4) **Compatible with language models:** Expressions can be seamlessly processed by language models, unleashing LLMs' reasoning capabilities to enhance circuit functional understanding. This functional expression also enables self-supervised pre-training for LLMs, such as expression contrastive learning, to improve LLMs' logic understanding from expression data itself.

For the physical characteristics, we annotate each gate with information extracted from the standard cell library, including characteristics such as power, area, delay, toggle rate, probability, load, capacitance, and resistance. Both functional and physical attributes are combined to form the text attribute for each gate.

Processing RTL and layout data. In addition to the target netlists, we utilize corresponding RTL and layout data to enhance NetTAG's cross-stage awareness. As shown in Fig. 3(a) and (c), RTL code is processed directly as text containing functional semantics, while layout data is represented as connectivity graphs annotated with physical characteristics. Specifically, nodes in the layout graphs are

(a) RTL Code (Text) (b) Netlist (Text-Attributed Graph) (c) Layout (Graph)

Fig. 3: Circuit data design stages and modalities. RTL code is processed directly as text. Netlists are represented as TAGs, with node attributes including gate name, type, symbolic expression, and physical property. Symbolic expressions are derived from each gate's k-hop input cone. Layout data is converted into graphs and annotated with physical information extracted from the SPEF file.

annotated with capacitance, resistance, and delay values extracted from the Standard Parasitic Extraction Format (SPEF) file.

Chunking sequential circuit into register cones. To handle large-scale sequential circuits, we propose chunking the original circuit into register cones. For each register, we backtrace through all driving logic up to other registers, creating a subcircuit cone that captures the complete state transition of the register, including update relationships and timing paths. This chunking process significantly reduces circuit size for our NetTAG, enhancing scalability. We apply this method consistently across netlist, RTL, and layout data, ensuring that cross-stage cones remain functionally equivalent[2] for subsequent alignment.

C. NetTAG Model Architecture

Fig. 4 illustrates the architecture of NetTAG, which comprises two main components: ExprLLM for gate-level text encoding and TAGFormer for further circuit-level graph encoding. Additionally, two auxiliary pre-trained encoders are employed to generate embeddings for the RTL code and layout graph, facilitating cross-stage alignment. We detail our NetTAG architecture below.

ExprLLM of NetTAG is initialized using an LLM-based text embedding model to encode gate text attributes as initial node embeddings. Following [38], we adapt a decoder-only LLM into a general-purpose text encoder by converting causal attention to bidirectional attention, which has shown superior encoding performance over encoder-only models (e.g., BERT) [39]. ExprLLM takes the gate text attributes t_i as input, converting them into the text embeddings T_i:

$$T_i = \text{ExprLLM}(t_i). \tag{1}$$

TAGFormer of NetTAG refines node embeddings from ExprLLM using a graph transformer model, which captures netlist graph structure via global attention. We include a `[CLS]` node connected to all other nodes in the graph, serving as the graph-level embedding. The initial embedding for each gate n_i is created by concatenating its text embedding T_i from ExprLLM with its physical characteristics vector $x_{\text{phys}i}$. TAGFormer then processes node embeddings $\{n_1, \ldots, n_m\}$ with their connectivity $\mathcal{E}$ into a sequence of netlist gate embeddings $\{N_1, \ldots, N_m, N_{\text{cls}}\}$, where N_{cls} represents the entire graph embedding:

$$\begin{aligned} n_i &= (T_i, x_{\text{phys}_i}), \\ \{N_1, \ldots, N_m, N_{\text{cls}}\} &= \text{TAGFormer}(\{n_1, \ldots, n_m\}, \mathcal{E}). \end{aligned} \tag{2}$$

Auxiliary RTL and Layout Encoders support cross-stage alignment for NetTAG by providing functional and physical insights from RTL and layout stages. The pre-trained RTL encoder, an LLM-based text encoder, generates RTL embeddings R_{cls}. Similarly, the layout encoder, a pre-trained graph transformer, produces layout embeddings L_{cls}. Please note that these auxiliary cross-stage encoders are used only during pre-training.

D. Pre-Training Step 1: Enhacing logic understanding in ExprLLM

We design pre-training objectives tailored for circuit netlists to capture both functional and structural information using our multimodal NetTAG. As shown in Fig. 4, the pre-training process is divided into two main steps: (1) Pre-training ExprLLM to strengthen its understanding of Boolean logic, and (2) Pre-training TAGFormer to fuse gate text semantics from frozen ExprLLM with circuit graph structure. Additionally, two pre-trained RTL and layout encoders are used for cross-stage alignment. We detail our pre-training objectives below.

Objective #1 Symbolic expression contrastive learning. In step1, we apply logic expression contrastive learning to enhance ExprLLM's understanding of Boolean expressions. As shown in Fig. 3, we begin by building a gate expression dataset from 2-hop symbolic expressions[3]. Then each expression is transformed using randomly applied Boolean equivalence rules[4] to generate a new positive sample. The InfoNCE loss [40] is then applied to differentiate each positive expression pair from other negatives, formulated as:

$$\mathcal{L}^{\#1}_{\text{expr}} = \mathcal{F}_{\text{CL}}(\boldsymbol{T}, T^+) = -\log \frac{\exp(T_{\text{ori}} \cdot T^+/\tau)}{\sum_{i=0}^{k} \exp(T_{\text{ori}} \cdot T_i/\tau)}, \tag{3}$$

where τ is the temperature scaling factor, T^+ is the positive embeddings, and $\boldsymbol{T}$ represents all k samples in the batch, including the original sample embeddings T_{ori} along with all other $(k-1)$ negative sample embeddings $T_i (i \neq \text{ori})$.

E. Pre-Training Step 2: Fusion in TAGFormer & Cross-Stage Align

1) Pre-training within TAGFormer for semantic and structure fusion: We propose gate-level and graph-level self-supervised objectives to jointly pre-train TAGFormer, fusing semantic-rich gate embeddings from pre-trained and frozen ExprLLM with the global circuit structure. The pre-training objectives are illustrated below:

Objective #2.1 Masked gate reconstruction. This objective aims to capture the structural roles of various gates by leveraging their connectivity within the netlist graph. Specifically, we propose to randomly mask a subset of gates in the netlist using a special `[MASK]` node. The model is then tasked with predicting the gate type (e.g., NOR, MUX, AND, etc.) of the masked gates based on the remaining unmasked nodes.

This objective is formulated as a multi-class classification problem, where the predicted gate types are treated as discrete labels. NetTAG first processes the masked graph to generate inputs and generates masked node embeddings N_i^{mask} for each masked gate in $\mathcal{T}^{\text{mask}}$. Then a classification Multi-layer Perceptron, denoted as $\text{MLP}_{\text{class}}$, takes the masked node embeddings N_i^{mask} as input and outputs the predicted probability distribution over gate types. The ground-truth gate type for each masked node i is denoted by $\boldsymbol{y}_i^{\text{mask}}$. The classification loss is defined using the cross-entropy loss as follows:

$$\mathcal{L}^{\#2}_{\text{gate}} = -\sum_{i \in \mathcal{T}^{\text{mask}}} \boldsymbol{y}_i^{\text{mask}} \log \left(\text{MLP}_{\text{class}}(N_i^{\text{mask}}) \right). \tag{4}$$

Objective #2.2 Netlist graph contrastive learning. This objective captures global structural and functional information by clustering similar netlists and separating dissimilar ones. Positive samples are generated via functionally equivalent transformations of each netlist graph [29], while negative samples are distinct graphs within the same batch. The InfoNCE loss is also applied to minimize the

[2]Most registers maintain unchanged throughout design stages.

[3]We choose 2-hop to balance the expression expansion and runtime.

[4]We implemented Boolean transformation rules such as De-Morgan's law, distributive law, commutative law, associative law, etc.

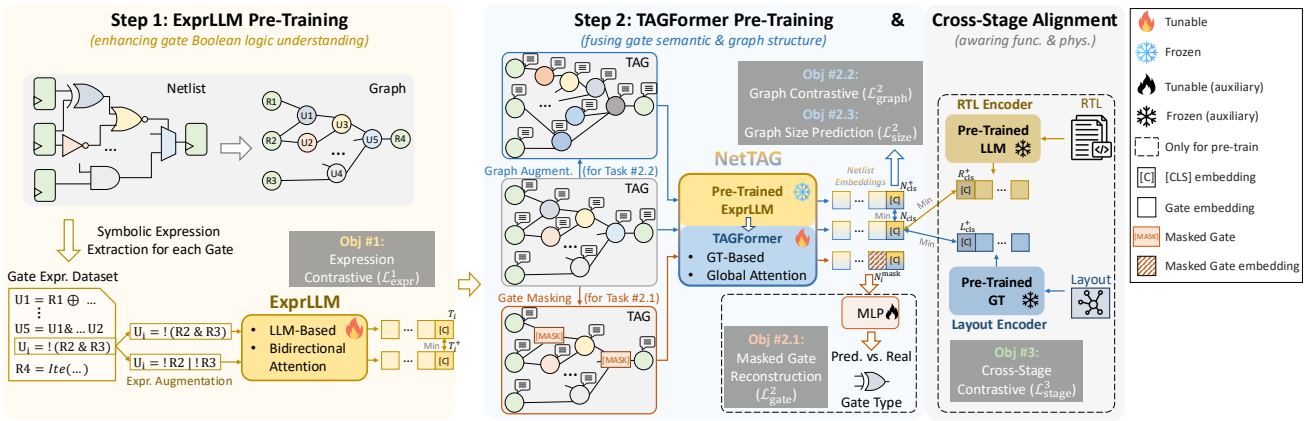

Fig. 4: NetTAG architecture and pre-training workflow. In step 1, we collect a dataset of gate symbolic expressions and pre-train ExprLLM to enhance its understanding of Boolean formulas. In step 2, ExprLLM is frozen, and we pre-train TAGFormer to fuse the gate semantics with the global graph structure. NetTAG embeddings are cross-stage aligned with those from pre-trained auxiliary RTL and layout encoders.

distance between positive pairs while maximizing separation from negative samples:

$$\mathcal{L}^{\#2}_{\text{graph}} = \mathcal{F}_{\text{CL}}(\boldsymbol{N}_{\text{cls}}, N^{+}_{\text{cls}}), \tag{5}$$

where N^{+}_{cls} denotes the positive sample embeddings, and $\boldsymbol{N}_{\text{cls}}$ includes the original and all other negative samples in the batch.

Objective #2.3 Netlist graph size prediction. This objective aims to predict the number of each type of gate in a given netlist graph based on the graph-level embedding, which is formulated as a regression problem. Denote $\boldsymbol{y}^{size}$ as the ground-truth gate counts for a netlist graph $\mathcal{G}_{\mathcal{N}}$. We employ an auxiliary model MLP_{regr}, which takes the graph-level embedding N_{cls} as input and outputs the predicted gate counts. The objective is to minimize the Mean Squared Error (MSE) between the predicted and actual gate counts, as formulated below:

$$\mathcal{L}^{\#2}_{\text{size}} = \frac{1}{n}\sum_{i=1}^{n}\left(\boldsymbol{y}^{size}_i - \text{MLP}_{\text{regr}}(N_{\text{cls}})\right)^2, \tag{6}$$

where n is the number of gate types, and each element in $\boldsymbol{y}^{size}$ corresponds to the predicted count for a specific gate type.

2) Pre-training beyond TAGFormer to enhance functional and physical awareness: **Objective #3 Cross-stage contrastive alignment.** Beyond the pre-training objectives within NetTAG's components, we introduce cross-stage alignment to integrate information from RTL-stage functionality and layout-stage physical implementation into NetTAG. This alignment enhances NetTAG's cross-stage awareness, benefiting both functional and physical downstream tasks, as further demonstrated in Section III-D. Using contrastive objectives, we align the circuit embeddings from RTL (i.e., R^{+}_{cls}), netlist (i.e., $\boldsymbol{N}_{\text{cls}}$), and layout (i.e., L^{+}_{cls}) within a shared latent space, as formulated below:

$$\mathcal{L}^{\#3}_{\text{align}} = \mathcal{F}_{\text{CL}}(\boldsymbol{N}_{\text{cls}}, R^{+}_{\text{cls}}) + \mathcal{F}_{\text{CL}}(\boldsymbol{N}_{\text{cls}}, L^{+}_{\text{cls}}). \tag{7}$$

To this end, we formulate the overall self-supervised pre-training objective of NetTAG as the following two-step process:

$$\mathcal{L}_{\text{NetTAG}} = \begin{cases} \mathcal{L}^1_{\text{expr}} & \text{(Step 1)} \\ \mathcal{L}^2_{\text{gate}} + \mathcal{L}^2_{\text{graph}} + \mathcal{L}^2_{\text{size}} + \mathcal{L}^3_{\text{align}} & \text{(Step 2)} \end{cases} \tag{8}$$

F. Fine-tuning for downstream tasks

NetTAG generates multi-grained embeddings for netlist elements, including combinational gates, register cones, and entire circuits. For sequential circuits, circuit-level embeddings are computed by summing the embeddings of all register cones, while for combinational circuits, their overall embeddings are directly obtained on the `[CLS]` node without the need for chunking into cones.

For downstream tasks, we fine-tune these embeddings with lightweight task models like MLPs or tree-based models (e.g., XGBoost). NetTAG's versatile embeddings support both regression and classification across functional and physical tasks for netlists. For functional tasks, the fine-tuning model predicts early RTL-stage information on netlists, such as gate functions and register types. As for physical tasks, it predicts late layout-stage metrics like register endpoint slack, power, and area. We will provide the detailed evaluation results in Section III-B.

III. Experimental Results

A. Experimental Setup

Data preparation. We collect circuits for pre-training from various sources, including benchmark RTL code from ITC99 [41], OpenCores [42], Chipyard [43], and VexRiscv [44]. All RTL designs are synthesized into netlists using Synopsys Design Compiler using NanGate 45nm technology library and then undergo physical design with Cadence Innovus. Gate and design quality metrics and statistics are obtained using Synopsys PrimeTime. For symbolic logic expressions, we use PySMT [37], a symbolic reasoning toolkit for formal verification, to construct and manipulate the Boolean expressions.

The statistical details of our dataset are shown in TABLE II. For the expression dataset used by ExprLLM, we collected 313k original expressions, each augmented with functionally equivalent transformations, resulting in a total of 626k expressions. As for the circuit netlist data, we collected 100k subcircuit cones after chunking, which were also functionally augmented to reach 200k samples in total. Additionally, we included 10k aligned RTL and layout cones for cross-stage alignment. When applying NetTAG to downstream tasks, we directly use the original task datasets if available. Otherwise, we utilize designs from the aforementioned open-source benchmarks.

TABLE II: Statistics of circuit expression and netlist dataset.

Source	Gate Expression		Circuit Netlist	
	# Data	# Tokens (Avg.)	# Data	# Nodes (Avg.)
ITC99	47k	6,960	4k	1,025
OpenCores	76k	212	55k	173
Chipyard	109k	9,849	20k	2,813
VexRiscv	81k	5,289	21k	901
Total	**313k**	**5,810**	**100k**	**855**

Implementation details. For the implementation of NetTAG, we initialize ExprLLM with LLM2Vec [38], an open-source LLM-based encoder based on Meta Llama-3.1-8B [45], with 8k maximum input tokens. For the graph transformer backbone of TAGFormer, we adopt SGFormer [46]. Additionally, we use NV-Embed [47] (maximum 32k input tokens) as the pre-trained RTL text encoder, and the layout encoder is pre-trained using a graph contrastive objective on SGFormer. Each MLP contains three layers with a hidden dimension of 256, and the output dimension of NetTAG is set to 768. We pre-train ExprLLM using LoRA on the full dataset for one epoch, followed by 50 epochs

of pre-training for TAGFormer. Afterward, fine-tuning is performed with lightweight models and task-specific labels. All experiments are conducted on 8 Nvidia 4090 GPUs and 4 Nvidia A6000 GPUs.

B. Performance on Various Downstream Tasks

We evaluate the pre-trained NetTAG on four representative netlist-stage tasks, including functional and physical tasks across combinational and sequential circuits. These tasks span multiple netlist granularities: combinational gates, register cones, and entire circuits, offering a thorough assessment of NetTAG's capabilities.

NetTAG consistently outperforms task-specific baselines in each task, demonstrating its ability to capture functional and physical circuit information. This highlights NetTAG's role as a foundation model that is capable of generating informative embeddings for netlists. Detailed evaluations for each task are as follows:

Task1: Combinational gate function identification. This task identifies the functional type of each netlist combinational gate (e.g., adder, multiplier, comparator) as described in the original RTL code. Accurate gate function identification is critical for applications such as reverse engineering, hardware security, and functional verification. We evaluate NetTAG on an open-source dataset from GNN-RE [14], ensuring no label-related text is included in the gate text attributes and using the same metrics for a fair comparison.

As shown in TABLE III, NetTAG significantly outperforms GNN-RE across all metrics, with an average improvement of 14% in accuracy (97% vs. 83%), 11% in precision, 14% in recall and F1-score. These improvements demonstrate NetTAG's robust ability to capture functional information on each gate, enabling superior generalization compared to the task-specific GNN-based method.

TABLE III: Performance comparison on Task1: combinational gate function identification.

Design	GNN-RE [14]				NetTAG			
	Acc. (%)	Prec. (%)	Recall (%)	F1 (%)	Acc. (%)	Prec. (%)	Recall (%)	F1 (%)
1	79	82	79	74	97	97	97	97
2	96	96	96	96	100	100	100	100
3	94	94	94	94	100	100	100	100
4	78	83	78	78	100	100	100	100
5	91	92	91	90	99	99	99	99
6	74	78	74	68	94	94	94	93
7	80	80	80	80	84	87	84	81
8	89	90	89	87	95	96	95	96
9	65	77	65	67	100	100	100	100
Avg.	83	86	83	82	**97**	**97**	**97**	**96**

Task2: Sequential state/data register identification. This task distinguishes state registers from data path registers, which is essential for understanding high-level control and data flow within low-level netlists, supporting security analysis and verification. We evaluate NetTAG against ReIGNN [15], a supervised method specifically designed for this task based on GNN. The evaluation metrics include sensitivity and balanced accuracy (the average of sensitivity and true negative rate).

As demonstrated in TABLE IV, NetTAG significantly outperforms ReIGNN in both metrics. It achieves a 44% improvement in sensitivity (90% vs. 46%) for state register identification and a 13% increase in overall accuracy (86% vs. 73%), highlighting its superior capability of capturing structural and functional information from register cones.

Task3: Endpoint register slack prediction. This task focuses on predicting sign-off timing slack at the netlist stage to provide early feedback, thereby expanding the optimization space in the physical design flow. The prediction is highly challenging due to substantial graph topology changes during physical design optimizations, as discussed in [2]. We compare NetTAG with the state-of-the-art GNN-based method from [2], extending their post-placement method to work at the post-synthesis stage. Performance is evaluated using correlation coefficient (R) and mean absolute percentage error (MAPE).

TABLE IV: Performance comparison on Task2: state/data register identification & Task3: endpoint register slack prediction.

Design	Task 2				Task 3			
	REIGNN [15]		NetTAG		GNN*		NetTAG	
	Sens. (%)	Acc. (%)	Sens. (%)	Acc. (%)	R	MAPE (%)	R	MAPE (%)
itc1	50	72	100	98	0.89	13	0.94	9
itc2	100	92	100	100	0.91	10	0.93	9
chipyard1	30	65	80	79	0.72	17	0.7	20
chipyard2	30	65	90	86	0.86	12	0.95	9
vex1	50	74	82	74	0.94	11	0.93	12
vex2	32	60	86	82	0.97	18	0.97	9
opencores1	42	73	93	84	0.99	26	0.92	29
opencores2	37	80	92	82	0.93	30	0.98	26
Avg.	46	73	**90**	**86**	0.9	17	**0.92**	**15**

* We adapt the GNN model from [2] for netlist-stage slack prediction, as it was originally designed for the layout stage.

As shown in TABLE IV, NetTAG outperforms the customized GNN baseline [2], achieving more accurate slack prediction with R of 0.92 vs. 0.9 and a MAPE of 15% vs. 17%.

Task4: Overall circuit power/area prediction. This task predicts final layout power and area metrics at the netlist stage, offering early estimates for physical design. We compare NetTAG with the synthesis tool and a customized GNN model adopted from PowPrediCT [7], a layout-stage state-of-the-art optimization-aware power predictor.

For area prediction, NetTAG achieves a 4% MAPE without optimization and 11% with optimization, outperforming the GNN's 5% and 18% and the synthesis EDA tool's 5% and 34%. For power, it yields an 8% MAPE without optimization and 12% with optimization, surpassing the GNN's 12% and 19% and the EDA tool's 34% and 38%. These results highlight NetTAG's strong accuracy and robustness for circuit-level tasks.

TABLE V: Performance comparison on Task4: overall circuit power/area prediction.

Target	Metric†	EDA Tool		GNN*		NetTAG	
		R	MAPE (%)	R	MAPE (%)	R	MAPE (%)
Area	w/o opt	0.99	5	0.99	5	**0.99**	**4**
	w/ opt	0.95	34	0.95	18	**0.96**	**11**
Power	w/o opt	0.99	34	0.99	12	**0.99**	**8**
	w/ opt	0.73	38	0.76	19	**0.86**	**12**

† Post-layout labels are collected in two scenarios: without considering optimization (denoted as "w/o opt") and with optimization as illustrated in [7] (denoted as "w/ opt").
* We adapt the GNN model from [7] for netlist power and area prediction, as it was originally designed for the layout-stage power prediction.

C. Comparision with pre-trained netlist encoders

In addition to the task-specific methods, we also compare NetTAG with pre-trained netlist encoders. Since they are all limited to combinational AIG circuits, we evaluate them only on Task 1, using an AIG-format dataset. As shown in Fig. 5, NetTAG outperforms SOTA AIG-based encoders, including FGNN [29] and DeepGate3 [27], achieving the highest average performance across all metrics. Notably, NetTAG achieves superior accuracy on the AIG dataset compared with more diverse gate datasets in TABLE III for Task 1, underscoring its adaptability. We also evaluate the standalone ExprLLM component of NetTAG, which performs well using symbolic expressions, highlighting the power of gate semantic understanding. These results emphasize NetTAG's advantage in combining semantic and structural information through the TAG format.

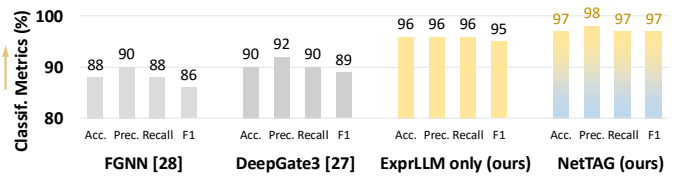

Fig. 5: Comparision with pre-trained AIG encoders on AIG dataset.

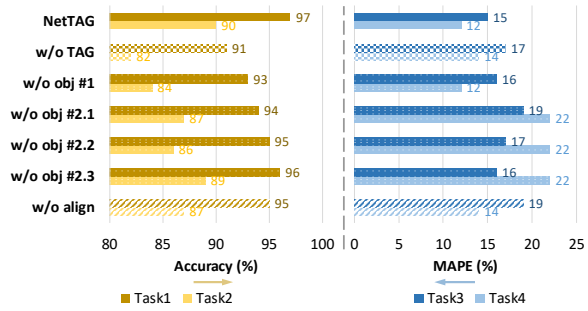

Fig. 6: Ablation study.

D. Ablation Study

This ablation study evaluates the contributions of three key aspects of NetTAG: TAG-based representation, self-supervised pre-training objectives, and cross-stage alignment. The analysis, shown in Fig. 6, highlights the impact of each component on the model's performance across the four tasks, with detailed analysis as follows:

Effectiveness of learning netlist via TAG. Removing text attributes and relying only on graph structure significantly reduces performance, especially on functional tasks. This indicates that semantic information from text attributes is crucial. Additionally, physical tasks also show a slight decline, suggesting that even structure-focused tasks benefit from the added semantic context in TAG.

Effectiveness of self-supervised pre-training objectives. The results demonstrate that the expression contrastive learning objective (#1) for ExprLLM has the greatest impact on functional tasks, suggesting it enhances the LLM's understanding of symbolic logic expressions. Objectives #2.1 (masked gate reconstruction) and #2.2 (graph contrastive learning) improve performance across both functional and physical tasks, highlighting their role in capturing both local and global netlist structure. Objective #2.3 (graph size prediction) shows the strongest effect on physical tasks, where a comprehensive understanding of the netlist's overall structure is essential.

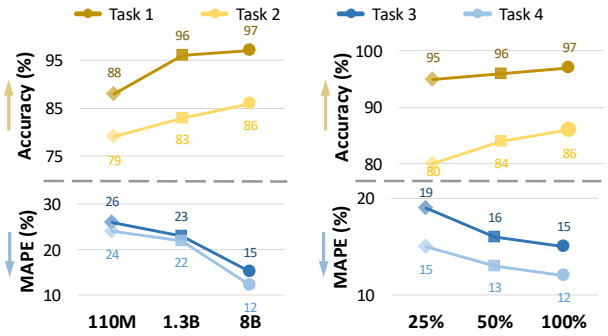
Effectiveness of cross-stage alignment. Removing cross-stage alignment leads to a notable drop in performance across all four tasks. This alignment effectively enhances NetTAG's ability to integrate both early-stage functional and late-stage physical information, which is crucial for downstream tasks.

E. Runtime Analysis

In TABLE VI, we present NetTAG's runtime across various benchmarks. Most runtime is spent on preprocessing (i.e., converting netlists into TAG format) and node-level inference using ExprLLM. Despite these steps, NetTAG demonstrates around a 10x speedup over traditional physical design workflows using commercial EDA tools. There is significant potential for further runtime improvements. For example, symbolic expression extraction for each gate can be highly parallelized, reducing preprocessing time. Additionally, the ExprLLM inference time could be largely reduced by scaling up GPU resources, as this runtime depends on GPU performance and quantity.

IV. Discussion

A. Scalability: Performance Scaling with Model and Data Size



In Fig. 7, we study how the downstream task performance of NetTAG scales with both model size and pre-training data size.

TABLE VI: Runtime (minutes) Comparision.

Source	EDA Tool	Ours (Avg.)			
	P&R (Avg.)	Pre*	Infer		Total
			ExprLLM	TAGFormer	
ITC99	164	2	5	0	7
OpenCores	288	18	12	1	31
Chipyard	251	15	10	1	26
VexRiscv	207	8	5	2	15
GNNRE	/	4	2	0	6

* Preprocessing (chunking into cones and converting netlist into TAG).

The plot shows the performance of each task after fine-tuning. Scaling ExprLLM backbone from 110M parameters (BERT) to larger models like Meta Llama 3.1 with 1.3B and 8B parameters results in significant performance improvements across all four tasks. Similarly, expanding data size from 25% to 100% of the dataset consistently enhances performance. These results demonstrate the scalability of NetTAG, suggesting that further increases in model and data size could lead to even greater improvements in accuracy and generalization.

(a) Increasing model size (b) Increasing data size

Fig. 7: Performance scaling with model and data size.

B. Demo: Reasoning Netlist's Arithmetic Function with NetTAG

Fig. 8 shows how NetTAG improves functional reasoning for arithmetic netlists. Using an LLM (e.g., OpenAI's o1-preview) to analyze post-synthesis netlist Verilog texts, we assess its ability to interpret the arithmetic function from the flattened netlists. Without NetTAG's gate-level function identification, the LLM struggles with interpreting functionality from flattened netlists. When integrated with NetTAG, the LLM accurately infers that the netlist module compares two 2-bit values, performs addition and multiplication, and selects the result based on the comparison outcome.

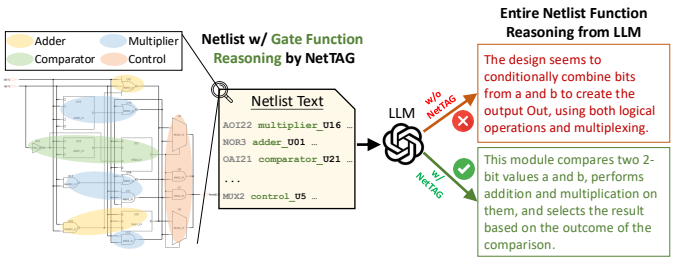


Fig. 8: A demo for reasoning arithmetic function from netlists.

V. Conclusion And Future Work

In this paper, we present NetTAG, a foundation model for netlist representation learning that accommodates diverse gate types and supports a range of functional and physical tasks. By formulating netlists as text-attributed graphs, NetTAG uniquely integrates gate semantics with graph structure through its multimodal architecture and self-supervised pre-training objectives. Future work will enhance NetTAG by extending pre-training to larger circuit datasets and exploring decoding methods to broaden task support capabilities.

***Abstract*—Hyperdimensional computing (HDC) based GNNs are significantly advancing the brain-like cognition in terms of mathematical rigorousness and computational tractability. However, the researches in this field seem to have a "*long vector consensus*" that the length of HDC-hypervectors must be designed to mimic that of cerebellar cortex, i.e., ten thousands of bits, to express human's feature-rich memory. To system architects, this choice presents a formidable challenge that the combination of numerous nodes and ultra-long hypervectors could create a new memory bottleneck that undermines the operational brevity from HDC. To overcome above problem, in this work, we shift our focus to rebuilding a set of more GNN-friendly HDC-operations, by which, short hypervectors are sufficient to encode rich features via enjoining the strong error tolerance of neural cognition. To achieve that, three behavioral incompatibilities of HDC with general GNNs, i.e., *feature distortion*, *structural bias*, and *central-node vacancy*, are found and successfully resolved for more efficient feature-extraction in graphs. Taken as a whole, a memory-efficient HDC-based GNN framework, called CiliaGraph, is designed to drive one-shot graph classifying tasks with only hundreds of bits in hypervector aggregation, which offers 1 to 2 orders of memory savings. The results show that, compared to the SOTA GNNs, CiliaGraph reduces the memory access and training latency by an average of 292× (up to 2341×) and 103× (up to 313×), respectively, while maintaining the competitively accuracy.**

***Index Terms*—GNN, hyperdimensional computing, memory, graph representation.**

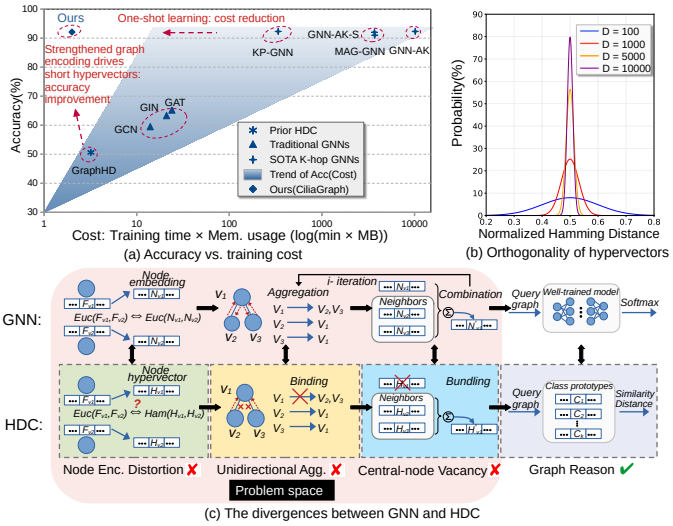

Fig. 1: Problem space of SOTA HDC and aims of our work.

I. Introduction

Hyperdimensional computing (HDC) utilizes long hypervectors to mimic the behaviors of the cerebellar cortex in brains, which successfully provides various desirable properties that other machine learning methods lack, such as simple operations, one-shot learning, and robustness to noise [1]. Accordingly, the brain-inspired HDC is introduced in traditional graph neural networks (GNNs) [2]–[5] to fully function its mathematical rigorousness [6] and computational tractability [7]. These HDC-based GNNs no longer require interminable training and expensive matrix operations, yet still achieve competitive model accuracy, as a result, being increasingly popular in graph cognitive tasks on edge devices [7]. Although the ultra-long hypervectors, e.g., tens of thousands bits, faithfully replicate the natural configuration in human brain, they pose a new challenge for system architects in terms of memory bottleneck, i.e., numerous nodes represented by long hypervector for each. Therefore, whether it is possible to encode rich features using shorter hypervectors remains an open question (Fig. 1(a)).

Hypervectors for rich features. Unlike NN-based feature encoding in general GNNs [8], HDC-based approaches commonly employ superposition of orthogonal hypervectors to fuse multiple features [9]. To forcibly convert numerical node features into hypervectors, two typical methods are widely adopted in their superposition: 1) ***random projecting*** [4], [5] and 2) ***leveled mapping*** [9]. The former directly scales the random hypervectors proportionally to their corresponding feature values and then sums them up to create a fused hypervector as the representation of multiple features, which always invokes a *majority function* [7] in final to revert the vectors to their binary forms, i.e., $(\{\mathbb{R}\}^D \rightarrow \{-1, 1\}^D$. The latter stochastically encodes feature values into pre-defined hypervectors as the weight to process "*bind-and-bundle*" operations (a.k.a. the "multiply-and-add" in HDC version) on corresponding orthogonal hypervectors, which removes the expensive *majority function*, meanwhile, retains the simple operation of binary. A common drawback of above methods is that features with clearly numerical implication become less distinguishable in hyper-dimensional spaces, particularly when a node has rich features, e.g., COIL-RAG [10] dataset even with 64 features. To compensate for the loss of feature representation, designers have been compelled to use a system-unfriendly choice that using a large amount of memory to hold much longer vectors [1], [4], [11], [12] for higher resolution of numerical features.

A key debate: Some fundamentalists of brain-inspire computing insisted on the necessity of ultra-long hypervectors for HDC-based GNNs. Their arguments come from a mathematical criterion that, in theory, hypervectors shorter than $10,000$-bits cannot ensure the high-quality of orthogonality (Fig. 1(b)), which has even been seen as the "*golden rule*" of any correct HDC [6], [11]. However, to system

*Corresponding author

architects, it's too expensive to use $10,000$-bits vectors to encode only one of node features. For example, to store one node with three features quantized to 8-bit FxP, its numerical embedding only needs 128 bytes in general GNNs [8], but unfortunately, the equivalent hypervector requires an unacceptable 29.3KB, which is almost out of reach at system level. Therefore, redundant hypervectors lead to severe inefficiency in memory, which casts doubt on the continued adherence of the "*golden rule*".

In this work, we find that the core difficulty of HDC-based GNNs is its inability to faithfully execute each steps involved in a standard GNN process [13], leading to three kinds of operational noises in below that significantly weaken the extraction of multiple features (Fig. 1(c)). ***Noise-1***: In feature encoding, by replacing the Euclidean distance with the simple Hamming one between hypervectors, both *random projecting* and *leveled mapping* introduce a distortion in the coding space, failing to accurately measure the relationships as the original numerical feature spaces. ***Noise-2***: The originally bidirectional and symmetric *aggregation* in GNNs has been simplified to a unidirectional tree-like *binding* in the existing HDC [3], [7], causing a structural bias of their graphs. ***Noise-3***: During *combination* stage, standard GNNs always fuse neighboring nodes with the central one (h^i) to generate a new embedding (h^{i+1}), however, existing HDCs, without exception, ignore central nodes via a socalled "equivalent" *bundling* [1], [4] which produces a *central-node vacancy* in the process of embedding fusion. As seen in Sec. II, these three divergences jointly result in the suppressed expressability of hypervectors, inevitably making low efficiency in memory usage.

To overcome the problems, we design a hypervector space that preserves the original numerical distribution of node features, meanwhile, enjoys the encoding efficiency of HDC. Based on the space, a fully symmetric on-edge *binding* is proposed to adhere the embedding aggregation in standard GNNs without the structural bias of graphs. To repair the vacated central nodes, a new concatenation operator is propose to merge periphery and central hypervectors before the final reason produced. Our proposed GNN framework, called CiliaGraph, demonstrates the feasibility of the aforementioned operations in one-shot graph classifying tasks using only 200-bit hypervectors. The results show that, compared with SOTA GNNs, CiliaGraph reduces memory usage and training time by 292× and 103× (up to 2341× and 313×) respectively. Our contributions include:

1. We identify the three sources of weak expression by hypervectors in HDC-based GNNs as the system-unfriendly compromise, i.e., long hypervectors, in the past.
2. CiliaGraph, including a set of new HDC operators, is proposed to mimics the information merging in GNNs, which demonstrates the feasibility of ultra short hypervectors in GNNs.
3. The results show the applicable of CiliaGraph in one-shot graph classifying tasks on widespread datasets and the great memory saving makes it well-suited for on-edge HDC-based GNNs.

II. Background and Motivation

A. HDC and the operators in GNNs

Traditional HDC models employ D-dimensional binary hypervectors as the fundamental elements for computation in $\mathcal{HD}$ space. Let's assume $\mathcal{H}_1, \mathcal{H}_2 \in \{-1, 1\}^D$ are two randomly generated hypervectors and their similarity $\delta(\mathcal{H}_1, \mathcal{H}_2) \approx 0$. ***Binding*** of $\mathcal{H}_1$ and $\mathcal{H}_2$, i.e., $\mathcal{H}_1 \otimes \mathcal{H}_2$, is component-wise multiplication (XOR in binary) and generates a new hypervector that is dissimilar to its two constituents, i.e., $\delta(\mathcal{H}_1 \otimes \mathcal{H}_2, \mathcal{H}_1) \approx 0$, which is used to find the association of two hypervectors [4]. ***Bundling*** is component-wise addition of two hypervectors, i.e., $\mathcal{H}_1 \oplus \mathcal{H}_2$, that memorizes its all

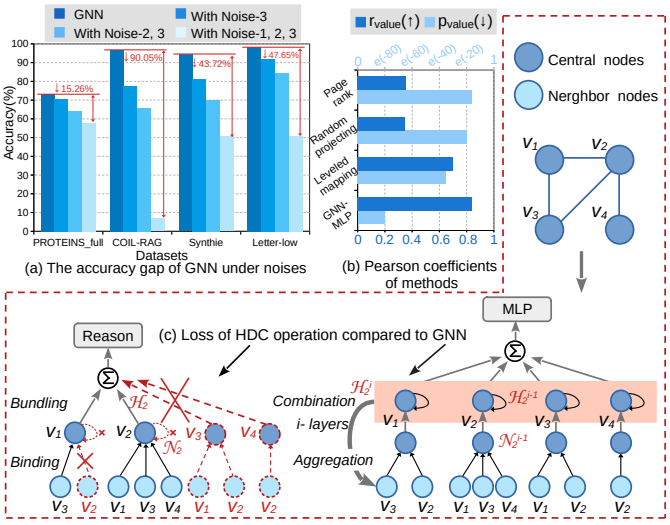

Fig. 2: A motivational analysis of accuracy loss under three noises introduced by HDC operators.

components, therefore, the result is similar to its every component, i.e., $\delta(\mathcal{H}_1 \oplus \mathcal{H}_2, \mathcal{H}_1) >> 0$. ***Reasoning*** is to measure the similarity of two hypervectors and generally utilizes Hamming distance or dot product [11]. The above three HDC primitives are adopted widely in the most HDC-based GNNs.

For a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, current HDC-based GNNs aim to mimic the feature extraction of traditional GNNs (Fig. 1(c)), where, 1) the node embeddings are recoded with ultra-long hypervectors, 2) the aggregation can be alternated as their binding, 3) the combination is just the bundling of all neighboring hypervectors, and 4) the final MLP is done efficiently with HDC reasoning. However, these purportedly "equivalent" operations exhibit unmatched capabilities in feature extraction on graphs. The ablation study (Fig. 2(a)) clearly demonstrates a stepwise decline, or noise, in the model inference accuracy as we progressively replace GNN operators with their HDC counterparts, i.e., combination→bundling (10.27% ↓), aggregation→binding (9.34% ↓), and embedding→hypervector (29.57% ↓) respectively. Resultantly, the SOTA HDC-based GNNs are generally 49.17% less accurate than traditional GNNs [3], [12], which has driven designers to the short-sighted solution of employing longer hypervectors, akin to a poisoned chalice. In next, the three deeper causes of these declines are analyzed.

B. Hypervector: Distortion of Distance in Feature Encoding

Effective numerical encoding using HDC has always been a challenging problem, primarily due to the inherent tension of ensuring both strict *orthogonality* and correct *numerical distances* between two hypervectors [6]. In practice, more efforts focus on maintaining the orthogonality, rather than the distances [1], [7], because they speculated that hypervectors, a.k.a. discrete random bit sequences, could represent the numerical disparities of features well as long as they are long enough. Unfortunately, our a comparative study on distance-isomorphism reveals a widespread severe distortion the hypervector spaces (Fig. 2(b)). This study summons Pearson's coefficient [14] to quantify **1)** r – the correlation between "the hypervector distances in $\mathcal{HD}$ spaces" and "the embedding distances of numerical features," and **2)** p – the error of r. The results shows that PageRank, Random-Projecting, and Leveled-Mapping, as the three most popular encoders in HDC ($r \downarrow, p \uparrow$), seriously deviate the expected GNN features ($r \uparrow, p \downarrow$), which confirms our doubt that long hypervectors are disable to encode the numerical features in GNNs. In this work, a plastic random bit-flip (PRBF) encoding is proposed

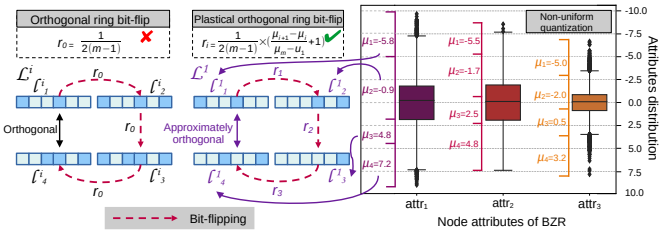

Fig. 3: Improved plastic orthogonal ring introduce a non-fixed flip rate compared to orthogonal ring.

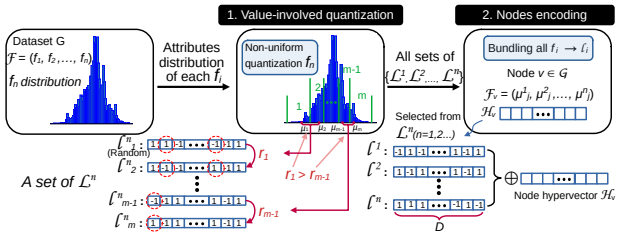

Fig. 4: The steps of plastic random bit-flip encoding

to fine-tune the random flips according to both feature values and their distributions, effectively overlaying numerical distance onto orthogonal hypervectors (Sec. III-A).

C. Binding: Structural Bias by Unidirectional Tree-like Aggregation

Standard GNNs are always capable of accurately learning graph structures, primarily by the bidirectional aggregation through edges, i.e., connectivity, which drives aggregation strictly adhering to the data-flow defined by a graph structure. In contrast, existing HDC-based one-shot solutions [3], which employ unidirectional binding to rapidly reduce long hypervectors to relieve memory pressure, simplify all complex graph structures into a tree that biases original graph structures. As shown in Fig. 2(c), while one edge in the original graph (e.g. $e_{1,2}$) triggers bidirectional binding in GNNs ($v_2 \rightarrow v_1$ for v_1 and $v_1 \rightarrow v_2$ for v_2), in HDC however, only the more important nodes (such as v_2) are responsible for collecting the neighbor features ($v_1 \rightarrow v_2$) and the reversed binding ($v_2 \rightarrow v_1$) are totally neglected. Reducing the symmetric GNN aggregations to half asymmetric ones limits the global structural information captured during the binding of HDC (Fig. 2(c)). In this work, a precise aggregation, i.e., *differential aggregation*, is proposed (Sec. III-B), which not only implements bidirectional symmetric aggregation as in GNNs but also leverages on-edge weights to modulate the strength of peripheral hypervectors, thereby achieving the full function of aggregating capabilities of GNNs.

D. Bundling: Vacancy of Central Nodes during Combination

The last drawback of HDC-based GNN lies in its perfunctory way in bundling, which abruptly overwhelms [4], [5], or even removes [3], the central nodes during the combination, resulting in a significant departure from the standard procedure of GNNs. As shown in Fig. 2(c), during the standard combination of GNNs, a node (e.g., v_2) stores a local embedding ($\mathcal{H}_2^{i-1}$) to memorize the embeddings of historical levels. By combining local embeddings with the aggregated peripheral ones of current layer, GNNs facilitate an embedding update of central node, e.g., $COMB(\mathcal{H}_2^{i-1}, \mathcal{N}_2^{i-1}) \rightarrow \mathcal{H}_2^i$, by which, peripheral features ($\mathcal{N}_2^{i-1}$) can incrementally contribute to a central node until all node features are well extracted. In opposite, as a one-pass algorithm, HDC inherently doesn't require storing the history of hypervectors, therefore, to save memory space, existing methods either exclude the features of central nodes from combination, e.g., $BUNDLE(\mathcal{N}_2) \rightarrow \mathcal{H}_2$, or degrade them equally with that of neighbors, e.g., $BUNDLE(\mathcal{N}_2 \oplus H_2) \rightarrow \mathcal{H}_2$. In this work, we propose a simple concatenation method, where, a central node and its peripheral nodes, as a whole, individually occupy half of the hypervector length to highlight central features like standard GNNs.

III. Strengthening the Representation of Hypervectors

A. Plastic Random Bit-Flip Encoding

Value-involved quantization for hypervectors. To overcome the distortion in hypervector encoding, inspired by a previous works [15], we propose an encoding method that utilizes the values of features to proportionally and randomly flip the bits to generate new hypervectors. Initially, the n features of a node constitute n independent hypervector spaces. For the i-th space $\mathcal{L}^i$, all possible values it can sample form a quantization space, which is defined by upper and lower bounds and a sampling distribution. Thus, the range between the upper and lower bounds can be divided into m quantization centers $(\mu_1^i, \mu_2^i, \ldots, \mu_m^i), \mu_x^i < \mu_y^i$ *when* $x < y$, called *clusters*, with each cluster mapped to a representative hypervector l_j^i. Consequently, $\mathcal{L}^i$ can be represented by m ordered hypervectors $\mathcal{L}^i = (l_1^i, l_2^i, \cdots, l_m^i)$ to encode the m quantization centers, that is, when the value of the i-th feature f_i falls into the j-th cluster μ_j^i, f_i is directly encoded as l_j^i. Under this method, the only remaining challenge is how to initialize an ordered set of hypervectors l_j^i to faithfully capture the distribution of feature values.

Plastical orthogonal ring. In order to achieve a quantization hypervector (l_j^i) that's equivalent to numerical space (μ_j^i), a orthogonal ring method is proposed in [7]. It constructs multi-level hypervectors $(l_2^i \cdots, l_{m-1}^i)$ with gradually and randomly flipping between two orthogonal vectors (l_1^i, l_m^i), ensuring the similarity between adjacent vectors is a fixed quantization step (Fig. 3), i.e., $\delta(l_j^i, l_{j+1}^i) = \frac{1}{2(m-1)}$ and $\delta(l_1^i, l_m^i) = 0$ (Note: the zero δ hints that there are half different bits between l_1^i and l_m^i). However, this method still introduces significant noise, which is primarily due to the poor accuracy in those dense regions, where finer granularity must be very useful in quantization. Therefore, an improved *plastical orthogonal ring* is built to allocate different bit-flipping rates (r_i) according to the numerical distance between two plastical clusters, rather than a fixed step, meanwhile ensuring $\delta(l_1^i, l_m^i) \approx 0$ (i.e., *approximately orthogonal*). By introducing a plastic factor $\frac{\mu_{i+1}-\mu_i}{\mu_m-\mu_1}$, each quantization step becomes flexible as:

$$r_i = \frac{1}{2(m-1)} \times \left(\frac{\mu_{i+1} - \mu_i}{\mu_m - \mu_1} + 1 \right) \quad \text{for} \quad 1 \leq i \leq m-1 \qquad (1)$$

where, the former term is the fixed step that divides half of a hypervector ($\frac{1}{2}$) into $m-1$ bit-flipping steps and the later term uses the plastic factor to decide the adaptation to each step (Fig. 3). This adaptation can provide more scalability for those dense regions, at the same time, guarantee the orthogonal ring like [7].

Non-uniform quantization with Hypervectors. Based on the plastical orthogonal ring, the non-uniform quantization in numeral space can be isomorphically mapped into the non-equidistant hypervector space. For example, in Fig. 4, the dense region is quantized as narrower clusters, dropped int which, the corresponding hypervectors also have larger similarity since they have undergone fewer bit flips during initialization. After obtaining the orthogonal hypervectors of all features ($f_i \rightarrow l^i, 1 \leq i \leq n$), those hypervectors are further bundled to generate the representation of a node, i.e., $\mathcal{H}_v = \oplus_{i=1}^n l^i, v \in \mathcal{V}$.

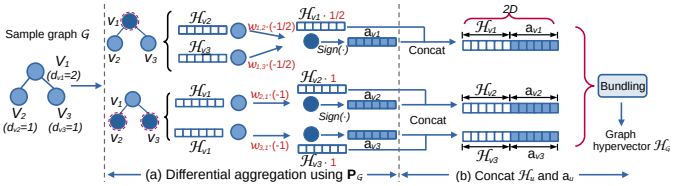

Fig. 5: Aggregation using hyper-weight matrix and equal concatenation.

B. Differential Aggregation for Structural Enhancement

Based on the discussion in Sec. II-C, to be equivalent to GNNs, an HDC-based aggregation should have the ability to 1) estimate the structures around a central node, 2) assess the strength of connections symmetrically between nodes, and 3) inject peripheral nodes into the central node as the aggregation (a_u). Recognizing the disability of the simple binding operation, we propose a novel differential scheme to take charge of the hypervector aggregation. Above all, in a graph, the feature distance between any two nodes can be represented by their similarity of hypervectors, i.e., $w_{u,v} = \delta(\mathcal{H}_u, \mathcal{H}_v), u, v \in \mathcal{V}$, which forms a weight matrix $\mathbf{W}_\mathcal{G} \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{V}|}$ among nodes to involve all connecting strength. Then, the connectivity $t_{u,v}$ between a central node u and all other nodes, e.g., v, is defined as: 1) $t_{u,v} = \frac{1}{d_u}$ if $u = v$, 2) $t_{u,v} = -\frac{1}{d_u}$ if $e_{u,v} \in \mathcal{E}$, and 3) otherwise $t_{u,v} = 0$, where d_u is the degree of node u. Therefore, all $t_{u,v}$ constitute another transition matrix $\mathbf{T}_\mathcal{G} \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{V}|}$ that asserts the peripheral structure of each node.

By a Hadamard product ($\circ$) of above two matrices, both of feature similarity and connectivity are merged into a sole ***hyper-weight matrix***, i.e., $\mathbf{P}_\mathcal{G} = \mathbf{W}_\mathcal{G} \circ \mathbf{T}_\mathcal{G}$, where $p_{u,v} = w_{u,v} \times t_{u,v}$. In short, the $\mathbf{P}_\mathcal{G}$ has three explainable properties in below. ***First***, $\mathbf{T}_\mathcal{G}$ structurally filter the similarity values of all elements in $\mathbf{W}_\mathcal{G}$, by which, the resultant matrix $\mathbf{P}_\mathcal{G}$ yields perfect alignment with graph structure. ***Second***, as the basis of u-centered aggregation, the u-th diagonal element $p_{u,u} = \frac{1}{d_u}$ is inversely proportional to the degree of node u, which hints that a central node could contribute less during aggregation when it has more neighbors. ***Third***, the off-diagonal elements in the u-th row, i.e., $p_{u,v} = -\frac{\delta(\mathcal{H}_u,\mathcal{H}_v)}{d_u}$ for $\forall u \neq v$, are the scaled-down similarities, in which, $\frac{1}{d_u}$ ensures an equal contribution of all neighbor as central, meanwhile, the negative sign ("$-$") is used to precisely extract the difference between a central and its environment. Our results in Sec. V-E show that the hyper-weight matrix is powerful in merging structure and similarity.

Aggregation using hyper-weight matrix. Since matrix $\mathbf{P}_\mathcal{G}$ incorporates both structural and distance information, we use it as the weight matrix for graph aggregation, such as a_u of node u, as shown in below:

$$a_u = Sign(\bigoplus_{v\in\mathcal{N}_u^*} (p_{u,v} \times \mathcal{H}_v)) \quad \text{with} \quad \mathcal{N}_u^* = \mathcal{N}_u \cup \{u\} \tag{2}$$

where, $\mathcal{N}_u$ contains all the neighbors of u, the bundling operation ($\oplus$) collects all weighted similarities, both central u and its periphery, as the aggregation on u, and the $Sign$ operation maps each elements to $+1$ or -1 according to the sign of the collected results for a convenient combination in next (Fig. 5(a)). In summary, the similarity and connectivity between centrals and peripheries are concentrated in the hyper-weight matrix to aggregate surrounding hypervectors, which faithfully mimics the embedding flow in traditional GNNs.

C. Concatenation for Lightweight Combination

As mentioned in Sec. II-D, current HDC methods always neglect central nodes, which weakens their bundling-based combination. To address this issue, in this work, we directly concatenate the feature hypervectors with its aggregation, i.e., $\tilde{\mathcal{H}}_u = CONCAT(\mathcal{H}_u, a_u)$, which allows a central to occupy half of its entire hypervector length and significantly enhances its role in the final *reasoning* (Fig. 5(b)). The effectiveness of this method stems from three sources: 1) a_u provides all peripheral situation of a node, including its neighbor similarity and connectivity; 2) as the initial feature, $\mathcal{H}_u$ memorizes the intrinsic properties of a central; and 3) the equal occupancies of the two information balance their impacts successfully. In addition, the ultra-short hypervectors used in our implementation removes the worry about the memory expansion by the twice length with $\tilde{\mathcal{H}}_u$ (Sec. IV-B).

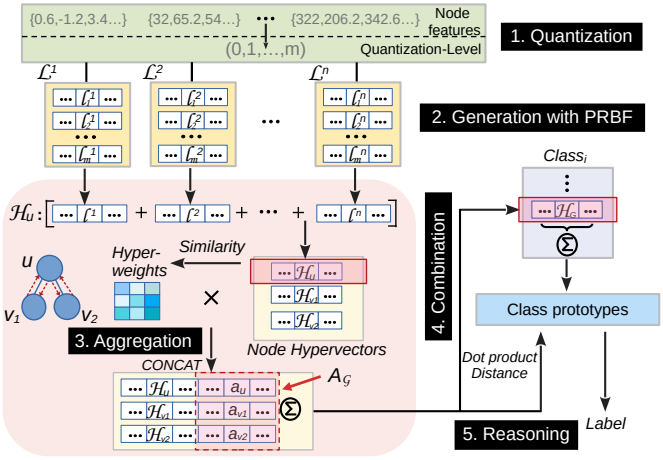

Fig. 6: The framework of CiliaGraph.

IV. Implementation of Memory-Efficient CiliaGraph

A. The Workflow of CiliaGraph

Based on the above operations, CiliaGraph, a new HDC-based graph processing framework, is proposed to achieve both memory-efficient and fast graph classifications, as shown in Fig. 6.

1) Quantization based on prior distribution. To determine the quantization levels mentioned in Sec. III-A, our approach necessitates a priori distribution of each feature that's pertinent to specific tasks, e.g., COIL-RAG, Synthie [10] ... The statistical outcomes are fed into a K-means algorithm [16] to be classified as m quantization centers, i.e., $(\mu_1^i, \mu_2^i, \ldots, \mu_m^i)$, which are associated with their hypervector $\mathcal{L}^i$ for a node i. This method is able to statically find fine-grained centers within sampling ranges, improving the representability compared to traditional uniform levels of quantization [7].

2) Generation of feature-rich hypervectors. To encode n numerical features of a node u into a hypervector, first of all, those features $F_u = (f_1, f_2, \cdots, f_n)$ are individually clustered into quantization centers and replaced with their hypervectors, i.e., $(l^1, l^2, \ldots, l^n)$, by being fetched from $\mathcal{L}^i$. After that, they bundled into a $\mathcal{H}_u$ hypervector, see Sec. III-A. In theory, this approach can merge and encode any number of feature elements without the memory explosion problem under feature-rich contexts.

3) Aggregation using symmetric flows. For symmetric aggregation like GNNs, CiliaGraph propagates hypervectors bidirectionally along all edges, resulting in a central aggregation process at each node. This flow is controlled by the Hyper-weight matrix and all aggregated results are stored in a aggregation matrix $A_\mathcal{G}(a_1, a_2, \cdots, a_{|\mathcal{V}|})$, occupying $|\mathcal{V}| \times D$ memory space. Due to the highly parallelizable nature with our vectorized aggregation, it can easily leverage almost all parallel architectures, such as multi-cores, GPUs and FPGAs.

4) Combination with high memory-efficiency. A concatenation-based combination requires accessing two data in memory: the feature hypervector and its aggregated hypervector. Then, these hypervectors are concatenated together, i.e., $[\mathcal{H}_i, a_i]$, and directly forwarded to subsequent *reasoning* step. By representing l^i and a_i with only a few hundred bits, e.g., $D = 120$ in our experiments (Sec. V-C), CiliaGraph ensures that the concatenation remains memory-efficient.

5) Reasoning for one-shot graph classification. The reasoning is same to the classical HDC processing that bundles all graph nodes together, i.e., $\oplus_{i=1}^{|\mathcal{V}|}[\mathcal{H}_i, a_i]$, and calculates the dot product distances between the result and all class prototypes (a set of label hypervectors). The class with the smallest distance is finally selected as the reasoning output. In next, we present the theoretical evidence about why our short hypervectors outperforms conventional long vectors in memory usage.

B. Memory Efficiency of CiliaGraph: A Theoretical Analysis
