The Unwritten Contract of Cloud-based Elastic Solid-State Drives

Yingjia Wang and Ming-Chang Yang
The Chinese University of Hong Kong

***Abstract*—Elastic block storage (EBS) with the storage-compute disaggregated architecture stands as a pivotal piece in today's cloud. EBS furnishes users with storage capabilities through the elastic solid-state drive (ESSD). Nevertheless, despite the widespread integration into cloud services, the absence of a thorough ESSD performance characterization raises critical doubt: when more and more services are shifted onto the cloud, can ESSD satisfactorily substitute the storage responsibilities of the local SSD and offer comparable performance?**

In this paper, we for the first time target this question by characterizing two ESSDs from Amazon AWS and Alibaba Cloud. We present an unwritten contract of cloud-based ESSDs, encapsulating four observations and five implications for cloud storage users. Specifically, the observations are counter-intuitive and contrary to the conventional perceptions of what one would expect from the local SSD. The implications we hope could guide users in revisiting the designs of their deployed cloud software, i.e., harnessing the distinct characteristics of ESSDs for better system performance.

I. Introduction

Elastic block storage (EBS) has become the cornerstone of today's cloud, underpinning the high-performance storage demand from diverse cloud services [1]–[5]. As shown in Figure 1, EBS typically adopts a storage-compute disaggregated architecture, with compute and storage clusters located separately and interconnected by the high-speed datacenter network. In EBS, the virtual machines (VM) for users are hosted in the compute cluster while the user data is persistently stored in the storage cluster. This architectural innovation not only enhances the efficiency and elasticity of the cloud infrastructure, but also improves the cost-effectiveness for users on a flexible and pay-as-you-go basis.

EBS provides storage resources for users in the form of *elastic solid-state drive*, which, for simplicity, is called *ESSD* in the following. ESSD is a virtualized storage device attached to the user VM, employing the block interface and supporting random access (e.g., read and write) in the storage space. From the perspective of the user, ESSD is similar to the well-known local SSD, on which the existing filesystems and applications can be directly deployed. But differently, the most noteworthy feature of ESSD is that it breaks the physical performance and capacity boundaries of the local SSD. This makes it possible to elastically guarantee performance level (e.g., in throughput and IOPS) and allocate storage capacity, to accommodate the ever-changing demands of users.

This work is supported in part by The Research Grants Council of Hong Kong SAR (Project No. CUHK14218522).

The rapid development of cloud computing has fostered the widespread adoption of ESSDs in numerous cloud services. *However, to the best of our knowledge, there has been no comprehensive performance characterization of cloud-based ESSDs.* As the majority of host software now is designed and optimized for the local SSD, this research gap raises concerns in the following question: *when more and more services are shifted onto the cloud, can ESSD satisfactorily substitute the storage responsibilities of the local SSD and offer comparable performance?*

To this end, we make the first endeavor to answer this question by characterizing two ESSDs from two leading cloud storage providers in the world: Amazon AWS [6] and Alibaba Cloud [7]. Based on extensive experiments, we surprisingly find that ESSD exhibits several counter-intuitive performance features, contrary to the common beliefs of the local SSD.

The Unwritten Contract of Cloud-based ESSDs

Observations

1) *The latency of ESSDs is tens to a hundred times higher than that of SSD when I/Os are not well scaled up (i.e., I/O size is small and/or I/O queue depth is low).*
2) *The performance impact of GC appears much later or even disappears.*
3) *The throughput of random writes outperforms that of sequential writes, reaching a maximum of 1.52× and 2.79× in two ESSDs, respectively.*
4) *The maximum bandwidth is deterministic and no longer sensitive to the access pattern.*

Implications

1) *Scale the I/O sizes and I/O queue depths up as much as possible.*
2) *Reconsider if and how existing GC-mitigated techniques based on local SSDs should be correspondingly adapted for ESSDs.*
3) *Rethink if it is still worthwhile to convert random writes in random-write-based software into sequential writes and if it is beneficial to proactively trigger random writes in sequential-write-based software.*
4) *Smooth the read/write I/Os to be evenly distributed across the timeline and below the guaranteed throughput budget.*
5) *Re-evaluate I/O reduction techniques (e.g., compression, deduplication) that were previously considered to impair performance.*

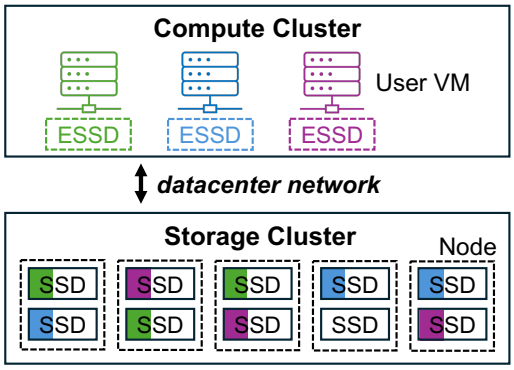

Fig. 1. **The storage-compute disaggregated architecture of elastic block storage (EBS).** ESSD is attached to the user virtual machine (VM) in the compute cluster. The physical storage space of an ESSD is distributed and replicated across different nodes and SSDs in the storage cluster.

We present an unwritten contract of cloud-based ESSDs, organized into four observations and five implications, as shown above. Over the past years, cloud storage users have been requesting ever-higher service-level agreements (SLA). This places higher expectations not only on cloud storage providers but also on users themselves in terms of their deployed software. The unwritten contract we offer in this paper could benefit cloud storage users to revisit their cloud software designs, specifically, to unleash the better potential of ESSDs by leveraging unique performance characteristics. We open-source the evaluation framework to stimulate the following studies[1].

In the following of this paper, we first provide the background of (local) SSD, EBS, and ESSD in §II. We present the unwritten contract in detail in §III. The related work and conclusion are introduced in §IV and §V, respectively.

II. Background

A. Flash-based Solid-State Drive (SSD)

Flash-based SSD has achieved a high and continuously increasing share in the storage market due to the benefits in performance, energy efficiency, and impact resistance. According to IDC, the byte shipment share of SSDs is expected to reach about 40% of the total in 2025 [8]. Flash-based SSD typically adopts a multi-level architecture, including channel, die, plane, block, and page. The flash die is the minimum unit of parallel operations while the flash page is the minimum unit of data storage. To improve SSD firmware management efficiency, flash blocks are typically grouped into superblocks, each of which comprises flash blocks across many flash dies to fully leverage flash parallelism.

To communicate with the host, the SSD longstandingly employs the *block interface*, which abstracts the storage space into an array of logical blocks (e.g., 4KB) that can be randomly read or written. While this simple abstraction has successfully contributed to the broad adoption of SSDs, a complex *flash translation layer (FTL)* is required in the SSD to bridge the gap with the underlying flash characteristics (e.g., erase-before-write). The two main duties of FTL are address mapping and garbage collection (GC). The address mapping converts logical addresses from the host to the physical addresses in the SSD by keeping track of a fine-grained (e.g., page-level) mapping table. The GC is carried out periodically to reclaim invalid space in the granularity of flash blocks, when the valid pages in some blocks are relocated and these blocks can be erased. FTL is also responsible for other tasks such as wear-leveling [9], error correction [10], and bad block management [11].

B. Elastic Block Storage (EBS)

As shown in Figure 1, *elastic block storage (EBS)* typically employs a storage-compute disaggregated architecture with independent compute and storage clusters, and the two clusters are not physically co-located but interconnected with the high-speed datacenter network. The *compute cluster* hosts virtual machines (VM) for users and forwards user requests to the backend storage cluster, while the *storage cluster* persists or fetches requested data in a distributed filesystem.

The disaggregation architecture of storage and compute brings out several benefits [1], [3], [5]. First, the storage and compute resources can be elastically paid and allocated according to the user target workloads. This allows for higher resource utilization while enhancing the cost-effectiveness for users, compared to offering general-purpose servers. Second, the resources in storage and compute clusters can be maintained and scaled independently, thereby realizing higher maintainability and scalability. Third, it is simpler and faster to migrate application services across compute servers, given that their states can be persistently stored in storage servers.

C. Elastic Solid-State Drive (ESSD)

EBS provides storage resources for users in the form of *elastic solid-state drive (ESSD)*, which is a virtualized storage device attached to user VM. ESSD can be created, attached, unattached, and destroyed without disrupting the user VM. Figure 1 illustrates the mapping relationship between the virtualized ESSD and the (multiple) physical SSDs. That is, the physical storage space of an ESSD is typically distributed and replicated (e.g., three-way [3]) across different nodes and SSDs in the storage cluster, for the purposes of load balancing and data availability.

From the user's point of view, ESSD is similar to the well-known local SSD in that ESSD also employs the block interface and supports random access in the storage space. This ensures seamless compatibility with the existing software ecosystem, and facilitates the existing file systems and applications can be directly deployed on ESSDs.

Nonetheless, beyond the local SSD, ESSD delivers several additional benefits [3], [6], [7]. First, ESSD is virtualized, which breaks the physical performance and capacity boundaries in the local SSD. As a result, both the performance level (e.g., in throughput and IOPS) and the storage capacity can

[1]https://github.com/yingjia-wang/UC

TABLE I
THE CONFIGURATIONS OF TWO ESSDS AND SSD.

	Provider and Type	Max. BW (GB/s)	Max. IOPS	Cap. (TB)	VM Type	Region
ESSD-1	Amazon AWS io2 [12]	∼3.0	25.6K	2	m6in.xlarge	Tokyo
ESSD-2	Alibaba Cloud PL3 [7]	∼1.1	100K	2	ecs.g5.4xlarge	Hangzhou

be flexibly requested in response to the ever-changing user requirements. Second, ESSD can ensure high data availability and reliability, thanks to the data replication across multiple nodes to prevent single-point failure. Third, ESSD also enables some advanced features such as encryption and snapshotting.

Cloud storage providers typically offer multiple ESSD types with varying performance levels. Different performance levels guarantee different budgets in maximum throughput and maximum IOPS (higher is usually more expensive). For reference, Amazon AWS [6] supports general-purposes types (i.e., gp2, gp3) and provisioned-IOPS types (i.e., io1, io2), where io2 is the most advanced one. Alibaba Cloud [7] supports four performance levels: PL0, PL1, PL2, and PL3 (the higher the number the better the performance).

III. UNWRITTEN CONTRACT OF CLOUD-BASED ESSDS

Despite the prevalent integration in diverse cloud services, to the best of our knowledge, the performance features of the ESSD have not been adequately investigated and revealed. In this section, we present an unwritten contract of cloud-based ESSDs. In the following, we begin with the experimental setups, and then introduce our unwritten contract in detail.

Note that this paper focuses on the device-level performance characterization as in prior work [14]–[16] without exploring specific pieces of software, in the hope of benefiting a wider range of cloud storage users to revisit their software designs.

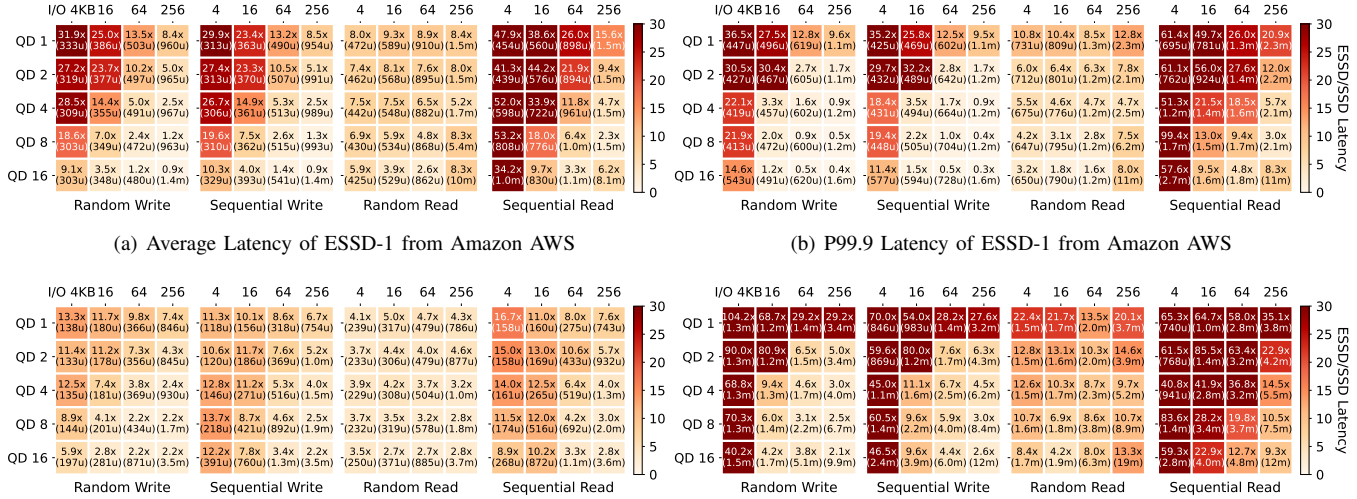
A. Experimental Setups

To strengthen the generalizability of findings, we characterize two ESSDs from two leading cloud providers in the world (i.e., Amazon AWS [6] and Alibaba Cloud [7]), and the configurations of ESSDs are summarized in Table I. Specifically, both ESSDs have the highest-class types available from their providers, making their maximum bandwidth comparable to that of the local SSD.

To demonstrate the features of the local SSD for comparison, we also evaluate Samsung 970 Pro [13], a popular SSD in research, and its configurations are also listed in Table I. Experiments on Samsung 970 Pro are running on a workstation PC, equipped with Intel® Xeon® W-2245 Processor, where the operating system is 64-bit Ubuntu 20.04 LTS with Linux kernel version 5.15.0.

We employ the widely-used FIO benchmark tool [17] to generate workloads with diverse loads (i.e., I/O size and I/O queue depth) and access patterns (i.e., random write, sequential write, random read, and sequential read). The detailed workload settings are introduced in each subsection below.

B. Latency Performance



Observation #1: *The latency of ESSDs is tens to a hundred times higher than that of SSD when I/Os are not well scaled up (i.e., I/O size is small and/or I/O queue depth is low).*

ESSD can meet the user's best expectations if it can provide comparable performance (e.g., throughput and latency) to the local SSD. However, even though the maximum throughput that ESSD can provide reaches the level of GBs, we discover that the latency of ESSDs is extremely unsatisfactory when I/Os are not well scaled up. Here, we define *"not well scaled up"* as workloads dominated by small-size I/Os and/or low I/O queue depths. Figure 2 demonstrates the average and P99.9 latency of two ESSDs under different access patterns (i.e., random write, sequential write, random read, and sequential read) with I/O sizes varied from 4KB to 256KB and I/O queue depths varied from 1 to 16. Particularly, let us focus on the multiples the ESSD latency is divided by the SSD latency (i.e., the top of each pixel in Figure 2), with smaller numbers being better. For simplicity, we call this metric *latency gap* in the following of this subsection.

We can first observe that, the latency gap effectively decreases when I/Os are scaled in either sizes or queue depths. This finding is generally consistent among two metrics (i.e., average and P99.9 latency), four access patterns (i.e., random write, sequential write, random read, and sequential read), and two ESSD providers (i.e., Amazon AWS and Alibaba Cloud). Specifically, the average latency gaps of two ESSDs are up to 47.9× and 16.7×, respectively, while the P99.9 latency gaps are even much higher at up to 99.4× and 104.2×. In comparison, when the I/O size is scaled up to 256KB, the average latency gaps of two ESSDs are reduced to up to 15.6× and 7.6×, respectively, while the P99.9 latency gaps are mitigated to 20.9× and 35.1× at most. This trend also holds true when scaling up the I/O queue depths.

The primary cause of the high latency of ESSDs would be the network latency and software processing overhead within the cloud storage, which is still substantial compared to the local storage. Scaling the I/O sizes and I/O queue depths can effectively reduce the latency gap by leveraging parallelism in I/O processing and storage access distribution (see §II-C).

We can also notice that, the latency gaps in two ESSDs are significantly smaller in the random read workload but much higher in the other three workloads (i.e., random write, sequential write, and sequential read). Taking ESSD-1 as an example, the average and P99.9 latency gaps are up to 9.3× and 12.8× in the random read workload, but as high as 31.9×

(a) Average Latency of ESSD-1 from Amazon AWS

(b) P99.9 Latency of ESSD-1 from Amazon AWS

(c) Average Latency of ESSD-2 from Alibaba Cloud

(d) P99.9 Latency of ESSD-2 from Alibaba Cloud

Fig. 2. **Latency performance of two ESSDs under workloads with different access patterns (i.e., random write, sequential write, random read, sequential read), I/O sizes, and I/O queue depths (QD).** The top of each pixel indicates the multiples the ESSD latency is divided by the SSD latency, with smaller numbers being better. The bottom of each pixel indicates the value of average or P99.9 latency of the ESSD (u: μs, m: ms).

and 36.5×, 29.9× and 35.2×, 53.2× and 99.4× in the other three workloads.

This performance discrepancy is because modern SSD typically employs a DRAM-based write buffer to improve (both random/sequential) write performance and also uses prefetching to enhance sequential read performance [18]. Thus, in random/sequential write and sequential read workloads, there are much fewer flash accesses on the critical I/O path. However, the prefetching techniques work poorly for random reads, resulting in a larger number of flash accesses. This would make the inherent overhead in cloud storage (e.g., network latency, software processing) less prominent than in the other three workloads, thereby leading to a smaller latency gap.

The above results and analysis suggest that, to save the cloud software from tens to a hundred times latency penalty, cloud storage users should revisit their software designs to *scale the sizes and queue depths of I/Os up as much as possible* (**Implication #1**). Especially, when I/Os are well scaled up in random and sequential write workloads, ESSD-1 even achieves up to 3.3× better P99.9 latency compared to the local SSD (see Figure 2b).

C. Garbage Collection (GC)

> ***Observation #2:*** *The performance impact of GC appears much later or even disappears.*

Device-side garbage collection (GC) is widely recognized as one of the main culprits for SSD performance degradation and unpredictability [19]–[21]. The main reason behind this is that, to reclaim the space occupied by the invalid data, FTL periodically relocates the valid data in some flash blocks to others. The relocation of data results in a large number of extra writes, which severely compete with foreground I/Os and thus degrade the user-perceived performance. Nevertheless, in contrast to this common anticipation, we find that the performance impact of GC appears much later or even disappears in ESSDs. Figure 3 depicts the runtime throughput of two ESSDs and SSD under a random write workload, and the total write volume is configured to be 3× storage capacity of each device.

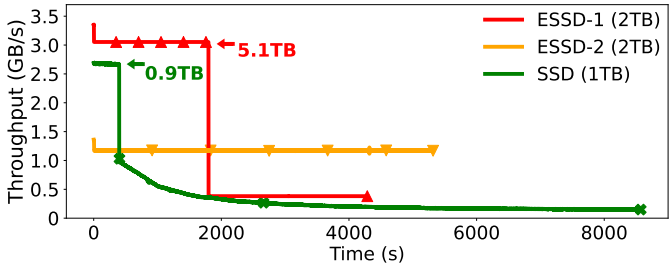


Fig. 3. **Runtime throughput of two ESSDs and SSD under a random write workload until writing 3× storage capacity.** Thus, the total write volumes towards ESSDs and SSD are 6TB and 3TB, respectively. The markers indicate the time when the total write volume reaches a multiple of 1TB.

We can first verify that, the SSD starts to experience a severe throughput drop when only writing 0.9TB (i.e., 90% storage capacity), and the throughput sharply decreases by 63% from 2.7GB/s to 1.0GB/s. After that, the throughput of SSD continues to decrease further as the write volume increases, down to a low of 149MB/s finally. The long-term low performance here demonstrates the sensitivity and powerlessness of the SSD performance to GC. Due to the high and constant write load, GC is unavoidably executed in the SSD almost all the time.

In contrast, ESSD can sustain high throughput over a much longer period even in this high-pressure workload, although the exact performance of an ESSD may depend on the provider. Specifically, ESSD-1 undergoes a sharp throughput

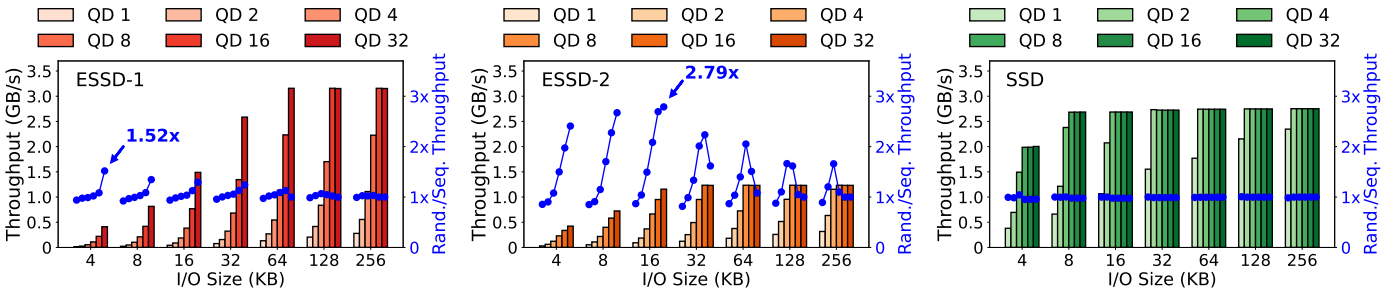

Fig. 4. **Throughput of ESSDs and SSD under random write workloads and throughput gain of ESSDs and SSD in random writes over sequential writes.** The I/O size varies from 4KB to 256KB and the I/O queue depth (QD) varies from 1 to 32.

decline when writing as large as 5.1TB (i.e., 2.55× storage capacity), after which the throughput is stabilized at about 305MB/s. On the contrary, ESSD-2 can maintain a high throughput consistently until writing 6TB (i.e., 3× storage capacity). We speculate on the rationale behind this as follows. On the one hand, cloud providers make efforts to utilize their plenty of storage resources to hide the GC impact transparently for better user experiences. On the other hand, cloud providers may trigger flow-limiting mechanisms when they can not hide the GC impact anymore.

Actually, it has been a long journey for researchers to study software techniques that can mitigate the performance impact of GC [22]–[24]. However, our results and analysis indicate that, cloud software should *reconsider if and how existing GC-mitigated techniques based on local SSDs should be correspondingly adapted for ESSDs* (**Implication #2**), due to the trade-offs they commonly entail.

D. Access Pattern

> ***Observation #3:*** *The throughput of random writes actually outperforms that of sequential writes, reaching a maximum of 1.52× and 2.79× in two ESSDs, respectively.*

Random writes have long been considered harmful to the SSD due to the exacerbated mix of valid/invalid data in the same flash blocks, which consequently results in higher valid data relocation overhead [25]–[27]. However, surprisingly, we discover that the throughput of the ESSD is generally better in the case of random rather than sequential writes. As shown in Figure 4, let us focus on the throughput gain of ESSDs and SSD in random writes over sequential writes (i.e., blue lines). For simplicity, we call this metric *throughput gain* in the following of this subsection. The I/O size varies from 4KB to 256KB and the I/O queue depth varies from 1 to 32.

We can first observe that, the throughput gains in two ESSDs are up to 1.52× and 2.79×, respectively. On the contrary, the throughput of the SSD does not show obvious differences in random or sequential writes (when GC does not occur). The main reason behind this would be the unique physical storage space mapping of ESSDs. As introduced in §II-C, the storage space of an ESSD is distributed and replicated across different nodes and SSDs in the storage cluster. Therefore, data from random writes is likely to embrace higher available SSD bandwidth, potentially leading to higher user-perceived throughput.

Additionally, we discover a notable variation in throughput gains amongst ESSD providers. Specifically, ESSD-1 has a smaller throughput gain, which is mainly concentrated on workloads with higher I/O queue depths and small-to-medium I/O sizes. For example, when the I/O size ranges from 4KB to 32KB and the I/O queue depth is 32, the throughput gain of ESSD-1 is 24.1%∼51.8%. In contrast, the throughput gain in ESSD-2 is much more significant, at up to 1.66× to 2.79× across a wide range of I/O sizes (i.e., 4KB to 256KB). The throughput gain in ESSD-2 also varies a lot in different workload scenarios. For small-size I/Os (e.g., 4KB to 16KB), the throughput gain generally increases as the queue depth increases. For medium-to-large I/Os (e.g., 32KB and larger), the throughput gain has a trend of growing and then declining as the queue depth increases; moreover, the peak of the throughput gain occurs earlier as the I/O size increases.

Converting random writes into sequential writes (e.g., log-structured [28] or copy-on-write [29]) has been widely recognized to reduce device-side GC overhead and improve SSD performance. However, given the ESSD performance is quite insensitive to GC (see §III-C) and the performance gain from random writes, it is now essential to *rethink if it is worthwhile to convert random writes in random-write-based software into sequential writes anymore and if it is beneficial to proactively trigger random writes in sequential-write-based software* (**Implication #3**).

E. Throughput Budget

> ***Observation #4:*** *The maximum bandwidth is now deterministic and no longer sensitive to the access pattern.*

The maximum throughput of the SSD largely depends on the access pattern, mainly due to the asymmetric latency of different flash operations. For example, since flash reads typically have shorter latency than flash writes, the maximum read bandwidth is usually higher than the maximum write bandwidth (e.g., 3.5GB/s vs. 2.7GB/s in Samsung 970 Pro, see Table I). However, we find that the maximum bandwidth of ESSDs is deterministic and no longer sensitive to the access pattern. Figure 5 shows the throughput of two ESSDs and

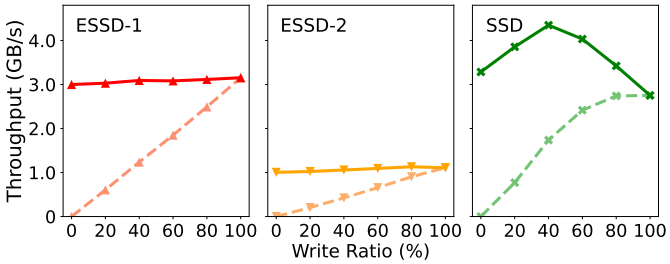

Fig. 5. **Throughput of two ESSDs and SSD under mixed read/write workloads with different write ratios.** The solid and dashed lines represent the total (i.e., read and write) throughput and the write throughput, respectively.

SSD under mixed read/write workloads. The workloads have different write ratios from 0 to 100, where 0 and 100 denote the random read and write workloads, respectively.

We can observe that, regardless of the specific write ratio, the throughput of two ESSDs is deterministically surrounded at the value guaranteed by the provider, i.e., 3.0GB/s and 1.1GB/s, respectively. In contrast, the throughput of the SSD is non-deterministic, varying between 2.5GB/s and 4.3GB/s in different write ratios. Note that this observation holds only for throughput and not for IOPS, as we find that the guaranteed IOPS in ESSDs is non-deterministic and is closely related to the I/O size.

The above results and analysis actually serve as a reminder to cloud storage users that, in contrast to the intricate performance engineering on the SSD, the throughput optimization target of the ESSD is straightforward and clear. For cloud storage users, this can deliver two implications.

First, since the throughput budget directly affects the system cost (see §II-C), to achieve higher cost-effectiveness through a smaller throughput budget, cloud software should *smooth the read/write I/Os to be evenly distributed across the timeline and below the guaranteed throughput budget* (**Implication #4**). This implication would be much more meaningful for software with frequent I/O bursts (i.e., I/O loads are very uneven across the timeline).

Second, to achieve higher cost-effectiveness, cloud software should also *re-evaluate I/O reduction techniques (e.g., compression [30], deduplication [31]) that were previously considered to impair performance* (**Implication #5**). The rationale behind this is that, for local SSDs with low latency, these I/O reduction techniques usually result in performance degradation due to high computational overhead [30], [31]. However, for ESSDs with network latency and software processing overhead that accompany cloud storage, the overhead of these techniques may not be the bottleneck, leading to not only cost reduction (i.e., accommodate workloads with a smaller throughput budget) but also performance improvement.

IV. Related Work

Depicting the performance characteristics of emerging storage devices is always a timeless topic. Prior works have investigated the performance features of HDD [32], flash-based SSD [27], Optane-based SSD [14], and flash-based SSD with new interfaces such as Key-Value (KV) [15] and Zoned Namespace (ZNS) [16]. Inspired by them, we first characterize the performance of the emerging cloud-based ESSD.

Some works introduce EBS's designs and evolution in storage, networking, and hardware acceleration [1], [3]–[5]. Li et al. characterize the I/O features of workloads on EBS from Alibaba Cloud and Tencent Cloud [2]. Cosine [33] searches for the best key-value storage engine with its cost models considering an input workload, a cloud budget, a target performance, and required cloud SLAs. Many works focus on data management between EBS and other faster/slower tiers (e.g., local SSD, object store such as Amazon S3 [34]). For example, Mutant [35] proposes to organize different SSTables in the key-value store into different storage tiers based on access frequencies. ROCKSMASH [36] proposes new cache and metadata structure designs to use local SSDs to store frequently accessed data and metadata while using EBS to hold the rest. MirrorKV [37] focuses on hybrid cloud storage consisting of EBS and object store, and proposes a series of designs to address the efficiency challenges of compaction and querying in this architecture.

Zhou et al. reveal the high latency variances in ESSDs when exceeding the paid IOPS budget and propose a range of I/O-regulated techniques in the key-value store to improve tail latency [38]. In contrast, we focus on the comprehensive performance characterization of ESSDs and deliver insights from many aspects (e.g., latency performance, GC, access pattern, throughput budget).

V. Conclusion and Future Work

This paper pioneers a thorough performance characterization of the cloud-based ESSD, and draws an unwritten contract that incorporates four counter-intuitive observations and five intriguing implications. We hope the unwritten contract could guide cloud storage users in revisiting their deployed cloud software designs, particularly, harnessing the distinct performance characteristics of ESSDs for better system performance.

Meanwhile, given the increasingly rapid growth of cloud computing and cloud storage, we believe this research direction deserves more investigation. We outline the future work as follows.

- **Comprehensiveness and generalizability.** We acknowledge that our current observations may not cover all the unique properties of ESSDs. In the future, we will continue to investigate, and also evaluate ESSDs from more cloud storage providers and validate our observations in this paper on these ESSDs.
- **Cloud-software-level exploration.** In the future, we will explore how cloud software can take advantage of the implications offered in this paper. In particular, we will first use RocksDB [39] (a popular persistent key-value store) as a case study. Although some works have explored building key-value stores on cloud storage (see §IV), these works may not fully exploit the potential of ESSDs.

***Abstract*—Multimodal Large Language Models (MLLMs) have achieved notable success in visual instruction tuning, yet their inference is time-consuming due to the auto-regressive decoding of Large Language Model (LLM) backbone. Traditional methods for accelerating inference, including model compression and migration from language model acceleration, often compromise output quality or face challenges in effectively integrating multimodal features. To address these issues, we propose AASD, a novel framework for Accelerating inference with refined KV Cache and Aligning speculative decoding in MLLMs. Our approach leverages the target model's cached Key-Value (KV) pairs to extract vital information for generating draft tokens, enabling efficient speculative decoding. To reduce the computational burden associated with long multimodal token sequences, we introduce a KV Projector to compress the KV Cache while maintaining representational fidelity. Additionally, we design a Target-Draft Attention mechanism that optimizes the alignment between the draft model and the target model, achieving the benefits of real inference scenarios with minimal computational overhead. Extensive experiments on mainstream MLLMs demonstrate that our method achieves up to a *2*× inference speedup without sacrificing accuracy. This study not only provides an effective and lightweight solution for accelerating MLLM inference but also introduces a novel alignment strategy for speculative decoding in multimodal contexts, laying a strong foundation for future research in efficient MLLMs. Code is availiable at https://github.com/transcend-0/ASD.**

***Index Terms*—Multimodal Large Language Model, Inference Acceleration, Speculative Decoding**

I. Introduction

The rapid development of Multimodal Large Language Models (MLLMs) is exerting a profound impact on the whole world. These models have demonstrated remarkable capabilities in various domains, including visual understanding, question answering, logical reasoning *etc.* [26, 27], and they are expected to further drive artificial intelligence toward Artificial General Intelligence. However, despite the widespread recognition of MLLMs' accuracy and versatility, inference speed remains a significant challenge in practical applications. Current multimodal models generally rely on autoregressive decoding, which, while ensuring coherent outputs, greatly limits inference speed. As model size and complexity increase, so do the computational cost and resource demands associated with their inference [6]. So how to accelerate the inference of the MLLMs is an important problem, which has both academic value and practical significance.

At present, research focusing on accelerating the inference of MLLMs remains relatively scarce. Algorithmic research primarily falls into three categories:

- Traditional model compression techniques: such as distillation [23], quantization [11, 18], and pruning [25, 37] aim to reduce model size and computational burden but encounter issues with fidelity loss and implementation complexity.
- Compact architectures: leveraging lightweight models [22, 33] and efficient encoders such as vision token compression [28, 30]; however, they may sacrifice multimodal alignment and overall performance.
- Adaptation of LLM acceleration techniques to MLLMs: such as efficient attention [22] and MoE [14], offers potential solutions but faces challenges in integrating visual features primely.

Most of these methods tend to compromise output quality, which is unacceptable for many precision-demanding applications. Recently, Speculative Decoding (SD) has emerged as a promising approach for accelerating inference without compromising accuracy, and it has shown effective utility in (Natural Language Processing) NLP tasks [7, 29, 36]. Recent work has attempted to migrate this technique to multimodal scenarios. Gagrani et al. (2024) proposes the speculative decoding with a language-only draft model to improve inference efficiency. However, a language-only draft model struggles to align closely with MLLMs, leading to limited acceleration benefits that fail to meet practical demands. On the other hand, speculative decoding usually requires a small

*Changwei Wang and Longxiang Gao are the corresponding authors (Email: chanweiwang@sdas.org; gaolx@sdas.org). This is work done by Chaoqun Yang and Ran Chen during their internship at the Shandong Computer Science Center.

model that has a high acceptance rate and low inference time to achieve an acceleration effect [29, 36]. This requirement is relatively easy to fulfill in NLP tasks but poses a significant challenge in multimodal contexts, where tokens are longer and encode more extensive information. Smaller models with fewer parameters struggle to capture these rich multimodal representations, hindering their ability to effectively align with the target model. Conversely, using a larger draft model to better capture this information adds computational overhead, thereby increasing inference latency.

To address these challenges, we proposed **AASD**: **A**ccelerate the inference by refined KV Cache and **A**lign **S**peculative **D**ecoding in Multimodal Large Language Models: **(1) Accelerate the inference by refined KV Cache.** Typical speculative decoding uses the *draft-then-verify* paradigm. During inference, the draft model first generates multiple draft tokens, which are then verified in parallel by the target model in a single call. We observed that during inference, the target model caches Key-Value (KV) pairs, which contain significant information about the target distribution. Leveraging this insight, we designed a speculating module that utilizes the last layer's KV Cache from the target model to extract pertinent information for generating draft tokens. Considering that the Key and Value of multimodal tokens are relatively long, which increases the inference costs and the training difficulty of the speculating module, we introduced the KV Projector. This projector is designed to compress information from the multimodal KV Cache and then calculate Cross Attention with the Query from the speculating module.

(2) Align speculative decoding in Multimodal Large Language Models. Utilizing the target model's KV Cache during inference allows the draft model to learn representations closer to those of the target model, but it poses a challenge for training. When generating the *k*-th draft token at the *i*-th step during inference, it requires access to the first *i-1* KV pairs from the target model and the *i*-th to *(i+k-1)*-th KV pairs from the draft model. Replicating this scenario exactly in training is complex and costly. A regular lower triangular causal mask cannot achieve this goal, and accurately mirroring inference conditions would incur $O(n^2)$ computational and memory costs, which is a tough problem. To overcome this, we developed the Target-Draft Attention (T-D Attn), an optimized mechanism that achieves the effects of real inference with minimal additional computation, thereby addressing the challenge of aligning training with the inference scenario in a computationally efficient manner.

Our extensive experiments on various mainstream MLLMs validate that the proposed method achieves an effective acceleration for inference (around $2\times$ speedup). Our work not only provides a lightweight acceleration solution for efficient MLLM inference, but also introduces a novel approach for aligning SD with multimodal contexts, establishing a solid foundation for future research in efficient MLLM inference. The main contributions of this study are summarized as follows: ***i)*** Lightweight inference acceleration method: A lightweight, efficient inference acceleration framework specifically designed for MLLMs, achieving significant speed improvements while maintaining model accuracy, providing a feasible solution for real-time MLLM applications. ***ii)*** Innovative multimodal alignment strategy: we proposed an innovative strategy to align SD with multimodal contexts, enabling the model to effectively leverage the synergy between visual and textual information in multimodal input scenarios, further enhancing decoding efficiency and information fusion. ***iii)*** Strong Empirical Evidence of Acceleration: Through extensive empirical validation, the proposed method achieved up to $2\times$ speedup in inference, demonstrating its high efficiency and robustness in practical applications.

II. Related Work

A. Accelerating Inference of Multimodal Large Language Models

Multimodal Large Language Models (MLLMs) are large language models (LLMs) that integrate multimodal capabilities, enabling them to receive, interpret, and generate outputs based on multimodal information [34]. These models are engineered to tackle complex tasks, including image description, visual question answering (VQA), multimodal translation, and instruction-following by jointly processing and generating natural language along with visual and other perceptual data.

A typical MLLM architecture comprises three core components: a multimodal encoder, a LLM backbone, and a multimodal connector to coordinate multiple modalities [5]. The input to an MLLM often includes raw multimodal data, such as images, audio, and text, which are first processed by modality-specific encoders and transformed into a standardized format suitable for the model's processing. The model's output depends on the task at hand, for instance, in VQA, the output may be a text answer to a visual query, while in image description, the output is a textual description of the image content.

MLLMs usually require significant computational resources for both training and inference. When handling high-resolution images or performing complex reasoning tasks, the inference latency can be considerable, which poses challenges for real-time applications [12]. As a result, accelerating MLLM inference has become an active research area, with key approaches including: **Vision Token Compression.** Techniques such as token pruning [35] and the design of novel vision-language bridging modules [4] aim to reduce the number of visual tokens, enhancing computational efficiency. **Bypassing Visual Tokens.** Speculative decoding methods enable selective bypassing of image tokens and associated processing components [3], which reduces computational load by withdrawing visual tokens at specific layers [16]. **Hardware Acceleration.** Solutions such as the development of elastic cache systems have been proposed to improve the inference efficiency of instruction-following multimodal models [19].

B. Speculative Decoding

Speculative Decoding uses the idea of *draft-then-verify* to fully leverage the parallel processing capabilities of GPU [13]. Specifically, this method initially utilizes a draft model, typically a small and rapidly executing model, to generate multiple draft tokens. Subsequently, the target model verifies these draft tokens in a single, parallel operation, reducing the number of auto-regressive decoding steps of the target model, thereby accelerating the overall inference process [29]. The speedup provided by speculative decoding mainly depends on the acceptance of the draft tokens [13, 31]. In other words, the alignment of the draft model and the target model largely determines the upper limit of acceleration.

III. Method

A. Preliminaries

Below we use lowercase letters for vectors and uppercase letters for matrices except $\boldsymbol{X}$, which represents model inputs. For ease of reading, all vectors default to row vectors for ease

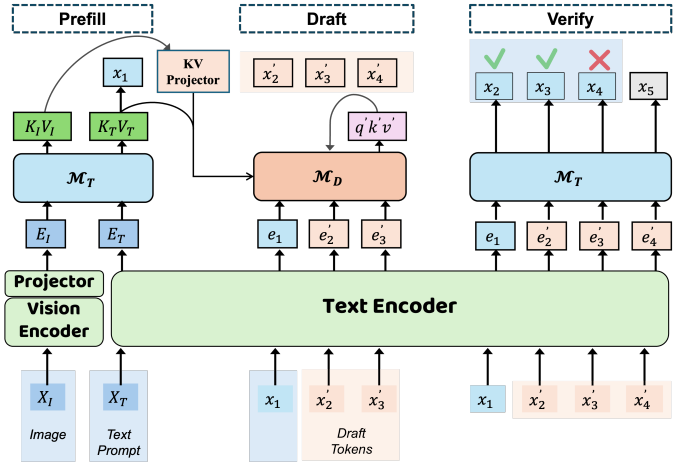

Fig. 1. The overview of the pipeline in the inference phase. We use refined KV cache from the target model (M_T) to enhance the draft model (M_D).

of reading and the representation of the partitioned matrix does not clearly distinguish the column and column directions, such as $K_n = (K_{1\sim i}, K_{i+1\sim n})$, where $K_n \in R^{n\times d}$, $K_{1\sim i} \in R^{i\times d}$ and $K_{i+1\sim n} \in R^{i\times d}$.

1) Multimodal Large Language Models: A typical Multimodal Large Language Model (MLLM) comprises 3 modules: 1) a modality encoder to encode visual inputs, 2) a connector to map the visual encodings to text embeddings, and 3) a LLM backbone to generate response. In inference, inputting an image $\boldsymbol{X}_I$ and a prompt text $\boldsymbol{X}_T$, the modality encoder converts the image $\boldsymbol{X}_I$ to visual encodings, which is then transformed into embeddings E_I in the text embedding space. Meanwhile, LLM's encoder converts the prompt text into text embeddings E_T. And then LLM backbone autoregressively generates tokens using these embeddings. The whole process can be expressed by the following formula:

$$x \sim p(x|\boldsymbol{X}_I, \boldsymbol{X}_T) = M(\boldsymbol{X}_I, \boldsymbol{X}_T) \tag{1}$$

where x denotes the token sampled from the probability space p generated by the model M conditioning on the input image $\boldsymbol{X}_I$ and prompt text $\boldsymbol{X}_T$.

2) Speculative Decoding: Speculative decoding is a lossless approach to accelerate the inference of autoregressive models, adopting a *draft-then-verify* paradigm. To expedite inference of a large model, commonly referred to as the *target model* (M_T), this method employs a small auxiliary model, referred to as the *draft model* (M_D), which is typically obtained through fine-tuning or distillation.

B. Accelerated Inference by Refined KV Cache

1) KV Cache: The core of LLM is the attention computing mechanism:

$$\boldsymbol{O} = \boldsymbol{A}\boldsymbol{V} = Softmax(\frac{\boldsymbol{Q}\boldsymbol{K}^T}{\sqrt{d}})\boldsymbol{V} \tag{2}$$

where $\boldsymbol{O} \in R^{n\times d}$ is the attention output, $\boldsymbol{A} \in R^{n\times n}$ is the attention weight, $\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V} \in R^{n\times d}$ correspond to query states, key states, and value states respectively. n denotes the sequence length, and d denotes the hidden dimension. Typically, the computation of $\boldsymbol{A}$ incorporates a lower triangular matrix known as a causal mask to prevent subsequent tokens from attending to preceding tokens, thereby maintaining the autoregressive property of the model. For ease of reading, we use simplified symbols ($\boldsymbol{Q}\boldsymbol{K}^T$) to represent $Softmax(\frac{\boldsymbol{Q}\boldsymbol{K}^T}{\sqrt{d}})$ below.

Due to the nature of autoregressive generation, where each computation step utilizes the $\boldsymbol{K}$ and $\boldsymbol{V}$ representations of preceding tokens, it is common practice to cache $\boldsymbol{K}$ and $\boldsymbol{V}$ at each inference step for subsequent use. This caching strategy is crucial for maintaining the efficiency of the generation process. The procedure in MLLMs can be detailed as follows:

(1) Prefilling stage. An input image $\boldsymbol{X}_I$ token sequence $\boldsymbol{X}_T$ is processed to compute the attention output. Concurrently, the key representations $\boldsymbol{K} = (\boldsymbol{K}_I, \boldsymbol{K}_T)$ and value representations $\boldsymbol{V} = (\boldsymbol{V}_I, \boldsymbol{V}_T)$ derived from this sequence are cached. This initial computation establishes the foundational context for the autoregressive generation process.

(2) Decoding stage. For each subsequent token input x, its corresponding query $\boldsymbol{q}$, key $\boldsymbol{k}$, and value $\boldsymbol{v}$ are computed. These are then concatenated with the previously cached $\boldsymbol{K}$ and $\boldsymbol{V}$ to calculate the attention outputs. That is

$$\boldsymbol{o} = (\boldsymbol{q}\tilde{\boldsymbol{K}})\tilde{\boldsymbol{V}} \tag{3}$$

where

$$\tilde{\boldsymbol{K}} = Concat(\boldsymbol{K}, \boldsymbol{k}), \tilde{\boldsymbol{V}} = Concat(\boldsymbol{V}, \boldsymbol{v}) \tag{4}$$

Our inference framework, shown in Figure 1, addresses the unique challenges of applying Speculative Decoding (SD) in multimodal tasks. Unlike NLP tasks, achieving satisfactory performance with a smaller draft model in multimodal settings is significantly more difficult. Current relatively compact models, such as KarmaVLM with a 0.4B vision encoder and a 0.5B LLM backbone [24], DeepSeek-VL with a 0.4B vision encoder and a 1.3B LLM backbone [20], and MiniCPM-V 2.0 with a 0.4B vision encoder and a 2.7B LLM backbone [33], still have a huge number of parameters. Moreover, it has been pointed out that a small MLLM as a draft model brings limited acceleration gain to SD, sometimes even worse than a draft model with language-only LLM [3]. This is most likely because learning directly from multimodal data is too difficult for small models. This motivated us to design **AASD**: An approach that accelerate the inference by effectively refining KV Cache generated by the target model to better align the draft model outputs with the target model. We structure our method in two key stages: Prefilling and Decoding.

(1) Prefilling stage. During the Prefilling stage, the target model processes the input image $\boldsymbol{X}_I$ and prompt text $\boldsymbol{X}_T$ to generate the initial KV Cache $\boldsymbol{K}_I, \boldsymbol{V}_I, \boldsymbol{K}_T, \boldsymbol{V}_T$ and the probability distribution over the next token. Although these KV Caches contain valuable information, the image KV Cache tends to be particularly large, creating both a learning barrier and a computational burden for the draft model. To address this, we introduce two feature projectors that compress the target model's KV Cache, enabling the draft model to better align with the target model during draft generation. Mathematically, this compression is represented as:

$$\boldsymbol{K}_I^* = \boldsymbol{W}_K \boldsymbol{K}_I, \boldsymbol{V}_I^* = \boldsymbol{W}_V \boldsymbol{V}_I \tag{5}$$

where

$$\boldsymbol{W}_K, \boldsymbol{W}_V \in R^{k\times n}, \boldsymbol{K}_I, \boldsymbol{V}_I \in R^{n\times d}, \boldsymbol{K}^*, \boldsymbol{V}^* \in R^{k\times d}$$

This operation compresses the lengthy sequence of visual key and value states into k tokens, here set to $k = 64$, effectively reducing approximately 90% of the redundant information. The

target model then passes the compressed KV pairs, $\boldsymbol{K}_I^*$, $\boldsymbol{V}_I^*$, $\boldsymbol{K}_T$, and $\boldsymbol{V}_T$, to the draft model to generate the draft tokens.

(2) Decoding stage.

(2.1) Draft process. First, the draft model builds upon foregoing KV Cache generated by the target model to produce a sequence of candidate tokens. Specially, the draft model M_D receives token $\boldsymbol{x}_i$ from the target model and computes corresponding $\boldsymbol{q}'_i, \boldsymbol{k}'_i, \boldsymbol{v}'_i$, which are then combined with the target model's key states $\boldsymbol{K}_{i-1} = \boldsymbol{k}_{\leq i-1}$ and value states $\boldsymbol{V}_{i-1} = \boldsymbol{v}_{\leq i-1}$ up to the previous token, namely

$$\hat{\boldsymbol{K}}_i = (\boldsymbol{K}_{i-1},\ \boldsymbol{k}'_i), \hat{\boldsymbol{V}}_i = (\boldsymbol{V}_{i-1}, \boldsymbol{v}'_i) \tag{6}$$

The draft model computes the attention using $\boldsymbol{q}'_i, \hat{\boldsymbol{K}}_i, \hat{\boldsymbol{V}}_i$, and generated next draft token $\boldsymbol{x}'_{i+1}$. Then draft model continues to generate subsequent tokens by incorporating the newly generated tokens into the KV Cache, namely

$$x'_{i+k+1} = M_D(\boldsymbol{q'}_{i+k}, \hat{\boldsymbol{K}}_{i+k}, \hat{\boldsymbol{V}}_{i+k}) \tag{7}$$

where

$$\hat{\boldsymbol{K}}_{i+k} = (\boldsymbol{K}_{i-1}, \boldsymbol{K}'_{i\sim i+k}) \tag{8}$$

$$\hat{\boldsymbol{V}}_{i+k} = (\boldsymbol{V}_{i-1}, \boldsymbol{V}'_{i\sim i+k}) \tag{9}$$

(2.2) Verify process. The Verify process involves the target model validating the draft tokens. This validation is done by once forwarding on draft tokens of the target model, which computes the true token probabilities.

The target model receives the sequence of draft tokens

$$\boldsymbol{X}'_{i\sim i+\gamma} = (x'_{i+1}, \cdots, x'_{i+\gamma}) \tag{10}$$

and computes the true token probabilities

$$\boldsymbol{P}_{i\sim i+\gamma} = (\boldsymbol{p}_{i+1}, \cdots, \boldsymbol{p}_{i+\gamma}) \tag{11}$$

where

$$\boldsymbol{p}_{i+k+1} = M_T(x_{i+k}, \boldsymbol{K}_{i+k-1}, \boldsymbol{V}_{i+k-1}) \tag{12}$$

Then get true tokens

$$\boldsymbol{X}_{i\sim\gamma} = (x_i, \cdots, x_{i+\lambda}) \tag{13}$$

and additional next token $x_{i+\gamma+1}$, by strictly match when doing greed decoding or speculative sampling when doing sampling decoding.

The process is recursively repeated until the entire generation is complete.

C. Aligned Training by Target-Draft Attention

The method outlined above offers improvements in inference efficiency but introduces challenges in training. A critical issue is the discrepancy between the training and inference phases. If we rely solely on the target model's KV Cache during training, a gap emerges during inference because the draft model's KV Cache also plays a role. Utilizing both the target and draft model's KV Caches during training is not straightforward. A naive approach would be to directly incorporate the target KV Cache into the training process, replacing the last KV with that from the draft model. However, due to the mask attention's matrix operations, this approach only accounts for the generation of the last draft token and fails to consider the preceding tokens. To address this, we designed Target-Draft Attention to simulate the actual inference scenario more accurately. To implement Target-Draft Attention, we modify the training procedure to blend the KV Caches from both the target and draft models, ensuring that

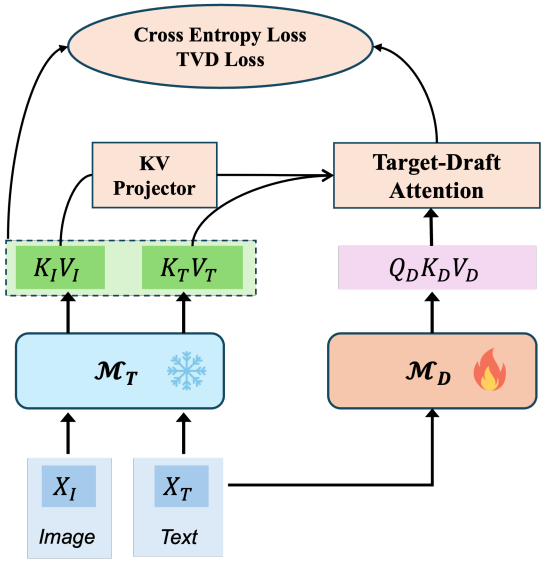

Fig. 2. Overview of training phases. Only a small number of parameters need to be trained.

the draft model learns to align with the target model's context while still leveraging its own contributions. Figure 2 shows our training framework. First let's recall the draft process of inference procedure. Assuming that now it will generate the *k*-th draft token

$$x'_{i+k+1} = M_D(\boldsymbol{q}'_{i+k}, \hat{\boldsymbol{K}}_{i+k}, \hat{\boldsymbol{V}}_{i+k}) \tag{14}$$

which involves the calculation of attention weights

$$\hat{\boldsymbol{a}}_{i+k} = (\boldsymbol{q'}_{i+k}\hat{\boldsymbol{K}}^T_{i+k}) \tag{15}$$

and subsequently, the cattention output

$$\hat{\boldsymbol{o}}_{i+k} = \hat{\boldsymbol{a}}_{i+k}\hat{\boldsymbol{V}}_{i+k} = (\boldsymbol{q'}_{i+k}\hat{\boldsymbol{K}}^T_{i+k})\hat{\boldsymbol{V}}_{i+k} \tag{16}$$

In training, we have the inputs

$$\boldsymbol{K}_n, \boldsymbol{V}_n, \boldsymbol{Q'}_n, \boldsymbol{K'}_n, \boldsymbol{V'}_n.$$

For $\gamma = 1$, a natural idea to do this is to replace $\boldsymbol{k}_n, \boldsymbol{v}_n$ in $\boldsymbol{K}_n, \boldsymbol{V}_n$ with $\boldsymbol{k'}_n, \boldsymbol{v'}_n$ from the draft model, but it yields $(\boldsymbol{Q'}_n\hat{\boldsymbol{K}}^T_n)\hat{\boldsymbol{V}}_n$, where $\boldsymbol{Q'}_n\hat{\boldsymbol{K}}^T_n = [\boldsymbol{Q'}_{n-1}\hat{\boldsymbol{K}}^T_n, \boldsymbol{q'}_n\hat{\boldsymbol{K}}^T_n]$ After masking, the result becomes $[\boldsymbol{Q'}_{n-1}\boldsymbol{K}^T_{n-1}, \boldsymbol{q'}_n\hat{\boldsymbol{K}}^T_n]$, where only the last vector $\boldsymbol{q'}_n\hat{\boldsymbol{K}}^T_n$ is what we need. To achieve accurate inference reproduction, construction n sets of qKV pairs $\{(\boldsymbol{q'}_i, \hat{\boldsymbol{K}}_i, \hat{\boldsymbol{V}}_i), i = 1, \cdots, n\}$ is necessary, but this approach imposes substantial memory overhead and inefficient resource usage.

So we need to optimize the calculation. From alignment purposes, we want to end up with

$$\hat{\boldsymbol{O}}_n = \{(\boldsymbol{q'}_i\hat{\boldsymbol{K}}^T_i)\hat{\boldsymbol{V}}_i, i = 1, \cdots, n\} \tag{17}$$

when the number of generated tokens is 1. To generate *(k+1)*-th token, we have

$$x'_{i+k+1} = M_D(\boldsymbol{q'}_{i+k}, \hat{\boldsymbol{K}}_{i+k}, \hat{\boldsymbol{V}}_{i+k}) \tag{18}$$

where

$$\hat{\boldsymbol{K}}_{i+k} = (\boldsymbol{K}_{i-1}, \boldsymbol{K'}_{i\sim i+k}) \tag{19}$$

$$\hat{\boldsymbol{V}}_{i+k} = (\boldsymbol{V}_{i-1}, \boldsymbol{V'}_{i\sim i+k}) \tag{20}$$

Because of the $softmax$, we must first compute the attention weights,

$$\begin{aligned}\hat{\boldsymbol{a}}_{i+k} &= (\boldsymbol{q'}_{i+k}\hat{\boldsymbol{K}}_{i+k}^{T}) \\ &= (\boldsymbol{q'}_{i+k}\boldsymbol{K}_{i-1}^{T}, \boldsymbol{q'}_{i+k}\boldsymbol{K'}_{i\sim i+k}^{T})\end{aligned} \tag{21}$$

then compute

$$\begin{aligned}\hat{\boldsymbol{o}}_{i+k} &= \hat{\boldsymbol{a}}_{i+k}\hat{\boldsymbol{V}}_{i+k} \\ &= \hat{\boldsymbol{a}}_{i+k}(\boldsymbol{V}_{i-1}, \boldsymbol{V'}_{i\sim i+k}) \\ &= \hat{\boldsymbol{a}}_{i+k}\boldsymbol{V}_{i-1} + \hat{\boldsymbol{a}}_{i+k}\boldsymbol{V'}_{i\sim i+k}\end{aligned} \tag{22}$$

Here, $\hat{\boldsymbol{A}}_n = \{\hat{\boldsymbol{a}}_{i+k},\ i = 1, \cdots, n-k\}$ is formed by $\boldsymbol{Q'}_n\boldsymbol{K}_n$ and $(\boldsymbol{Q'}_n\boldsymbol{K'}_n)$, while $\hat{\boldsymbol{O}}_n$ is formed by $\boldsymbol{A'}_n\boldsymbol{V}_n$ and $\boldsymbol{A'}_n\boldsymbol{V'}_n$. To avoid redundant calculations, we precompute these matrices and index relevant values to construct the target matrix, which greatly reduced training time and memory overhead.

IV. Experiments

A. Experimental setup

Models, datasets and tasks. We conducted experiments on LLaVA-7B and LLaVA-13B [17], encompassing the common sizes of current mainstream MLLMs. We evaluated our method across multiple tasks including mixed generic tasks (conversation, detailed description, and complex reasoning) on LLaVA-Bench In-the-Wild [17] dataset, Image captioning task on images from **coco** [15] dataset, and chain-of thought (CoT) reasoning on Science QA [21] dataset.

Metrics. Like other work about speculative decoding [2, 13, 32], we assess acceleration effects using the following metrics:

- *Walltime speedup ω:* The actual test speedup ratio relative to vanilla auto-regressive decoding.
- *Acceptance rate α:* The average ratio between the number of accepted tokens and the number of speculative tokens.
- *Block efficiency τ:* The average number of generated tokens per block (or target model forward) for a block size γ (or speculative steps).
- *Decoding speed δ:* The average number of generated tokens per second.

B. Main Results

1) Comparison with Usual Methods: Drawing on common practices from NLP tasks, we selected different small draft models as baselines. Since there are no small models suitable for rapid draft generation included in the LLaVA suite, we trained a series of small models to support our experiments, including finetuned-LLaMA (FT-LLaMA in Table I), distilled-LLaMA (DT-LLaMA), finetuned-LLaVA (FT-LLaVA), distilled-LLaVA (DT-LLaVA). All these small LLaMA model and the language model part of LLaVA is of 112M parameters. Specially, first, following Gagrani et al. (2024), we trained a small LLaMA-2 model from scratch (pretrained on RedPajama-Data-1T-Sample [1], then finetuned [8] on OIG-small-chip2 [10] and OpenAssistant [9], and distilled by seq-level distillationn. Furthermore, we use the small LLaMA model above as the language backbone of the LLaVA model. As shown in Table I, our method exhibits superior performance across several key metrics, significantly surpassing traditional draft models. Overall, our model showed significant walltime speedup on multiple datasets such as LLava bench in the wild, coco caption, and SQA. For instance, with a $\gamma = 3$ configuration, it achieved a speedup of 2.02 (mean of 3 datasets), far exceeding other baseline methods by $45.3\% - 61.6\%$. This indicates our method's efficiency in reducing actual processing time relative to the target model. In terms of acceptance rate, our model also achieved outstanding results across datasets, notably reaching rates of 0.62, clearly outperforming baseline models like finetuned-LLaMA and distilled-LLaVA.

TABLE I
Comparison with usual methods (the mean of different metrics across 3 datasets). Note: FT refers to the finetuned, and DT refers to the distilled.

Target Model	γ	Draft Model	ω	α	τ	δ
LLaVA-7B	3	FT-LLaMA	1.39	0.35	1.93	46.13
		DT-LLaMA	1.33	0.34	1.96	45.00
		FT-LLaVA	1.27	0.28	1.68	40.57
		DT-LLaVA	1.25	0.27	1.69	39.50
		Ours	**2.02**	**0.62**	**2.72**	**63.59**
LLaVA-7B	5	FT-LLaMA	1.37	0.34	2.55	42.77
		DT-LLaMA	1.37	0.34	2.54	43.71
		FT-LLaVA	1.21	0.28	2.22	38.35
		DT-LLaVA	1.21	0.28	2.21	38.34
		Ours	**2.06**	**0.62**	**3.92**	**65.02**
LLaVA-13B	3	FT-LLaMA	1.46	0.35	1.89	46.06
		DT-LLaMA	1.44	0.34	1.87	45.20
		FT-LLaVA	1.36	0.30	1.75	42.46
		DT-LLaVA	1.35	0.29	1.71	41.83
		Ours	**2.14**	**0.63**	**2.74**	**67.78**
LLaVA-13B	5	FT-LLaMA	1.44	0.35	2.60	45.29
		DT-LLaMA	1.44	0.35	2.61	45.66
		FT-LLaVA	1.32	0.30	2.35	42.20
		DT-LLaVA	1.31	0.29	2.37	41.64
		Ours	**2.24**	**0.62**	**3.99**	**70.45**

Our approach also excels in block efficiency, with the value up to 2.72, demonstrating robust capability in generating tokens. In decoding speed, our method stands out with speed reaching up to 64 token/s, exceeding the baseline by $37.8\% - 61.0\%$, indicating its suitability for real-time applications where quick response is crucial. In summary, the data in Table I convincingly demonstrates that our method, which integrates the strengths of enhanced speculative decoding and visual processing techniques, outperforming conventional methods across multiple performance metrics, thereby constituting an effective strategy for accelerating the inference of MLLMs.

C. Ablation study

1) Effectiveness of Target Model's KV Cache: To evaluate the impact of using the KV Cache from the target model, we conducted experiments comparing the inference performance with and without using the target model's cache. KV Cache provides valuable contextual information accumulated in previous steps, which can be leveraged by the draft model in speculative decoding. By accessing the cached information directly from the target model, the draft model can achieve better alignment with the target's state, thus enhancing the acceptance rate and speedup.

As shown in Figure 3, our experimental results indicate that using the target model's KV Cache leads to a significant im-

LLaVA-7B	3	w/o	1.64	0.49	2.33	51.48
		w/	2.02$^{\uparrow}$	0.62$^{\uparrow}$	2.72$^{\uparrow}$	63.59$^{\uparrow}$
LLaVA-7B	5	w/o	1.56	0.47	3.21	48.98
		w/	2.06$^{\uparrow}$	0.62$^{\uparrow}$	3.92$^{\uparrow}$	65.02$^{\uparrow}$
LLaVA-13B	3	w/o	1.72	0.49	2.30	54.27
		w/	2.14$^{\uparrow}$	0.63$^{\uparrow}$	2.74$^{\uparrow}$	67.78$^{\uparrow}$
LLaVA-13B	5	w/o	1.70	0.48	3.26	53.69
		w/	2.24$^{\uparrow}$	0.62$^{\uparrow}$	3.99$^{\uparrow}$	70.45$^{\uparrow}$

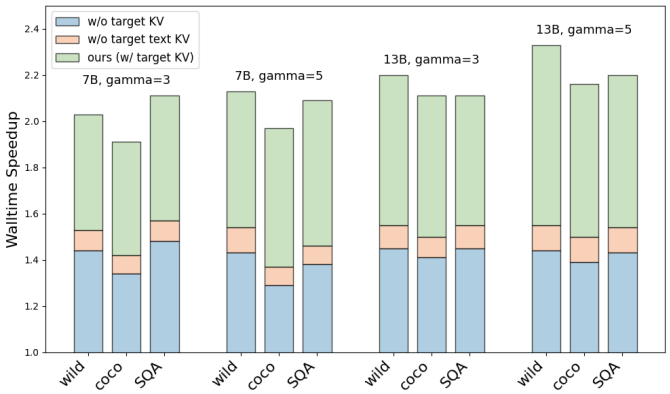

Fig. 3. Ablation on target model's KV Cache.

provement in walltime speedup. Specifically, KV Cache of the target model is directly related to the final output results, enabling the draft model to make more accurate predictions. This reuse of context not only improves the overall coherence of generated sequences but also speeds up the speculative decoding process. In contrast, models without access to the KV Cache are prone to deviate from the target distribution, resulting in a lower acceptance rate and slower inference. Therefore, KV Cache from the target model plays a crucial role in improving the efficiency of speculative decoding in multimodal large language models.

2) Effectiveness of Vision KV Projector: To evaluate the impact of the Vision KV Projector module, we conducted experiments that compared the model's performance with and without this module. The Vision KV Projector is designed to selectively compress and extract relevant vision key-value pairs, enabling the model to efficiently leverage visual context in speculative decoding. By employing Vision KV Projector, our method enables the draft model to align more closely with the target model on visual tasks, thereby enhancing the effectiveness of speculative decoding.

As shown in Table II, our experiments indicate that Vision KV Projector significantly improves both acceptance rate and walltime speedup. With Vision KV Projector enabled, the model demonstrates faster decoding, particularly in tasks with high visual complexity, as irrelevant visual data is filtered out. Additionally, we observed that the Vision KV Projector helps maintain coherence in multimodal contexts by preserving only the most relevant

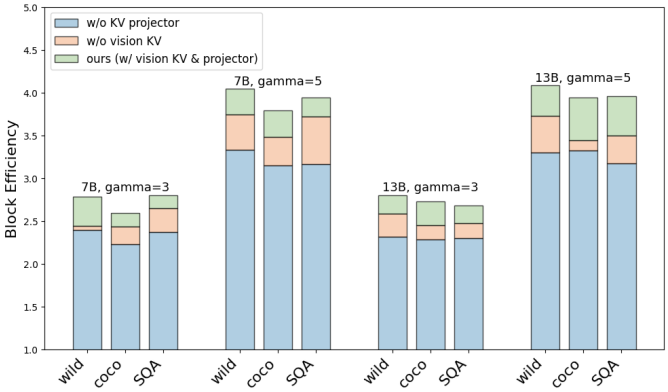

Fig. 4. Ablation on vision KV Cache.

visual cues, allowing the model to align visual information more effectively with textual context. In contrast, without this module, the model processes a larger volume of visual data, resulting in slower decoding and reduced alignment between the draft model and the target model. In summary, Vision KV Projector enhances the efficiency of speculative decoding by focusing on essential visual elements. This approach not only optimizes resource usage but also improves the alignment between the draft model and the target model in multimodal tasks.

3) Do Vision Information Really Important?: To investigate the relative importance of vision and text information in the KV cache, we conducted experiments by selectively disabling either the image KV cache or the text KV cache. This comparison allows us to analyze the impact of each modality on the performance of the draft model during speculative decoding.

As shown in Figure 4, our experimental results reveal that disabling the text KV cache has a more substantial negative effect on block efficiency compared to disabling the image KV cache. Specifically, without the text KV cache, the model experiences a significant drop in block efficiency. This is because text information provides a critical sequential context that is essential for accurate token prediction and verification. In contrast, while image information contributes to the overall context, it does not require the same level of sequential dependency as text, making it relatively less crucial for maintaining the flow of decoding. In summary, text information plays a important role, but uncompressed visual information may impair the performance of the draft model. This finding emphasizes that in speculative decoding of multimodal large models, textual information is a necessity, while visual information is a bonus that needs to be effectively utilized to be effective.

V. CONCLUSION

In this study, we introduced an innovative approach to accelerate the inference processes of MLLMs, focusing on the synergistic integration and information reuse of image and text modalities within MLLMs. This method makes efficient use of KV Cache and aligns the draft model and the target model for speculative decoding in multimodal scenario, greatly increasing the inference speed of MLLMs. Our experimental results demonstrate that this approach can achieve up to a 2x speedup across a variety of multimodal tasks, from visual question answering to complex reasoning, fully validating the effectiveness and potential of our method.

***Abstract*—Modular arithmetic, particularly modular reduction, is widely used in cryptographic applications such as homomorphic encryption (HE) and zero-knowledge proofs (ZKP). High-bit-width operations are crucial for enhancing security; however, they are computationally intensive due to the large number of modular operations required. The lookup-table-based (LUT-based) approach, a "space-for-time" technique, reduces computational load by segmenting the input number into smaller bit groups, pre-computing modular reduction results for each segment, and storing these results in LUTs. While effective, this method incurs significant hardware overhead due to extensive LUT usage. In this paper, we introduce ALLMod, a novel approach that improves the area efficiency of LUT-based large-number modular reduction by employing hybrid workloads. Inspired by the iterative method, ALLMod splits the bit groups into two distinct workloads, achieving lower area costs without compromising throughput. We first develop a template to facilitate workload splitting and ensure balanced distribution. Then, we conduct design space exploration to evaluate the optimal timing for fusing workload results, enabling us to identify the most efficient design under specific constraints. Extensive evaluations show that ALLMod achieves up to $1.65\times$ and $3\times$ improvements in area efficiency over conventional LUT-based methods for bit-widths of 128 and $8,192$, respectively.**

I. Introduction

Privacy computing, a crucial approach for safeguarding data security, has gained considerable attention in recent years due to increasing concerns about privacy and the protection of personal data on the Internet. This field encompasses a variety of applications, including homomorphic encryption (HE) [1], which protects the privacy of user data and models, and zero-knowledge proofs (ZKP) [2], [3], which ensure user privacy during transactions. These applications rely on public-key cryptography algorithms, such as Elliptic Curve Cryptography (ECC) [4] and RSA [5], which use modular reduction as a fundamental component to prevent overflow.

The modular reduction used in these algorithms often requires extremely high bit-widths. For instance, ECC demands a bit-width of at least 224 bits [6], while RSA typically requires at least $1,024$ bits [7]. Moreover, for most cryptographic schemes, higher bit-widths correspond to enhanced security [8]. Such high-bit-width operations pose challenges for efficiently deploying these algorithms and their applications on hardware. Common algorithms, like Barrett [9] and Montgomery [10], implement modular operations through multiplication. However, as bit-width increases, constructing high-performance multipliers to meet latency and throughput requirements becomes increasingly difficult.

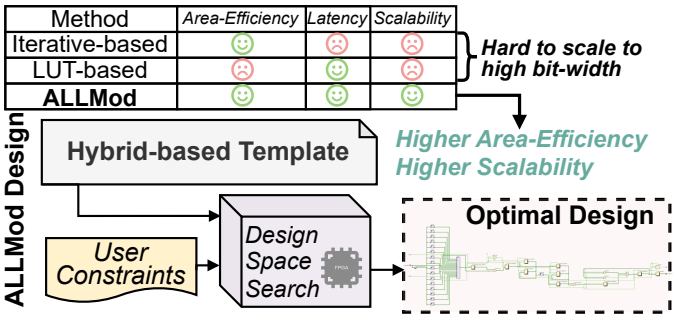

Fig. 1. Comparison of ALLMod to the existing modular reduction methods and ALLMod design overview.

Recently, lookup-table-based (LUT-based) methods [11], [12] have been proposed to achieve low-latency and high-throughput large-number modular reduction. This approach divides input bits into segments and pre-computes possible modular reduction results for each segment. These results are organized into lookup tables (LUTs), which can be implemented using block RAMs (BRAMs) on FPGAs. For each segment, the corresponding modular result is retrieved from the LUTs and combined through an adder tree to yield the final modular reduction result.

This approach converts complex modular reduction operations into simple lookup operations within LUTs, significantly reducing operational complexity and enabling high-throughput, low-latency large-number modular reduction. As a "space-for-time" trade-off, it utilizes BRAMs to store the LUTs and DSPs to implement adder trees that aggregate lookup results. However, as bit-width increases, this method

† These authors contributed equally. faces the challenge of excessive resource overhead, resulting in suboptimal area efficiency. On the other hand, the iterative method, though straightforward, requires only a minimal number of subtractors but exhibits high latency.

To address these challenges, we propose combining iterative and LUT-based methods to enhance area efficiency in modular reduction implementations. Our solution, ALLMod, reduces area overhead by partitioning input bits into distinct workloads and distributing these across different modular modules, maintaining high throughput. To facilitate workload partition and achieve balanced workload distribution, we design a template that guides implementation. Building on this, we introduce a design space exploration method to identify the optimal design under specified constraints. Experimental results show that ALLMod improves area efficiency by up to 3× compared to the conventional LUT-based method.

In summary, our contributions are as follows:

- We present a novel method to improve the area efficiency of LUT-based large-number modular reduction by smartly distributing the workload, enabling the integration of the iterative method with the LUT-based approach.
- We design a flexible template to facilitate workload division for implementations of varying bit-widths. This template, informed by latency analysis of both methods, ensures balanced workloads while minimizing area usage.
- Using such a template, we propose a design space exploration approach focused on achieving high area efficiency. This approach includes a resource evaluator and an iterative search algorithm, enabling the identification of Pareto-optimal designs under specified constraints, such as latency and area requirements.

II. Background

A. Large-Number Modular Reduction Methods

In cryptographic algorithms, large-number modular reduction can be expressed as $R = A \ mod \ M$, where A is a $2n$-bit number and M is a fixed n-bit number.

1) LUT-based Method: The LUT-based method [11], [12] employs lookup tables to store precomputed modular reduction results for possible segments of A, effectively reducing the computational load during runtime at the cost of additional space overhead. To leverage LUTs, the modular reduction operation must be transformed as follows:

$$\begin{aligned} R = A \ mod \ M &= \sum_{i=0}^{2n-1} (2^i a_i) \ mod \ M \\ &= (\sum_{i=n}^{2n-1} (2^i a_i) + \sum_{i=0}^{n-1} (2^i a_i)) \ mod \ M \\ &= ((\sum_{i=0}^{\frac{n}{k}-1} \sum_{j=0}^{k-1} (2^{n+ki+j} a_{n+ki+j})) + \sum_{i=0}^{n-1} (2^i a_i)) \ mod \ M \\ &= (\sum_{i=0}^{\frac{n}{k}-1} ((\hat{a}_i \times 2^{n+ki}) \ mod \ M) + \sum_{i=0}^{n-1} (2^i a_i)) \ mod \ M \end{aligned} \tag{1}$$

Algorithm 1: LUT-based Modular Reduction [12].

18 $R_1 \leftarrow$ **Add**$(results, \sum_{i=0}^{n-1}(2^i R_0[i]))$ **Adder (Tree)**
19 $R \leftarrow R_1 \ or \ R_1 - M \ or \ R_1 - 2M$ **Subtract**

where $\hat{a}_i = \sum_{j=0}^{k}(2^j a_{n+8i+j})$, i.e. $\hat{a}_i$ is a k-bit number. The $\frac{n}{k}$ red items can be pre-computed offline and stored using LUTs, as the modulus M is typically fixed. Specifically, we use LUTs to pre-compute and store the values of $\hat{a}_i \times 2^{n+ki} \ mod \ M$. A k-input and n-output LUT is used to store all the possible values of $\hat{a}_i \times 2^{n+ki} \ mod \ M$. For the $(n = 128)$ case, an FPGA's BRAM with $36k$-bit capacity can be configured as an 8-bit input and 128-bit output LUT and 16 BRAMs are required in total. The retrieved results from LUTs and the blue item are added together using a $\frac{n}{k} + 1$-input adder tree to get an $(n + log_2 d)$-bit number, where $d = \frac{n}{k}$. The high $log_2 d$ bits of the sum are then input to the LUTs for an additional lookup, and the result is added to the low n bits. Finally, several subtractions are performed for adjustment.

Algorithm 1 outlines the detailed process of the LUT-based modular reduction. The high n-bits are divided to d segments, denoted as $\hat{a}_i$s, each containing k bits. Initially, each segment $\hat{a}_i$ is sent to the corresponding BRAM-based LUT to look up the pre-computed modular result of $\hat{a}_i \times 2^{n+ki} \ mod \ M$. Then, the d n-bit modular results, along with the low n-bit $\sum_{i=0}^{n-1}(2^i a_i)$, are added together to obtain a $n + log_2 d$-bit number R_0. The high $log_2 d$ bits of R_0 are then sent to the LUTs again, and the looked-up results are added with the low

n bits for R_0 to obtain R_1. The second round of lookups helps refine R_1 to the final result R, assisted by several subtraction operations for adjustment.

2) Iterative-based Method: The iterative-based modular reduction method [13] is much more straightforward: the modular operation is performed by repeatedly subtracting the modulus from the input number until the result is smaller than the modulus. To optimize the process, shift operations are employed during each iteration to facilitate efficient subtractions. It is worth noting that because the lower n-bits of the aligned modulus M are zeros, the subtractor only needs to handle the subtraction of up to n-bit numbers.

B. FPGA Implementation for Modular Reduction

Modular reduction implementations are widely deployed on FPGAs due to their high-performance parallel computing capabilities and the flexibility they offer for designing custom solutions tailored to specific needs. These implementations are primarily divided into two categories: multiplier-based methods and LUT-based methods.

Notable examples of multiplier-based methods include Barrett's algorithm [9] and Montgomery's algorithm [10], which rely on multiple high-performance high-bit-width multipliers to achieve high throughput and low latency. However, as bit-width increases, the complexity of designing these multipliers grows significantly, making it challenging to meet throughput requirements.

On the other hand, LUT-based methods [11], [12], as discussed earlier, are better suited to support high throughput in large-number modular reduction. However, with increasing bit-width, this approach faces significant resource overhead, resulting in poor area efficiency. LUTMR [14] proposes using the FPGA's native LUTs instead of BRAMs for implementing lookup tables, aiming to reduce latency and improve LUT usage by reusing patterns. While this optimization helps at the implementation level, it does not address the inherent limitations of the method itself, resulting in only modest improvements (no more than 5% LUT savings).

III. Analysis and Motivation

We conduct an in-depth analysis of the LUT-based and iterative methods for large-number modular reduction. Based on our profiling, we highlight key insights as follows:

Observation: Trade-offs between area-efficiency and latency. We analyze the area efficiency and latency of both methods across various bit-widths, as shown in Figure 2.[1] The LUT-based method offers lower latency but suffers from higher area overhead, while the iterative method exhibits better area efficiency at the cost of higher latency, especially for large bit-widths. In the LUT-based approach, lookup tables reduce online computation, thus minimizing latency. However, the area overhead increases significantly with larger bit-widths, as more BRAMs are needed to store the LUTs, and larger adder trees are required for result aggregation. Moreover, as

[1]The overhead of BRAMs, adders, and subtractors is converted into LUTs, based on the utilization report from Vivado's IP generator.

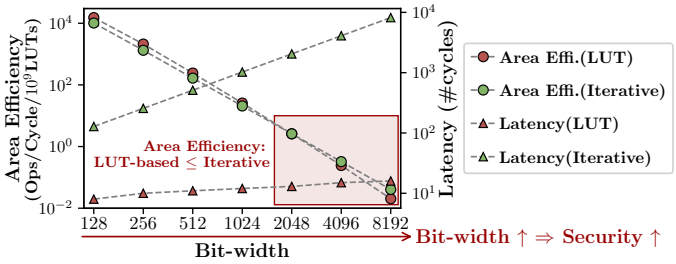

Fig. 2. Comparison of area efficiency and latency between LUT-based method and iterative-based method.

BRAM capacity is fixed, a higher bit-width limits the number of mappings a BRAM can store, increasing the number of result aggregations needed.

For example, with $n = 128$, a $36k$-bit BRAM can store an 8-bit input and 128-bit output LUT, requiring 16 BRAMs and a 16-input, 128-bit adder tree. However, for $n = 2,048$, a BRAM can only store a 4-bit input and $2,048$-bit output LUT, requiring 512 BRAMs and an adder tree with 512 inputs, where each adder must support at least $2,048$-bit addition.

Key Insight: Achieving Pareto Optimal Design through Method Fusion. From the previous observation, the LUT-based method offers low latency but suffers from high area overhead, while the iterative method provides better area efficiency at the cost of higher latency. Therefore, it is feasible to balance area efficiency and latency by distributing the workload in a way that explores the Pareto optimal design space. Existing methods have inherent trade-offs between area efficiency and latency, with no systematic approach to achieving both high area efficiency and low latency. This gap motivates our investigation into fusing the two methods to optimize modular reduction.

By leveraging the unique advantages of each method, we aim to reduce area consumption while maintaining efficient large-number modular reduction. In this paper, we analyze hybrid workloads across both methods to achieve enhanced performance and use this analysis to design a template for balanced workload distribution. We also explore the design space, considering area overhead and latency as flexible constraints, and identify the Pareto optimal boundary of our design. Finally, we propose an automatic search method to efficiently find the optimal design that aligns with user-specified constraints.

IV. Proposed ALLMod Design

A. Method Fusion based on Hybrid Workloads

For formal modeling, we assume that a BRAM can store mappings from a k-bit input to an n-bit output. We use TP, the number of modular reductions per cycle, to indicate the throughput of the design. The upper bound of TP is $MaxTP = 0.5Ops/cycle$, because each modular reduction requires 2 cycles for the lookup in the BRAMs. For a $2n$-bit input A, we divide it into two parts: the high $n - m$ bits are processed using the LUT-based method, while the low $n + m$ bits are handled by the iterative-based method.

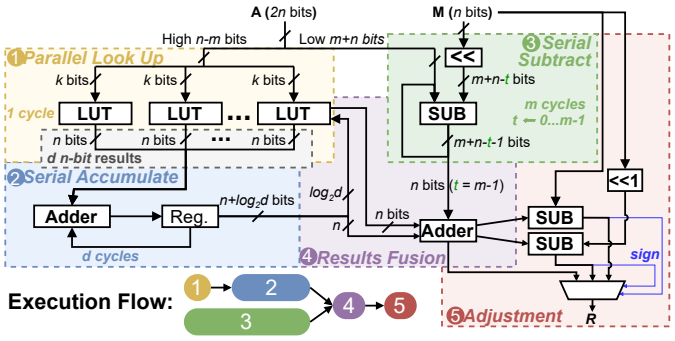

Fig. 3. ALLMod Template for balanced workload. Part ① and part ② support lookup and accumulation for LUT-based method. Part ③ supports serial subtraction for iterative-based method. Part ④ and part ⑤ are designed for fusing and adjusting the results.

Here, m is a design parameter that governs the workload distribution between the two methods. The specific derivation of this partitioning is as follows:

$$\begin{aligned} A &= \sum_{i=0}^{2n-1}(2^i a_i) = \sum_{i=n+m}^{2n-1}(2^i a_i) + \sum_{i=0}^{n+m-1}(2^i a_i) \\ &= (\sum_{i=0}^{\frac{n-m}{k}-1}\sum_{j=0}^{k-1}(2^{n+m+ki+j}a_{n+m+ki+j})) + \sum_{i=0}^{n+m-1}(2^i a_i) \\ &= \sum_{i=0}^{\frac{n-m}{k}-1}(\hat{a}_i \times 2^{n+m+ki}) + \sum_{i=0}^{n+m-1}(2^i a_i) \end{aligned} \tag{2}$$

where $\hat{a}_i = \sum_{j=0}^{k-1}(2^j a_{n+m+ik+j})$. Thus, the modular reduction can also be split into two parts of workloads:

$$\underbrace{(\sum_{i=0}^{\frac{n-m}{k}-1}(\hat{a}_i \times 2^{n+m+ki}))\ mod\ M}_{\textbf{Workload I} \text{ for LUT-based method}} + \underbrace{(\sum_{i=0}^{n+m-1}(2^i a_i))\ mod\ M}_{\textbf{Workload II} \text{ for iterative method}} \tag{3}$$

In ALLMod, **workload I** is solved by the LUT-based method, and **workload II** is solved by the iterative-based method. For scalability and area efficiency considerations, we employ serial adders to implement accumulation instead of an adder tree.

B. Template Design for balanced workload

Based on hybrid workloads, we propose a template design to maximize computation efficiency. As illustrated in Figure 3, the template consists of five parts. Part ① are d BRAMs for storing the pre-computed results of $\hat{a}_i \times 2^{n+m+ki}\ mod\ M$, where $d = \frac{n-m}{k}$. The high $n-m$ bits are fed into the BRAMs for parallel lookup. Part ② uses an adder for serially accumulating the d results from the BRAMs. Part ③ consists of a subtractor and a shifter for iterative subtractions. Part ④ is an adder for fusing the results from the two methods, including the low n bits of the accumulation results from part ②, the second round lookup result from part ①, and the serail subtraction result from part ③. Part ⑤ deploys several subtractors and a multiplexer for adjusting the final result.

The dataflow is also illustrated in Figure 3. For the **left workload**, the high $n-m$ bits are sent to part ① for parallel lookup, which takes one cycle. The results are then serially accumulated in part ② over d cycles. After accumulating the $n+\log_2 d$-bit result in part ②, the high $\log_2 d$ bits are sent back to part ① for a second round of lookup. Meanwhile, for the **right workload**, the low $n+m$ bits are sent to part ③, where they undergo $m-1$ cycles of subtraction. In part ④, the results from the previous three parts—part ①, part ②, and part ③—are added together for fusion. The final result is then adjusted using several subtractions in part ⑤. Regarding resource reuse, since the execution of part ② and part ③ does not overlap with that of part ④ and part ⑤, resource reuse is possible. The adder in part ② can be reused in part ④ for aggregation, and the subtractor in part ③ can also be reused in part ⑤ for adjustment. This further optimizes the design by reducing redundant hardware resources and enhancing efficiency.

Given that the two workloads are executed in parallel, the latencies of the two workloads should ideally be equal to ensure a balanced workload and minimize resource waste. The latency of the left workload is $d+1$ cycles ($d = \frac{n-m}{k}$), and the latency of the right workload is m cycles. Therefore, the following equation should be satisfied:

$$\frac{n-m}{k} + 1 = m \ \Rightarrow \ m = \frac{n+k}{k+1} \tag{4}$$

Apart from the BRAMs, the adder and subtractor in the template need to be copied $d \times TP$ times to ensure the throughput.

The template can reduce the area overhead of both BRAMs and adders/subtractors. Compared to the LUT-based method, the template can achieve $\frac{m}{n} = \frac{n+k}{n(k+1)} \approx \frac{1}{k+1}$ BRAM savings. Moreover, the original LUT-based method needs $\frac{2n}{k}$ adders/-subtractors, while ours just needs $d = \frac{n-m}{k} =$ pieces to reach maximum throughput $MaxTP$. For $n = 8,192$, a BRAM can only store mappings with 2-bit input, meaning $k = 2$. Consequently, our template can save up to 50% of the required BRAMs and over 65% of the required adders/subtractors.

C. Template-aided Design Space Exploration

To accommodate a broader range of design requirements, we explore the design space of ALLMod. Using the proposed template, which focuses on balanced workloads, we investigate the design space by considering both latency and area constraints as key parameters.

1) Parallel-Serial Hybrid for More Strict Latency Constraint: In cases where stricter latency requirements are imposed, the single-pass algorithm must be completed in fewer cycles. Since the iterative method cannot be parallelized, we propose reducing its workload while shifting more work to the table lookup method. Additionally, we aim to enhance the parallel processing capacity of specific components within the table lookup method.

To achieve this, we introduce a small adder tree into part ② of the template, which works alongside the serial accumulator to accelerate the accumulation process. This setup allows the

workload in the left part of the design to be completed in fewer cycles, helping to meet the stricter latency constraints. When configured with an adder tree that has x inputs, part ② can be completed in $\frac{n-m}{k} - x$ cycles, while part ③ will still take m cycles. The optimal design point is determined by finding m and x that satisfy the following conditions:

$$max(1 + \frac{n-m}{k} - x, m) \leq Latency_{req} \tag{5}$$

where $Latency_{req}$ is the user-specified number of cycles required for the design.

2) More Strict Area Constraint: When area constraints become more stringent, we assign a larger portion of the workload to part ③ (iterative subtraction) to reduce the BRAM overhead of part ② (parallel lookup). However, since the workload in part ③ cannot be accelerated in parallel, we need to ensure throughput by duplicating more of the components in part ③.

Assuming that part ③ is duplicated y times, its throughput is approximately $\frac{y}{m}$Ops/cycle. To guarantee throughput, we set $y = m \times TP$. Similarly, part ② must be duplicated $d \times TP$ times. Consequently, the task is to determine the value of m such that the design meets both area and throughput requirements:

$$\begin{aligned} &\frac{n-m}{k} \times Area_{BRAM} + d \times TP \times Area_{Adder} \\ &+m \times TP \times Area_{Subtractor} \leq \text{Area}_{req} \end{aligned} \tag{6}$$

where $Area_{req}$ is the user-specified area limit, and $Area_{BRAM/Adder/Subtractor}$ represents the area of a BRAM/adder/subtractor.

3) Automatic Search: The analysis of the design space only focuses on either lower latency or smaller area consumption. In practice, the design usually has constraints on both latency and area. Therefore, based on the previous analysis, we propose an automatic search approach to find the Pareto optimal design schemes that meet various constraints provided by users. As shown in Algorithm 2, our search method takes the bit-width n, and user-specified constraints as input, and outputs a list of Pareto optimal schemes. Users' constraints include latency requirement $Latency_{req}$, area requirement $Area_{req}$, and expected throughput TP.

First, we enumerate m from 0 to n to explore different workload segmentations. Specifically, $m = 0$ corresponds to the pure LUT-based method, while $m = n$ corresponds to the pure iterative method. Next, we enumerate the input width of the adder tree, $Width_{Tree}$, from 0 to $n - m$. When $Width_{Tree} = 0$, the template with a balanced workload, as introduced in Section IV-B, is used; when $Width_{Tree} = n - m$, part ② is entirely implemented using an adder tree for parallel accumulation. Each pair of values (m, $Width_{Tree}$) forms a key *parameter pair* for a candidate scheme.

For each *parameter pair*, we compute the cycles required to complete the modular reduction, as outlined in Section IV-B, and verify whether the latency requirement is met. Then, we calculate the number of BRAMs, adders, and subtractors needed for the scheme and estimate the corresponding area overhead. Feasible schemes that satisfy both latency and area constraints are added to a candidate list, $SchemeList$. Finally, we identify the Pareto optimal schemes from this list. Through such an automatic search process, users can easily identify the Pareto optimal design schemes that meet their specific constraints.

Algorithm 2: Automatic Design Space Search.

Data: Bit-width n, Input bit-width of BRAM(LUT) k, user-specified latency and area constraints $Latency_{req}$ and $Area_{req}$, expected throughput TP

Result: Pareto optimal scheme list $OptSchemeList$

```
SchemeList ← [ ]
for m ← 0 ... n do
    for Width_Tree ← 0 ... n − m do
        Latency_LUT ← 1 + max(n−m/k − Width_Tree, log2(Width_Tree))
        Latency_iter ← m
        Latency ← max (Latency_LUT, Latency_iter )
        if Latency ≤ Latency_req then
            N_BRAMs ← n−m/k
            N_Adders_Tree ← 2 × Width_Tree − 1
            N_Adders_Serial ← (n−m/k − Width_Tree) × TP
            N_Adders ← N_Adder_Tree + N_Adder_Serial
            N_Subtractors ← m × TP
            Area ← AreaEstimate(N_BRAMs, N_Adders, N_Subtractors)
            if Area ≤ Area_req then
                Scheme_feasible ← (m, Width_Tree, Cycles, Area)
                SchemeList.append(Scheme_feasible)
            end
        end
    end
end
OptSchemeList ← FindParetoOptimal(SchemeList)
```

In addition, our approach efficiently identifies Pareto optimal schemes. By enumerating both m and $Width_{Tree}$, the total number of feasible schemes, denoted as S, can be at most n^2. Using a priority queue to sort and select the optimal schemes, the time complexity for finding the Pareto optimal solutions is $O(S \log S) = O(n^2 \log n)$. Even for very large values of n, such as $8,192$, the entire search process completes in approximately ten minutes[2].

V. Evaluations

A. Evaluation Methodology

We compare ALLMod with the standard LUT-based method [12] and iterative method [13]. We implement a 128-bit prototype system for ALLMod on FPGA using Verilog, with a working frequency set to 200MHz. To validate the

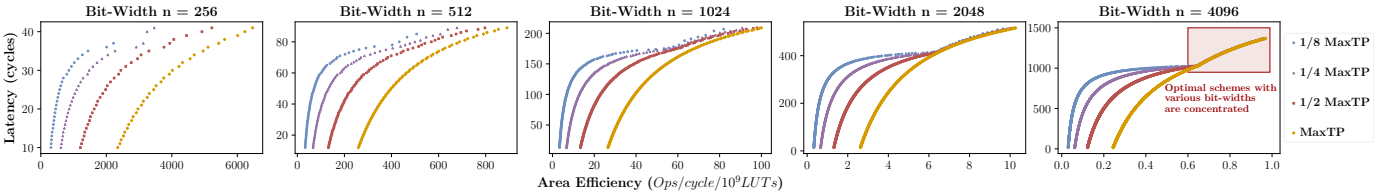

Fig. 4. Pareto optimal schemes of ALLMod for various throughputs and bit-widths. The optimal schemes with high area efficiency gradually converge as the bit-width increases.

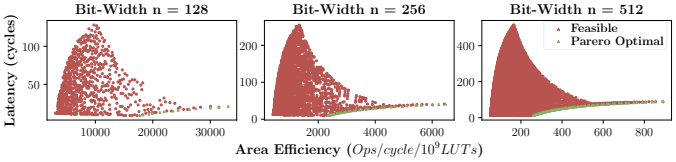

Fig. 5. Visualization of searched schemes for various bit-width at maximum throughput $MaxTP$. **Red** points indicate the feasible schemes and **green** points indicate the Pareto optimal schemes.

timing and functionality of our models, we synthesized them using the Xilinx Vivado Design Suite [15]. For evaluation, we use $\frac{Ops/cycle}{10^9 LUTs}$ as the metric of area efficiency. Given that the working frequency for both the baseline and our method is primarily determined by the latency of the n-bit adder/subtractor, we utilize $cycles$ as a standardized metric for latency comparison, assuming a similar frequency across implementations. This allows for a fair comparison of execution time independent of absolute clock speeds. The overhead of BRAMs, adders, and subtractors is converted with LUTs, based on the utilization report from the IP generator of Vivado.

B. Overall Performance

Table I compares the performance of our ALLMod template with the baseline method. The methods are all aligned to the maximum throughput $MaxTP$ that the LUT-based method can achieve. We show the area efficiency, latency, and the breakdown of resources for each method, and segmentation for hybrid workloads of ALLMod.

For small bit-width $n = 128$, ALLMod achieves the area efficiency of $25,000\ Ops/Cycles/10^9 LUTs$, which is $1.65\times$ higher than the LUT-based method. For large number modular reduction with $n = 8,192$, ALLMod achieves up to $3.0\times$ area efficiency improvement over the LUT-based method. It's worth noting that although the LUT-based method has lower latency, it needs too much area overhead to achieve the same throughput as ALLMod.

The breakdown results demonstrate that ALLMod can save a significant number of BRAMs and adders/subtractors. For $n = 8,192$, ALLMod saves over 30% of BRAMs and 66% of adders/subtractors compared to the LUT-based method. As the bit-width increases, the proportion of workload allocated to the right parts in the template gradually increases, which illustrates the significance of introducing a hybrid workload design for optimizing the LUT-based method.

C. Pareto Optimal with various throughput requirements

Figure 4 shows the Pareto optimal schemes of ALLMod for various throughputs and bit-widths. We iterate the throughput requirement from $MaxTP/8$ to $MaxTP$ for each bit-width. As the bit-width increases, the Pareto optimal schemes for different throughputs are more concentrated in the region with high area efficiency, meaning that the design gradually converges. Such a convergence demonstrates that ALLMod can effectively explore the design space and find optimal schemes for guiding the design.

D. Design space exploration with automatic search

Figure 5 visualizes the design space exploration results of ALLMod for various bit-widths. The distributions of feasible schemes under different bit-widths are basically the same. A significant concentration of feasible schemes is observed within the region of lower area efficiency and high latency, whereas a small number of feasible solutions are identified in the region of higher area efficiency. This distribution underscores the criticality of identifying Pareto optimal schemes. Our automatic search effectively filters out schemes with low area efficiency and high latency and finds area-efficient schemes with low latency.

VI. CONCLUSION

This paper presents ALLMod, an area-efficient method for large-number modular reduction, combining LUT-based and iterative approaches. We then design a balanced workload template to guide the segmentation. Additionally, we present an automatic search approach to explore the design space of ALLMod based on this template. Evaluations show that ALLMod outperforms the LUT-based method in terms of area efficiency and latency.

***Abstract*—The increasing complexity of high-frequency circuits calls for efficient and accurate passive macromodeling techniques. Existing passivity enforcement methods, including those in commercial tools, often encounter convergence issues or compromise accuracy. The Domain-Alternated Optimization (DAO) framework seeks to restore accuracy through an additional optimization step but is hampered by high memory consumption and slow convergence, particularly for large-scale problems. This paper presents G-SpNN, a novel GPU-accelerated framework that recasts the passivity-enforced macromodeling problem as a neural network training task. This approach significantly enhances both the speed and scalability of passivity enforcement. Experimental results show that G-SpNN achieves an average speedup of 7.63× in convergence compared to DAO, while reducing memory usage by two orders of magnitude. This enables G-SpNN to handle complex, high-port-count circuits with greater accuracy and efficiency, paving the way for robust high-frequency circuit simulations.**

I. INTRODUCTION

S-parameters, and frequency-domain parameters in general, pose significant challenges in circuit simulation. Running time-domain analyses with them, which typically involves frequency-domain interpolation and extrapolation, causality enforcement, impulse response computation and the convolution analysis, is computationally intensive and often leads to convergence issues. Macromodeling, also known as broadband SPICE (bbspice) in the circuit design community, offers a preferred alternative [1], but its effectiveness hinges on robust passivity enforcement to guarantee accurate and stable high-frequency simulations.

Early attempts to address passivity enforcement through convex optimization faced limitations due to their high computational complexity, scaling with $O(n^6)$ [1], where n represents the number of poles. This restricted their applicability to small-scale problems ($n < 100$) [1]. Mainstream methods typically adopt a two-step approach: first generating a macromodel without considering passivity constraints, often using techniques like Vector Fitting (VF) [2], and then applying specialized algorithms to restore passivity, such as the Eigenvalue Perturbation (EPM) [3], Residue Perturbation (RPM) [4], and Local Compensation (LC) [5]. However, these methods frequently compromise model accuracy, significantly increase computational costs, and are not robust in their performances, making them challenging to implement in practice.

Despite these challenges, almost all commercial solutions rely on these two-step methods. In practice, designers routinely observe commercial broadband SPICE fitting tools struggling to fit S-parameter data from Touchstone files, particularly for the simulations of radio-frequency integrated circuits (RFICs) and chip packaging. The iterative nature of these methods often introduces cumulative fitting errors, leading to reduced accuracy. To mitigate this, commercial tools often relax passivity constraints, either by internally setting a tolerance for violations or enforcing passivity only within limited bandwidths. While this approach may improve fitting success rates, it can hinder simulation convergence later in the design process.

The Domain-Alternated Optimization (DAO) framework [6] seeks to enhance accuracy by incorporating a third optimization step after the conventional two-step approach. By transforming the original modeling problem constrained by passivity criteria into an unconstrained optimization problem, DAO enables the use of unconstrained optimizers to improve macromodel accuracy while maintaining passivity throughout the process. However, DAO still suffers from high memory consumption and slow convergence, particularly when dealing with large-scale problems, limiting its practical adoption. For example, using the DAO method on a 64-port system resulted in an average memory usage of 22GB per iteration, while a 138-port system exceeded 31.8GB.

Therefore, passivity enforcement is arguably still an unsolved problem, especially for large-scale systems with many ports. Today, the increasing prevalence of complex integrated circuits, with a rising number of ports driven by trends like chiplets and multi-core architectures, further exacerbates the challenges of passivity enforcement [7]. This surge in complexity renders existing methods inadequate, necessitating new solutions capable of efficiently and accurately enforcing passivity in large-scale systems.

In the meanwhile, the development of neural networks, combined with the emergence of large-scale optimizers and optimization frameworks for training these networks, presents new possibilities for addressing the challenge of passivity enforcement [8]. These frameworks, which can be accelerated using GPUs, provide a missing piece in the three-step DAO

framework. By drawing an analogy between passivity enforcement and neural network training, specifically the process of finding optimal weights [9] [10], it becomes possible to handle large-scale problems more effectively.

This work proposes G-SpNN, a novel GPU-accelerated framework that recasts passivity-enforced macromodeling as a neural network training problem. This framework, built upon the deep learning toolkit PyTorch, maps the constrained optimization problem of passivity enforcement onto an unconstrained optimization objective within the neural network training process. By leveraging PyTorch's automatic differentiation mechanism, G-SpNN eliminates the need for manual gradient derivation, simplifying the implementation and improving efficiency. Moreover, G-SpNN employs vectorized representations and QR decomposition to streamline error function calculations and utilizes the LBFGS method to approximate the Hessian inverse matrix, thereby accelerating convergence.

G-SpNN's key contributions include:

1) Casting the passive macromodeling problem to neural network training, thus leveraging GPU acceleration.
2) Using the LBFGS method to efficiently approximate the Hessian inverse matrix, proven to work the best in practice.
3) Keeping the memory usage almost constant with an increasing number of ports. Experimental results show that G-SpNN not only converges more stably and quickly than DAO, with a average speedup of 7.63×, its memory usage can be reduced by two orders of magnitude in test cases.

From above, G-SpNN offers a robust passivity-enforced macromodeling framework, presented in more detail in the following sections.

II. PRELIMINARIES

A. Macromodel Generation of S-Parameters

S-parameters describe signal scattering in the frequency domain. Macromodeling fits a rational function to frequency data s_k (frequency points) and $H(s_k) \in \mathbb{C}^{m\times m}$ (system response):

$$f(s_k) = \sum_{n=1}^{N_q} \frac{c_n}{s_k - a_n} + d + s_k h \tag{1}$$

where c_n, a_n, d, h are fitting coefficients.

To improve stability and efficiency, Eq. (1) is often expressed in a state-space form [11]:

$$G(s_k) = C(s_k \cdot I - A)^{-1}B + D \tag{2}$$

where $A \in \mathbb{C}^{n\times n}, B \in \mathbb{C}^{n\times m}, C \in \mathbb{C}^{m\times n}, D \in \mathbb{C}^{m\times m}$, and I as the identity matrix.

For this system, $G(s_k)$ needs to satisfy two conditions [12]:

1) The error needs to be minimized.

$$Error = \min\left(\sum_k |G(s_k) - H(s_k)|\right) \tag{3}$$

2) It needs to satisfy the passivity requirement [13].

$$G(s_k) + G^H(s_k) \geq 0 \tag{4}$$

where G^H represents the conjugate transpose of G.

B. Three-Step Modeling Framework

The first step in passivity macromodeling is to fit Eq. (1) using methods such as VF [2] or Rational Fitting [14], and then transform it into the state-space representation as shown in Eq. (5), thereby obtaining the initial matrix.

$$G_0(s_k) = C_0(s_k \cdot I - A_0)^{-1}B_0 + D_0 \tag{5}$$

Although this step can easily provide a locally optimal fit with minimal error, the resulting matrix may not necessarily satisfy the required passivity [15].

The second step involves passivity fixing on the initial $G_0(s_k)$ to construct $G_1(s_k)$ by using EPM, RPM and LC, such that $G_1(s_k)$ satisfies the passivity [16].

The third step begins with $G_1(s_k)$ and solves the optimization model shown in Eq. (6) to find a system $G_2(s_k)$ that minimizes the error [17].

$$\begin{cases} \min\limits_{C,D} \sum\limits_k |G_2(s_k) - H(s_k)| \\ \text{subject to: } G_2(s_k) \text{ is passive} \end{cases} \tag{6}$$

C. Domain-Alternated Optimization

Actually, the third step of the Three-Step Modeling Framework often faces challenges in enforcing passivity constraints. Robust implementation of Eq. (6) is impractical [18] [19]. To address this problem, the DAO framework simplifies the optimization process by introducing a system $W(s_k)$ as optimization variables, thereby removing passivity constraints and converting the problem into an unconstrained form [6].

Algorithm 1 DAO Algorithm

1: **Step 1 :** Perform SPF on the initial passive system $G_1(s_k)$ to obtain $W(s_k)$.
2: **Step 2 :** Use the matrices (L, Q) of $W(s_k)$ as parameters and perform unconstrained optimization to minimize error.
3: **Step 3 :** Perform PFE to the optimized $W(s_k)$ to obtain the final system $G(s_k)$.

The Spectral Factorization (SPF) operation in Algorithm 1 is given by Eq. (7)-(10). Its essence lies in computing the matrices L and Q in order to derive $W(s_k)$ as shown in Eq. (11) [20].

$$R = Q^T Q = D + D^T \tag{7}$$

$$\tilde{A} = BR^{-1}C - A, \quad \tilde{B} = BQ^{-1}, \quad \tilde{C} = C^T R^{-1} C \tag{8}$$

$$K\tilde{A} + \tilde{A}^T K - K\tilde{B}\tilde{B}^T K - \tilde{C} = 0 \tag{9}$$

$$L = Q^{-T}C - Q^{-T}B^T K \tag{10}$$

$$W(s_k) = L(s_k \cdot I - A)^{-1}B + Q \tag{11}$$

The Partial Fractional Expansion (PFE) operation, defined by Eq. (12)-(14), focuses on computing the matrices C and D to transform $W(s_k)$ into $G(s_k)$ [21] [22] [23].

$$M = \text{kron}(A^T, I_n) + \text{kron}(I_n, A^T) \tag{12}$$

$$\text{vec}(K) = -M^{-1}\text{vec}(L^T L) \tag{13}$$

$$C = B^T K + Q^T L, \quad D = \frac{1}{2}Q^T Q \tag{14}$$

where kron$(\cdot)$ represents the Kronecker product, and vec(K) represents the vectorized form of matrix K [24].

Based on the principles and theorems related to SPF and PFE [21], the system $G(s_k)$ derived from $W(s_k)$ is guaranteed to maintain passivity. Consequently, the original optimization problem in Eq. (6) can be reformulated as an unconstrained optimization problem in Eq. (15).

$$\begin{cases} \min\limits_{L,Q} \sum\limits_{k} |G(s_k) - H(s_k)| \\ \text{subject to:} \\ W(s_k) = L(s_k \cdot I - A)^{-1} + Q \\ G(s_k) = pfe(W(s_k)) \end{cases} \tag{15}$$

III. G-SpNN

For the optimization problem defined in Eq. (15), it is feasible to directly compute the gradient vector and Hessian matrix [25]. However, compared to Eq. (6), the larger computational scale results in increased time costs and memory consumption, brings significant challenges. To this end, we propose G-SpNN, which achieves an optimal passive macromodel with faster convergence and lower memory consumption. More importantly, it exhibits excellent scalability, capable of handling ultra-large-scale passive macromodeling problems.

The overall workflow of G-SpNN is shown in Figure 1. Starting with a given passive system $G_1(s_k)$, an unconstrained system $W(s_k)$ is first derived by SPF transformation and represented as a layer in the neural network. Next, the PFE transformation is applied to generate a new network layer $G(s_k)$, corresponding to a passive system. This reformulates the problem as a neural network training task. During forward propagation, the system, together with the tabulated data $H(s_k)$, is used to compute the loss value. For efficient training, the LBFGS method is futher incorporated with backpropagation to compute gradients and update the network parameters. Once the iteration stopping criteria are satisfied, the optimized passive system is obtained. Details are in Algorithm 2.

Algorithm 2 Proposed G-SpNN Algorithm

1: **Preprocess:** Calculate R_F, b, δ, M^{-1} from (20), (22) and (12)
2: **SPF Transformation:** Apply SPF to matrices A, B, C, D from (2) to obtain A, B, L, Q
3: **Initialize:** Set optimizer with parameters L, Q, define number of epochs
4: **for** i in {1, 2, ..., epoch} **do**
5: Apply PFE to transform L, Q into C, D
6: Vectorize C, D into y, and L, Q into x
7: Compute loss: $f(x)$ from (21)
8: Backpropagate and using chain rule: $\frac{\partial f}{\partial x} = \frac{\partial f}{\partial y} \cdot \frac{\partial y}{\partial x}$
9: Approximate the Hessian inverse via k LBFGS iterations
10: Update L, Q
11: **end for**
12: **Final Transformation:** Convert L, Q to final C, D using PFE to obtain final $G(s_k)$

A. Analogy to Neural Network Training

Both solving Eq. (15) and training a neural network represent fundamentally nonlinear optimization challenges. In this context, the error function in Eq. (15) can be viewed as analogous to the prediction error encountered in neural network training, highlighting a direct connection between the two optimization frameworks. This analogy not only emphasizes the shared nature of the problems but also suggests that leveraging neural network techniques can facilitate faster optimization. As illustrated in Figure 2, the comparison between the two problem-solving approaches is visually clear. In neural network training, each data instance consists of an input vector x_i and a corresponding label y_i, and the predicted label $\phi(x_i, w)$ is obtained through the neural network. The training task is to minimize an objective function, which primarily consists of prediction errors.

By drawing an analogy between unconstrained optimization, as expressed in Eq. (15), and neural network training, we represent parameters L, Q in simplified form as w, and treat parameters s_k and $H(s_k)$ (derived from the simulation or measurement process) as data instances. The neural network processes these data instances and computes $g(s_k, w)$ ($g(\cdot, w)$ represents $G(s)$ in Eq. (15), where A and B are constants), after which the corresponding objective function is calculated to iteratively update the network, ultimately yielding the optimal solution to Eq. (15). Through this construction, the unconstrained optimization problem can be seamlessly transformed into the neural network training process, making it possible to leverage advanced deep learning techniques to address the issues in the DAO framework.

It is important to note that, as shown in Figure 1, during the complete equivalent neural network training process, the transformations between L, Q and C, D through PFE and SPF do not affect the gradient computation. The gradient still follows the chain rule and is automatically handled by PyTorch, a feature that the DAO framework lacks.

B. Loss Function

During the forward propagation phase of neural network training, the need to compute prediction errors N times, with each error computed through matrix norm calculations, introduces significant complexity throughout the training process. To address this issue, this section will reformulate the objective function from Eq. (15) to make the neural network training process more computationally efficient.

For the objective function in Eq. (15):

$$Error = \min_{C,D} \sum_{k} |G(s_k) - H(s_k)| \tag{16}$$

We can vectorize it as follows:

$$Error_vec = |Fy - h| \tag{17}$$

where:

$$y = \begin{bmatrix} \text{vec}(C) \\ \text{vec}(D) \end{bmatrix} \qquad \text{F}_i = \begin{bmatrix} \text{kron}([s_i I - A]^{-1}, I_n) & I_m^2 \end{bmatrix} \tag{18}$$

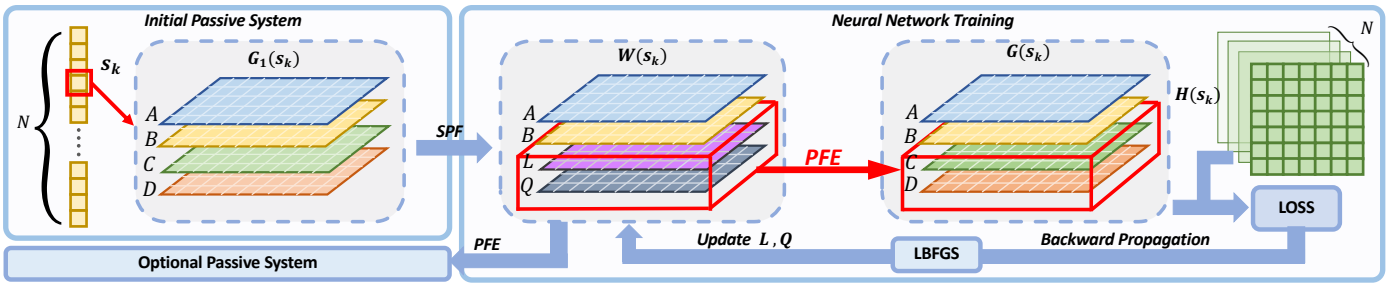

Fig. 1: The overall framework of G-SpNN.

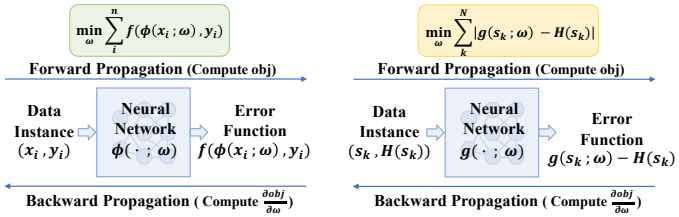

Fig. 2: Analogy between unconstrained optimization and neural network training. (a) Train a network for weights $\mathbf{w}$. (b) Solve a set of parameters for macromodel with $\mathbf{w} = (\mathbf{L}, \mathbf{Q})$.

To further simplify the computation of the objective function, a more detailed decomposition of Eq. (17) can be performed. The specific decomposition process is as follows. Firstly, QR factorization can be applied to F in Eq. (19):

$$h = \begin{bmatrix} \mathrm{vec}(\mathrm{Re}(H(s_1))) \\ \vdots \\ \mathrm{vec}(\mathrm{Re}(H(s_N))) \\ \mathrm{vec}(\mathrm{Im}(H(s_1))) \\ \vdots \\ \mathrm{vec}(\mathrm{Im}(H(s_N))) \end{bmatrix} \quad F = \begin{bmatrix} \mathrm{Re}(F_1) \\ \vdots \\ \mathrm{Re}(F_N) \\ \mathrm{Im}(F_1) \\ \vdots \\ \mathrm{Im}(F_N) \end{bmatrix} \tag{19}$$

$$F = Q_F R_F \tag{20}$$

Subsequently, Eq. (17) can be further transformed into the following form Eq. (21), which also represents the final definition of the loss function:

$$loss = Error_vec = (R_F y - b)^T (R_F y - b) + \delta^2 \tag{21}$$

where:

$$b = Q_F^T h, \quad \delta^2 = h^T h - b^T b \tag{22}$$

By decomposing F into Q_F and R_F, the quadratic term $(R_F y - b)^T (R_F y - b)$ is simplified to a standard least-squares problem, which is computationally more efficient. This simplification reduces the need for repeated computation of matrix norms, which would otherwise be required for every iteration in the optimization process. Furthermore, the decomposition helps in minimizing the number of operations required to update gradients and compute the loss, thereby enhancing overall computational efficiency.

C. Further Optimization for Memory and Time Consumption

Based on the new definition of the loss function, optimization problem Eq. (15) can be further refined as follows:

$$\begin{cases} \text{variable: } L, Q \\ \text{min: } f(y) = (R_F y - b)^T (R_F y - b) + \delta^2 \\ \text{subject to:} \\ x = \begin{bmatrix} \mathrm{vec}(L) \\ \mathrm{vec}(Q) \end{bmatrix} \\ y = pfe(x) \end{cases} \tag{23}$$

For nonlinear optimization problems like Eq.(23), traditional methods such as DAO typically compute the gradient vector and Hessian matrix to determine the search direction and step size, thereby accelerating convergence. However, the full calculation of the Hessian matrix imposes significant memory and time overhead [26], especially for high-dimensional optimization problems. Therefore, we employ the LBFGS method [27] to approximate the inverse of the Hessian matrix, which reduces memory usage while still accurately selecting the gradient descent direction, thus accelerating neural network convergence.

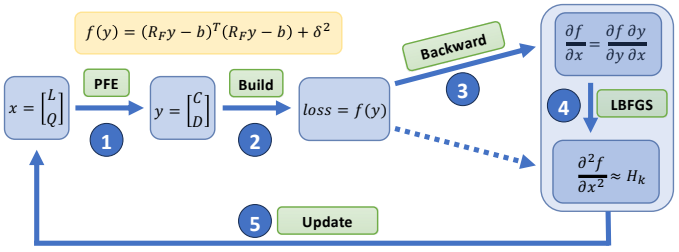

Fig. 3: Computational graph with LBFGS Method.

Figure 3 illustrates the computational graph. The input parameters are derived from Eq.(11) (the unconstrained system $W(s)$ in Figure 1), which include the parameter matrices L and Q. These matrices are vectorized into x. The computational graph includes five steps. ***Step 1***, x undergoes the PFE operation to generate parameters y (the passive system $G(s)$). ***Step 2***, using y along with other matrices from Eq. (20) and Eq. (22), the loss function is constructed. ***Step 3***, automatic differentiation is employed to compute the gradient information, applying the chain rule to perform backpropagation and calculate the first-order derivative of the loss function with respect to the network weights x. ***Step 4***, the LBFGS method is used to approximate the inverse Hessian matrix. ***Step 5***, the previously calculated

first-order derivative information and the approximated inverse Hessian matrix are used to update the parameters L and Q of the initial passive system. Above all, this completes one optimization iteration.

In the approximation process of ***Step 4***, it is important to note that the LBFGS algorithm does not store the full Hessian matrix directly [28]. Instead, it maintains a limited history of recent iterations to perform the calculations. The update formula for the Hessian inverse approximation in LBFGS is given by:

$$H_{k+1} = H_k - \frac{H_k \Delta g_k \Delta g_k^T H_k}{\Delta g_k^T \Delta x_k} + \frac{\Delta x_k \Delta x_k^T}{\Delta x_k^T \Delta g_k} \tag{24}$$

where:

1) H_k is the Hessian inverse approximation at iteration k.
2) $\Delta g_k = (\frac{\partial f}{\partial x})_{k+1} - (\frac{\partial f}{\partial x})_k$ is the change in the gradient.
3) $\Delta x_k = x_{k+1} - x_k$ is the change in the parameter.

The LBFGS is well-suited for this optimization problem due to its efficiency in managing large-scale variables and its ability to converge rapidly to a solution with a limited memory overhead. As experiments have shown, this optimization method, which combines efficient memory management and rapid convergence speed, provides robust support for optimizing complex circuit models.

IV. Experiments

A. Experimental Setup

We implement and test the proposed G-SpNN on an i7-14700KF @5.6GHz CPU with 32GB of memory, and a GeForce RTX 4070 SUPER GPU with 12GB of VRAM. G-SpNN is implemented based on PyTorch and compared against the state-of-the-art (SOTA) framework DAO, which is implemented in MATLAB and is open-sourced on GitHub[1].

For the DAO, we utilize MATLAB's built-in method $user.MemUsedMATLAB$ to record the memory consumption. For the G-SpNN, we monitor the GPU memory usage by calling PyTorch's $torch.cuda.memory_allocated()$.

The input files used in the experiments are standard Touchstone format files, derived from actual real-world simulations. After reading the files, the parameters s_k and $H^{m\times m}(s_k)$ $(1 \le k \le N)$ can be obtained. Before conducting the comparative experiments, the first two steps of macromodeling (as outlined in the preliminaries section) need to be performed on the raw data. Specifically, this involves applying the VF and LC method to process the data and generate four matrices: $A^{n\times n}$, $B^{n\times m}$, $C^{m\times n}$, and $D^{m\times m}$. The detailed information about these matrices and the results of the VF and LC method can be found in Tables I and II.

In this experiment, steady-state error (SS Error) is used as the basis for comparison. According to the data in Table II, the VF method initially produces a result with a very low steady-state error for the test samples. However, this result does not satisfy the passivity requirement. After applying the LC method for passivity correction, the passivity condition is met, but the steady-state error increases to some extent.

[1]https://www.github.com/yezuochang/pmm

TABLE I: Touchstone files.

5	pll_testcase	138	727	138	300

TABLE II: Fitting results of VF and LC.

Num	VF			LC		
	SS Error	Time(s)	Passivity	SS Error	Time(s)	Passivity
1	1.52e-4	0.8906	non-passive	5.91e-1	0.1875	passive
2	1.72e-7	17.78	non-passive	6.56e-5	7.64	passive
3	6.29e-4	25.59	non-passive	6.56e-4	6.906	passive
4	4.27e-3	96.89	non-passive	5.16e-3	17.21	passive
5	5.49e-4	75.23	non-passive	5.70e-4	91.79	passive

B. Passivity and Error

Table III presents the passivity results and steady-state errors for the G-SpNN and DAO methods. It is important to note that the steady-state error of the VF method represents the theoretical lower bound of the errors for both the G-SpNN and DAO methods. From the results, it is clear that both methods maintain passivity and further reduce errors compared to the LC method, with the G-SpNN error being closer to the VF error. Figure 4 shows the fitting results and errors for two points (H_{11} and H_{14}) in the H matrix of Case 1. It can be seen that G-SpNN provides a better overall fit to the original data, with errors lower than both the VF and LC method and the DAO method.

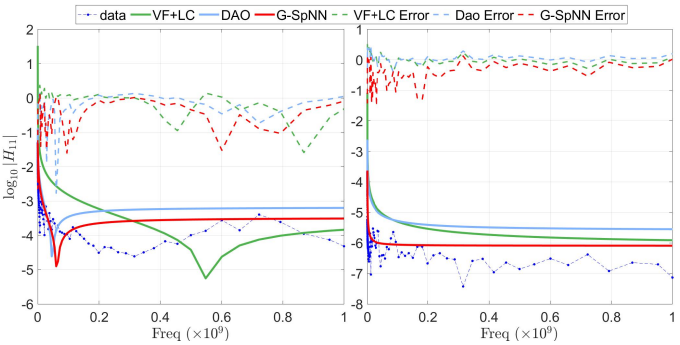

Fig. 4: Fitting accuracy of LC, DAO and G-SpNN.

C. Convergence Speed and Memory Usage

In Table III, we present the runtime, iteration count, initial loss, and final loss for both the G-SpNN and DAO methods. The convergence criterion is defined as a change in the loss function $\Delta\text{Loss} < 10^{-3}$. It is important to note that for Case 1, although the runtime of DAO appears shorter, the comparison of the final loss and steady-state error shows that DAO actually experiences pseudo-convergence and does not reach the optimal solution. In contrast, G-SpNN demonstrates better convergence performance. For Case 3 and Case 4, it should be noted that the DAO method is forcibly terminated during the iteration process due to memory overflow and does not reach the predefined convergence criterion. For Case 5, DAO experiences a memory overflow during the first iteration and could not complete the iteration.

TABLE III: Comparison of G-SpNN and DAO. The "–" indicates memory overrun during execution.

Num	Initial Loss	DAO [6]					G-SpNN				
		Time (s)	#Iteration	Final Loss	SS Error	Passivity	Time (s)	#Iteration	Final Loss	SS Error	Passivity
1	6.17e12	17.47	93	4.8656	2.26e-3	passive	94.19	232	4.19e-2	2.46e-4	passive
2	6.50e8	104.65	7	3.86e-2	2.65e-5	passive	97.93	328	3.89e-2	2.65e-5	passive
3	17.36	2116.48	4	17.21	6.51e-4	passive	300.46	803	17.15	6.47e-4	passive

5	78.32	–	–	–	–	–	403.35	456	77.62	5.58e-4	passive
Average		1540.44	28	565.53	1.98e-3		214.49	458	446.97	1.23e-3	

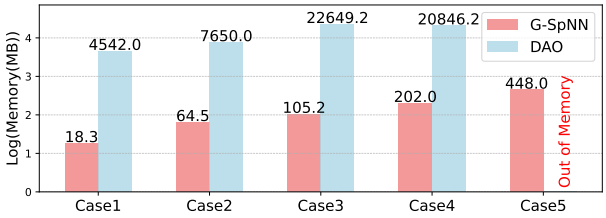

Fig. 5: G-SpNN vs. DAO in memory consumption.

For the tested cases, G-SpNN achieves an average speedup of 7.63× compared to DAO, and this speedup will increase even further with larger test cases. Therefore, G-SpNN is highly suitable for stable iterative convergence on large-scale cases.

We record the memory usage at each iteration to calculate the average memory consumption, as shown in Figure 5. Due to the high time and space complexity of the DAO method, we limit the number of poles in the VF method for cases 3-5 to ensure computational feasibility (which leads to higher SS Error and limits the reduction in loss). Nevertheless, it is still evident that as the test scale increases, DAO's memory usage rises significantly, while G-SpNN's memory usage remains relatively stable. The test results show that DAO's average memory consumption is 171.3 times that of G-SpNN.

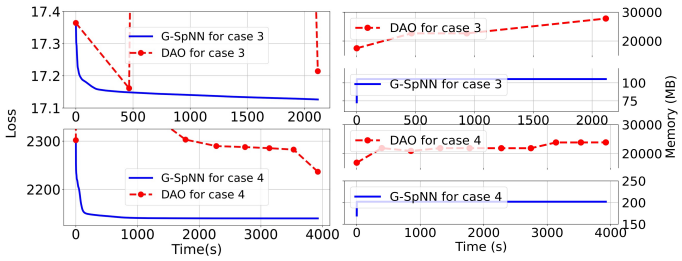

Fig. 6: G-SpNN vs. DAO in loss and memory over time (Case 3 and Case 4).

D. Detailed Analysis

To further compare the convergence efficiency of DAO and G-SpNN, we use Case 3 and Case 4 as examples, taking DAO's runtime for these cases as the benchmark. Figure 6 shows the loss and memory usage variations during iterations. It can be observed that G-SpNN has a smoother convergence process with better performance, achieving lower loss values per unit time compared to DAO. In contrast, DAO experiences gradient explosion, causing poor convergence and high memory usage, with significant fluctuations leading to memory explosions and premature termination. G-SpNN maintains significantly stable and lower memory usage throughout.

E. Comparison with Adam

For neural network training, optimization algorithms can leverage either first-order or higher-order gradient information. A commonly used first-order method is Adam, which is less sensitive to learning rate selection and performs well in many scenarios. We conduct tests comparing G-SpNN + Adam and G-SpNN + LBFGS on case 3 (using the same learning rate and configurations, only substituting the gradient computation method), with G-SpNN running for 80 seconds.

As shown in Figure 7, the Adam optimizer not only fails to reach lower loss values but also demonstrates instability, making its convergence behavior unpredictable. In contrast, the LBFGS method enables G-SpNN to progress steadily toward convergence, owing to second-order information guiding more effective update directions.

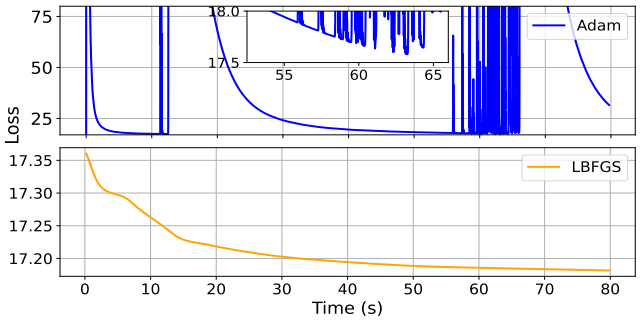

Fig. 7: Loss over time for G-SpNN with Adam and with LBFGS (Case 3).

V. Conclusion

In this paper, we introduce a novel perspective by mapping the passivity-enforced macromodeling problem into a neural network training task. The proposed optimization framework, G-SpNN, leverages advanced deep learning techniques as well as the LBFGS method. Compared to the current SOTA framework DAO, G-SpNN achieves significant improvements in both convergence speed and memory efficiency, which showcases exceptional capabilities to handle larger systems with a greater number of ports effectively.

***Abstract*—Deep learning has significantly advanced Electronic Design Automation (EDA), with circuit representation learning emerging as a key area for modeling the relationship between a circuit's structure and functionality. Existing methods primarily use either Large Language Models (LLMs) for Register Transfer Level (RTL) code analysis or Graph Neural Networks (GNNs) for netlist modeling. While LLMs excel at high-level functional understanding, they struggle with detailed netlist behavior. GNNs, however, face challenges when scaling to larger sequential circuits due to long-range information dependencies and insufficient functional supervision, leading to decreased accuracy and limited generalization. To address these challenges, we propose MOSS, a multimodal framework that integrates GNNs with LLMs for sequential circuit modeling. By enhancing D-type Flip-Flop (DFF) node features with embeddings from fine-tuned LLMs on RTL code, we focus the GNN on critical anchor points, reducing reliance on long-range dependencies. The LLM also provides global circuit embeddings, offering efficient supervision for functionality-related tasks. Additionally, MOSS introduces an adaptive aggregation method and a two-phase propagation mechanism in the GNN to better model signal propagation and sequential feedback within the circuit. Experimental results demonstrate that MOSS significantly improves the accuracy of functionality and performance predictions for sequential circuits compared to existing methods, particularly in larger circuits where previous models struggle. Specifically, MOSS achieves a 95.2% accuracy in arrival time prediction.**

I. Introduction

The application of deep learning (DL) techniques in EDA has garnered significant attention [1], [2], leading to notable advancements in areas such as routing [3], [4], synthesis [5], [6], and testing [7], [8]. Among these DL-driven EDA innovations, circuit representation learning [9], [10] has emerged as a promising research paradigm that propels predictions in subsequent EDA tasks. To further advance the development of circuit representation learning, modeling sequential circuits is particularly crucial, as they constitute the most commonly used circuit modules in practical electronic designs.

Existing works on circuit representation learning can mainly be divided into two categories, each modeling different modalities of circuit descriptions. The first category focuses on the register transfer level (RTL) code–a formal language that abstractly describes circuit behavior–utilizing large language models (LLMs) to provide a high-level understanding of functionality [11]. However, this approach faces challenges when it comes to analyzing the specific behavior and connectivity of individual cells in the netlist [12]. The second category employs graph neural networks (GNNs) for end-to-end learning, modeling the relationship between circuit functionality and structure [13]. Compared to the first approach, GNNs are closer to circuit structures, allowing for a more accurate representation of circuit details. Correspondingly, GNN-based models have achieved approximately 80% prediction accuracy for the toggle rates of sequential circuits within 1,000 gates. Such fine-grained tasks appear to be challenging for language models. Therefore, it seems to be a promising approach to use GNNs to model circuit structures for circuit representation.

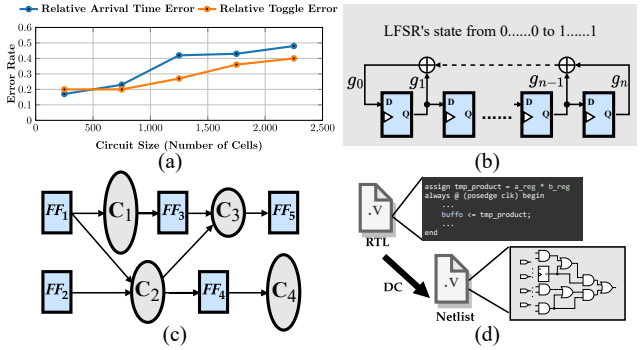

Fig. 1 Challenges and motivations for representation learning on sequential circuits. (a) Challenge 1: Performance degradation of existing methods in complex circuit prediction tasks. Both metrics are computed by summing the error ratio to the true value for each node and then averaging over all nodes. (b) Challenge 2: Sequential circuits can have almost infinite truth tables. (c) Motivation 1: DFFs divide sequential circuits. (d) Motivation 2: Different modalities provide different levels of abstraction in structure and functionality.

Unfortunately, when using GNNs to model larger sequential circuits for predicting their functionality and performance, we encounter significant challenges. The first challenge is the difficulty in handling long-range information dependencies, which leads to decreased accuracy on larger circuits. We implemented a GNN model, adopting asynchronous updates and other techniques from [14], and conducted tests on circuits of varying sizes to predict toggle rates and arrival times. The results, shown in Fig. 1(a), indicate that existing methods exhibit a substantial increase in error rates when applied to larger sequential circuits. For example, in a circuit with 2,000 gates, the prediction error rate exceeds 40%. One primary reason for this decline is that modeling larger circuits requires learning information from more distant nodes compared to smaller circuits. Despite employing asynchronous update strategies to propagate long-range information layer by layer, these advanced GNN designs remain susceptible to the loss of distant information, leading to decreased accuracy.

The second challenge is the difficulty in forming effective training supervision for the functionality of sequential circuits, resulting in weak capability in functionality-related tasks. Sequential circuits exhibit complex functional behaviors due to their stateful nature, making it challenging to capture functionality effectively with GNNs. The latest work, DeepSeq2 [14], artificially compresses the truth tables of individual nodes to form training supervision. However, this method has several drawbacks: Inefficiency for Large-Scale Circuits: As shown in Fig. 1(b), sequential circuits can have almost infinite truth tables because of the myriad possible states and input sequences over time. This makes the approach of compressing truth tables inefficient. Inadequate Description of Overall Circuit Functionality:

Manually extracting features from truth tables on each cell for training may aid in comparing individual nodes, but it is challenging to form a complete functional description of large-scale sequential circuits. This approach limits the ability to predict the complete circuit behavior and restricts the model's generalization capability. Consequently, this constraint limits performance on downstream tasks that require understanding the circuit's global functionality.

Interestingly, the structural characteristics of sequential circuits can be exploited to reduce the long-range dependencies encountered when modeling larger circuits. As shown in Fig. 1(c), sequential circuits inherently contain certain "anchor points", specifically D-type Flip-Flops (DFFs). These anchor points aggregate upstream input information and propagate it downstream, thereby driving the circuit's functional state. Furthermore, the interconnections between DFFs determine performance metrics such as arrival times. Therefore, by progressively and accurately modeling each DFF and its immediate connectivity network, we can localize the critical information within shorter-range dependencies. This approach reduces the reliance on long-range information propagation. However, existing methodologies have not yet taken advantage of this aspect for targeted modeling.

On the other hand, compared to the vast number of cell-level nodes present in the netlist, the RTL code offers a more macroscopic description of circuit connections and the functionality they form. As illustrated in Fig. 1(d), complex connectivity structures in a netlist can be succinctly represented by a single line of RTL code, providing a clear overview of the circuit's functionality. Therefore, if we can simultaneously learn from both RTL code and circuit netlist structures, integrating local and global information collaboratively, it will significantly enhance the efficiency of circuit representation learning. Moreover, by utilizing the formal language of RTL code-which provides an effective abstraction of functionalityand an LLM fine-tuned on circuit data to interpret the RTL, we can generate more accurate functional descriptions.

In this paper, we propose MOSS, a multimodal framework that integrates GNN with LLMs. We fine-tune an LLM on RTL code to generate embeddings that capture global circuit functionality. These embeddings enhance the features of DFF cells in the netlist, enabling the GNN to focus on critical anchor points and reduce reliance on long-range dependencies. The LLM also provides a global functionality embedding, offering efficient supervision for functionality-related tasks. Additionally, we introduce an adaptive aggregation method and a two-stage propagation mechanism to better model signal propagation and sequential feedback within the circuit. By combining structural insights from GNNs with functional understanding from LLMs, MOSS improves the accuracy of functionality and performance predictions for sequential circuits, particularly in larger circuits where existing methods struggle.

The contributions of this paper are summarized as follows:

- We propose MOSS, a multimodal framework that combines LLMs with GNNs for sequential circuit modeling, enhancing the collaboration between local node embeddings and global representations for circuit functionality and structure.
- We introduce an adaptive aggregation method and a two-phase propagation mechanism in the GNN to better model signal propagation and sequential feedback within circuits.
- MOSS significantly improves the accuracy of functionality and performance predictions for sequential circuits, outperforming existing methods on larger circuits. For example, it achieves a 95.2% accuracy in arrival time prediction.

II. Background and Related Work

A. Graph Neural Networks for EDA Tasks

Graph neural networks (GNNs) are a class of deep learning models specifically designed to process graph-structured data [15]. By operating directly on graphs, they capture complex dependencies and interactions between nodes. GNNs iteratively aggregate information from neighboring nodes to update node representations [16], enabling them to capture both local and global structural features [17]. In the field of EDA, GNNs are widely used for tasks such as circuit representation learning, performance prediction, and fault detection due to their high adaptability to circuit structures [18], [19].

For instance, FGNN2 [20] and DeepGate2 [21] focused on combinational circuits, which lack the timing dependencies inherent in sequential circuits. The DeepSeq series [14], [22] sought to incorporate temporal information into GNNs by training on logic and flip probabilities to model timing behavior. DeepSeq2 advanced this approach by introducing disentangled structure, function, and timing representations. However, as in Fig. 1, DeepSeq series struggles with long-range information dependencies. This shortcoming leads to a substantial decline in accuracy when applied to larger-scale circuits. Additionally, the DeepSeq series performs learning on And-Inverter Graphs (AIGs), which, compared to real netlists composed of standard cells, have nodes with simpler and uniform functions. In EDA scenarios, crucial labels such as timing are annotated at the standard cell level rather than the AIG level. Thus, AIG-based models cannot capture these metrics directly, limiting industrial applicability. In contrast, our work models netlists composed of standard cells.

B. Large Language Models and Fine-Tuning for EDA Tasks

Large language models (LLMs) have shown promise in various EDA tasks, such as design flow automation, error detection, and hardware generation [23]. Pre-trained on vast amounts of textual data, LLMs excel at understanding RTL code and descriptions [24]. Fine-tuning techniques like low-rank adaptation (LoRA) enable efficient adaptation of LLMs to EDA-specific tasks [25]. However, while LLMs can capture the functional semantics from RTL code, their ability to model the complex structural dependencies inherent in circuits is limited, as they were initially designed for processing textual data [26]. Therefore, LLMs alone are insufficient for circuit design tasks that require both functional understanding and detailed structural representation.

C. Multimodal Alignment and Contrastive Learning

Multimodal alignment and contrastive learning have been successfully employed to integrate diverse data types [27], such as text and images [28], by aligning their representations in a shared embedding space [29]. Prominent models like CLIP [30] demonstrate the potential of contrastive learning for cross-modal tasks, including retrieval and classification. These approaches leverage different modalities' strengths to enhance the performance of representation learning [31].

III. Problem Formulation

Sequential circuits, modeled as directed graphs $G = (V, E)$, where V represents circuit components (e.g., logic gates, DFFs) and E represents component connections, pose unique challenges due to the temporal dependencies introduced by state elements. The key problem is to learn node embeddings $\mathbf{H} \in \mathbb{R}^{|V| \times d}$ that encode both structural and temporal features. These embeddings should support downstream tasks such as toggle rate prediction, arrival time prediction, and circuit classification:

$$\mathbf{H} = f(G, \mathbf{X}, \mathbf{T}) = f(V, E, \mathbf{X}, \mathbf{T}), \tag{1}$$

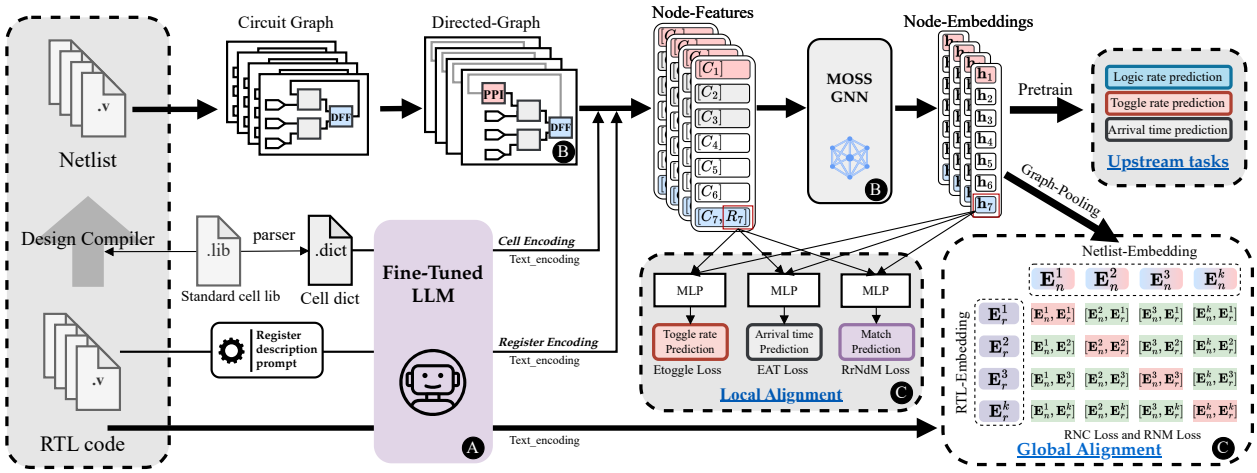

Fig. 2 Overview of the MOSS framework.

where $\mathbf{X} \in \mathbb{R}^{|V| \times d_x}$ represents structural features, and $\mathbf{T} \in \mathbb{R}^{|V| \times d_t}$ represents temporal features.

The main challenge of circuit representation learning is capturing long-range dependencies and temporal dynamics in sequential circuits, while most current GNNs struggle with over-smoothing and fail to retain critical temporal information. Integrating multimodal data, such as netlists and RTL descriptions, is crucial for comprehensively understanding functional and structural aspects.

IV. MOSS Framework

Fig. 2 describes MOSS's framework. We integrate LLM and GNN to capture both functional semantics from RTL code and structural dependencies from netlists. Our key approaches are listed below:

- LLM-enhanced node features (Fig. 2 Ⓐ): The LLM is fine-tuned on RTL data to generate contextual embeddings, enriching the GNN's node features, particularly for register nodes (DFFs). Details are described in Section IV-A.
- Graph construction and modeling (Fig. 2 Ⓑ): The netlist is represented as a directed graph. MOSS uses multiple aggregators and Pseudo Primary Input (PPI)/DFF nodes to model temporal dependencies in sequential circuits. Details are described in Section IV-B.
- Local and global alignment (Fig. 2 Ⓒ): MOSS aligns GNN embeddings with LLM-generated RTL embeddings. Locally, tasks like toggle rate and arrival time prediction are optimized using Etoggle Loss (enhanced toggle loss), EAT Loss (enhanced arrival time loss) and RrNdM (RTL-register to Netlist-DFF matching loss). Globally, RNC Loss (RTL-Netlist contrastive loss) and RNM Loss (RTL-Netlist matching loss) align the netlist and RTL embeddings. Details are described in Section IV-C.

A. LLM Fine-Tuning and Node Feature Enhancement

To address the challenges of modeling sequential circuits, we enhance the GNN's node features by leveraging a fine-tuned LLM to generate contextual embeddings for DFF nodes and embeddings for each logic cell. Additionally, to provide more effective training supervision for circuit functionality tasks, we use the LLM to generate embeddings for the complete RTL code. To this end, we specifically fine-tuned an LLM to enhance its understanding of RTL code.

LLM Fine-Tuning. We fine-tuned Yi-Coder-9B-Chat [32], an open-source code generation model, on 31,701 RTL descriptions to extract contextual embeddings for registers and logic cells.

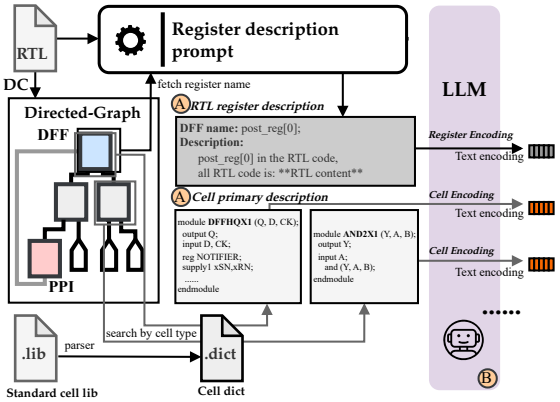

Fig. 3 LLM feature extraction process for GNN nodes.

Data Extraction and RTL Descriptions. To enhance the features of circuit nodes, we identify each node in the circuit and extract its description as shown in Fig. 3 Ⓐ . We first use Design Compiler (DC) [33] to synthesize the netlist, resulting in a directed graph structure. We then identify each elements of DFFs and logic cells. Further, for each node in the netlist, we extract its cell description, which typically includes structural and functional information. Specifically for DFFs, we locate the corresponding registers in the RTL code and generate Register Description Prompts. These prompts enable the LLM to describe the context and functionality of each DFF, capturing both local and global functional relationships.

LLM-GNN Feature Integration and Alignment. Using the extracted node information and descriptions, we generate embeddings with the LLM as illustrated in Fig. 3 Ⓑ . We use mean pooling to aggregate token embeddings from the LLM, providing a comprehensive representation of the input sequence. LLM-generated node embeddings are concatenated with each node's structural features in the GNN. For DFFs, the produced embeddings combine the RTL description and the DFF cell description, capturing both structural and functional information. For logic cells, the embeddings corresponds to each cell's cell description.

B. Graph Construction and Temporal Dependency Modeling

In our GNN design, we first utilize the multimodal characteristics of MOSS to generate node embeddings. Next, we design an adaptive aggregator to better accommodate standard cell-level netlists. Finally,

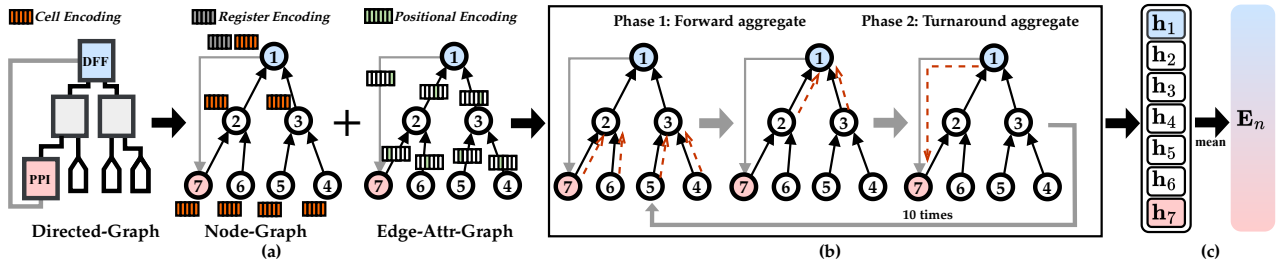

Fig. 4 (a) Graph structure in MOSS; (b) Two-phase Asynchronous temporal propagation with multi-encoding; (c) Mean-pooling strategy for graph representation.

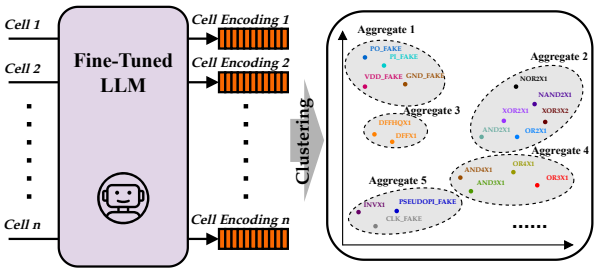

Fig. 5 Adaptive-aggregator design with adaptive clustering.

we employ a two-phase asynchronous temporal propagation mechanism to more accurately model signal propagation in circuits.

Graph Construction. In constructing the graph, we diverge from prior works that rely on manually embedding labels derived from the circuit graph's structural information. Instead, we leverage the multimodal capabilities of MOSS by utilizing the LLM to process descriptions of the RTL code and cell nodes. This approach generates embeddings for the graph nodes, as illustrated in Fig. 4(a).

First, for each cell node, we utilize the LLM to generate embeddings based on the cell's functional and structural descriptions in the standard cell library. Specifically, for the "anchor points" in sequential circuit structures, the DFFs, we further enhance their embeddings. We overlay the LLM embeddings of the contextual structure and functional descriptions of the corresponding register nodes from the RTL code onto the DFF nodes. This enhancement helps the GNN to capture a wider range of information more accurately at DFF nodes.

Finally, since different edges of cells have varying propertiesfor example, in certain logic gates, different inputs have different influences on the outputwe perform positional encoding on the edges.

Adaptive-Aggregator Design. Because we operate at the standard cell level rather than at the AIG level used in existing designs, our netlists contain cells with diverse functions and structures, and different cell libraries may include varying cell types. Therefore, we propose a clustering-based adaptive aggregator for standard cell-level netlists to adapt to different kinds of cells automatically.

As shown in Fig. 5, MOSS first uses Density-Based Spatial Clustering of Applications with Noise (DBSCAN) and hierarchical clustering to dynamically group nodes based on their LLM-derived embeddings. DBSCAN clusters nodes based on functional similarity, detecting clusters of varying density without specifying the number of clusters in advance. Hierarchical clustering further refines these clusters by considering both functional similarities and structural dependencies such as fan-in and fan-out.

Then, each group is processed by a dedicated aggregator that learns to aggregate information based on the characteristics of the nodes. Notably, we employ graph attention mechanisms for aggregation, ultimately forming different attention-based aggregators for each category. This adaptive aggregator approach enables MOSS to flexibly adapt to different node types and interactions, capturing unique behaviors essential for modeling complex circuits.

Two-Phase Asynchronous Temporal Propagation Mechanism. To accurately model temporal dependencies in sequential circuits, MOSS adopts a two-phase asynchronous temporal propagation mechanism as in [14]. The propagation mechanism, illustrated in Fig. 4(b), includes forward and backward phases to handle the feedback behavior of DFFs. It is worth noting that both phases use asynchronous updates to more closely resemble signal propagation in circuits.

In the first phase, Forward Propagation, signals are propagated from primary inputs (PIs) to the inputs of DFFs through combinational logic gates. This phase captures the forward signal flow in the circuit, simulating how input signals affect downstream components.

In the second phase, referred to as Turnaround Propagation, the outputs from the DFFs are fed back into the circuit, simulating the characteristic feedback loops of sequential elements. This feedback is crucial for modeling the timing dependencies and state transitions intrinsic to sequential circuits, allowing the GNN to capture how past states influence future behavior. To capture both short-range and long-range dependencies, the two-phase propagation process is repeated multiple times (e.g., 10 iterations).

Afterward, as shown in Fig. 4(c), the final node representations are aggregated using mean-pooling, generating comprehensive embeddings that effectively summarize the temporal and structural information in the circuit.

C. Local and Global Alignment Strategy

Our local and global alignment strategy ensures that the GNN-generated netlist embeddings remain consistent with the LLM-derived RTL embeddings, capturing both local and global circuit characteristics. This section details the loss functions used to achieve alignment, focusing on key tasks such as toggle rate prediction, arrival time prediction, and register-DFF matching.

Local alignment aims to align nodes through task-specific losses, optimizing the GNN's ability to represent local circuit behavior. The local alignment contains several prediction tasks, and their loss functions are Etoggle loss, EAT loss, and RrNdM loss. Etoggle Loss minimizes the difference between predicted and actual toggle rates, capturing logic gates' dynamic behavior. EAT Loss focuses on predicting signal arrival times, ensuring the GNN accurately models timing dependencies. RrNdM Loss ensures proper alignment between RTL registers and netlist DFFs, minimizing mismatches in register-to-DFF mapping. We implement these loss functions as smooth L1 loss functions.

Global alignment ensures consistency between the overall structure and functionality of netlist and RTL embeddings through graph

```
# rtl_encoder - Text Transformer
# netlist_encoder - GNN
# R[n, l] - minibatch of aligned RTL codes
# N[n, c, m] - minibatch of aligned netlists

             for i in range(n) for j in range(n)]
RNMLabels = np.eye(n)
RNMLoss = SmoothL1Loss(RNMLogits, RNMLabels)
```

Fig. 6 Numpy-like pseudocode for loss function of global alignment.

pooling and alignment losses. While RNC loss aligns the global structure, RNM loss enforces functional consistency between netlist and RTL. RNC and RNM calculation method is shown in the pseudocode in Fig. 6.

MOSS employs a multi-task learning strategy to generalize across multiple circuit-related tasks. By optimizing a weighted combination of task-specific loss functions, MOSS captures local node-level behaviors and global circuit-wide patterns. The overall loss is formulated as:

$$L_{\text{total}} = \sum_{i=1}^{n} \lambda_i L_{\text{taski}}, \tag{2}$$

where λ_i dynamically adjusts to balance the contribution of each task, ensuring that no single task dominates the learning process. This approach enhances the model's ability to generalize effectively across diverse sequential circuit tasks.

MOSS employs a dual alignment strategy that integrates local task-specific losses (Etoggle, EAT, and RrNdM) with global consistency losses (RNC and RNM). This approach captures both fine-grained circuit dynamics and global structural behavior, enhancing the model's accuracy and generalizability, particularly for complex sequential circuits.

V. Experimental Results

A. Experimental Settings

Datasets. We collected 31,701 RTL designs and synthesized them using Synopsys Design Compiler (DC), applying multiple rounds of optimization. For each RTL, we generated several distinct circuits, with sizes ranging from 100 to 5000 cells, all based on real-world designs. From this collection, we further selected a subset of RTLs with diverse functionalities and significant variations as our experimental dataset.

Model Variants. We evaluate several MOSS variants to understand the impact of critical components: "MOSS" is the full model; "MOSS w/o A" is the full model withoutht local-global alignment strategy; "MOSS w/o AA" includes LLM features but omits adaptive-aggregator and alignment; "MOSS w/o FAA" is the model without all the LLM feature enhancement, the adaptive-aggregator design, and the alignment strategy. Besides, we implement DeepSeq2 [14], the state-of-the-art GNN-based model, for the comparison.

Evaluation Metrics. We assess all models using four metrics: the accuracy of arrival time prediction (ATP) for each DFF, the accuracy of toggle rate prediction (TRP) for each cell, the accuracy of power prediction (PP) for the circuit, and the accuracy of functional equivalence prediction (FEP). Note here the prediction accuracy is measured by

$$\text{accuracy} = 1 - \text{mean relative error}. \tag{3}$$

FEP measures the rate of correctly identifying functionally equivalent RTL-netlist pairs. Higher values indicate better performance. Ground truth data is collected using commercial EDA tools. Arrival Time (AT) is obtained via timing analysis on DFF nodes using PrimePower [34] and Synopsys DC [33]. Toggle Rate is derived from VCS [35] simulations over 60,000 cycles with random inputs, and power is reported by PrimePower based on their toggle rates. These ground truths ensure accurate benchmarking of MOSS's predictions.

Platform Configuration. Experiments were performed on an 8-GPU system with NVIDIA A100 GPUs. We implemented MOSS in PyTorch and trained using the Adam optimizer, with a learning rate of 6×10^{-4} and a batch size of 32. Each experiment ran for 45 epochs, with early stopping based on validation performance to prevent overfitting.

B. Experimental Results and Analysis

In this section, we evaluate the performance of MOSS across various tasks, comparing it with its variants and the baseline model DeepSeq2. The experiments focus on critical tasks such as arrival time prediction, toggle rate prediction, power prediction, and functional equivalence checking. We list results in TABLE I and TABLE II, and analyze the training loss curves shown in Fig. 7 and Fig. 8.

Arrival Time Prediction (ATP). For arrival time prediction (ATP), MOSS achieves an average accuracy of 95.2%, significantly outperforming DeepSeq2 (79.1%). In larger circuits, such as *mult_16x32_to_48*, MOSS maintains high accuracy (94.3%), while DeepSeq2 drops to 57.6%. This highlights MOSS's ability to handle long-range dependencies, a known challenge in larger circuits. The alignment strategy has a limited impact on this task, as demonstrated by the performance of MOSS w/o A (94.9%), which remains high but is slightly lower than the full model.

Toggle Rate Prediction (TRP). For toggle rate prediction (TRP), MOSS achieves 87.5% accuracy, outperforming DeepSeq2 (76.4%). In circuits such as *pipeline_reg*, MOSS reaches 92.4%, whereas MOSS w/o FAA drops to 63.6%, underscoring the importance of the adaptive aggregation and LLM enhancements, which are key for capturing dynamic behaviors in sequential circuits.

Power Prediction (PP). For power prediction (PP), MOSS leads with 96.3% accuracy, compared to DeepSeq2's 88.4%. The LLM-enhanced node features allow MOSS to model power consumption patterns more effectively, particularly in circuits like *wb_data_mux*, where MOSS achieves 96.2%, significantly higher than MOSS w/o FAA (82.6%). The smaller performance gap between MOSS and MOSS w/o A (95.1%) indicates that alignment is less critical for power estimation compared to feature enhancement.

Functional Equivalence Prediction (FEP). We selected several datasets with 512 pairs of RTL and netlist in each set and calculated the average correctness of their predictions. In functional equivalence checking, MOSS excels with an average accuracy of 93.7%, far

TABLE I Performance Comparison of MOSS Framework Variants

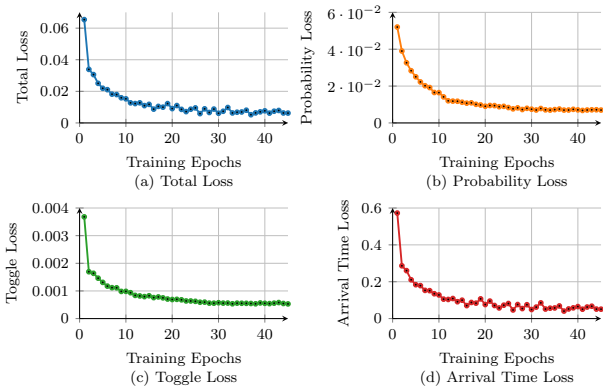

Fig. 7 Losses in the pre-training section.

exceeding MOSS w/o FAA (8.5%) , MOSS w/o AA (19.9%) and MOSS w/o A (26.6%). This significant drop in variants highlights the necessity of both feature enhancement and alignment to maintain functional consistency between RTL and netlist representations. For example, in the *github_0* circuit sets, MOSS achieves 91.4%, while MOSS w/o A only reaches 24.1%, confirming the critical role of multimodal alignment. This experiment shows that by leveraging multimodal learning, MOSS achieves superior circuit functionality modeling, enabling functional equivalence checking.

Loss Analysis. As illustrated in Fig. 7, in the pre-training phase, all loss components steadily decrease, with the total loss (see Fig. 7(a)) showing continuous improvement. Probability loss (see Fig. 7(b)), toggle loss (see Fig. 7(c)) and arrival time loss (see Fig. 7(d)) decrease steadily, indicating that MOSS learns to capture both timing and dynamic behaviors effectively.

Fig. 8 shows the global loss in multimodal alignment. The total

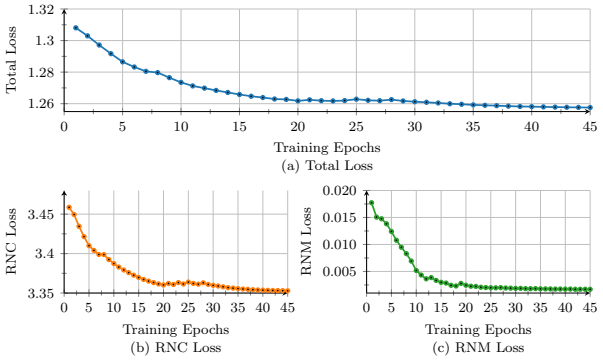

Fig. 8 Global Losses in the multimodal alignment section.

loss stabilizes around 1.26 after 45 epochs, indicating effective convergence. The RNC loss (see Fig. 8(b)) and RNM loss (see Fig. 8(c)) also converge smoothly, confirming the success of the alignment strategy. The RNM loss reaches as low as 0.002, indicating that the RTL-netlist matching is highly accurate.

The experimental results demonstrate that MOSS effectively addresses the challenges of circuit representation learning, particularly in handling larger circuits with long-range dependencies. By integrating LLM-enhanced features and GNN-based structural learning, MOSS significantly improves the accuracy of arrival time, toggle rate, and power predictions, while ensuring functional consistency through multimodal alignment.

VI. Conclusion

We propose MOSS, a multimodal framework combining GNNs and LLMs to enhance sequential circuit representation. MOSS addresses long-range information loss by leveraging LLMs for global semantic understanding and GNNs for local structural features. It also introduces adaptive aggregation and two-stage propagation to improve signal modeling. Experimental results show that MOSS significantly boosts accuracy for tasks like toggle rate and arrival time prediction, achieving 95.2% accuracy in arrival time prediction for large circuits, outperforming existing methods. We hope that MOSS can not just offer an effective solution for circuit functionality and performance prediction, but also stimulate more future research.

***Abstract*—As functional safety of electronic chips gains importance in autonomous vehicles and aerospace, standards like ISO 26262 mandate high diagnostic coverage, requiring extensive gate-level fault simulations. However, for large-scale industrial sequential circuits, these simulations are time-consuming, creating a significant bottleneck in chip development. Prior approaches have focused on reducing computational complexity and optimizing CPU hardware usage by minimizing redundant computations during fault propagation and leveraging bit-level parallel processing capabilities. Techniques like parallel-pattern and event-driven simulations have improved performance in combinational circuits but face limitations in sequential circuits due to timing dependencies within loops. The challenge lies in parallelizing simulations across different cycles without violating these dependencies, which is exacerbated by the complex feedback structures in SCCs. In this work, we propose a novel parallel-pattern fault simulation framework that combines loop fusion with efficient event traversal to accelerate sequential circuit simulations. By compiling simple loops into larger nodes, we reduce the number of feedback events without introducing excessive redundancy. For larger SCCs, we develop specialized algorithms for selecting loop entrance nodes based on indegree analysis and implement the lazy propagation strategy for internal nodes. This approach minimizes simulation events caused by inaccurate predictions and reduces overhead associated with false event propagation. We integrate these techniques into our simulation framework, EPICS, which strategically mixes compiled and event-driven simulations to optimize performance. Experimental results demonstrate that EPICS achieves a 5.94× speedup over state-of-the-art commercial tool while maintaining the same fault coverage.**

I. Introduction

Since sectors like autonomous vehicles and aerospace have become critical to modern life, the functional safety of electronic chips has gained increased attention [1]. ISO 26262 standard [2] outlines safety requirements for automotive-grade chips [3], including MCUs, ASICs, and SoCs [4]. Meeting the requirements demands high diagnostic coverage [5], requiring extensive fault simulations [6]. Fine-grained fault simulation requires injecting faults into gate-level netlist and analyzing output changes under input patterns [7]. Due to the large scale of industrial circuits and numerous fault insertion points, sequential circuit gate-level fault simulation can take weeks [8], creating a significant bottleneck in chip development [9]. Accelerating gate-level fault simulation is urgent [10].

Despite the current apparent and ongoing demand for acceleration, the challenge of speeding up fault simulation in sequential circuits is far from new [11]. This long-standing issue continues to be of critical importance, with significant room for improvement. Previous research can be divided into two main areas [12]: reducing computational complexity and optimizing for CPU hardware. The focus has been on minimizing redundant computations while propagating good and faulty values across the circuit and efficiently executing bit-level gate simulations on CPUs with high bit-parallel processing capabilities. The concurrent simulation uses event differentials to avoid redundant faults and good values simulations under the same inputs [13]. To better utilize CPUs' multi-bit parallel processing abilities, PARIS introduced the parallel pattern fault simulation [14], and PROOFS introduced the parallel fault simulation [15]. They merge the propagation of multiple single-bit signals into a single word for bit-level parallel processing [16]. In the latest tools, parallel-pattern and event differentials strategies have been used to achieve significant performance improvements in the simulation of combinational circuits [17], [18]. However, for sequential circuits, the use of parallel-pattern or parallel-fault is limited, and further improvement in simulation performance is difficult.

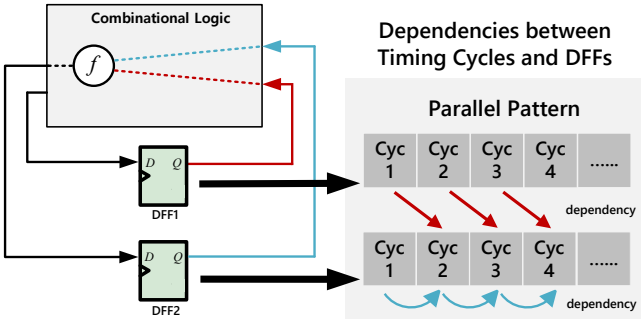

Fig. 1 Feedback Loop Example in Circuit.

This is because sequential fault simulation with parallel patterns or faults presents challenges. Placing parallel faults on different bits for parallel processing conflicts with concurrent algorithms that consolidate consistent events between fault occurrences. Parallel-pattern simulates inputs from different cycles on different bits. However, there exists a contradiction between parallel patterns and the timing dependencies. As illustrated in Fig. 1, the state of DFF 2 at cycle $n+1$ depends on the state of DFF 1 at cycle n and the state of DFF 2 at cycle n. This dependency makes it difficult to parallelize the simulation across different cycles. In large-scale sequential circuits, strongly connected components (SCCs), defined in graph theory as nodes that can mutually reach each other

along directed edges, further complicate this issue. The method proposed in [14] predicts the future states of DFFs for 64 cycles and then simulates them. However, due to potential prediction errors, all 64 cycles still need to be executed sequentially to determine the true values of all registers for each cycle. If the actual values of registers for a specific cycle match the predictions, subsequent pathways need not be executed. Nevertheless, updating the predicted future value of a DFF leads to simulations of all cells along the loop. In summary, the timing dependencies introduced by loops limit the performance improvements achievable with parallel patterns in sequential circuit fault simulation.

One insight is to compile and fuse loops into larger nodes, reducing simulation events caused by feedback. However, compiling loops into single nodes can prevent the detection of redundant events within the internal nodes, introducing excessive redundancy. Therefore, we opt to compile only simple loops. When traversing nodes in large SCCs, selecting loop entrance nodes is crucial, as it guides event propagation within the loop. If entrance nodes receive more feedback, prediction errors may increase, leading to greater simulation overhead. Additionally, allowing each node to receive inputs from preceding nodes directly can overly rely on the prediction accuracy of entrance nodes, increasing simulation costs. Therefore, another key insight is developing specialized algorithms for loop entrance selection and node updates in complex, large SCCs to reduce the simulation overhead associated with parallel patterns.

To this end, we propose a parallel-pattern framework that combines loop fusion with efficient event traversal, ultimately surpassing the performance of commercial tools. Initially, we employ a hybrid approach that integrates compiled fusion and event-driven methods within the circuit, merging shorter loop feedbacks within SCCs into single nodes to reduce the number of feedback events. For larger SCCs, we introduce loop entrance selection algorithms based on node indegree analysis and implement node lazy propagation algorithms. These algorithms, in conjunction with a guess-based parallel-pattern mechanism, significantly reduce the number of events propagated on loops caused by inaccurate predictions. We have realized these technologies in a system we call EPICS. Experimental results show that EPICS is faster than the latest commercial tool. Our contributions are summarized as follows:

- We propose a novel traversal framework for parallel-pattern simulation in sequential circuits, specifically designed for SCCs. Our method includes heuristic loop entry point selection based on structural analysis and a lazy propagation strategy for nodes, which reduces the overhead of false event propagation.
- We leverage the strengths of both compiled and event-driven simulations by strategically mixing them within the circuit, optimizing memory access and reducing scheduling overhead during the simulation process.
- Utilizing these techniques, we developed an efficient fault simulation framework for sequential circuits, achieving a 5.94× performance improvement compared to the commercial tool while maintaining the same fault coverage.

II. Background and Related Work

A. Temporal Correlation and Feedback Loops

The complexity of sequential circuits arises from state dependencies and feedback loops [19]. Unlike combinational circuits, the state of a sequential circuit depends on both current inputs and previous states, creating temporal correlations across multiple clock cycles and significantly increasing simulation complexity [20]. Feedback loops introduce cyclic dependencies, represented in graph theory as Strongly Connected Components (SCCs) [21], where any two nodes can reach each other through directed edges [22]. SCCs force simulators to iteratively update circuit states over multiple cycles, adding to the computational burden [23]. Algorithms such as Tarjan's [24] and Kosaraju's [25] are commonly used to identify SCCs, optimizing feedback loop handling and reducing redundant computations [26].

B. Fault Simulation in Sequential Circuits

Fault simulation is essential for verifying functional safety of sequential circuits and evaluating test pattern effectiveness [27], [28]. Stuck-at fault model is commonly used [29]. Due to the need to track state across multiple clock cycles, fault simulation in sequential circuits is inherently more complex than in combinational circuits [30]. Feedback loops further complicate this process, requiring the management of extensive state information and repeated computations [7], [31].

C. Parallel Simulation Techniques

Various parallel simulation techniques have been proposed to alleviate computational bottlenecks [32]. Parallel pattern single fault propagation (PPSFP) simulation method processes multiple input patterns simultaneously, leveraging hardware word length for speedup [14], [33]. While this method excels in combinational circuits [34], state dependencies and feedback loops in sequential circuits limit the achievable parallelism [35], resulting in diminished speedups [36]. Parallel fault simulation reduces redundant computations by simulating multiple faults concurrently [37], yet its efficiency is constrained by fault interdependencies and the overhead of managing large state information in complex circuits [38].

Classic simulators like PROOFS [15] and PARIS [14] employ different optimization strategies. PROOFS uses event-driven parallel fault simulation, focusing on sparse fault effects to minimize unnecessary computation [15], while PARIS is a parallel-pattern fault simulator [14]. Despite their successes in specific scenarios, both struggle with the performance demands of large-scale sequential circuits with intricate feedback loops. Later tools like HOPE [16] and VISION [33] enhance these approaches by optimizing fault dropping and state initialization, improving simulation efficiency.

D. Compiled and Event-Driven Simulation

Sequential circuit simulation typically uses compiled and event-driven methods [39], [40]. Compiled simulation translates circuit logic directly into machine code, eliminating interpretation overhead and improving speed, particularly in

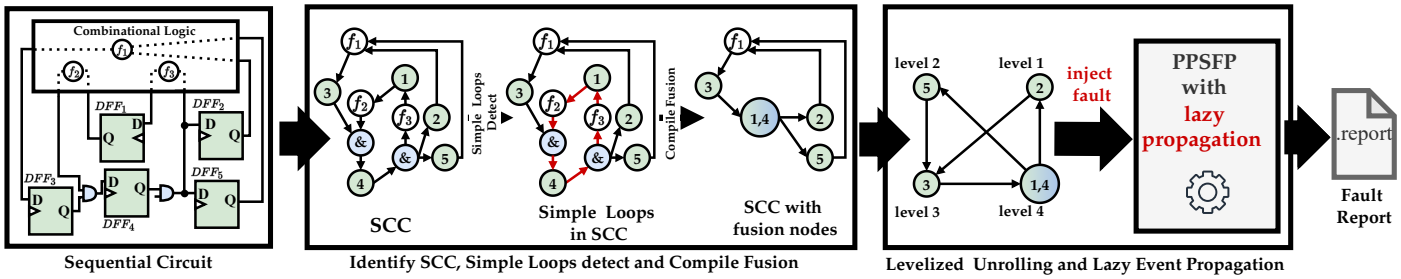

Fig. 2 EPICS Hybrid Fault Simulation Framework.

combinational circuits. However, the exponential growth of state space in sequential circuits due to flip-flops and feedback loops makes the approach less efficient, as it incurs significant compilation and storage overhead. Event-driven simulation triggers computations only when signal changes occur, reducing unnecessary calculations [41]. While effective in circuits with sparse changes, frequent event scheduling in circuits with many feedback loops can result in performance bottlenecks.

III. EPICS Framework

Our proposed framework, illustrated in Fig. 2, takes a gate-level circuit, input patterns, and a fault list as inputs to produce a fault simulation report. The framework consists of two main components: Firstly, we process the netlist by identifying the SCCs using Tarjan's algorithm [24]. For simple timing loops within these SCCs, we compile them into single nodes to reduce the number of simulation events. Secondly, for traversing large SCCs, we propose an indegree-based strategy to select the least dependent node as the entry point for speculative SCC traversal. Additionally, we introduce a lazy propagation strategy, where updates are deferred until upstream values confirm that the current node's prediction is incorrect. Finally, the framework outputs a fault coverage report.

IV. Compiled Simulation for Simple Timing Loops

In sequential circuit simulation, small timing loops typically consist of a few DFFs and simple combinational logic. Due to their short feedback paths and low dependency, compiled simulation is efficient in handling such loops. Based on SCC identification, we select small timing loops containing 1-2 DFFs and fewer combinational logic gates for compiled simulation. This approach integrates the combinational logic and DFF state transitions into a single functional composite node, avoiding event-driven simulation's frequent event scheduling overhead. By processing machine word length bit pattern data in parallel, the system simulates multiple states in a single event until the circuit reaches a stable state. Compiled simulation consolidates state changes over multiple clock cycles into one computation, significantly enhancing simulation efficiency.

As shown in Fig. 3, in the feedback loop, input a and b affect the states of DFFs A and B through logic gates C and D, and these state changes are fed back into the logic gates, forming a closed loop. Compiled simulation converts this loop into an equivalent instruction sequence, eliminating the need for frequent scheduling in event-driven simulations. State updates

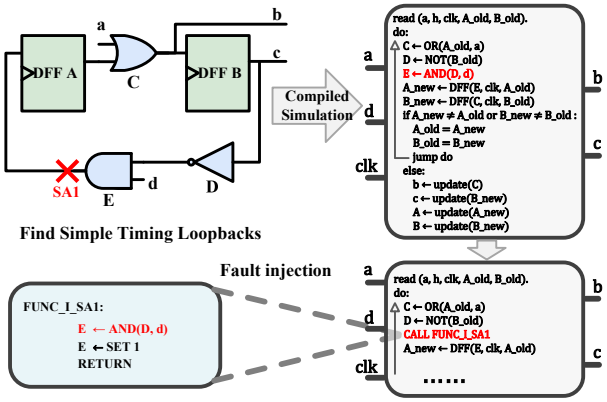

Fig. 3 Compiled Simulation and Fault Injection Example

and output computations for each clock cycle are handled in parallel until the feedback loop reaches a stable state.

Meanwhile, fault injection is achieved by modifying the compiled instruction sequence. For example, Fig. 3 shows a stuck-at-1 (SA1) fault injected at gate E, where the output of E is forced to 1, propagating the fault through the circuit, reducing memory access delays and improving fault simulation efficiency. Fault injection directly modifies the instruction sequence with minimal changes to the original instructions.

Compiled simulation is particularly well-suited for efficiently simulating small timing loops. Combined with fault injection techniques, this significantly reduces simulation time and avoids the cyclic scheduling issues of event-driven simulations while maintaining accuracy and improving performance.

V. Levelized Unrolling and Lazy Event Propagation

The loop simulation requires starting from an entry point, traversing the loop, and feeding the timing values back to the entry. Since the entry node guides the value updates for all nodes in the loop, the accuracy of the entry node's predicted value significantly impacts the number of simulations required. Therefore, we select the node with the highest prediction accuracy as the loop entry. Upon establishing the foundation of each loop, we propose a lazy propagation strategy at each node. To prevent significant redundant computations across all nodes on a loop due to inaccurate predictions at the entrance, each node refrains from readily accepting event propagation from higher levels until it can ascertain the presence of errors in subsequent predictions.

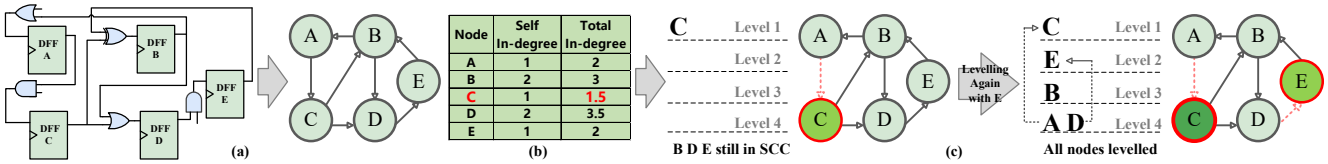

Fig. 4 Indegree-Based Levelized Unrolling of SCC.

A. *Indegree-based Levelized Unrolling of SCC*

Given the complexity of the circuit structure and connections, we propose a heuristic method based on analyzing the structure of the DFF graph. Through experimental analysis, we found that if a DFF depends on more sequential nodes—i.e., it has a higher indegree—its future cycle values become more uncertain and harder to predict. Conversely, a DFF with a lower indegree is more likely to generate future values based on its own past state, resulting in lower uncertainty.

Based on this observation, we propose Algorithm 1, which uses indegree analysis to identify efficient entry points for SCC simulation. Algorithm 1 consists of three main steps: calculating indegrees, selecting entry points, and then leveling the nodes based on the selected entry points. We illustrate this process using an example shown in Fig. 4.

Algorithm 1: Indegree-based Levelized Unrolling of Nodes in SCC

Input: SCC of a circuit graph
Output: Hierarchically unrolled node sequence L

1 Layer list $L \leftarrow \emptyset$, Processed node set $U \leftarrow \emptyset$,
2 Current layer $level \leftarrow 0$;
3 **foreach** $v \in SCC$ **do**
4 $\quad d_{\text{self}}(v) \leftarrow$ self indegree;
5 $\quad d_{\text{pred}}(v) \leftarrow$ predecessor indegree;
6 $\quad d_{\text{total}}(v) \leftarrow d_{\text{self}}(v) + \frac{1}{2} d_{\text{pred}}(v)$;
7 **while** $SCC \neq \emptyset$ **do**
8 $\quad v_{\min} \leftarrow \arg\min_{v \in \text{SCC}} d_{\text{total}}(v)$;
9 $\quad$ Cut input edges of $v_{\min}$;
10 $\quad$ **if** $L[level]$ *does not exist* **then**
11 $\quad\quad L[level] \leftarrow \emptyset$;
12 $\quad L[level] \leftarrow L[level] \cup \{v_{\min} \cup$ nodes with all predecessors in higher layers$\}$;
13 $\quad$ SCC $\leftarrow$ SCC $\setminus L[level]$;
14 $\quad U \leftarrow U \cup L[level]$;
15 $\quad$ **if** *cycles remain in SCC* **then**
16 $\quad\quad$ continue;
17 $\quad level \leftarrow level + 1$;
18 **return** L;

The first step (lines 4-5 of the algorithm) calculates the self indegree ($d_{\text{self}}(v)$) and predecessor indegree ($d_{\text{pred}}(v)$) for each node v in the SCC, and then computes the total indegree ($d_{\text{total}}(v)$) using the following formula:

$$d_{\text{total}}(v) = d_{\text{self}}(v) + \frac{1}{2} \sum_{u \in \text{Predecessors}(v)} d_{\text{self}}(u). \quad (1)$$

In Fig. 4(b), each node's calculated indegrees are shown. For instance, node C has a self-indegree of 1 and a total indegree of 1.5, making it a suitable candidate for the initial levelized unrolling step due to its lower dependency on other nodes.

Next, lines 7-10 of the algorithm select the node with the smallest total indegree-$v_{\min}$-and begin the unrolling process. As shown in Fig. 4(c), node C is selected first because it has the smallest total indegree. This node is then placed in Level 1 of the unrolling hierarchy, and its input edges are temporarily disconnected to break any cyclical dependencies.

The algorithm then places $v_{\min}$ and all other nodes whose predecessors are already assigned to higher layers into the current layer. This ensures that nodes dependent on already processed nodes are handled in a topologically valid unrolling.

If cycles still exist in the SCC after the initial unrolling (lines 13-14 of the algorithm), the process is repeated by selecting the next node with the smallest total indegree. In Fig. 4(c), nodes B, D, and E still form an SCC after processing C. The algorithm proceeds by selecting node E due to its lower total indegree and continues the unrolling process.

Finally, the current layer is incremented, and the algorithm proceeds until all nodes are unrolled, as illustrated in Fig. 4(c), where all nodes are assigned to respective levels. The result is a hierarchical node sequence that can be efficiently simulated while minimizing redundant computations.

Algorithm 2: Lazy Event Propagation

Input: Sequential circuit with DFFs, SCCs, initial states, and input stimuli
Output: Updated circuit states and simulation results

1 Initialize a lazy event table L to record lazy events;
2 Set current_time_point = 0;
3 **while** *Simulation is not complete* **do**
4 $\quad$ **for** *each DFF* v **do**
5 $\quad\quad$ **if** *Event triggered at current_time_point* **then**
6 $\quad\quad\quad$ Update state of v;
7 $\quad\quad\quad$ Propagate event to dependent nodes;
8 $\quad\quad\quad$ Clear lazy events of v from L;
9 $\quad\quad$ **if** *Lazy event exists for* v *at current_time_point in* L **then**
10 $\quad\quad\quad$ Propagate event to dependent nodes;
11 $\quad\quad\quad$ Clear lazy events of v from L;
12 $\quad$ **for** *each DFF* v **do**
13 $\quad\quad$ **if** v *is scheduled to change at a future time* t' **then**
14 $\quad\quad\quad$ Update state of v;
15 $\quad\quad\quad$ Record lazy event for v at time t' in L;
16 $\quad$ **if** *All events at current_time_point are processed* **then**
17 $\quad\quad$ Increment current_time_point;
18 **return** *Updated circuit states and simulation results*;

B. *Lazy Event Propagation*

Building on the hierarchical unfolding of SCCs, we propose a lazy propagation algorithm 2 aimed at reducing unnecessary state propagation and event scheduling. This strategy is particularly effective when managing complex SCCs and fault propagation. The core idea is to propagate events only when absolutely necessary, thus avoiding redundant computations.

The first part of algorithm 2 (lines 1-2) initializes a lazy event table, which records events that are postponed to be processed at an appropriate time. This event table helps the

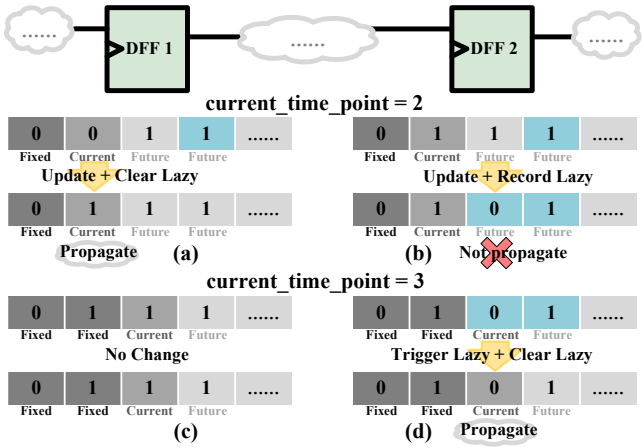

Fig. 5 Lazy event propagation in sequential circuits (lazy events are indicated in blue).

simulator efficiently manage which events need immediate processing and which can be delayed.

Figure 5(a) illustrates a scenario where DFF1 has an event triggered at current_time_point = 2. At this moment, DFF1's state is updated, and the event is propagated to dependent nodes. Simultaneously, DFF1's lazy event record is cleared to ensure no redundant computations occur. This behavior is described in lines 5-8 of the algorithm. If no event is triggered at a clock cycle (such as current_time_point = 3 in Figure 5(c)), the algorithm simply waits without making any state changes, thereby reducing unnecessary propagations and scheduling.

Lines 13-15 in algorithm 2 handle situations where state changes are scheduled to occur in the future. In Figure 5(b), at current_time_point = 2, DFF2 records a lazy event to be triggered at current_time_point = 3 and updates itself, but the event is not propagated immediately. This delayed processing helps avoid multiple unnecessary event propagates. When the future clock cycle arrives (as in current_time_point = 3 in Figure 5(d)), the lazy event is processed, DFF2's event is propagated forward, and DFF2's lazy event record is cleared. This process is described in lines 10-11, ensuring unnecessary propagations do not occur before the appropriate time.

Finally, once all events for a clock cycle have been processed, current_time_point increments, as described in line 17 of algorithm 2, and the simulator continues to process pending events for the next clock cycle. This design allows the simulator to perform simulations efficiently, minimizing computation while ensuring correctness.

VI. Experimental Results

A. Experimental Settings

We implemented EPICS in C++ and evaluated it on a Red Hat Enterprise Linux Server 7.9, equipped with an Intel Xeon® Platinum 8260 CPU @ 2.40GHz and 1.5TiB of RAM. For our evaluation, we compared EPICS against two other simulators that support gate-level fault simulation, representing both commercial and academic tools. The first is Z01X [42], a state-of-the-art commercial simulator. The second is VISION [33], a well-known academic simulator. Since the results reported for VISION in [33] were obtained on an outdated Sun Sparc 2 workstation, we reimplemented VISION to run on our modern hardware platform, resulting in a version we refer to as VISION+. This reimplemented version demonstrated significantly shorter simulation times than the original, owing to modern hardware advancements and optimizations. To ensure a fair and consistent comparison, we evaluated all simulators, including EPICS, Z01X, and VISION+, on the same platform and under the same settings.

TABLE I Statistics of Benchmark Circuits

Circuit	#Gates	#Cycles
b20	19,358	20,000
b22	28,929	20,000
b18	103,838	20,000
openC906	624,058	20,000
openC910	5,323,400	20,000
Comm1	78,739	28,286
Comm2	3,103,038	36,800
Comm3	4,300,720	23,480

Benchmark Circuits. We evaluated EPICS on a diverse set of benchmark circuits, including both academic and industrial designs, to assess its scalability and applicability. TABLE I summarizes the benchmarks circuits used in this paper, which cover small cores in academic papers ITC'99 [43] (*b20*, *b22*, *b18*), open-source RISC-V CPUs [44] (*openC906* , *openC910*), and commercial processors (*Comm1*, *Comm2*, *Comm3*). In our experiments, real functional patterns were used for commercial processors (*Comm1*, *Comm2*, *Comm3*), while random patterns were applied to other circuits. The simulation cycles for each circuit are also shown in TABLE I.

Fault list and fault coverage. We generated stuck-at faults for gates and DFFs in the circuits and set observation points at all outputs. The performance of each simulation was evaluated and the simulation runtime was reported. The fault coverage achieved by our proposed framework is consistent with that of the commercial tool Z01X across all benchmarks, demonstrating the correctness of the proposed fault simulation framework.

B. Evaluation on Benchmarks and Comparisons

We conducted performance tests on all the aforementioned benchmark circuits and compared the runtime of the proposed EPICS with that of the baseline methods. The experimental results are shown in Fig. 6, including the runtime of each algorithm and the corresponding speedup ratios. As observed, the proposed EPICS achieves the best performance across all benchmark circuits. For a small circuit b20 with 19,358 gates, the runtime of Z01X, VISION+, and EPICS are 405s, 172s, and 42s, respectively. For the commercial circuit Comm3 with 4,300,720 gates, the runtime of Z01X, VISION+, and EPICS are 82,968s, 117,314s, and 22,084s, respectively. For the largest circuit openC910 with 5,323,400 gates, the runtime of Z01X, VISION+, and EPICS are 26,904s, 23,906s, and 6,719s, respectively. On average, EPICS achieves a 5.94× speedup over Z01X, and a 4.23× speedup over VISION+ across all benchmark circuits. The experimental results demonstrate that the proposed EPICS exhibits excellent simulation performance

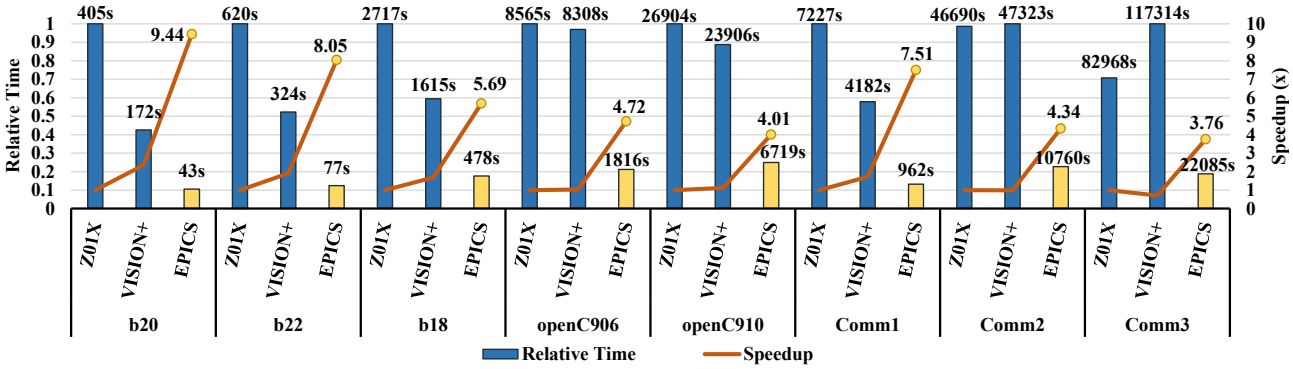

Fig. 6 Performance comparison of various simulators.

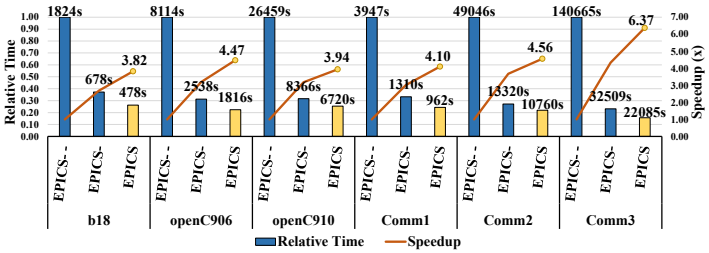

Fig. 7 Ablation Study on Optimizations: EPICS-- (No Optimization), EPICS- (Includes the SCC traversal strategy), EPICS.

across circuits of various scales, achieving significant acceleration compared to both the commercial tool and the state-of-the-art academic approach. Notably, EPICS reduces the simulation time for the commercial circuit Comm3 from approximately 22 hours with commercial tools to just 6 hours.

C. Ablation study

We conducted an ablation study to evaluate the acceleration effect of small loop compilation and SCC traversal strategy. We implemented another two versions of EPICS: EPICS--, which excludes both the small loop compilation and SCC traversal strategies, and EPICS-, which includes the SCC traversal strategy but excludes small loop compilation. Aside from these optimizations, both versions have the same implementation as the original EPICS. The results are listed in Fig. 7. It shows that EPICS- achieves 3.28× speedup over EPICS-- on average. Meanwhile, EPICS achieves 1.32× speedup over EPICS- on average, and 4.33× speedup over EPICS--. These indicate that both the SCC traversal strategy and the compilation of small loops contribute significantly to simulation acceleration.

TABLE II compares the total number of simulation events processed by each version. EPICS demonstrates a significant reduction in event count, which directly contributes to its reduced simulation time overhead. The compilation for small SCCs reduces event-driven overhead by eliminating the need for frequent event scheduling within these regions. As a result, EPICS processes 51% fewer events than EPICS-- in b18. The SCC traversal strategy is crucial in minimizing event count, especially in circuits with complex feedback loops. In Comm3, EPICS processes only 13.6% of the events required by EPICS--, demonstrating the efficiency of these combined strategies. On average, EPICS achieves a 47% reduction in event count compared to EPICS- and a 4.63× reduction compared to EPICS--, confirming the impact of its optimizations.

TABLE II Event Counts and Ratios Compared to EPICS

Circuit	EPICS Events	EPICS- Events	EPICS- Ratio(×)	EPICS-- Events	EPICS-- Ratio(×)
b20	**1.06e9**	1.31e9	1.24	3.75e9	3.55
b22	**1.71e9**	2.29e9	1.34	7.21e9	4.21
b18	**1.31e10**	1.98e10	1.51	5.51e10	4.20
openC906	**1.69e10**	2.48e10	1.47	8.02e10	4.74
openC910	**6.13e10**	9.49e10	1.55	2.60e11	4.24
Comm1	**1.04e10**	1.59e10	1.52	4.43e10	4.24
Comm2	**1.10e11**	1.62e11	1.48	4.95e11	4.50
Comm3	**2.38e11**	3.97e11	1.67	1.75e12	7.35
Average	-	-	1.47	-	4.63

Events: Number of simulation events generated.
Ratio (×): Event count ratio compared to EPICS.

The performance gains achieved by EPICS stem from the synergistic effect of its optimizations. Compiled simulation reduces event scheduling overhead in simple loops, while the SCC traversal strategy avoids unnecessary event propagation. Together, these optimizations enable EPICS to efficiently handle SCCs with minimal computational overhead.

VII. Conclusion

This paper introduced EPICS, an efficient framework for parallel-pattern fault simulation in sequential circuits, addressing the challenges of strongly connected components (SCCs). Combining compiled simulation, lazy event propagation, and hierarchical SCC unrolling, EPICS reduces computational overhead and enhances performance without sacrificing fault coverage. Experimental results show that EPICS achieves 5.94× speedup over commercial tool Z01X while maintaining equivalent fault coverage, demonstrating its scalability for large-scale industrial designs.

***Abstract*—In automatic test pattern generation (ATPG), SAT-based methods are typically used to complement structural approaches, especially for addressing hard-to-detect faults. However, as the size and complexity of circuits grow, SAT-based ATPG faces challenges like pattern inflation and excessive runtime, limiting its overall performance. The key problem lies in the fact that current mainstream SAT solvers perform complete assignments for all primary inputs of the fault's transitive fanin cone without considering the detection of other faults, making test compaction extremely difficult and time consuming. In this paper, a novel SAT solver PA-MiniSat is proposed, which is capable of generating partial assignments for solving variables and significantly reduces the number of specified bits in test cubes. As an extension of MiniSat, it employs a full-literal watching technique and a circuit-adapted heuristic branching strategy, achieving overall improved performance in ATPG. Based on PA-MiniSat, a hybrid ATPG framework PastATPG is proposed for better test compaction, which tightly integrates structural algorithms with the SAT solver into the unified test compaction flow. Experimental results demonstrate that our method outperforms other SAT solvers in pattern compaction and, in some cases, even surpasses commercial ATPG tools in terms of speed. The code is available at https://github.com/sklp-eda-lab/PastATPG.**

I. Introduction

With the growing complexity of integrated circuits, identifying deeply embedded faults becomes increasingly challenging for automatic test pattern generation (ATPG), leading to a rise in pattern count and a decline in fault coverage. For hard-to-detect faults, traditional structural algorithms like the D-algorithm [1] and PODEM [2] often struggle to generate test patterns within a limited time. After running these structural methods with limited backtracks, the remaining single-fault test generation problems are typically encoded into conjunctive normal form (CNF) and solved using SAT solvers [3]–[10].

Although SAT ATPG exhibits strong fault detection capabilities and guarantees completeness, it often generates a significant number of patterns to detect a small subset of hard-to-detect faults, leading to a sharp increase in testing costs. The root cause of pattern explosion is the difficulty in compacting the test cubes generated by SAT solvers. Test compaction [11]–[13] is a common component in structural ATPG, with the fundamental idea being to use a single pattern to detect multiple faults by attempting to merge the test cubes generated for a set of faults. However, since the SAT solver only considers the transitive fanin cone for individual faults and assigns values to all primary inputs within that cone, while lacking awareness of the control values of logic gates, these factors result in redundancy. It becomes challenging for test compaction algorithms to effectively reduce the number of patterns. Fig. 1 illustrates the test cubes generated by the SAT solver for two faults. For the faults, f_1, f_2, presented in the circuit on the left, the SAT solver produces the cubes *10010* and *X1111*, respectively. *X* represents an unspecified bit, which can be either 0 or 1. However, when considering the case with minimal assignments to the primary inputs, we observe that the test cubes *10XXX* and *XXXX1* together are capable of detecting both faults and can be merged into a single pattern, *10XX1*. This aspect presents a challenge for the SAT solver to address during the solving process. To enhance the performance of test compaction, it is essential to maximize the number of unspecified bits (X bits) for test cubes. To the best of our knowledge, no existing research has effectively addressed the issue of excessive specified bits in the test cubes generated during the SAT engine's solving process. This challenge complicates the integration of SAT-based ATPG into the test compaction frameworks commonly utilized in structural methodologies.

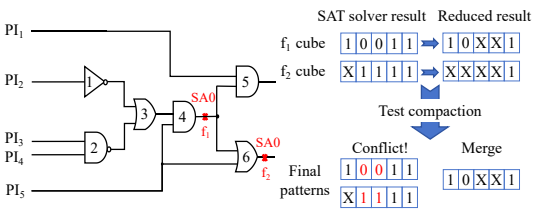

Fig. 1: An example of obstacles to test compaction caused by current mainstream SAT solvers in generating test cubes.

This paper proposes a hybrid ATPG framework, PastATPG, which integrates SAT-based ATPG and structural methods into a unified test compaction approach. To enable more efficient test compaction, a SAT solver with the ability to generate partial

*Equal contribution. †Corresponding authors.

assignments for variables, PA-MiniSat, is introduced. To the best of our knowledge, PA-MiniSat is the first SAT solver in the world capable of generating as many unspecified bits in test cubes as possible without introducing additional CNF encoding overhead. The main contributions are summarized as follows:

- We extended MiniSat [14] to develop PA-MiniSat, a partial assignment SAT solver that maximizes unspecified variables, significantly reducing the specified bits in test cubes. With a circuit-adapted heuristic branching strategy, test generation efficiency is improved compared with the original MiniSat solver in some cases.
- We design a hybrid framework which tightly integrates structural algorithms and the SAT solver into the unified test compaction flow with sufficient unspecified bits (X bits) PA-MiniSat provides.
- Experimental results indicate that PastATPG, integrated with PA-MiniSat, produces more compact patterns compared to other mainstream SAT solvers. In some cases, it also demonstrates a speed advantage, even surpassing commercial ATPG tools.

II. Preliminaries

A. ATPG System Overview

SAT based ATPG.

SAT-based ATPG leverages efficient SAT solvers to address ATPG problems by converting them into a conjunctive normal form (CNF) model, which represents the fault conditions and signal propagation between primary inputs (PIs) and primary outputs (POs). A CNF formula consists of clauses that are disjunctions of literals, with each literal being a variable or its complement, assigned a logic value of 0 or 1. The SAT solver either finds an assignment that satisfies the CNF formula or proves that no such assignment exists (UNSAT). Modern SAT solvers are powered by the conflict-driven clause learning (CDCL) algorithm [15], widely used in various applications.

In the context of ATPG, a fault is detectable if at least one bit in the faulty circuit's POs differs from the corresponding bit in the good circuit, for a given input pattern. If all outputs match, the fault is undetected. SAT-based ATPG transforms both the faulty and good circuits into CNF models, linking them through an XOR gate at the outputs to detect differences. In this setup, solving SAT corresponds to finding a test cube, while UNSAT proves a fault is untestable. For instance, in a stuck-at-fault scenario, the affected sub-circuit is extracted as shown in Fig. 2, and the circuit structure is then converted into CNF, where each signal path is represented by boolean variables and constraints.

Traditional SAT ATPG is typically used as a supplement to structural ATPG frameworks, as shown in Fig. 3. In the first phase, structural ATPG attempts to generate test patterns for all faults within a specified number of backtracks. Faults that exceed the backtrack limit are marked as ATPG aborted and passed to the second phase, where SAT ATPG either generates test patterns for the remaining hard-to-detect faults or determines them as untestable.

Test Compaction.

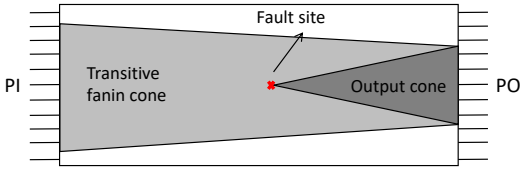

Fig. 2: Extraction of the relevant circuit parts: the shaded region of the circuit is encoded as the good circuit, while the darker shaded area representing the output cone is encoded again using different variables as the bad circuit.

Test compaction techniques are applied in structural ATPG to reduce the number of test patterns, categorized into static and dynamic compaction [16], [17]. Static compaction attempts to merge multiple test cubes, while dynamic compaction uses the remaining unspecified bits (X bits) in a test cube to generate tests by iteratively invoking the ATPG engine for other faults without affecting the previously assigned bits. The test compaction techniques used in structural ATPG are difficult to directly apply to SAT ATPG due to the excessive number of specified bits in its test cubes, making compaction challenging.

In [11], [13], dynamic compaction was introduced into SAT ATPG, but it did not address the core issue of excessive specified bits in SAT ATPG test cubes. Another challenge associated with the application of dynamic compaction in SAT ATPG is its extremely slow speed, as it necessitates invoking the SAT solver at each iteration. Moreover, when applied solely to hard-to-detect fault sets, the high frequency of solver failures results in substantial waste of computational resources.

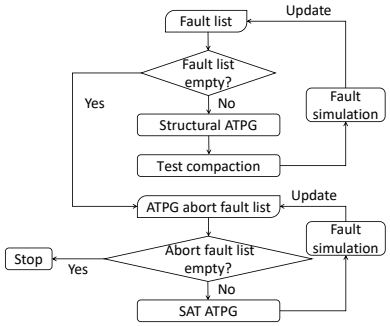

Fig. 3: In the traditional ATPG framework, the structural method is performed first, with the SAT solver applied to faults that result in aborts.

B. Related Work

In [3], SAT solvers were firstly applied for generating test patterns for stuck-at faults. TranGen [4] introduced an efficient error path pruning technique for the transition fault model, effectively identifying the longest sensitization path for each fault. PASSAT [5] incorporated multi-valued logic encoding to handle unknown and tri-state values, addressing more complex circuit design needs. TG-Pro [9] improved ATPG efficiency by modifying the semantics of sensitization variables and introducing new fault propagation constraints, thereby reducing

the number of variables. In [10], SAT ATPG was accelerated through CNF preprocessing and designing new conflict management heuristics. TIGUAN [8] proposed a two-phase parallel SAT ATPG framework.

Previous methods have sought to optimize SAT ATPG test cubes. For instance, PASSAT introduced X bits via multi-variable encoded CNF, but this increased CNF size and impacted performance without reducing specified bits in test cubes. In [18], local justification analysis was used to relax primary inputs, but integrating this with SAT ATPG is slow due to SAT ATPG's lack of necessary information. In [19], a PBO-based static compaction method added post-ATPG required extensive preprocessing and overhead. Multiple-target test generation (MTTG) [20]–[23] generated single test cubes for related faults, but selecting compatible fault groups is challenging and adds overhead with high failure rates.

III. PastATPG: A Hybrid ATPG Framework with Unified Test compaction Leveraging PA-MiniSat

A. Overview

We propose a hybrid and high-performance ATPG framework, PastATPG, as outlined in Fig. 4. By designing a partial assignment SAT solver named PA-MiniSat, previously structural test compaction techniques can now be directly applied to the test cubes generated by SAT ATPG. We designed a unified test compaction framework as shown in the dashed box in Fig. 4. For each fault processed in dynamic compaction, a

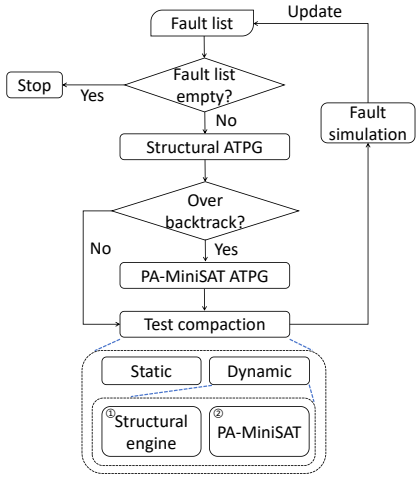

Fig. 4: Overview of PastATPG.

structural algorithm engine is first invoked. After reaching the backtrack limit, the SAT solver is then called. To enhance processing speed, we employ a circuit-adaptive branching strategy to select new assignment variables, which enables a measurable improvement in acceleration. We chose to extend MiniSat due to its high performance, lightweight design, ease of integration, and strong extensibility. MiniSat often demonstrates excellent performance on CNF encodings of circuit problems, making it an ideal foundation for our work.

B. PA-MiniSat Design

SAT is an effective tool but is generally time-consuming in most cases. Calling the SAT solver once for a fault, we can obtain a test cube in which all primary inputs within the fault's transitive fanin cone are assigned specific values. However, suppose SAT solvers can generate a partial assignment solution, i.e., with 'X' values. In that case, we can maintain the efficiency of the SAT-based ATPG method while also providing a test cube easy to compact.

The CDCL Framework and 2-literal Watching.

Modern SAT solvers are based on the CDCL framework, and the main reasoning method is boolean constraint propagation (BCP). BCP iteratively finds unit clauses (clauses with all falsified literals except for one unassigned literal) and assigns the unassigned variables until there is no unit clause or a conflict is driven. Here, "falsified" refers to assigning values of 0 to positive literals and 1 to negative literals. For "satisfied", the assignments are vice versa. All the mainstream SAT solvers cannot provide models with 'X' values because their internal BCP implementations are based on 2-literal watching [24], which is a popular clause management technique and will be explained later. To fetch partial assignments from SAT solvers, we proposed to use full-literal watching and introduced a counter for unsatisfied original clauses.

Algorithm 1: PA-MiniSat Framework

Input: ACNF formula F
Output: 'UNSAT' or assignment with 'X' value.

1 $\alpha := \emptyset$; # assigned variable trail
2 $_{pa:}$ $n := nClauses(F)$; # unsatisfied clauses number
3 **while** $True$ **do**
4 $\quad (conf, \alpha') \leftarrow BCP(\alpha)$;
5 $\quad _{pa:}$ $n \leftarrow n - upd_satisfied(\alpha' \setminus \alpha)$;
6 $\quad \alpha \leftarrow \alpha'$;
7 $\quad$ **if** $conf \neq NULL$ **then**
8 $\quad\quad pos \leftarrow analyze()$;
9 $\quad\quad \alpha \leftarrow \alpha[0 : max(0, pos)]$; # backtrack;
10 $\quad\quad _{pa:}$ $n \leftarrow n + upd_falsified(\alpha[max(0, pos) :])$;
11 $\quad\quad$ **if** $pos < 0$ **then return** 'UNSAT';
12 $\quad$ **else**
13 $\quad\quad$ ~~$_{org:}$ **if** no unassigned variable **then return** α;~~
14 $\quad\quad _{pa:}$ **if** $n = 0$ **then return** α;
15 $\quad\quad lit \leftarrow branching()$; $\alpha \leftarrow \alpha \cup \{lit\}$;
16 $\quad\quad _{pa:}$ $n \leftarrow n - upd_satisfied(lit)$;

To better understand our method, we need to introduce the necessary parts of CDCL and 2-literal watching. A typical CDCL is shown in Algorithm 1 (ignoring lines marked $_{pa:}$). CDCL maintains a trail α for currently assigned literals (positive literals mean variables assigned true and vice versa), which is empty at the beginning (line 1). In the main loop, CDCL performs BCP based on the current α, which can be updated to α' with some newly assigned literals $\alpha' \setminus \alpha$ (lines 4, 6). If there is a conflict in BCP (a variable assigned true and

false at the same time) (line 7), then CDCL will analyze it, getting a learnt clause and a backtrack position pos (line 8). The variables' assignment after pos in the trail will be canceled (line 9). Further, if the conflict is from the original clauses, CDCL returns 'UNSAT' (line 11). On the other hand, if BCP fails to find conflicts (line 12), CDCL first checks whether all the variables have been assigned and returns the full assignment if so (line 13). Otherwise, CDCL will pick a new unassigned variable, choose the assignment, and update the trail (line 15).

During the BCP process, a typical CDCL scans the clauses containing the negation of the newly assigned literal to check whether there are new unit clauses or conflicts. Modern SAT solvers use the 2-literal watching technique to scan clauses. For each clause, only two unassigned literals are watched at the beginning; and with the updation of α, a falsified watched literal is updated to another unassigned literal (if it exists). The references of a clause can only be reached from the watched two literals when BCP. The advantage is that it can reduce some unnecessary clause visiting, and the watch table does not need to be updated when backtracking. But with this lazy data structure, we cannot dynamically update and quickly count the exact number of satisfied clauses, other than completely scan through all the clauses. A small example is presented below to illustrate the implementation details of the 2-literal watching.

Consider the clause:

$$C = (x_1 \vee x_2 \vee \neg x_3 \vee x_4)$$

Initially, we choose to watch the literals x_1 and x_2, and the clause C is satisfied. If x_1 is assigned the value *false*, the solver does not immediately traverse the entire clause. Instead, it lazily checks x_2 to determine whether the clause can still be satisfied. If x_2 is *true* or unassigned, no further action is needed, and the clause remains satisfied. Only when x_2 is also assigned the value *false* does the solver lazily check the remaining literals, $\neg x_3$ and x_4, to find a new literal to watch or to propagate an assignment. Although the 2-literal watching based on the lazy data structure is efficient, it cannot produce partial assignments.

Full-literal Watching Technique.

To address this issue, we propose to use the full-literal watching technique. In comparison, it is an earlier and simpler technique. In the full-literal watching model, every literal in a clause is monitored. Whenever the value of any literal changes, the solver re-evaluates the entire clause to determine if BCP is necessary. Algorithm 1 presents the pseudocode, with distinctions from the traditional approach marked by $_{pa:}$. We maintain a global counter for unsatisfied clauses (falsified and undecided clauses) n (line 2), and it returns current α if $n = 0$ under α (line 14). Simultaneously, we establish clause counters for each clause to track the number of satisfied literals, to monitor the satisfiability changes. For each clause, its reference can be accessed by all the internal literals. Upon assigning a value to a variable, it is necessary to examine the associated clauses that include this variable, and the variable n should be decremented by the number of clauses that have now become satisfied (lines 5, 16). Conversely, when a variable's assignment is canceled, n should be incremented by the number of clauses that have now become undecided (line 10). Moreover, if all the clauses, in which a variable v appears, are still satisfied by cancel v's assignment, then v can be assigned with 'X'.

The example in Fig. 5 illustrates how the full-literal watching technique can yield partial assignments with X bits. In this example, we assume that BCP is not taken into consideration. For a three-input AND gate, the CNF is encoded into four clauses: $\{C_1, C_2, C_3, C_4\}$ involving four variables: $\{x_1, x_2, x_3, x_4\}$. The branching order for variable assignments is from x_1 to x_4. The lower part of the figure shows tables for both 2-literal watching and full-literal watching techniques, detailing the clauses monitored by each variable. In the 2-literal watching technique, each clause can appear in the table a maximum of two times, allowing full-literal watching for x_1 and x_2 to monitor an additional clause, C_4. Suppose the current partial assignment is $\alpha : \{x_1 = 1, x_2 = 0\}$. If C_1 is not satisfied, a backtrack occurs, changing the assignment to $\alpha' : \{x_1 = 0, x_2 = 0\}$. At this point, with 2-literal watching, the lazy data structure requires that all variables be fully assigned to determine whether all clauses are satisfied. In contrast, with full-literal watching, it is already possible to check that the current assignment satisfies all clauses. Thus, the algorithm can return the partial assignment result, yielding $\{x_1 = 0, x_2 = 0, x_3 = X, x_4 = X\}$.

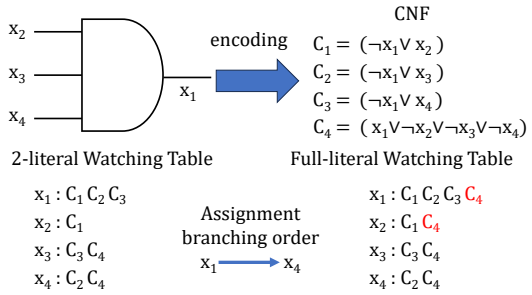

Fig. 5: The difference between 2- and full-literal watching.

With our full-literal watching method, CDCL is capable of yielding an assignment with 'X' values, which can help compact the test cubes better. However, the full-literal scans more clauses, leading to increased time consumption: First, our method scans clauses and updates counters not just throughout the BCP reasoning process, but also during the backtracking process. Secondly, in the process of scanning a literal's watched table, all clauses in which the literal appears should be scanned, which is the worst case of 2-literal watching.

To improve the efficiency, we only use the full-literal watching method for the original clauses. The original clauses are usually modeled short, which narrows the gap of scanning times between the two methods. The number of learnt clauses increased rapidly, and most of them are long clauses. As learnt clauses are implications of original clauses, i.e., learning clauses have no relation to evaluating whether the current assignment α satisfies all clauses. Thus, we keep the 2-literal watching method for learnt clauses.

Circuit-adapted Heuristic Branching Strategy.

In SAT solvers, *branching* involves selecting a variable to assign a truth value, crucial for guiding the search efficiently. The VSIDS heuristic [25] aids this process by assigning each variable a dynamic score. The key steps are:

- **Initialization**: All variables are initially assigned an activity score, typically set to zero.
- **Conflict-Based Updates**: After a conflict, variables involved in the conflict have their scores increased, prioritizing them for future branching.
- **Exponential Decay**: Scores are periodically reduced to give more weight to recent conflicts, preventing overemphasis on past ones.
- **Selection**: The variable with the highest score is chosen for branching.

The original VSIDS heuristic in MiniSat is based solely on conflict clauses during solving. We modify it by incorporating information from the circuit structure in the structural ATPG process to guide initialization. Each variable receives an initial score based on its gate's position within the circuit, creating a circuit-adaptive heuristic. As shown in Fig. 2, ATPG detects faults by propagating fault values through the output cone of the faulty circuit while justifying values in the good circuit. We sort variables by the logical depth of their corresponding gates, with the bad circuit sorted from input to output and the good circuit in reverse order. This sequence is mapped to the interval $[threshold, 0]$, with the threshold set to 10.

IV. Experimental Results

A. Experimental Setup

The structural ATPG components are derived from an open source ATPG program [26]. We compare PA-MiniSat with three popular SAT solvers: two solvers that have won championships in global SAT competitions CaDiCaL, Kissat, [27] and the original version of MiniSat [14]. Our benchmarks consist of combinational circuits, including large-scale circuits from ISCAS 85, ISCAS 89, and ITC 99, as well as an industrial circuits e203 [28], a RISC-V CPU core. To ensure a fair comparison, all circuits were synthesized into netlists using Design Compiler and subsequently processed by a well-known commercial ATPG tool C to generate fault lists. Our program runs on a Linux machine equipped with Intel Xeon processor.

B. Performance Evaluation

We conduct three experiments to validate the effectiveness of the proposed method. The first two experiments evaluate the test compaction effects and time overhead of pure PA-MiniSat SAT ATPG, while the latter one assess the performance of the whole hybrid framework PastATPG. To align with real-world scenarios applications, the first two experiments are performed on hard-to-detect fault sets, specifically faults with runtime exceeding the structural ATPG threshold. Due to the excessive time consumption associated with the invocation of pure SAT solvers for dynamic test compaction, in the second experiment we only run 30% of the hard-to-detect faults for benchmarks b17, b20, b21, and b22, while for b19 and e203, the limit is 10%. The final experiment is conducted on the entire fault set to evaluate the performance of the framework under real ATPG applications. The last two experiments are conducted on the complete ATPG system incorporating commonly used test compaction techniques from structural algorithms into SAT ATPG, including static [12] and dynamic [13] compaction methods, but differ in the configuration for fault simulation. In the second experiment, we eliminated the random 0/1 bit-filling for the final test cubes to exclude interference from random pattern fault simulation.

Evaluation of X bits Generation Effectiveness.

Fig. 6 illustrates the effectiveness of X bits generation by PA-MiniSat. For hard-to-detect faults of different circuits, we examine the proportion of X bits genetared by PA-MiniSat in the inputs of the transitive fanin cone for each fault's test cube without test compaction. It can be observed that the proportion of X bits varies significantly across different circuits. Overall, compared to a fully assigned SAT solver, our PA-MiniSat is able to generate, on average, 35.8% of the X bits for the transitive fanin cone portion of each test cube.

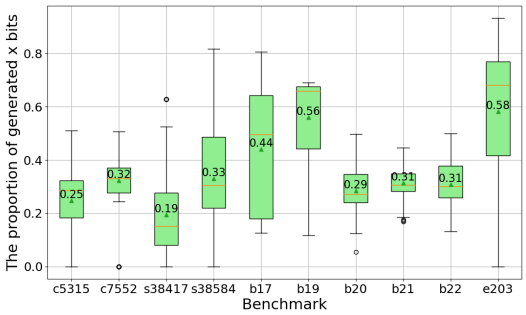

Fig. 6: The figure presents box plots illustrating the proportion of X bits in the inputs of the transitive fanin cone within the test cubes generated by the PA-MiniSat solver for various hard-to-detect fault sets in circuits; each box plot shows the median, interquartile range (IQR), and potential outliers (denoted by hollow circles), while the numbers indicate the average.

Evaluation of Solver Performance.

Left half of TABLE I presents the experimental results of the hard-to-detect fault set, a full SAT-only ATPG process is conducted with consistent test compaction parameters: the test cube bucket size for static compaction is set to 32, and the conflict limit for dynamic compaction is 100. TABLE I also shows the results without test compaction techniques in the right half. The results show that under test compaction, PA-MiniSat significantly reduces the number of patterns compared to other SAT solvers. In terms of time overhead, PA-MiniSat achieves significant acceleration on circuits such as c5378, c7552, s38417, and s38584 compared to other solvers with and without test compaction. This demonstrates the effectiveness of our proposed circuit-adaptive heuristic variable branching technique. However, for the ITC 99 circuits, PA-MiniSat incurs a higher time overhead. This is due to the presence of numerous redundant faults in these circuits, which substantially increase the time overhead of the full-literal watching technique men-

TC represents test coverage, all test coverages of SAT solvers are 100%.

TABLE II: Comparison of test metrics across different circuits' full-fault-sets under different SAT solvers and the original structural method [26] with test compaction techniques, and commercial ATPG at limited parameters set.

tioned in Section III-B. In the best case, PA-MiniSat achieves a speedup of up to 82.53× compared to CaDiCaL for the hard-to-detect fault set in circuit s38584, and the number of patterns is reduced to 10.71% of MiniSat's result. This is because the generated X bits within the test cubes provide ample space for test compaction, significantly reducing the probability of test generation failures in dynamic test compaction due to fault incompatibility, thereby saving the wasted time.

Evaluation of Framework Performance.

TABLE II presents the overall performance of the PastATPG framework using different SAT solver engines, including the number of patterns, time overhead and test coverage. We also compared our approach with the original structural method [26] and the commercial tool C. The test compaction parameter settings are kept the same. We maximized the test compaction capability and ATPG abort limit of C to achieve the highest possible test coverage and the fewest patterns. The experimental results show that, in terms of the number of patterns, the framework incorporating PA-MiniSat consistently generates the fewest patterns compared to the other three solvers, with the exception of the b21, where it falls short of the original MiniSat. Although the test cubes generated by MiniSat contain fewer X bits, they demonstrate better fault compatibility in b21, as evidenced by the uncompacted results in TABLE I. Regarding runtime, the following trend is observed: PastATPG with PA-MiniSat demonstrates an advantage in small to medium-sized circuits and can even outperform commercial tools for medium-sized circuits (b20, b21, b22). However, for large circuits (b17, b19, e203), the overhead of full-literal watching results in a performance disadvantage.

V. Conclusion

This paper presents PastATPG, a hybrid ATPG framework that integrates structurally generated test cubes with those from a SAT solver into a test compaction process. Using a custom SAT solver, PA-MiniSat, which generates test cubes with more X bits for better compaction and speed, PastATPG outperforms other SAT solvers in most cases and commercial ATPG tools in some cases in comparative experiments.

***Abstract*—Portfolio optimization is one of the most important financial problem, suffering from huge computational pressure due to arithmetic complexity. Quantum computing offers polynomial or even exponential speedup that turns out to be a promising approach. However,existing quantum methods is fundamentally limited by either poor scalability or insufficient accuracy. In this paper, we propose SAPO, which formally articulates the quantum circuit that seamlessly integrates financial theory and historical data characteristics with quantum algebra. The circuit design is extended from the HHL algorithm incorporating mean-variance theory, which promotes scalability by equivalent transformation. Then, we present a min-max eigenvalue model that leverages historical financial information to refine parameter settings with high accuracy. Experiments conducted on market data demonstrate that SAPO can effectively reduce the complexity by 36.94% compared to basic HHL [1], [2] and improve the accuracy by 1.46× compared to hybrid HHL [3].**

I. Introduction

Portfolio optimization identifies the best asset allocations to balance the risk and return, which is grappling with computational bottlenecks [4]. Through qubit entanglment and superposition, quantum computing offers an alternative for portfolio optimization. Extending from the mean-variance portfolio theory [5], classical solutions introduce various models, including the standard model, Tobin-Sharpe-Lintner model, and Black's model [6]. It has been demonstrated in recent researches that quantum algorithms are particularly well-suited for optimizing portfolios subject to the simple equality constraints in Black's model [7], [8].

Quantum approaches can be categorized into the quantum Ising solver [9], [10], [11] and the Harrow-Hassidim-Lloyd (HHL) algorithm [1], [2], [3]. The quantum Ising solver handles a quadratic unconstrained binary optimization problem, where asset holdings are represented by superpositions of 0 or 1, with the final strategy determined by the qubit state. On the other hand, the HHL algorithm formulates Black's model as a linear system, computing allocations by projecting the vector space onto quantum states. Despite the significant parallelism of quantum computing, existing attempts listed in Table I suffer from either poor scalability or low accuracy. The quantum Ising solver only tell the strategy of "buy" or "not buy". In other words, it lacks the capability to quantify the weight for each asset, leading to low accuracy. Conversely, the HHL algorithm can provide concrete weights. However, it exhibits overwhelming computational complexity in terms of circuit scale. For example, the circuit for 2-assets portfolio optimization has a depth over 3.7×10^8 after being compiled by Qiskit [12]. Though there are hybrid HHL algorithms [3] attempt to reduce the circuit complexity by inserting classical operations, they still rely on numerical properties and require massive qubits to obtain precise eigenvalues.

*Corresponding author.

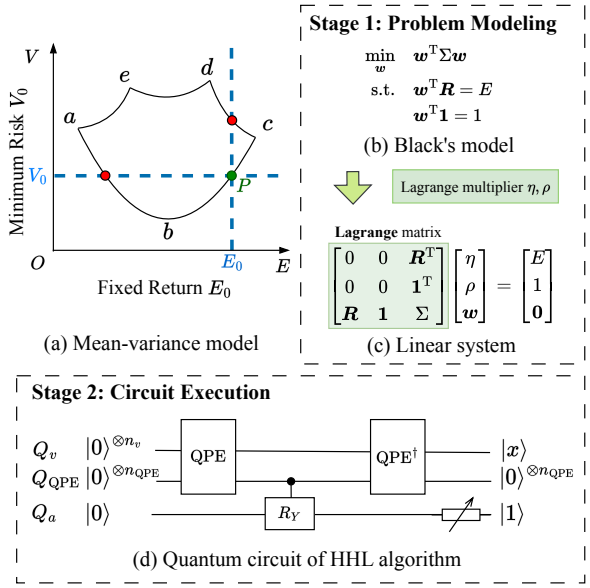

Fig. 1. Portfolio optimization using HHL algorithm.

These limitations originate from the absence of financial theory and historical financial information. When applied to portfolio optimization, the quantum Ising solver is hard to involve the intrinsic features. Consequently, the implementation on a quantum annealer [9] or parameterized quantum circuit [10], [11] is a coarse-grained coding scheme, resulting in overly simplistic recommendations for investment. On the other hand, the drawbacks of existing HHL algorithms are primarily attributed to the complexity of solving the linear system, fundamentally bounded by the large condition number of the matrix in it. Specifically, the condition number serves as an indicator when solving linear equations [13], which is a squared term in the asymptotic complexity of the HHL algorithm [1]. For 2-asset portfolio optimization, the condition number can reach an order of 10^5. Even with the hybrid method [3], which reduces the number of controlled rotation gates by inserting measurements in the midst of the HHL algorithm, it fails to mitigate the substantial complexity of the HHL circuit. Moreover, its accuracy hinges on the matrix's eigenvalue characteristics, making it difficult to estimate the necessary qubit number for the quantum phase estimation (QPE) module.

To overcome these challenges, we propose SAPO that exploits financial theory and data to improve both scalability and accuracy for portfolio optimization. Building upon the HHL algorithm, we observe that previous approaches are significantly limited by the large condition number, leading to poor scalability. To tackle this, we propose a novel constraint scaling technique with equivalent transformation to

TABLE I
EXISTING QUANTUM APPROACHES FOR PORTFOLIO OPTIMIZATION.

shrink it while adhering to the principles of Black's model. Then we develop an iterative algorithm to identify the optimal scaling factors for a given financial dataset. Moreover, with the economic understanding, we present a meticulous circuit parameterization to further improve the accuracy. This is grounded in prior knowledge derived from historical financial data, making it a static model that only depends on the dataset.

The contribution of this work is summarized as follows:

- This paper represents an exploratory endeavor aimed at an in-depth understanding of applying quantum computing to financial scenarios. The key is to profoundly leverage the intricacies of financial knowledge and data. We investigate the optimization opportunities of Black's model at both arithmetic level and quantum circuit level.
- We propose the constraint scaling technique for significant reduction of the condition number, which exploits the equality constraints in Black's model, leading to low complexity.
- We propose a prediction model, which estimates the minimum and maximum eigenvalues to delicately parameterize the quantum circuit, resulting in high accuracy.

In our experiments, SAPO achieves around 34.64%-36.94% complexity reduction compared to basic HHL [1], [2] with different settings of the absolute error. Furthermore, compared to Qiskit HHL [12] and hybrid HHL [3], SAPO improves the accuracy by $1.52\times$ and $1.46\times$ under fixed qubit number, and by $1.28\times$ and $1.39\times$ under fixed asset number, respectively.

II. BACKGROUND

A. Portfolio Optimization

H. Markowitz details the *mean-variance theory* for portfolio optimization [5], which aims to find the optimal asset allocation vector $\boldsymbol{w}$, with the objective of minimizing the risk while maximizing the expected return. First, we consider the returns of n assets across each of the T time periods, denoted as:

$$\boldsymbol{r}_t = \left[r_1^t, r_2^t, \cdots, r_n^t\right]^{\mathrm{T}}, \quad t = 1, 2, \cdots, n \tag{1}$$

Subsequently, the historical expected return vector, denoted as $\boldsymbol{R}$, and the covariance matrix, denoted as Σ, can be estimated using the data from the past T time slices as follows:

$$\begin{aligned} \boldsymbol{R} &\equiv \mathbb{E}(\boldsymbol{r}_t) \approx \frac{1}{T}\sum_{t=1}^{T} \boldsymbol{r}_t \\ \Sigma &\equiv \mathbb{V}(\boldsymbol{r}_t) \approx \frac{1}{T-1}\sum_{t=1}^{T} (\boldsymbol{r}_t - \boldsymbol{R})^{\mathrm{T}} (\boldsymbol{r}_t - \boldsymbol{R}) \end{aligned} \tag{2}$$

Under a given $\boldsymbol{w}$, the expected return E and risk V can be defined:

$$\begin{aligned} E &\equiv \boldsymbol{w}^{\mathrm{T}} \boldsymbol{R} \\ V &\equiv \boldsymbol{w}^{\mathrm{T}} \Sigma \boldsymbol{w} \end{aligned} \tag{3}$$

For instance, as depicted in Fig. 1(a), the optimal $\boldsymbol{w}$ corresponds to the minimized risk V_0 for a specified expected return E_0. Typically, the problem can be formulated as a quadratic programming problem, where $\boldsymbol{w}$ constitutes the solution (Fig. 1(b)). In particular, Black's model [6] presents the problem with equality constraints. By employing the Lagrange multiplier method, the optimization can be converted into a linear system with a Lagrange matrix M_L (Fig. 1(c)).

B. HHL Algorithm

Considering A as a Hamiltonian matrix with eigenvalues $\{\lambda_j\}_{j=1}^n$ and eigenvector $\{|\mu\rangle_j\}_{j=1}^n$ and $\boldsymbol{b}$ as a normalized vector represented by $\sum_{j=1}^n \beta_j |\mu_j\rangle$. The solution to the linear system $A\boldsymbol{x} = \boldsymbol{b}$ can be represented as a quantum state:

$$|x\rangle = \sum_{j=1}^{n} \frac{\beta_j}{\lambda_j} |\mu_j\rangle \tag{4}$$

Fig. 1(d) illustrates the quantum circuit of the HHL algorithm [1]. The circuit is comprised of three primary components, including QPE, uniformly controlled R_Y gate, and QPE†. There are also three quantum registers for different functions: a) Q_v is used to load the vector $\boldsymbol{b}$ as part of the QPE module; b) Q_{QPE} stores the output of QPE, recording eigenvalue information; c) Q_a only contains an auxiliary qubit controlled by Q_{QPE} through the uniformly controlled R_Y gate.

- **QPE module.** In the HHL algorithm, the QPE part is used to extract eigenvalues of the input Hamiltonian matrix A. Specifically, QPE generates a superposition state of phases $\varphi \in [0, 1)$ and records this in the quantum register Q_{QPE}, establishing an entanglement with Q_v. Each phase and eigenvalue adhere to the relationship:
$$e^{2\pi i \varphi_j} = e^{i\lambda_j H_t} \tag{5}$$
where H_t is a key hyperparameter named *Hamiltonian simulation time*. Increasing the number of qubits for the QPE module can improve the preciseness of the phase, making the eigenvalue obtained by Eq. (5) more accurate. Thus, the number of qubits in Q_{QPE},represented as n_{QPE}, is an important hyperparameter. In addition, QPE† is the inverse operation of QPE, which is applied at the end of the quantum circuit to disentangle Q_v and Q_{QPE}.
- **Uniformly Controlled R_Y Gate.** The uniformly controlled R_Y gate is a multi-qubit controlled gate. In the HHL algorithm, according to the phase φ_j stored in Q_{QPE}, $R_Y(2\arcsin(Const/\lambda_j))$ gate is applied to the single qubit stored in Q_a so that the eigenvalue can be placed on the denominator of the amplitude of the quantum state. Here, $Const$ is a *normalization constant*, another critical hyperparameter in the HHL algorithm.

The result is obtained by measuring the auxiliary qubit stored in Q_a at the end of the quantum circuit. Ideally, if the result is 1, the quantum state collapses to the normalization of Eq. (4). For the sake of simplicity, this paper assumes that we can directly obtain

the quantum state vector after executing the circuit, which is post-processed to get the desired solution, denoted as $\tilde{\boldsymbol{w}}$.

III. SAPO Overview

A. Evaluation Metrics

As aforementioned, our goal is to improve the scalability and accuracy in portfolio optimization. To achieve this, we define two metrics, named *complexity* and *accuracy*, to evaluate quantum approaches.

First, we model the complexity in both spatial and temporal dimensions by counting the consumed quantum resources and the circuit depth. According to the HHL algorithm, the total number of qubits N^q is the summation of three quantum registers.

$$N^q = n_v + n_{\text{QPE}} + n_a \tag{6}$$

Besides, we use N^{CNOT} and N^d to represent the number of CNOT gates and the circuit depth after compilation. This is because the CNOT gate is the dominant source of errors on most existing NISQ devices [14], and the circuit depth is also an important indicator to evaluate the complexity of quantum algorithm [15]. Putting it all together, we formulate the complexity metric as follows.

$$\Theta = N^q + \lg\left(N^{\text{CNOT}}\right) + \lg\left(N^d\right) \tag{7}$$

Here, for simplicity, we employ lg function on N^{CNOT} and N^{d} since these two terms exhibit exponential growth with the number of qubits.

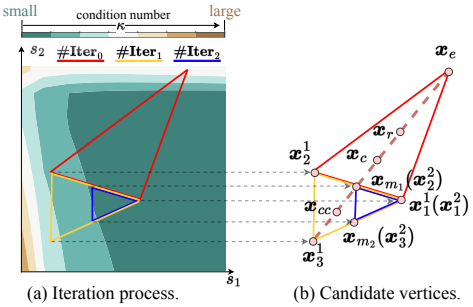
The accuracy is evaluated by quantifying the discrepancy between the calculated allocation $\tilde{\boldsymbol{w}}$ and the optimal choice $\boldsymbol{w}$. Thus, we formulate the accuracy in terms of cosine similarity:

$$\Delta = \frac{1}{2}\left(1 + \frac{\boldsymbol{w}^{\text{T}}\tilde{\boldsymbol{w}}}{\|\boldsymbol{w}\|\|\tilde{\boldsymbol{w}}\|}\right) \tag{8}$$

where Δ always falls within the interval $[0, 1]$. The closer it is to 1, the more accurate it is.

B. SAPO Advantages

The novelty of SAPO is that it leverages the knowledge of financial theory and data to optimize the design of the quantum approach. Extending from the Black's model, we observe that the condition number of the Lagrange matrix derived from real market data is typically large. This could markedly increase the circuit complexity, thereby limiting the scalability with respect to problem size. To address this, we propose a constraint scaling technique that adopts an equivalent transformation.



Next, we propose min-max eigenvalue model to enhance the accuracy of portfolio optimization. Our approach relies on the insight that knowing only the minimum and maximum eigenvalues of the Lagrange matrix is sufficient for setting the hyperparameters of the HHL circuit. We provide a quantitative formulation linking circuit hyperparameters to these eigenvalues obtained from a static predictor trained on historical data. In a word, we demonstrate that SAPO exhibits a lower end-to-end complexity compared to previous methods while achieving much higher accuracy for portfolio optimization.

IV. Equivalent Scaling of Lagrange Matrix

A. Equivalent Transformation

For the Lagrange matrix M_L featuring a set of eigenvalues $\{\lambda_j\}$, we first define min/max eigenvalue $|\lambda|_{\min} = \min\{|\lambda||\lambda \in \{\lambda_j\}\}$ and $|\lambda|_{\max} = \max\{|\lambda||\lambda \in \{\lambda_j\}\}$. We start by optimizing the condition number $\kappa = |\lambda|_{\max}/|\lambda|_{\min}$ of the Lagrange matrix.

Mathematically, the condition number indicates the difficulty of matrix calculus using approximation algorithms [13]. For example, when the condition number is exactly one, it means that the matrix is a scalar multiple of a linear isometry. In contrast, a larger condition number suggests that the linear system is hard to solve using an approximation solution, e.g., Jacobi method [16] and conjugate gradient method [17]. According to the HHL algorithm [1], the upper-bound complexity is $O(\log n \cdot \kappa^2/\epsilon)$, where n is the matrix size and ϵ is the given upper bound of absolute error. In the portfolio optimization problem, the condition number is usually in the scale of 10^5, which implies a huge complexity.

(a) Iteration process. (b) Candidate vertices.

Fig. 2. iterative method for searching the optimal scaling factor.

Conventional method to deal with large condition number involves rescaling the matrix by rows or columns [18]. However, such rescaling fails to keep the equivalence, reducing the expressiveness of the linear system. Thus, this method has to introduce various parameters that need to be tuned to compensate for the gap. Instead of directly scaling the matrix, we choose to modify Black's model by multiplying two scaling factors s_1, s_2 with the equations in Fig. 1(b).

$$\begin{aligned} \min_{\boldsymbol{w}} \quad & \boldsymbol{w}^{\text{T}}\Sigma\boldsymbol{w} \\ \text{s.t.} \quad & s_1\boldsymbol{w}^{\text{T}}\boldsymbol{R} = s_1 E \\ & s_2\boldsymbol{w}^{\text{T}}\boldsymbol{1} = s_2 \end{aligned} \tag{9}$$

In this manner, we have an equivalent Lagrange matrix as follows, which is an equivalent transformation with only two scaling factors.

$$\begin{bmatrix} 0 & 0 & s_1\boldsymbol{R}^{\text{T}} \\ 0 & 0 & s_2\boldsymbol{1}^{\text{T}} \\ s_1\boldsymbol{R} & s_2\boldsymbol{1} & \Sigma \end{bmatrix} \begin{bmatrix} \eta \\ \rho \\ \boldsymbol{w} \end{bmatrix} = \begin{bmatrix} s_1 E \\ s_2 \\ \boldsymbol{0} \end{bmatrix} \tag{10}$$

B. Search Algorithm of Scaling Factor

The scaling factor helps to adjust the condition number, providing the opportunity to reduce the difficulty of portfolio optimization. Empirically, we test that outstanding scaling factors can significantly reduce the condition number from 10^5 to ˜10. However, the optimal scaling factor varies in different Lagrange matrices. Therefore, we try to find a static scaling factor on a target dataset, which achieves optimal reduction on average in this dataset.

We adopt a iterative algorithm inspired by Nelder-Mead simplex algorithm [19] to search the optimal scaling factor. Here, we use a two-dimensional vector $\boldsymbol{x}$ to notate the tuple of (s_1, s_2) as shown in Fig. 2(a). First, given a set of Lagrange matrices derived from a specific dataset, we define a loss function that calculates the average of condition numbers after applying the scaling factor. The algorithm begins with the initialization of three scaling factors, labeled as $\boldsymbol{x}_1^0$, $\boldsymbol{x}_2^0$, and $\boldsymbol{x}_3^0$, drawing a triangle region in $s_1 - s_2$ plane. For each iteration, we generate multiple candidates according to the vertex of the current triangle. In Fig. 2(b), each candidate is the midpoint of its line segment (x_m , x_m , x_{cc}, etc.). After determining the candidates, we keep one vertex from the current three vertices for the next iteration, which shows the minimum loss for the given dataset in current iteration. The other two optimal vertices are selected from the remaining vertices and candidates. After several iterations, we choose

the best vertex as the scaling factor. As a result, the average condition number gradually decreases during iterations as Fig. 2 shown. Note that, to ensure quantum speedup, the scaling factor is pre-obtained by running the algorithm on the target dataset.

V. Min-Max Eigenvalue Model

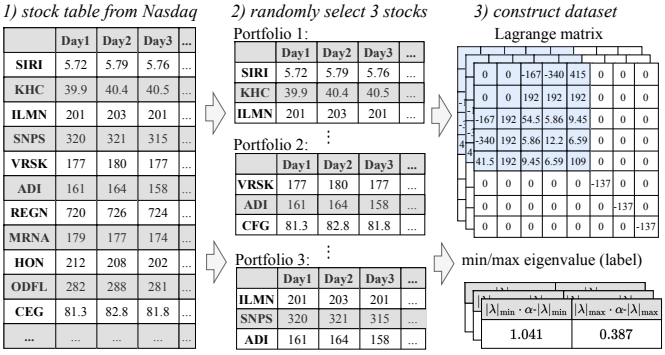
A. Parameterization Using Min-Max Eigenvalue

As mentioned in Section II-B, the QPE module, taking up most of the qubits, is used to extract eigenvalues of the input matrix. Furthermore, since eigenvalues play an important role in characterizing the linear system, their preciseness significantly affects the final output accuracy of the HHL circuit. Thus, the prior knowledge of eigenvalues can naturally improve the output accuracy. However, profiling all eigenvalues requires a huge computational cost that destroys the quantum advantage. Considering that the eigenvalues are inherently related to the hidden information of the portfolio optimization problem, we predict $|\lambda|_{\min}$ and $|\lambda|_{\max}$ and leverage them to set hyperparameters. We choose these two eigenvalues rather than the largest two for two reasons:

- In the view of economics, $|\lambda|_{\min}$ captures the microeconomic details, which describes macroeconomic patterns of asset changes. While $|\lambda|_{\max}$ governs the long-term behavior of the system.
- The condition number κ, serving as the complexity metric, is calculated by $|\lambda|_{\max}/|\lambda|_{\min}$. Thus, the knowledge of these two eigenvalues helps to guide the qubit need of QPE, and then provides the opportunity to quantitatively evaluate the overall circuit.

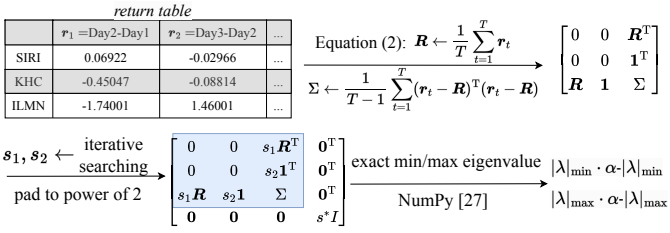
The hyperparameter settings require that all eigenvalues of the input matrix are within $(-1, 1)$. To ensure this, we perform a standardization operation on the Lagrange matrix as a preprocessing.

$$M_L^{\text{std}} \equiv \frac{l}{|\lambda|_{\max}} M_L, \quad l \in (0, 1) \tag{11}$$



In this paper, we set $l = 0.5$ for simplicity, which makes eigenvalues of M_L^{std} lie in $[1/2\kappa, 1/2)$, but the value of κ does not change.

- **Hamiltonian Simulation Time: $H_t \equiv \pi$.** When $H_t = \pi$, the relationship between the output phase φ of QPE and the eigenvalue λ of M_L^{std} can be represented by a piece-wise function as follows



$$\lambda = \begin{cases} 2\varphi, & \varphi < \frac{1}{2}, \\ 2(\varphi - 1), & \varphi > \frac{1}{2}. \end{cases} \tag{12}$$

  Other methods usually set $H_t = 2\pi$ [12], [3] or randomly [20], which makes different value φ may map to the same eigenvalue, leading to low accuracy. In detail, through standardization by $|\lambda|_{\max}$, we ensure $|\lambda| < 1$ so that we can split the interval of $\varphi \in [0, 1)$ into two halves and map to the case of either the eigenvalues being positive or negative bounded by $1/2$. In a word, this one-to-one map results in more preciseness of all eigenvalues.
- **Number of Qubits for QPE: $n_{\text{QPE}} \geq 2 + \left\lceil \log_2 \frac{|\lambda|}{|\lambda| \cdot \epsilon} \right\rceil$.** The minimum n_{QPE} ensures that the absolute error of the solution output by HHL algorithm does not exceed ϵ. Essentially, this calculation uses the quotient of $|\lambda|_{\min}$ and $|\lambda|_{\max}$, which is the condition number. This also further illustrates the fact that the larger the condition number, the more difficult to solve portfolio optimization problems, because we need more qubits to perform QPE.
- **Normalization Constant: $Const \equiv |\lambda|_{\min}$.** The state before final measurement is

$$\sum_{j=1}^{n} \beta_j |\mu_j\rangle_{Q_v} \left(\sqrt{1 - \frac{Const^2}{\lambda_j^2}} |0\rangle_{Q_a} + \frac{Const}{\lambda_j} |1\rangle_{Q_a} \right) \tag{13}$$

(a) Constructing the dataset for 3-assets problem using Nasdaq maket data.The values in the Lagrange matrix need to multiply 10^{-5}.

(b) Details of calculating the dataset.

Fig. 3. Workflow of dataset construction.

For auxiliary qubit in Q_a, $Const \leq |\lambda|_{\min}$ must be satisfied. On the other hand, it is expected that the probability of measuring the auxiliary qubit is close to 1 as high as possible, which means the algorithm has a high success rate. Thus, we set $Const \equiv |\lambda|_{\min}$.

B. Min-Max Eigenvalue Predictor

Most conventional approaches deliver inefficient eigenvalue information. For example, [21] only predicts eigenvalues of Σ, and [22] only estimate the eigenvalue counts. On the contrary, [23] aims to figure out all eigenvalues, necessitating massive computational costs. We develop a predictor to quickly predict the min-max eigenvalue by leveraging historical financial information without any prior knowledge. More importantly, this prediction model is dataset-dependent and can be trained offline, which greatly reduces the computational pressure of the classical part.

We apply support vector regression (SVR) as our basic model. Starting from the matrix in Eq. (10), elements of $s_1\boldsymbol{R}$ are concatenated with the upper triangular portion of Σ into a vector and take this vector as the input of the SVR. The output is the predicted $|\lambda|_{\min}$ and $|\lambda|_{\max}$ multiplied by α-$|\lambda|_{\min}$ and α-$|\lambda|_{\max}$, respectively. Here, we introduce the tunable parameter α to mitigate the truncation error of floating-point.

The training data is collected from three representative stock exchanges listed in Table III. Fig. 3(a) illustrates the detailed workflow for constructing the 3-asset dataset from Nasdaq market. First, we collect the data of 3100 stocks within 251 days and randomly select three stocks to formulate a series of portfolio optimization problems. Then, we can derive the Lagrange matrix and label it with the exact min/max eigenvalues. To be specific, we build a return table by calculating the increments on adjacent days as shwon in Fig. 3(b). Using Eq. (2), we can obtain the historical expected return vector and the covariance matrix to construct the Lagrange matrix. Finally, we can compute the min/max eigenvalue using NumPy [24], regarding it as the label for SVR model training. In particular, since the HHL algorithm can only deal with matrices with size of the power of 2, the Lagrange matrix is padded with zeros and identity matrix. For

TABLE II
MODELS FOR PREDICTING MIN/MAX EIGENVALUES.

Model	# Parameter	#Operations	ℓ_2-loss of $\lvert\lambda\rvert_{\min}, \lvert\lambda\rvert_{\max}$
SVR	1640	1.6×10^3	0.033, 0.39
Decision Tree	1969	2×10^2	0.066, 1.66
MLP	2137	2×10^3	0.034, 0.024
LeNet	20411	2×10^4	0.088, 15.8

example, the 3-asset problem leads to a 5×5 Lagrange matrix, which is then padded by putting a scaled identity matrix at right-bottom.

We have also tried other methods like decision tree and deep learning. Table II evaluates four models for eigenvalue prediction. The other three show limited improvement yet are accompanied by a disproportionately high computational complexity. The effectiveness of SVR lies in its generalization performance, which is demonstrated by portfolio optimization based on the stock pre-selection [25]. Since the computational complexity of SVR is independent of the input space dimensionality [26], our method avoids the computational bottleneck caused by large-scale training to some extent and preserves the quantum advantages.

VI. EVALUATION

A. Experiment Setup

Implementation. SAPO is constructed based on Qiskit [12]. The QPE module and uniformly controlled R_Y gate is implemented by *PhaseEstimation* and *UCRYGate* in the framework. The optimization level of transpiler is set to 0. Scaling factor searching is extended from Nelder-Mead module in SciPy library[27]. The min-max eigenvalue predictor is implemented using Scikit-Learn [28]. Table III gives the configurations of SAPO on each dataset.

Comparison. We compare SAPO with three HHL implementations: basic HHL [1], [2], Qiskit HHL [12] and hybrid HHL [3]. Rebentrost et al. [2] images applying basic HHL [1] to the Black's model, but without any specific parameterizations and experiments. Thus, when compared to basic HHL, we assume eigenvalues have been pre-calculated, only comparing the complexity metric. In Qiskit HHL [12], the Hamiltonian simulation time is 2π, and the uniformly controlled R_Y gate is implemented using *ExactReciprocal*. Hybrid HHL [3] involves both classical and quantum computing. Both Qiskit HHL and hybrid HHL require specifying the number of qubits for QPE, which cannot adaptively balance the trade-off between complexity and accuracy. Thus, we only compare the accuracy metric with them, under the same number of qubits for QPE. Due to the huge complexity of simulating the HHL circuit, we consider the portfolio optimization problem ranging from 2 assets to 6 assets.

B. Scalability and Accuracy Improvement

Complexity analysis. Table IV compares the circuit complexity in terms of the number of necessary qubits, circuit depth, the number of CNOT gates, and the total complexity defined by Eq. 7. Overall, SAPO achieves around 34.64%-36.94% complexity reduction with the absolute error ϵ ranging from $1/16$ to $1/4$. In the case of $\epsilon = 1/8$, the detailed resource consumption is listed. SAPO shows a remarkable reduction, especially N^{CNOT} (achieving a maximum reduction of 99.996% for 2-asset portfolio optimization). According to the value of n^{QPE}, such resource-saving results from our scaling technique that shrinks the condition number. The complexity reduction lightly decreases for smaller ϵ, which comes from the logarithmic function when calculating complexity in Eq. (7).

We find that the complexity is significantly higher when handling 3-asset portfolio optimization problems. This may arise from the infinitesimally small or large condition number in several Lagrange matrices. To confirm this, we also give the median value of each metric in the footnote of Table IV, which turns out to be a much more reasonable value, following the trend of the other cases.

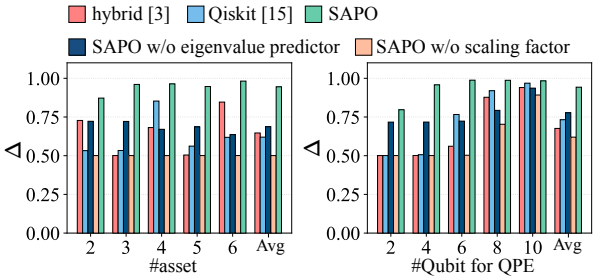
TABLE III
CONFIGURATIONS OF SAPO ON EACH DATASET.

Dataset	#Stocks	Scaling factor search			Min-max predictor	
		s_1	s_2	#iter	α-$\lvert\lambda\rvert_{\min}$	α-$\lvert\lambda\rvert_{\max}$
Nasdaq	3100	0.56	1.9e-3	119	3000	100
NYSE	400	0.25	3.2e-4	152	5000	800
AMEX	40	0.28	6.6e-4	125	4000	400

Accuracy analysis. Fig. 4 gives the accuracy improvement compared to hybrid HHL [3] and Qiskit HHL [12], where the accuracy Δ is defined by Eq. (8). Fig. 4(a) sets a fixed number of qubits, which shows that SAPO improves the accuracy by $1.52\times$ on average compared to Qiskit HHL, and $1.46\times$ on average compared to hybrid HHL. For limited available qubits, SAPO reduces the difficulty of solving linear systems and identifies more reasonable parameter settings for the HHL algorithm, thus, being able to solve more complex problems. In the case of the 5-asset portfolio optimization problem, Fig. 4(b) shows that SAPO improves the accuracy by $1.28\times$ on average compared to Qiskit, and $1.39\times$ compared to hybrid HHL. Particularly, the accuracy of SAPO, with a 4-qubit QPE circuit ($\Delta = 0.96$), outperforms all other approaches, even if they involve a 10-qubit QPE circuit. In a word, SAPO makes a better trade-off between accuracy and scalability by leveraging the features of Black's model and historical financial information.

We conduct an ablation study to quantitatively evaluate the advantages of scaling factor and eigenvalue prediction. Here, SAPO without scaling factor means we train the eigenvalue predictor using original Lagrange matrices. For SAPO without eigenvalue predictor, we adopt the same scheme as Qiskit HHL. Fig. 4(a) demonstrates that the scaling factor contributes most, improving the accuracy $1.74\times$-$1.96\times$ under the constraint of 5-qubits QPE module, and improves the accuracy $1.10\times$-$1.96\times$ for 5-asset portfolio optimization. This mainly benefits from our search algorithm. The accuracy of SAPO without the scaling factor is a little bit lower than hybrid HHL and Qiskit HHL. This is because a huge condition number makes it difficult to predict eigenvalues, leading to a less effective or even counterproductive eigenvalue predictor. However, the other two do not make any use of predicted eigenvalues. The gain from the eigenvalue predictor is $1.21\times$-$1.54\times$ and $1.05\times$-$1.37\times$ for fixed qubit number and fixed asset number, respectively. By leveraging prior knowledge, SAPO is able to capture the min-max eigenvalue more precisely, therefore, achieving high accuracy. Fig. 4(b) also suggests that the technique of scaling factor exhibits more improvement for small QPE modules.

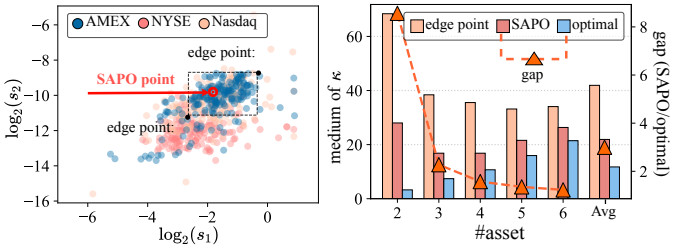
C. Evaluation of the Scaling Factor



This section provides a detailed evaluation of the scaling factor that serves to squeeze the condition number. Fig. 5(a) draws the distribution of the optimal scaling factor under different datasets, where we randomly select a series of portfolio optimization problems. We can observe that most of their optimal scaling factors lie in a small region, demonstrating that the scaling factor can be static. The figure outlines the region and its edge point of AMEX dataset as an example. SAPO searches the point via the iterative algorithm, which is close to the central in this region.

We also compare the resultant condition number using the scaling factor from the edge point and the optimal scaling factor, as illustrated

TABLE IV
COMPLEXITY COMPARISON WITH BASIC HHL [1], [2].

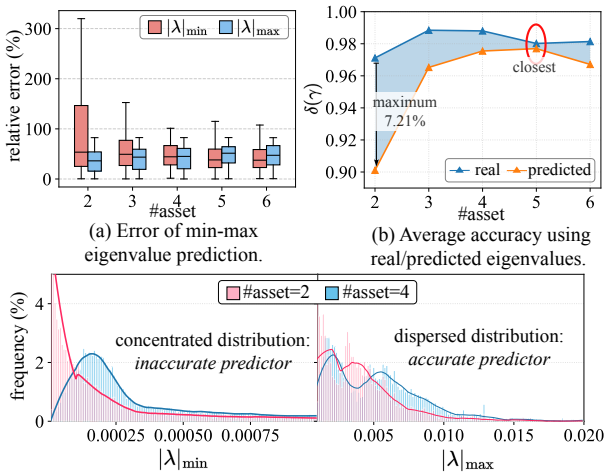


#Asset	The absolute error rate $\epsilon = 1/8$								$\epsilon = 1/16$		$\epsilon = 1/4$	
	N^q		N^d		N^{CNOT}		Θ		Θ		Θ	
	basic HHL	**SAPO**	basic HHL	**SAPO**	basic HHL	**SAPO**	basic HHL	**SAPO**	basic HHL	**SAPO**	basic HHL	**SAPO**
2	19.77	11.80	2.148×10^9	8.016×10^4	1.123×10^9	4.202×10^4	33.82	21.05	35.42	22.65	32.22	19.45
3	21.00	13.87	1.782×10^8	2.523×10^7	9.381×10^7	1.328×10^7	36.76	25.32	38.36	26.93	35.16	23.72
4	21.88	13.23	6.274×10^8	6.454×10^5	3.304×10^8	3.399×10^5	38.17	24.30	39.77	25.91	36.57	22.70
5	22.37	13.21	9.526×10^8	7.062×10^5	5.016×10^8	3.719×10^5	38.94	24.27	40.55	25.87	37.34	22.66
6	22.75	13.42	9.558×10^8	6.737×10^5	5.033×10^8	3.549×10^5	39.56	24.61	41.16	26.22	37.96	23.01
Reduction	39.16%		97.12%		97.12%		36.13%		34.64%		36.94%	

The medium value for #asset=3: $N^q = 13$, $N^d = 4.048 \times 10^5$, $N^{\text{CNOT}} = 2.132 \times 10^5$, $\Theta = 23.94$.

(a) Accuracy under 5-qubit QPE across different number of assets. (b) Accuracy under 5-asset problem across different number of qubits.

Fig. 4. Accuracy comparison with hybrid HHL[3] and Qiskit HHL [12].



(a) The optimal scaling factor for different portfolios from each dataset. (b) Condition number across different scaling factor.

Fig. 5. Evaluation of the scaling factor.

in Fig. 5(b). Even choosing the edge point still shows a great reduction in the condition number. We also draw the gap between SAPO and the optimal setting, calculated as $\frac{\kappa \text{ of SAPO}}{\kappa \text{ of optimal}}$. The gap is narrowed when more assets are taken into account, from $8.56\times$ (2-asset) to $1.23\times$ (6-asset), demonstrating the validness of static scaling factors. This is because a large number of assets results in more combinations of assets (i.e., more Lagrange matrices), which makes the scaling factor fit the problem better. As a result, the condition number of the Lagrange matrix is dramatically reduced by at least 98.59% through a fixed scaling factor.

D. Evaluation of the Eigenvalue Predictor

In this section, we evaluate the preciseness of the eigenvalue predictor and investigate how it affects the accuracy of the final result. First, we collect the predicted min-max eigenvalues across 1500 cases. Then, we calculate the relative error compared to the real eigenvalues, as shown in the box plot of Fig. 6(a). Overall, the relative error of most predicted values is within 50%. The relative error of some samples is more than 100%, and even exceeds 300% when #asset=2. This is because some eigenvalues are close to zero. Fig. 6(b) depicts the gap of accuracy using the real eigenvalues and the predicted ones, calculated as $\left(1 - \frac{\Delta \text{ using predicted}}{\Delta \text{ using real}}\right) \times 100\%$. The maximum gap is 7.21% under the case of #asset=2, which is still an

(a) Error of min-max eigenvalue prediction. (b) Average accuracy using real/predicted eigenvalues.

(c) Distribution of min/max eigenvalues.

Fig. 6. Evaluation of the min/max eigenvalue predictor.

acceptable accuracy ($\Delta = 0.901$). Especially when #asset=5, the gap almost disappears, resulting from our precise prediction model.

We also picture the distribution of the real $|\lambda|_{\min}$ and $|\lambda|_{\max}$, as shown in Fig. 6(c). We observe that $|\lambda|_{\min}$ is concentrated in the interval $(0, 0.0001]$ when the number of assets is 2, which makes this eigenvalue hard to predict. That's why the relative error of $|\lambda|_{\max}$ is much lower than $|\lambda|_{\min}$ in Fig. 6(a).

VII. CONCLUSION

We propose SAPO to improve the scalability and accuracy for quantum portfolio optimization, indicating the idea that the algorithm design for quantum finance should be based on the deep integration of quantum computing and financial knowledge. SAPO is a novel design of HHL algorithm, which incorporates mean-variance theory and leveraging financial data characteristics. Depending on the equivalent transform, the condition number of the Lagrange matrix is extremely reduced, which improves the scalability. Considering the close connection between eigenvalues and the HHL algorithm, we propose a min-max eigenvalue model to guide parameter settings for highly accurate computation. Our experiments demonstrate that SAPO can achieve lower complexity and higher accuracy than conventional quantum methods.

***Abstract*—Inverse lithography technology (ILT) is an advanced resolution enhancement technique that achieves mask optimization at the pixel level. However, application of ILT is hindered by time-intensive physical simulation. Herein, we propose an efficient ILT algorithm leveraging a deep learning model. A novel loss function is constructed to guide the model training in a self-supervised manner, eliminating the requirement of labelled data that might be nontrivial to acquire. The trained model outputs final mask patterns without further ILT optimization. Sub-resolution assist features (SRAFs) are generated automatically, the complexity of which can be adjusted during the training process to control mask manufacturability. The model was trained and validated on ICCAD-2013 CAD contest dataset. Better pattern fidelity and up to 12,000 times speedup are observed compared to other SOTA models. The trained model also shows good generalization ability to geometrically-different design patterns from another dataset, via a few-shot learning approach.**

Keywords—ILT, self-supervised, deep learning, SRAF, few-shot learning

I. INTRODUCTION

Lithography is the optical process of creating pre-designed circuit patterns on a silicon wafer, and a mask is the template used to create these patterns. As the critical dimension of the design layouts gets increasingly smaller than the optical wavelength, strong imaging distortion/displacement effect occurs that has to be corrected in the process of mask design.

Optical proximity correction (OPC) is a major type of mask optimization technique. Mainstream OPC approaches include rule-based [1] and model-based OPC [2], [3]. Rule-based OPC corrects the mask pattern based on predefined rules or empirical formulas, which, however, are difficult to generalize to complex patterns. Model-based OPC simulates the imaging process of the optical system using physical models, allowing for more precise correction of distortions in mask patterns, but this method may suffer from limited solution space since the design patterns are optimized segment by segment [4]. Inverse lithography technology (ILT) [5] is an advanced mask optimization method used to address the challenges of shrinking feature size. ILT generates an optimized mask pattern by inversely solving the lithography process. Different from conventional OPC, ILT performs optimization at the pixel level, resulting in stronger flexibility and better fidelity. One of the major technical bottlenecks limiting the widespread application of ILT is the high computational demand and low efficiency.

With the development of artificial intelligence technology, deep-learning-based ILT algorithms reformulates the mask optimization problem as an image-to-image translation problem. Namely, pre-trained neural network models predict mask patterns from target layouts directly, eliminating the need for solving complex physical models. Additionally, by utilizing GPU hardware acceleration, the computational efficiency is improved. Several state-of-the-art (SOTA) deep learning based ILT methods have shown improved performance compared to conventional ILT approaches, such as GAN-OPC [6], Neural-ILT [7], DevelSet [8], and A2-ILT [9]. A common workflow for these methods requires the pretraining of a deep learning model in a supervised manner, providing the model with thousands of design layout/mask pattern data pairs to learn the underlying mapping relationship. The output of the trained model serves as an initial guess for further ILT optimization to produce the final mask. This workflow is not computationally efficient. On the other hand, the supervised model training process may have limited fidelity or generalization ability when the training dataset is not adequate.

In this paper, we propose a self-supervised deep learning based ILT model (SSDL-ILT) for mask optimization with improved fidelity and efficiency. The contribution of our work is fivefold:

(1) a novel self-supervised learning strategy is proposed utilizing a tailored loss function, which only requires design patterns as the training dataset;

(2) end-to-end mask generation is realized without the need of further ILT correction;

(3) sub-resolution assist features (SRAFs) are generated automatically, the complexity of which can be adjusted in the model training stage;

(4) significant speedup is achieved at both the model training and inference stages compared to other SOTA deep-learning-based ILT models;

(5) good generalization ability is demonstrated via a few-shot transfer learning approach.

The rest of the paper is organized as follows. Section II provides an introduction of the related lithography simulation background, mask optimization problem formulation, and the corresponding evaluation criteria. Section III describes in detail our proposed self-supervised deep learning based ILT algorithm. Section IV provides the experimental results, and conclusion is provided in Section V.

II. BACKGROUND

A. Forward lithography simulation

The forward lithography simulation computes the wafer image from the mask. It consists of an optical model and a photoresist model. The optical model produces an aerial image $\mathbf{I}$, which represents the light intensity distribution on the wafer surface. For a partially coherent optical system, the commonly used optical model is the Hopkins diffraction model [10]. By simplifying the model through singular value decomposition, a series of optical convolution kernels $\mathbf{h}$ can be obtained. The spatial image can be computed through the convolution operation between the mask image $\mathbf{M}$ and the optical convolution kernel $\mathbf{h}$:

$$\mathbf{I}(x,y) = \sum_{k=1}^{N} \omega_k |\mathbf{M}(x,y) \otimes \mathbf{h}_k(x,y)|^2, \quad (1)$$

where $\mathbf{h}_k$ is the kth optical kernel and ω_k is the corresponding weight; N is the total number of optical kernels used in the simulation, and here we set $N = 24$; $\otimes$ denotes the convolutional operation.

The photoresist model converts the continuous light intensity image $\mathbf{I}$ into a binary wafer image $\boldsymbol{Z}$. Here, we adopt a simplified threshold-based photoresist model. To smooth the wafer image allowing effective loss back-propagation in the deep learning model training process, a sigmoid function is further applied:

$$\boldsymbol{Z} = \frac{1}{1+\exp[-(\mathbf{I}-I_{th})]}, \quad (2)$$

where I_{th} is the light intensity threshold. Here, I_{th} is set to 0.225 consistent with other related works [6, 7].

B. Mask optimization problem formulation

Given a target layout $\mathbf{Z}_t$, the goal of mask optimization is to obtain an optimized mask $\mathbf{M}$ that could produce a wafer image as close to $\mathbf{Z}_t$ as possible, with acceptable runtime, low process variation band, and acceptable printability and manufacturability. The deep-learning-based mask optimization strategy is to replace the physics-based optimization process with a pre-trained surrogate model, which predicts the mask pattern directly from the target layout.

C. Evaluation metrics

***Definition** 1* (Squared L_2 error). Squared L_2 error is calculated by $\|\mathbf{Z}_t - \mathbf{Z}_{norm}\|_2^2$, given the target image $\mathbf{Z}_t$ and the wafer image $\mathbf{Z}_{norm}$. Here $\mathbf{Z}_{norm}$ denotes the wafer image under nominal dose and focus conditions.

***Definition** 2* (Process variation band, PVB). PVB denotes the summation of bitwise-XOR between two wafer images $\mathbf{Z}_{min}$ and $\mathbf{Z}_{max}$, which are generated under $\pm 2\%$ dose conditions, using the same settings as in the ICCAD-2013 CAD contest [11].

***Definition** 3* (Turnaround time, TAT): TAT is defined as the time elapsed during the model application for one mask optimization case, including the model prediction time and (if any) the ILT re-optimization time.

III. ALGORITHMS

A. Deep learning model for mask generation

We adopt a deep learning model to perform end-to-end mask optimization. An attention-based residual recurrent U-Net model (R2U-Net) is used which takes the target layout as input and outputs the corresponding mask pattern that would produce the target design. The attention R2U-Net model is a combination of R2U-Net [12] and attention U-Net [13]. The network architecture is shown in Fig. 1. In general, the U-Net model is composed of an encoder and decoder. The encoder down-samples the input target layout through convolutional and pooling operations to extract high-level features, whereas the decoder up-samples the extracted features and restore the image to the original resolution. Skip-connection [14] is applied at each up-sampling stage that fuses the features from the corresponding down-sampling stage to improve the model's memory of lower-level information. Attention mechanism [13] is added to the decoder so that the model learns the importance weights of each channel and attend to most related regions in the images to improve feature generation. Furthermore, the recurrent residual convolutional layers ensures better feature representation for training deep architecture. In the final layer of the decoder, a Sigmoid function is applied that restricts the output values to a range of 0-1, aligning with the value range of a binarized image.

B. Self-supervised learning strategy

Unlike traditional supervised deep learning models, the training process of our model is unsupervised, which is not guided by the data mismatch between predicted and referenced mask patterns. A novel loss function is constructed to incorporate physical guidance into the modeling training process. The loss function consists of three terms used to evaluate the quality of the generated masks. Given a series of layout patterns $(Z_{t_1}, Z_{t_2}, \ldots, Z_{t_{N_t}})$ similar in geometry and design to the target layout T, the neural network model ϕ_{NN} predicts the corresponding mask patterns

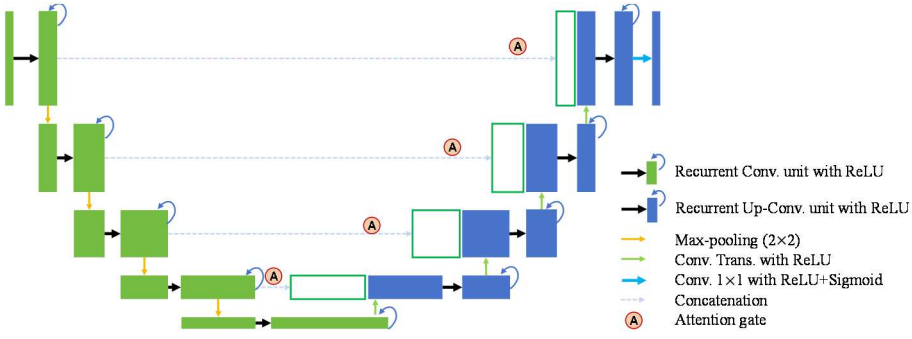

Fig. 1. Schematic of the attention R2U-Net model architecutre.

$(M_1, M_2, \dots, M_{N_t})$, which are then subject to lithographical simulation ϕ_{sim} described in Section II to obtain the corresponding wafer images $(Z_1, Z_2, \dots, Z_{N_t})$. The first term $Loss_{L_2}$ in the loss function quantifies the similarity between the simulated wafer images and the corresponding design patterns:

$$Loss_{L_2} = \frac{1}{N_t}\sum_{i=1}^{N_t}\left(Z_i - Z_{t_i}\right)^2, \tag{3}$$

where Z_t is the design pattern in the training set; N_t is the total number of design patterns used for model training; $\boldsymbol{w}$ is the parameter set of the neural network; Z is the simulated wafer image, and $Z = \phi_{sim}\left(\phi_{NN}\left(Z_{t_i}; w\right); \text{norm}\right)$. Here 'norm' indicates the dose and focus are at nominal conditions for the optical model.

The second term $Loss_{PVB}$ in the loss function evaluates the PVB of the generated mask:

$$Loss_{PVB} = \frac{1}{N_t}\sum_{i=1}^{N_t}[\phi_{sim}(\phi_{NN}(Z_t; \boldsymbol{w}); \min) - \phi_{sim}(\phi_{NN}(Z_t; \boldsymbol{w}); \max)]^2, \tag{4}$$

where 'min' indicates the wafer image generated under the nominal focus and −2% dose condition, and 'max' indicates the wafer image generated under nominal focus and +2% dose condition.

Theoretically, the mask complexity and manufacturability can be quantified by the number of shots performed during the mask creation process. However, the shots calculation can be cumbersome and time-consuming. Herein we define a new evaluation metric $Loss_{com}$, which is the third term in the loss function to heuristically quantify the mask complexity:

$$Loss_{com} = \frac{1}{N_t}\sum_{i=1}^{N_t}\left[\text{sum}(Z_{norm_i})/(H \times W)\right]^2, \tag{5}$$

where H and W indicate the image height and width in unit of total number of pixels. $Loss_{com}$ calculates the percentage of the image occupied by the mask pattern. Larger area of SRAF patterns will lead to higher value of $Loss_{com}$.

In the training process, the following total loss function is iteratively optimized:

$$\underset{\boldsymbol{w}}{\text{argmin}}\left\|\alpha Loss_{L_2} + \beta Loss_{PVB} + \gamma Loss_{com}\right\|_2^2, \tag{6}$$

where α, β, γ indicate the weight of the corresponding term. These weights can be tuned to generate mask patterns tailored to certain demand. Therefore, the model iteratively learns the physics behind mask optimization and generates masks that satisfy the defined evaluation criteria. The whole training process is in a self-supervised manner by providing the model with only certain amount of target layouts. The overall model training design is illustrated in Fig. 2.

During the training process, the backward calculation of the derivatives can be obtained as follows:

$$\begin{aligned}
\frac{\partial Loss_{L_2}}{\partial \boldsymbol{w}} &= \frac{\partial Loss_{L_2}}{\partial \mathbf{M}}\frac{\partial \mathbf{M}}{\partial \boldsymbol{w}} \\
\frac{\partial Loss_{PVB}}{\partial \boldsymbol{w}} &= \frac{\partial Loss_{PVB}}{\partial \mathbf{M}}\frac{\partial \mathbf{M}}{\partial \boldsymbol{w}} \\
\frac{\partial Loss_{com}}{\partial \boldsymbol{w}} &= \frac{\partial Loss_{com}}{\partial \mathbf{M}}\frac{\partial \mathbf{M}}{\partial \boldsymbol{w}}
\end{aligned} \tag{7}$$

$\frac{\partial Loss_{L_2}}{\partial \mathbf{M}}$, $\frac{\partial Loss_{PVB}}{\partial \mathbf{M}}$, and $\frac{\partial Loss_{com}}{\partial \mathbf{M}}$ can be calculated explicitly by deriving the lithographical model formula, the details of which can be referenced in [7]. $\partial \mathbf{M}/\partial \boldsymbol{w}$ can be obtained using the automatic differentiation feature provided by PyTorch [15]. The parameter set $\boldsymbol{w}$ of the neural network can then be updated by the following formula:

$$\boldsymbol{w}_{n+1} = \boldsymbol{w}_n + lr\frac{\partial Loss_{L_2}}{\partial \boldsymbol{w}}, \tag{8}$$

where lr represents the learning rate of the optimizer, and n represents the n^{th} iteration step.

Additionally, an early-stop mechanism is used during the training process to prevent overfitting and improve training efficiency. The training process stops when the loss function does not further reduce over the last ten epochs.

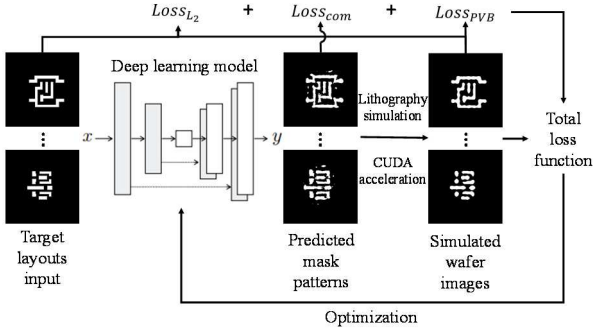

Fig. 2. Schematic of the self-supervised model training process.

C. Model inference

Once the model is adequately trained, it can be used for mask prediction given a target layout. If a target design is not in an image format (e.g. GDS files), it should first be converted into images, and the image size should be adjusted to match the input size of the model. The model's prediction result ϕ_{NN} needs to be converted into a binary image using a threshold value t.

$$\phi_{NN} = \begin{cases} 1, for\ \phi_{NN} \geq t \\ 0, for\ \phi_{NN} < t \end{cases} \tag{9}$$

Here we set $t = 0.5$. The entire self-supervised deep learning based ILT workflow is described in Algorithm 1.

Algorithm 1 The self-supervised deep learning based ILT workflow

Require: Target layout T for which a mask is to be generated, series of design patterns $\mathbf{Z}_t$ similar to T, lithography simulation model ϕ_{sim}, optical kernels $\mathbf{h}$, weights of the terms in the loss function α, β, γ, learning rate lr, maximum training epoch $E_{\max}$.

Model training:

1: Initialize deep learning model architecture ϕ_{NN} and parameters $\boldsymbol{w}$;

2: Set $itr = 0$;

3: **repeat**

4: Mask prediction: $\mathbf{M}_{pred} \leftarrow \phi_{NN}(\mathbf{Z}_t; \boldsymbol{w})$;

5: Lithography simulation under different dose/focus conditions: $\mathbf{Z}_{norm}, \mathbf{Z}_{min}, \mathbf{Z}_{max} \leftarrow \phi_{sim}(\mathbf{M}_{pred}, \mathbf{h};\ \text{norm}, \min, \max)$;

6: Loss function calculation: $Loss_{L_2} \leftarrow \frac{1}{N_t}\sum_{i=1}^{N_t}\left[Z_{norm_i} - Z_{t_i}\right]^2$, $Loss_{PVB} \leftarrow \frac{1}{N_t}\sum_{i=1}^{N_t}\left[Z_{min_i} - Z_{max_i}\right]^2$, $Loss_{com} \leftarrow \frac{1}{N_t}\sum_{i=1}^{N_t}\left[\mathrm{sum}(Z_{norm_i})/(H \times W)\right]^2$, $Loss \leftarrow \alpha Loss_{L_2} + \beta Loss_{PVB} + \gamma Loss_{com}$

7: Gradient calculation: $\frac{\partial Loss}{\partial \boldsymbol{w}} \leftarrow \left(\frac{\partial Loss_{L_2}}{\partial \mathbf{M}} + \frac{\partial Loss_{PVB}}{\partial \mathbf{M}} + \frac{\partial Loss_{com}}{\partial \mathbf{M}}\right)\frac{\partial \mathbf{M}}{\partial \boldsymbol{w}}$;

8: Network parameters update: $\boldsymbol{w} \leftarrow \boldsymbol{w} + lr\frac{\partial Loss}{\partial \boldsymbol{w}}$;

9: Learning rate lr update based on cosine annealing;

10: $itr \leftarrow itr+1$;

11: **until** $itr \geq E_{max}$ or $\min(Loss_{itr-10:itr}) > \min(Loss_{0:itr})$

Model inference:

12: $M \leftarrow \phi_{NN}(T; \boldsymbol{w})$

13: mask binarization: $M = \begin{cases} 1, for\ \mathrm{M} \geq 0.5 \\ 0, for\ \mathrm{M} < 0.5 \end{cases}$

model training and evaluation is a single NVIDIA RTX 4070 GPU card, and a 13th Gen Intel(R) Core(TM) i9-13900K@3.00 GHz CPU. The training dataset is obtained from the GAN-OPC paper [6], including 4000 synthesized target layouts based on the existing 32nm M1 layout topologies. The lithography model used for model evaluation is obtained from ICCAD 2013 contest [11].

A. Baseline performance test

For each design layout image in the training set, a smallest rectangle enclosing the patterns is cropped from the original image and mapped to the center of a 2048×2048 image. This operation is to center the patterns and improve optimization efficacy. The image size is then downscaled to 256×256 via an average pooling operation to reduce the computational cost and GPU memory requirement without losing necessary details. The output image is then interpolated to the original 2048×2048 size for calculation of Squared L_2 error and PVB.

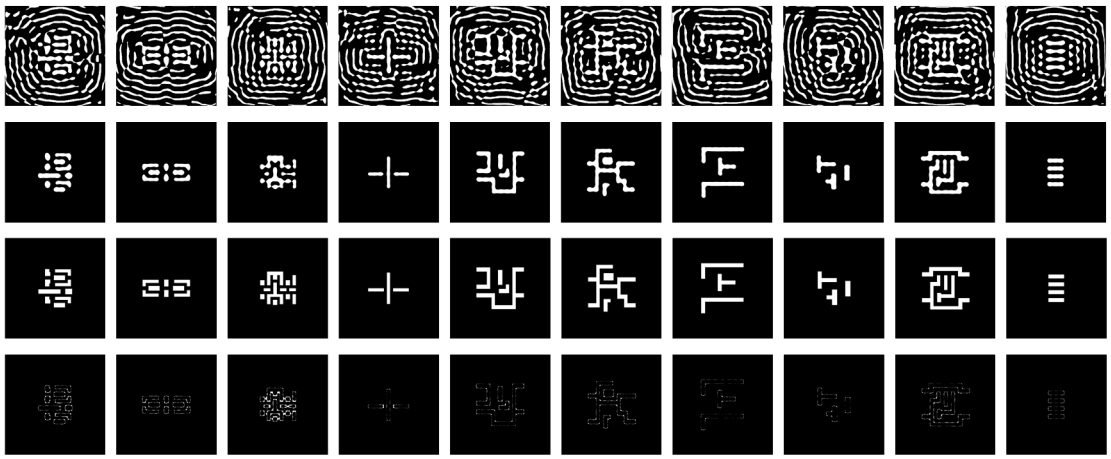

Fig. 3. The performance of our SSDL-ILT model on 10 test cases from ICCAD-2013 CAD contest. Rows from top to bottom indicate the predicted mask patterns, the corresponding simulated wafer images, the target layouts, and the absolute error between simulated wafer images and target layouts, respectively.

IV. EXPERIMENTAL RESULTS

The deep learning model is developed with PyTorch. The forward lithography model is adapted from the related module in OpenILT [16]. The entire workflow is deployed on CUDA to improve the solution efficiency. The hardware used for

α, β, γ in the loss function (6) is set to 1, 0.01, and 0, respectively. Adam is used as the optimizer and the learning rate is set to 0.0001. A cosine annealing learning rate decay scheduler is applied to improve loss convergence. The maximum training epoch is set to 50. The loss function converges after 32 epochs and the training takes about two

hours. 10 test cases provided by the ICCAD 2013 contest [11] are utilized to evaluate the model performance.

We show in Fig. 3 the predicted masks using our model, the simulated wafer images using the predicted masks, target layouts, and the absolute error between simulated wafer images and target layouts. The detailed performance results for each test case are shown in Table I, in comparison with conventional ILT [17] and other SOTA deep-learning-based ILT models. Table II shows the training time spent using our self-supervised training strategy and other supervised-learning-based models reported in the literature.

In general, deep learning based ILT models outperform conventional ILT by a large margin. Among deep learning ILT models, our model has the lowest L_2 error (on average 24915), achieving on average about 30% reduction compared to other SOTA models. The wafer images generated using our optimized masks show high fidelity to the target layouts, which indicates the effectiveness of our proposed self-supervised learning strategy. PVB reported by our model is also lower than all the other listed SOTA models (on average about 10% reduction) but A2-ILT (very close, though). Such PVB reduction results from the SRAF patterns generated by our model (Fig. 3). The most significant performance improvement using our model is the total TAT (on average 0.031s). Our model outputs the final optimized mask directly without further ILT optimization, achieving inference efficiency improvement of at least ~150 times compared to A2-ILT, and at most ~12,000 times compared to PGAN-OPC. Furthermore, as shown in Table II, the model training time is significantly reduced. Although the hardware used for training is not the same across different models, we expect a speedup of at least 5 times.

TABLE II. Model training time comparison

	SSDL-ILT	Re-optimization models		
		PGAN-OPC [6]	Neural-ILT 2.0 [7]	A2-ILT [9]
Training data size	4000	4000	4300	1000
Hardware	1 NVIDIA RTX 4070 GPU	1 NVIDIA Titan X GPU	1 NVIDIA Titan V GPU	1 NVIDIA RTX 3090 GPU
Training time (h)	2	10	19	25

B. Limited training data scenario

The baseline case in the previous section uses 4000 training samples to be roughly consistent with other SOTA models for comparison. Here we test the model's learning capacity in cases of limited training data, using 100, 500, and 2000 training samples, respectively, extracted randomly from the GAN-OPC training dataset. The results are shown in Table III. For comparison, we also train a supervised attention R2U-Net model, using the same network architecture and 4000 target layouts as training inputs, whereas the corresponding reference mask patterns are provided as well. As shown in Table III, our model's performance improves with the amount of the provided training data. The worst case scenario using only 100 training samples outperforms the supervised attention R2U-Net that uses 4000 training samples, and has comparable results to other SOTA models, indicating the strong generalization ability of our self-supervised learning strategy. The model trained using 500 samples achieves better performance compared to other SOTA models. 2000 samples are enough to provide decent results comparable to 4000 samples as shown in Table I. In summary, our self-supervised learning strategy guarantees fidelity and robustness in the case of limited training data.

TABLE III. Effect of training data size on the model performance

Test case #	SSDL-ILT						Supervised attention R2U-Net	
	100 training samples		500 training samples		2000 training samples		4000 training samples	
	L_2 (nm^2)	PVB (nm^2)	L_2 (nm^2)	PVB (nm^2)	L_2 (nm^2)	PVB (nm^2)	L_2 (nm^2)	PVB (nm^2)
1	54415	53640	40226	54386	37648	54272	70836	56619

9	47908	56574	38284	60842	33184	61978	66007	62066
10	15652	16985	8935	16957	9013	16647	19441	19454
Average	38852	43209	29668	45716	26178	45410	49854	46083

C. Mask complexity ajustment

The weight γ in (6) controls the complexity of the mask, especially the generation of SRAFs. The baseline case is trained without any constraint of SRAF generation (γ=0). Here we show two more cases trained using γ=0.005 and 0.06. The generated masks and corresponding wafer images are shown in Fig. 4. For γ=0.005, the third term in the loss function reduces the extent of SRAF generation, leaving only necessary patterns around the center design. The average L_2 error and PVB evaluated on the 10 cases are 25772 and 46167, respectively. For γ=0.06, SRAF generation is completely inhibited which improves the mask manufacturability. Similar L_2 error is reported (26636) but PVB is significantly larger (54477). Therefore, the major role of SRAF is the improvement of process window. In practical wafer production, the balance between PVB and mask manufacturability should be delicately determined.

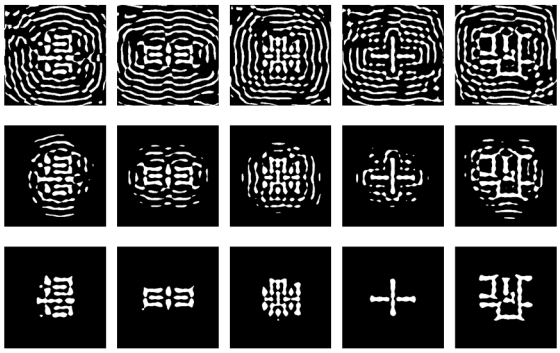

Fig. 4. Mask complexity adjustment demonstration. The rows from top to bottom are predicted masks using the trained model with γ=0, 0.005, and 0.06, respectively. For the sake of brevity, five test cases are shown.

D. Generalization ability test

We test the generalization ability of the model by applying the baseline model directly to 12 design patterns randomly extracted from the 2019 ISPD initial detailed routing contest, which are different in design and geometry from the training set. The results (5 out of 12 cases) are shown in Fig. 5. In general, good fidelity can be observed between simulated wafer images and design patterns (average L_2=61460). However, due to the existence of thicker and thinner pattern features than the training set, the wafer images obtained from the predicted masks show holes or missing/breaking thin lines in these regions. To further improve the model generalization ability, we adopt a few-shot transfer learning strategy using the pre-trained baseline model, by providing it with the remaining 7 design patterns from the 12 patterns as the training set. The network parameters are initialized to be consistent with the baseline model, and a smaller learning rate is applied. The model training is fast due to this small dataset, which completes in about two minutes after 300 epochs. The newly-trained model's performance is evaluated using the same five samples. As shown in Fig. 5, the holes in the previous wafer images are filled and feature resolution with small critical dimension is significantly improved compared to the original baseline model, which proves the strong adaptivity of our model (average L_2=40687). The few-shot transfer learning capability demonstrates potentially broad application scenarios of our model.

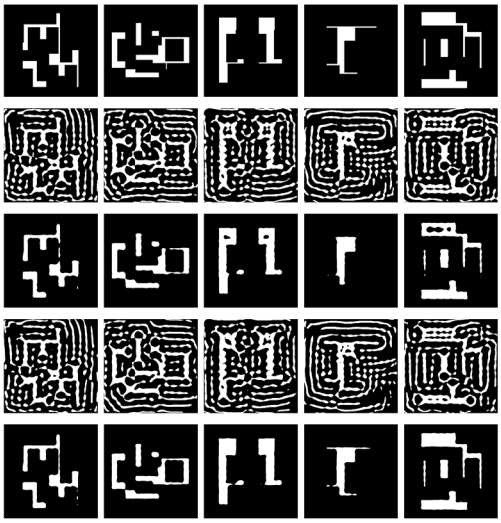

Fig. 5. Generalization ability test of the pre-trained model applied to design patterns extracted from ISPD 2019 initial detailed routing contest. The first row shows the five design patterns. The second and third rows are the predicted masks and simulated wafer images, respectively, obtained by the baseline model. The last two rows are results obtained by the few-shot transfer learning model.

V. CONCLUSION

In this paper, we propose a self-supervised deep learning model for direct mask prediction with high fidelity and efficiency. Critical lithography performance evaluation criteria is used to construct a novel physics-based loss function to guide the model training process. An attention-based R2U-Net architecture is applied to improve the model learning capability. Only hundreds of target layouts are required in the model training process instead of thousands of target/mask data pairs as in supervised learning based SOTA models to achieve comparable results, which effectively alleviates the data acquisition burden. SRAF patterns of varying complexity can be generated automatically during the inference process, which effectively improves PVB. Experimental results on ICCAD-2013 CAD contest dataset prove better fidelity and efficiency of our model compared to other SOTA deep-learning-based ILT models. A few-shot transfer learning strategy applied on the ISPD 2019 initial detailed routing contest dataset shows that the pre-trained model can be efficiently adapted to predict masks from different layout structures with high fidelity.

ChatLS: Multimodal Retrieval-Augmented Generation and Chain-of-Thought for Logic Synthesis Script Customization

Haisheng Zheng[1†], Haoyuan Wu[2], Zhuolun He[2,3†]
[1]Shanghai Artificial Intelligence Laboratory [2]The Chinese University of Hong Kong [3]ChatEDA Tech

***Abstract*—Large Language Models (LLMs) have demonstrated significant potential in automating the Electronic Design Automation (EDA) process through effective integration with EDA tools. This paper targets the customization of logic synthesis scripts, which is crucial for accommodating the unique characteristics of each design in the EDA workflow. The proposed framework, called ChatLS, integrates multimodal retrieval-augmented generation (RAG) and chain-of-thought (CoT) reasoning, enabling LLMs to collaboratively analyze design features and precisely customize synthesis scripts. Experimental results demonstrate that ChatLS has achieved superior performance in customizing synthesis scripts with a commercial logic synthesis tool.**

I. Introduction

Electronic design automation (EDA) encompasses a suite of software tools designed for the creation, analysis, and verification of electronic systems. These tools have evolved to support intricate design flows and cater to the complex requirements of advanced semiconductor manufacturing. To enhance the user experience and development efficiency, application engineers are deployed by vendors to offer tailored on-site support. However, the significant costs associated with training and manpower have led to considerations of automating support services, eliminating the need for human involvement.

Recent advancements in large language models (LLMs) have prompted the proposal of various techniques that utilize LLMs to enhance the usability of EDA tools. For instance, addressing the challenge of navigating extensive and intertwined functionalities in EDA tool documentation, several studies [1]–[3] have developed customized retrieval-augmented generation (RAG) frameworks, which improve the accuracy of LLM-generated responses, enabling the efficient retrieval of relevant information to resolve user queries. Additionally, the complexity of numerous EDA commands can overwhelm users. In response, studies [4], [5] have fine-tuned LLMs specifically for the EDA domain, facilitating the automated generation of tool call scripts based on user requirements.

While these developments represent significant advances in harnessing LLMs to assist users with EDA tools, there remains room for further enhancement. As for logic synthesis tools, a crucial aspect is the integration of user designs and target libraries with insights derived from logic synthesis tool reports. Commercial logic synthesis tools [6], [7] offer numerous optional commands aimed at improving design quality, which need to be selected based on user preferences and the analysis of the design [8], [9]. Additionally, the constraint settings included in synthesis scripts must be based on the characteristics of the design and the target library [10]. Moreover, logic synthesis is generally an iterative process, not a one-time execution. After the initial synthesis, users may employ resynthesis strategies to resolve violations within the netlist or to enhance netlist quality, with strategy choices informed not only by the design and target library but also by insights from logic synthesis tool reports [10]. Therefore, the customization of synthesis scripts, informed by a comprehensive understanding of the designs, target libraries, and the feedback from logic synthesis tool reports, is essential.

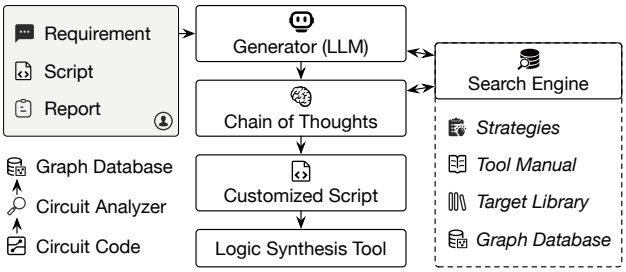

Fig. 1 An Illustration of ChatLS.

To achieve this goal, several challenges need to be addressed. The primary challenge involves a comprehensive analysis of design characteristics at both global and local levels to inform script creation. Global characteristics, such as the architecture and hierarchy of the design, guide the selection of appropriate compilation strategies [10], while local characteristics, including critical path analysis, inform constraint specifications in the scripts. Recent research [11]–[13] has demonstrated the capability of LLMs to understand register-transfer level (RTL) code snippets, suggesting potential applications in analyzing circuit design characteristics for customizing scripts. However, LLMs have significant limitations when processing long-context inputs, which affects their effectiveness in analyzing large codebases [14] and executing lengthy reasoning sequences [15].

Numerous logic synthesis algorithms [16]–[18] use graph-based representations of circuit designs to facilitate analysis and optimization. This graph-based representation allows for efficient exploration of design characteristics through a structured representation of the topology. Additionally, the graph-based representations of circuit designs have enabled numerous studies to leverage graph neural networks (GNNs) to extract meaningful characteristics from complex circuits [19]–[24]. Thus, leveraging graph-based analysis methods may help the LLMs overcome challenges in understanding complex circuit designs.

The second major challenge involves selecting synthesis commands within scripts that align with specific design characteristics. For instance, consider a scenario where a design requires timing optimization. Techniques such as retiming [25] and buffer balancing, both integrated into logic synthesis tools, can effectively reduce path delays. However, choosing the appropriate technique requires thorough consideration. Retiming is particularly effective for designs with extended critical paths that experience timing violations due to unbalanced register placement or excessively long combinational logic. Alternatively, buffer balancing is advantageous for mitigating timing issues in high-fanout nets. Therefore, a careful assessment of the strengths of each technique is essential for optimizing timing.

Techniques like retrieval-augmented generation (RAG) [26] and chain-of-thought (CoT) [27] reasoning have proven effective in assisting LLMs with complex decision-making tasks. In our context, RAG could help the LLMs retrieve relevant information and context

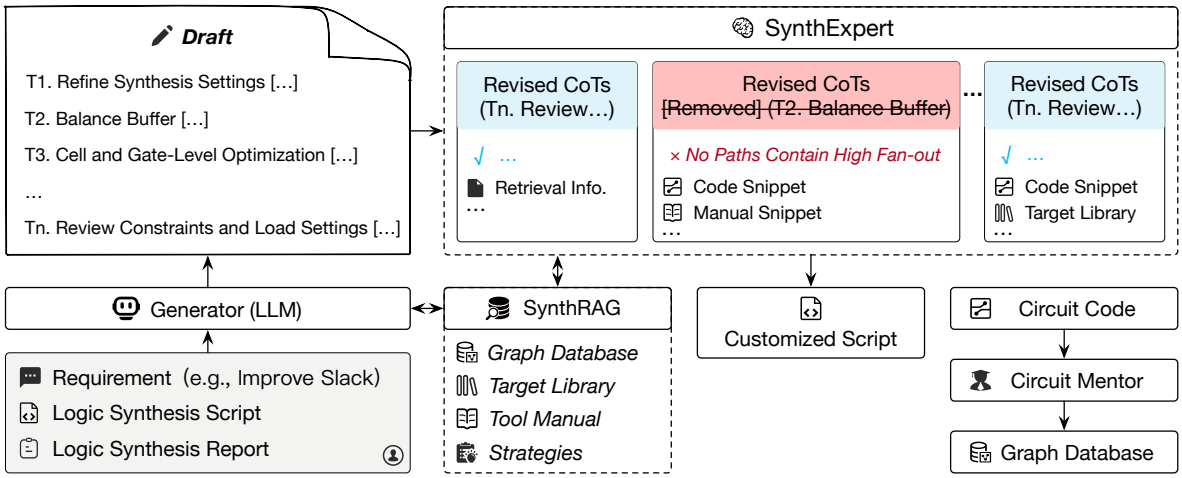

Fig. 2 The Overall Flow of ChatLS.

from circuit design snippets, target library, tool manuals, or past use cases, providing a well-informed foundation for decision-making. CoT then enables step-by-step reasoning to evaluate the trade-offs and select the most suitable solution from multiple options. It guides the LLMs through a logical progression of decisions, considering the impact of each command on design performance, ensuring that the final synthesis script is both optimal and aligned with user preferences.

In this paper, we present ChatLS, a framework for customizing logic synthesis scripts to meet specific requirements expressed in natural language. As illustrated in Fig. 1, ChatLS consists of four main components: a circuit analyzer for assisting LLM analyze and understand circuit designs, a search engine for retrieving relevant information, a CoT for decision-making during script refinement, and an LLM that interprets and generates synthesis scripts from natural language instructions.

Our major contributions are summarized as follows:

- We propose a graph-based method that enhances the ability of LLMs to analyze and understand circuit designs by transforming them into graph databases, with GNN supporting the analysis process.
- We introduce a domain-specific multimodal RAG framework that efficiently retrieves information to enhance LLMs for customizing logic synthesis scripts.
- We present a task-specific CoT mechanism, in tandem with the multimodal RAG framework, that enables iterative refinement of synthesis scripts by revising reasoning steps based on retrieved data.
- We conduct comprehensive experiments, demonstrating that ChatLS achieves superior performance in customizing logic synthesis scripts.

The remainder of this paper is structured as follows: Section II provides the preliminary background. Section III presents the problem formulation. The detailed description of the ChatLS framework is discussed in Section IV. The experimental results are presented and analyzed in Section V. Finally, conclusions are drawn in Section VI.

II. Preliminaries

Abstract Syntax Tree (AST) represents the hierarchical structure of source code, where each node corresponds to a specific construct or element in the program. It enables efficient analysis, transformation, and manipulation by abstracting the logical structure while omitting unnecessary syntactic details. ASTs are fundamental in compiler design, serving as an intermediate representation for syntax analysis, semantic validation, and optimization. They are also extensively used in static code analysis, automated reasoning, and code refactoring, effectively bridging raw code with its logical representation and enhancing software quality.

Retrieval-Augmented Generation (RAG) [26] targets the problem of enhancing natural language generation by combining the strengths of retrieval-based and generative approaches to improve both knowledge and contextual accuracy, making it effective for LLMs. RAG augments the generative process with a retriever module that dynamically retrieves relevant information $\{r_i\}_{i=1}^{k}$ from an external resource $\mathcal{R}$, such as a document corpus or knowledge base, based on an input query q. The retrieved information is then utilized by a generative model to produce a response y. In RAG, the objective is to maximize the conditional probability $P(y|q)$, which can be expressed as:

$$P(y|q) = \sum_{i=1}^{k} P(y|r_i, q)P(r_i|q), \tag{1}$$

where $P(r_i|q)$ represents the probability of retrieving a piece of information r_i given the query q, and $P(y|r_i, q)$ is the probability of generating the output y conditioned on both the query and a specific retrieved piece of information. By retrieving diverse and relevant information, RAG grounds the LLMs in external knowledge, thereby improving response quality and factual accuracy in complex tasks.

Chain of Thoughts (CoT) reasoning [27] enhances the performance of LLMs in tasks requiring complex reasoning, such as multi-step math word problems. Instead of generating the final answer directly, CoT prompts LLMs to generate intermediate steps, called thoughts, that serve as a scratch space guiding the model towards the solution. Given an input x, CoT introduces intermediate steps $s_1, s_2, \ldots, s_k$, forming a path from input to output:

$$x \rightarrow (s_1, s_2, \ldots, s_k) \rightarrow y, \tag{2}$$

this explicit reasoning framework helps LLMs break down complex tasks into manageable components, improving both accuracy and interpretability.

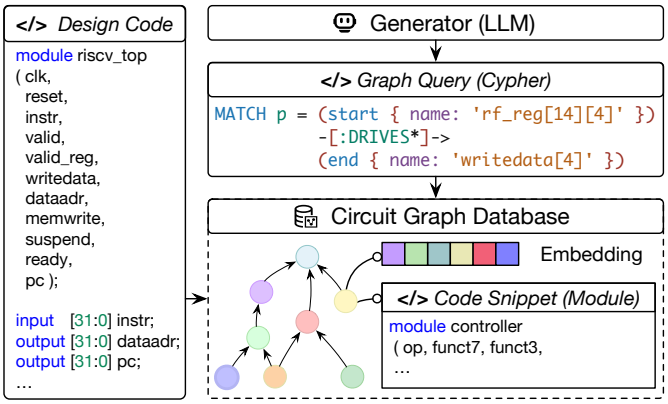

Fig. 3 Workflow Visualization of CircuitMentor.

III. The Scope of ChatLS

ChatLS is an innovative framework that provides a conversational interface, allowing users to employ natural language to customize synthesis scripts tailored to the specific requirements of each design. By interpreting both the design code and user requirements, ChatLS generates synthesis scripts that align with particular design attributes and user preferences.

Problem 1 (Objective of ChatLS)**.** *Design novel methodologies to enhance the capability of LLMs in customizing logic synthesis scripts to meet user preferences and address specific design characteristics.*

IV. Algorithms

Fig. 2 illustrates the overall workflow of ChatLS. The process begins with the user providing the requirements, circuit design code, corresponding logic synthesis scripts, and reports generated by the logic synthesis tool. Based on this input, the following steps are carried out to generate a customized logic synthesis script for the design:

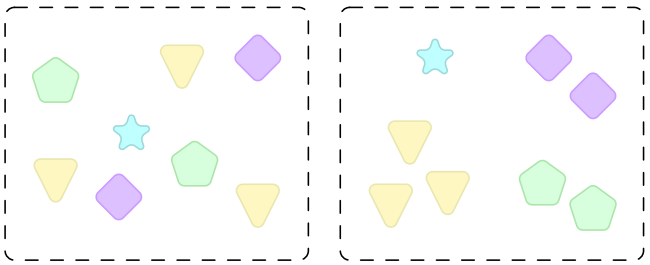
- **CircuitMentor** is a circuit design analysis tool that transforms the circuit design into a graph representation and employs GNN to extract high-level features from the circuit design.
- **SynthRAG** is a multi-modal RAG framework used to retrieve relevant information for LLMs when customizing logic synthesis scripts.
- **Generator (LLM)** drafts a customized logic synthesis script based on user requirements, incorporating the reports from the logic synthesis tool, the compilation and optimization strategies retrieved by **SynthRAG**, and high-level information matched by **SynthRAG** using embeddings extracted from the circuit design by **CircuitMentor**.
- **SynthExpert** is a CoTs mechanism that uses **SynthRAG** to fetch additional information and iteratively evaluates the suitability of the drafted logic synthesis script for the circuit design. During this process, **SynthRAG** is prompted to provide code for netlist paths, high-level information for corresponding modules, usage details for commands in the logic synthesis manual, and specifics of the target library. These elements ensure the generated logic synthesis script complies with design requirements and command specifications.

A. CircuitMentor: Graph-Based Assistant for Circuit Analysis

Circuit Representation. LLMs encounter significant challenges in comprehending complex circuit code, as discussed in Section I. Given that circuits can naturally be represented as graphs, we introduce CircuitMentor, which exploits this graph-based representation to enhance the capacity of LLMs to customize logic synthesis scripts.

As visualized in Fig. 3, the circuit code is transformed into a graph, specifically an AST. This graph structure is hierarchical, with nodes representing different levels of the circuit design. At the highest level, the graph contains nodes representing the overall design, with subnodes corresponding to individual modules. Each module node stores its associated Verilog code, enabling LLMs to analyze the structure and functionality of paths when customizing scripts. Within each module, subnodes represent the circuit components, such as gates and registers. This hierarchical organization allows for efficient traversal and multi-level analysis of the design. Customizing logic synthesis scripts often requires analyzing critical paths within the circuit. Therefore, our goal is to identify an appropriate graph database to store the circuit graph, enabling efficient path extraction and analysis. Neo4j [28] is well-suited for this purpose, as it supports Cypher [29], a query language that can be leveraged to extract paths and subgraphs from circuit graphs, facilitating efficient graph traversal and analysis.

Global Circuit Feature Extraction. Understanding the characteristics of a circuit is crucial for customizing logic synthesis scripts. Different circuit components, such as arithmetic and memory-based modules, require distinct compilation strategies. Arithmetic components focus on optimizing speed and area, while memory components prioritize access time and power efficiency. Tailoring the compilation strategy to the function of each component is essential for achieving overall circuit optimization. Nevertheless, effectively conveying these characteristics through LLMs presents significant challenges, as previously outlined in Section I.



Since the circuit can be represented as a graph, GNNs can be employed to extract meaningful features from its design. We propose a hierarchical GNN based on GraphSAGE [30] to learn embeddings for the circuit. By treating each module as a subgraph, our approach captures the unique characteristics of each module. This hierarchical approach is crucial for capturing both local and global structural patterns within the circuit design. GraphSAGE aggregates features from neighboring nodes and their respective subgraphs, facilitating the extraction of hierarchical features. The key operation of GraphSAGE is defined as:

$$\boldsymbol{h}_v^{(k)} = \sigma\left(\boldsymbol{W}^{(k)} \cdot \text{Aggregator}\left(\{\boldsymbol{h}_u^{(k-1)}, \forall u \in \mathcal{N}(v)\}\right)\right), \quad (3)$$

where $\boldsymbol{h}_v^{(k)}$ represents the embedding of node v at the k-th iteration, $\mathcal{N}(v)$ denotes the set of neighboring nodes of v, and Aggregator refers to the aggregation function. This aggregation step effectively encodes local circuit structural features into a compact and informative node representation.

The type of circuit design also plays a crucial role in customizing logic synthesis scripts. In cases where the design consists of a single module or has been flattened for synthesis, the graph representation collapses into a single node, rendering it ineffective for GNN-based operations. To address this, global pooling strategies are employed to obtain a global embedding. The global embedding is computed as the mean of all node embeddings in the design, given by $\boldsymbol{z}global = \frac{1}{N}\sum i = 1^N \boldsymbol{h}_i$. where N is the total number of modules in the circuit. This ensures that even when the design is flattened or consists of a single module, a meaningful global feature representation for the entire design can still be derived.

Metric Learning. Since our hierarchical GNN aims to extract

(a) (b)

Fig. 4 Illustration of the Metric Learning Process. (a) Initially, the embeddings are randomly scattered across the space. (b) After training, embeddings of similar data points converge, while embeddings of dissimilar data points diverge, forming distinct clusters.

embeddings from modules in the circuit graph, we need first address the challenge that topology-based approaches may fail to identify identical components due to structural variations. Given that GNNs are inherently topology-dependent, this poses a considerable challenge.

To address this, we adopt a metric learning approach, which focuses on learning a similarity function or distance metric that ensures similar designs are close in the embedding space, while dissimilar designs are placed farther apart. Various loss functions, such as contrastive loss [31] and multi-similarity loss [32], are commonly used to optimize the embedding space. These methods encourage the model to learn an embedding space where the geometry of the embeddings aligns with the desired similarity relationships between designs. Fig. 4 illustrates the evolution of embeddings during training. Initially, the embeddings are dispersed across the space, but after training, similar designs are pulled closer together, while dissimilar ones are pushed farther apart. This enhances the discriminative power of the embeddings, making them more effective for tasks such as design retrieval and similarity comparison.

By learning these discriminative embeddings, we capture the underlying structure of designs, enabling the efficient retrieval of relevant circuit designs based on their embeddings.

B. SynthRAG: Multimodal RAG for Domain-Specific Retrieval

The RAG framework substantially improves the generative capabilities of LLMs. Building on this advancement, we present SynthRAG, a domain-specific, multimodal RAG framework designed to enhance the ability of LLMs in customizing logic synthesis scripts. To support this goal, we first establish a database that stores the relevant information. TABLE I provides a summary of the different retrieval types, their corresponding representations, and the query methods employed in our approach.

Graph Embedding-Based Retrieval. In SynthRAG, graph embeddings serve as the foundation for information retrieval, linking related circuit designs with their respective compilation and optimization strategies. These embeddings are computed using CircuitMentor, which generates vector representations of circuit designs or modules. The resulting embeddings are used to query the graph database, retrieving relevant circuit designs with their respective compilation and optimization strategies.

Given a query embedding, $\boldsymbol{z}_{query}$, the retrieval process relies on nearest neighbor search over the database of graph embeddings. The nearest neighbor search is formalized as:

$$\boldsymbol{z}_{Retrieved} = \arg\min_{\boldsymbol{z}_{db}} \left(\text{sim}(\boldsymbol{z}_{query}, \boldsymbol{z}_{db})\right), \tag{4}$$

TABLE I Summary of Query Methods.

Category	Representation	Query Method	Retrieval Content
High Level Information of Circuit Design	Graph Embedding	Join	Compile Strategy Optimization Strategy
Code of Circuit Design	Graph Structure	Direct	The code of the module where the path is located
Target Library	Graph Structure	Direct	Gate Cell Information
Logic Synthesis Tool User Manual	LLM Embedding	Direct	Command Usage Command Requirement

where $\boldsymbol{z}_{db}$ represents the embeddings of designs in the database, and sim denotes the cosine similarity function. This ensures that the most semantically similar designs to the query are retrieved, facilitating efficient information retrieval for logic synthesis.

In RAG frameworks, reranking plays a crucial role in refining retrieved results to better fit the requirements of the target domain. Existing reranking methods [33], [34], commonly used in text-based retrieval, cannot be directly applied to our graph embeddings due to the unique characteristics of circuit designs. For instance, although both an arithmetic logic unit (ALU) and a systolic array are categorized as arithmetic components, they differ considerably in terms of scale and complexity. To address this, we introduce a domain-specific reranking function that incorporates additional criteria, such as timing, area, and power consumption, to reorder the retrieved graph embeddings.

Let $\boldsymbol{z}_{retrieved} = \{\boldsymbol{z}_1, \boldsymbol{z}_2, \ldots, \boldsymbol{z}_K\}$ represent the set of Top-K retrieved embeddings, and let $c_1, c_2, \ldots, c_K$ denote their corresponding performance metrics (e.g., timing, area, power). The reranking function, $f(\boldsymbol{z}_{retrieved}, \boldsymbol{c})$, computes a new ranking score for each design by considering both the similarity of embeddings and the additional characteristics. The reranking is computed as:

$$\text{Score}(\boldsymbol{z}_i) = \alpha \cdot \text{sim}(\boldsymbol{z}_{query}, \boldsymbol{z}_i) + \beta \cdot c_i, \tag{5}$$

where $\text{sim}(\boldsymbol{z}_{query}, \boldsymbol{z}_i)$ is the cosine similarity between the query embedding $\boldsymbol{z}_{query}$ and the retrieved embedding $\boldsymbol{z}_i$, c_i is the domain-specific characteristic for design i, and α and β are weighting parameters that balance the contribution of similarity and characteristics in the final ranking.

The reranking process selects the designs with the highest scores, prioritizing those that meet the functional requirements and resource constraints of the query. This ensures that the retrieved designs are not only semantically similar to the query but are also optimized according to specific design criteria.

Graph Structure-Based Retrieval. In SynthRAG, the graph-based retrieval system utilizes Cypher queries, which can be generated by LLMs, to extract specific design details and information about the target library from the database. Each query retrieves a single result, thereby eliminating the need for reranking. The target library is integrated into the database to avoid inefficiencies associated with directly inputting it into the LLMs for processing.

LLM Embedding-Based Retrieval. Several studies, such as [1], have adapted RAG frameworks to retrieve information from EDA user manuals, which contain hybrid information. In our context, we focus exclusively on retrieving descriptions of logic synthesis commands within the user manual. Accordingly, SynthRAG utilizes the `text-embedding-3-large` model[1] to transform the user manual into text embeddings. Subsequently, to enhance the accuracy

C. SynthExpert: Iterative Customization with CoT and RAG

Although RAG and CoT techniques can significantly enhance LLMs by facilitating complex decision-making tasks, their integration into ChatLS demands careful consideration.

Despite **RAG** is effective in general applications, it faces limitations in handling complex reasoning tasks requiring multi-step reasoning. These tasks are difficult to encapsulate into simple search queries, often leading to challenges in retrieving relevant information, thus limiting the applicability of RAG. Specifically, RAG approaches typically retrieve all pertinent information in a single step, disregarding the dynamic and iterative nature of information requirements throughout the synthesis script customization process. In our context, logic synthesis script customization involves multi-dimensional data, including design characteristics, user manuals, and the target library. Retrieving all relevant information at once may overwhelm the LLMs, complicating the prioritization and application of the most pertinent data at each reasoning step. Consequently, relying solely on the initial task prompt often lacks the depth needed to effectively guide subsequent reasoning and generation, leading to suboptimal retrieval performance.

Similarly, **CoT** facilitates LLMs in breaking down complex tasks into manageable steps, which is crucial for generating accurate and optimized synthesis scripts. However, without explicit guidance, LLMs may introduce errors due to incomplete domain knowledge [42] or be influenced by hallucinations [43]. In our scenario, these inaccuracies may render customized logic synthesis scripts non-executable, as LLMs could generate nonexistent or incompatible commands for the circuit design. To address these challenges, we propose SynthExpert, which synergistically integrates CoT with RAG for logic synthesis customization. As shown in Fig. 2, SynthExpert mines each reasoning step to generate the final synthesis script.

Given a task prompt I, the LLM initially generates a series of thought steps, represented as $T := \{T_i\}_{i=1}^{n}$, where T_i is the i-th thought step. In SynthExpert, these steps correspond to intermediate reasoning stages, where the synthesis script is drafted based on user inputs. Recognizing potential inaccuracies in these steps, SynthExpert utilizes RAG to revise each step sequentially.

For each thought step T_i, the LLM formulates a query Q_i by incorporating the task prompt I to retrieve information R_i pertinent to this step, thereby refining T_i in the subsequent reasoning phase. Once Q_i is formulated, the retrieval mechanism fetches the relevant information $R_i = \text{Retrieve}(Q_i)$. The retrieved information R_i is then used to revise the current thought step, producing a revised thought step$T_i^\star$:

$$T_{1:i}^\star = p_\theta(\cdot|I, T_{1:i-1}^\star, T_i, R_i) \tag{6}$$

where $p_\theta(\cdot)$ represents the probability function of the LLM generating the revised thought $T_i^\star$ based on the integrated inputs and retrieved data.

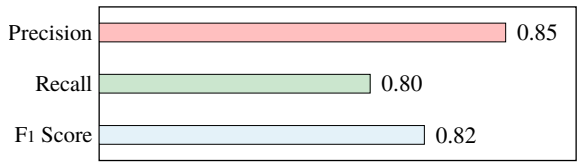

Fig. 5 Performance of SynthRAG.

This approach effectively mitigates the limitations of RAG and CoT by ensuring that each reasoning step is reinforced with the most pertinent and contextually relevant information. By revising each thought step individually, SynthExpert ensures that the LLM receives the appropriate context at every stage of the synthesis script customization process. This sequential retrieval and revision mechanism enhances the relevance and accuracy of the information used, providing richer contextual cues that align with the specialized demands of logic synthesis. Furthermore, focusing on revising individual thought steps minimizes the risk of introducing new errors into previously accurate reasoning steps, thereby preserving the integrity and reliability of the reasoning process.

As illustrated in TABLE III, integrating SynthExpert within ChatLS ensures that each aspect of synthesis script customization is informed by accurate and relevant data, thereby substantially improving the quality and reliability of the customized scripts.

V. Experimental Evaluation

ChatLS is implemented using PyTorch [49], PyTorch Geometric [50], FAISS [51], Neo4j [28], with GPT-4o (Version 2024-08-06) [35] employed as the generator. To construct the database for SynthRAG, numerous open-source designs were synthesized using the `Nangate 45nm`[2] library as the target technology, alongside the `5K_heavy_1k` wireload model, employing various optimization and compilation strategies. The corresponding logic synthesis scripts were then converted to the Design Compiler format, where they are treated as expert drafts. TABLE II presents a selection of hardware designs included in the database. Comprehensive experiments are conducted to evaluate the efficiency of ChatLS in customizing logic synthesis scripts.

A. Evaluation of SynthRAG

To evaluate SynthRAG, experiments were conducted using Chipyard [37] to generate SoCs with various configurations. These configurations provided a diverse set of circuit designs, enabling the assessment of the model's ability to retrieve relevant logic synthesis scripts and optimization strategies. The primary goal was to retrieve designs and components with high similarity to the query while considering resource usage to ensure effective customization of synthesis strategies. The F_1 score was selected for evaluation, as it balances precision and recall, making it well-suited for this task, where both false positives (irrelevant designs) and false negatives (missed relevant designs) can significantly impact performance:

$$F_1 = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}, \tag{7}$$

where Precision is $\frac{TP}{TP+FP}$ and Recall is $\frac{TP}{TP+FN}$. Here, true positive (TP) refers to correct predictions, false positive (FP) to incorrect predictions, and false negative (FN) to missed predictions. The results, summarized in Fig. 5, show that SynthRAG successfully retrieved relevant designs and modules, enabling effective customization of logic synthesis scripts.

B. Evaluation of ChatLS

Benchmark and Baseline. The evaluation uses design benchmarks from OpenROAD [47], as summarized in TABLE IV. The Design Compiler is employed as the logic synthesis tool. The original OpenROAD synthesis scripts are adapted to ensure compatibility with Design Compiler [6], and these adapted scripts serve as the baseline for evaluating ChatLS. This baseline provides a reference for assessing improvements or deviations in synthesis performance compared to the proposed methods.

Model Comparison. The performance of ChatLS is compared with two state-of-the-art LLMs: GPT-4o (Version 2024-08-06) [35] and Claude 3.5-Sonet (Version 2024-10-22) [44]. For this evaluation, ChatLS, GPT-4o, and Claude 3.5 each customize the logic synthesis script based on a baseline script, with only a single iteration of customization performed. To ensure a fair and consistent evaluation, all language model baselines are tested using identical prompt engineering techniques, and basic configurations, including the time period, are not allowed to change. The quality of each customized logic synthesis script was evaluated after this iteration. In cases where the design code exceeds the token limits of the models, it is partitioned into segments, each containing no more than 128,000 tokens.

The `Nangate 45nm` library is used as the target technology, along with the `5K_heavy_1k` wireload model. Timing optimization is a key focus, as it ensures sufficient slack that can be traded for improvements in area and power without compromising timing closure. Accordingly, the evaluation emphasizes ChatLS ability to customize logic synthesis scripts for optimal timing.

Evaluation Metrics. The evaluation employs the following key metrics to assess the synthesis script quality:

- **Timing**: Measures the ability of the design to meet operational speed requirements, including worst negative slack (WNS), critical path slack (CPS), and total negative slack (TNS).
- **Area**: Assesses the total hardware resources utilized by the synthesized circuit.

These metrics offer a thorough evaluation of the quality of logic synthesis scripts.

Evaluation Results The evaluation results for ChatLS are summarized in TABLE III. All models, including GPT-4o, Claude 3.5-Sonet, and ChatLS, improve design timing relative to the baseline. ChatLS consistently delivers the best timing performance, showing the most substantial improvements across all evaluated designs. This underscores the superior capability of ChatLS in customizing logic synthesis scripts for timing optimization. Both `ethmac` and `tinyRocket` exhibit timing violations, as only a single iteration was executed. However, logic synthesis is inherently an iterative process, not a one-time execution. Additional iterations are required to further resolve timing issues. While GPT-4o achieves the best area results in some cases, the primary objective of this evaluation is timing improvement, a goal that is not fully satisfied by GPT-4o. In contrast, ChatLS produces the highest-quality synthesis scripts, outperforming the baseline LLMs and demonstrating its effectiveness in customization.

VI. Conclusion

It is crucial to customize synthesis scripts, guided by a thorough understanding of design, target libraries, and feedback from logic synthesis tool reports. To address this need, we propose methods to enhance the ability of LLMs to customize synthesis scripts. To improve the ability of LLMs to understand circuit designs, we introduce CircuitMentor, which efficiently extracts the global characteristics of designs while assisting LLMs in understanding their local characteristics. Additionally, to enhance the ability of LLMs to customize high-quality logic synthesis scripts, we present SynthRAG, which supplies relevant information for script customization. Futhermore, to aid LLMs in selecting the appropriate commands within logic synthesis tools based on design and user specifications, we introduce SynthExpert, which works in tandem with SynthRAG. Experimental results demonstrate that the proposed framework, ChatLS, effectively and efficiently customizes synthesis scripts, aligning with user preferences and optimizing design performance. Future work could explore extending this framework to collaborate with a wider array of logic synthesis tools, such as PrimePower [52], to further advance the automation of the logic synthesis workflow.

Acknowledgment

***Abstract*—The rapid growth of model sizes in advanced artificial intelligence algorithms, particularly in Transformer-based large language models (LLMs), has led to significant computational overhead. Mixture-of-Expert (MoE) models offer a solution through their sparsely gating mechanism but introduce new challenges of extensive all-to-all communication and model computational inefficiencies. This paper presents Hydra, a software/hardware co-design aimed at accelerating MoE inference on chiplet-based architectures. In software, Hydra employs a popularity-aware expert mapping strategy to optimize inter-chiplet communication. In hardware, it incorporates Content Addressable Memory (CAM) to eliminate expensive explicit token (un)-permutation based on sparse matrix multiplications and a redundant-calculation-skipping softmax engine to bypass unnecessary division and exponential operations. Evaluated in 22 nm technology, Hydra achieves latency reductions of 14.2× and 3.5× and power reductions of 169.1× and 18.9× over GPU and state-of-the-art MoE accelerator, respectively, thereby offering a scalable and efficient solution for MoE model deployment.**

***Index Terms*—Mixture-of-expert model, chiplet, large language model**

I. Introduction

Transformer-based large language models (LLMs) have demonstrated exceptional performance in natural language processing tasks [1]–[3]. However, their advancements are primarily driven by the growing model sizes, which hinder efficient deployment on resource-constrained devices. Recently, Mixture-of-Expert (MoE) models have emerged as an effective solution to mitigate the computational overheads of LLMs [4]–[6]. As illustrated in Fig. 1, in an MoE model, the standard feed-forward network (FFN) layer in Transformers is replaced by an MoE FFN layer comprising multiple sparsely activated experts controlled by a gating network. This sparse gating mechanism enables further model expansion with only a slight increase in computational cost.

Despite their advantages, accommodating the entire MoE model on a single chip remains impractical due to limited on-chip memory. To overcome the cost and area limitations of monolithic chips, multi-chiplet modules (MCM) have emerged as a promising approach for building energy-efficient accelerators [7], [8]. By connecting multiple smaller chiplets through a silicon interposer or organic substrate, MCMs significantly expand system capacity [9], [10]. Additionally, their flexible interconnect supports various parallelism strategies commonly used in popular inference frameworks [11], especially model parallelism [6] and expert parallelism [12], to improve MoE inference efficiency [13]–[16].

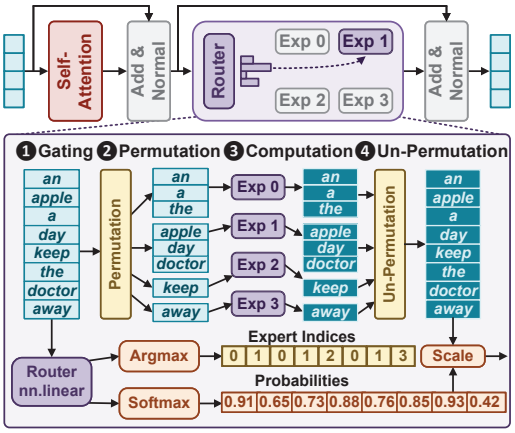

Fig. 1. Illustration of Mixture-of-Expert (MoE) mechanism in Transformer-based models.

However, deploying MoE models on chiplet-based architectures faces several challenges. First, as expert parallelism places different experts on different chiplets and executes them in parallel, extensive token dispatch and gathering operations across chiplets become necessary, resulting in extensive all-to-all communication. Previous studies have shown that this communication pattern can lead to network contention and congestion, limiting bandwidth utilization and ultimately becoming a bottleneck during inference [17]–[19]. Second, key operations in MoE layers remain computationally inefficient, including *permutation*, *un-permutation*, and *gating*. The (un)-permutation stage relies heavily on sparse matrix multiplications for token reordering, resulting in computational complexity of $O(S^2M)$, where S denotes the token length and M is the model hidden dimension. Moreover, the softmax function in the gating stage requires time-intensive exponential and division computations, incurring significant latency.

Prior approaches, including Pre-gated MoE [20] and FLAME [21], have focused on reducing the memory footprint of MoE models with an optimized expert prefetching strategy. However, these methods do not effectively address the all-to-all communication overhead or the intrinsic computational inefficiencies in MoE layers. To address these challenges, we propose Hydra, a hardware-software co-design. To our

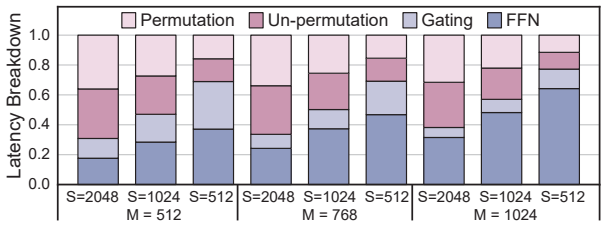

Fig. 3. Runtime analysis of four stages in an MoE layer (communication is excluded) for varying token lengths (S) and model hidden dimensions (M).

knowledge, Hydra is the first chiplet-based system specially designed for MoE deployment. The contributions of this work are as follows:

- We implement a popularity-aware dynamic expert mapping strategy derived from an analysis of conditional probabilities for expert selection across layers, significantly cutting all-to-all communication latency.
- We utilize CAM for parallel searching to establish a mapping between tokens and experts, eliminating the overhead of explicit (un)-permutation operations.
- We design a softmax engine with hybrid token/expert-wise calculation skipping, effectively removing redundant division and exponent operations in the gating stage.
- We develop the Hydra accelerator with 4×4 chiplets in 22 nm CMOS technology, achieving a 14.2× latency reduction and 169.1× power savings over the NVIDIA RTX 3090 GPU, positioning Hydra as a highly efficient solution for MoE-based LLM deployment.

II. Background and Motivation

A. MoE Execution in Chiplet-based System

As shown in Fig. 1, an MoE layer consists of four key steps: ❶ ***Gating***, where a gating network allocates input tokens to experts. Here, a linear layer first determines experts-token relevance, followed by softmax computation for probability assignment. An argmax unit then selects the target expert for each token and assigns the corresponding probability as the gate value to weight the output. Softmax computation, due to its division and exponential operations, dominates the computational cost of this stage. ❷ ***Permutation***, which groups tokens by their assigned experts, leveraging the *einsum* operator for sparse matrix multiplication $(S \times S) \times (S \times M)$, with a computational complexity of $O(S^2M)$. ❸ ***Computation***, where each expert processes their allocated tokens. ❹ ***Un-permutation***, which restores tokens to their original order, acting as the reverse of permutation stage. Together, these steps define MoE layer execution on a single device.

For multi-chiplet systems, MoE model deployment involves various parallelism strategies to improve throughput and reduce memory footprint, necessitating inter-chiplet communication. For attention layers, ***model parallelism*** partitions weight tensors across different chiplets, with all-reduce operations performed within model-parallel groups to aggregate results. For MoE layers, ***expert parallelism*** places different experts on distinct chiplets, reducing memory requirements per chiplet while enabling parallel execution. However, as each chiplet holds only a subset of experts, tokens assigned to experts on other chiplets must be dispatched to the appropriate chiplet and gathered back after step ❸ , resulting in two rounds of all-to-all communication. Fig. 2 illustrates this process, showing tokens of the same color aggregated onto their designated chiplets and subsequently retrieved.

B. Challenges and Motivations

1) All-to-all Communication: This communication pattern has been identified as a major bottleneck, contributing up to 74.9% of the total runtime of an MoE layer [17]. Although previous studies have introduced device-limited or topology-aware routing mechanisms along with token-dropping techniques to reduce communication costs and limit expert capacity, they risk degrading model performance and introducing additional training overhead [4], [22], [23].

As prior works suggest, the routing decisions in MoE models tend to be highly skewed due to the specialized knowledge domain of each expert [17], [19]. Usually, only a small subset of experts, such as E_0 and E_1 in Fig. 2, are heavily utilized. While these skewed routing decisions overload certain chiplets with the majority of tokens and lead to imbalanced data traffic that intensifies the all-to-all bottleneck, they also introduce correlation in expert choices across consecutive MoE layers, according to [18], [20]. However, this insight has not been fully explored for all-to-all communication optimization. ***By leveraging this intrinsic inter-layer correlation as a predictive basis for expert popularity on each chiplet***, we propose a dynamic expert mapping strategy to improve bandwidth utilization, as detailed in Section III.

2) Inefficient Computation: To identify computational bottlenecks in MoE inference, we analyze the runtime breakdown of the four key stages across different token lengths and model hidden dimensions. As shown in Fig. 3, excluding inter-chiplet communication, the (un)-permutation and gating stages together account for 62.7% of the runtime of an MoE layer on average, highlighting opportunities for further optimization. Although prior work has suggested using data replication for equivalent layout transformation [11], the complexity remains $O(S^2M/E)$, where E is the number of experts. Meanwhile, while optimizations for operators like argmax have been proposed [24], softmax remains unoptimized.

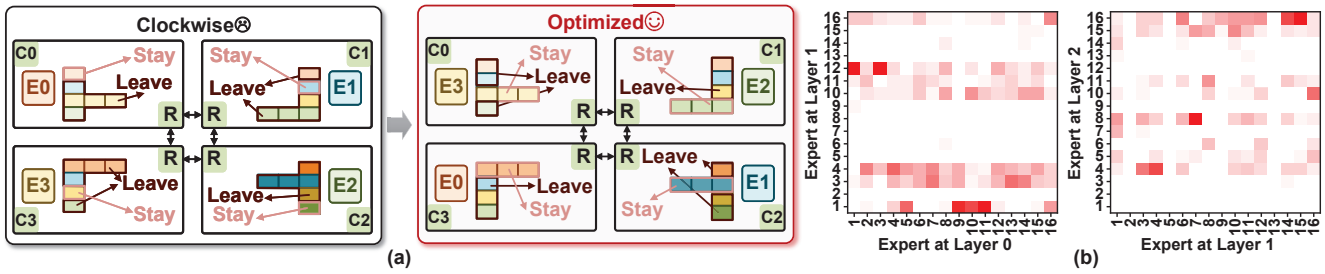

Fig. 4. (a) A 2×2-chiplet MCM example from a straightforward clockwise mapping scheme without considering expert popularity to an optimized mapping scheme that accounts for expert popularity across chiplets. (b) Heatmap of conditional probabilities for the Switch-base-16 model in the first two MoE layers.

To alleviate the computational burden, this paper introduces two key insights. First, ***a token-to-expert mapping established by parallel search*** can eliminate the need for sparse matrix multiplication. Second, the ***parallelism strategy combined with MoE's sparse gating mechanism introduces redundant computations*** in softmax operation. Based on these insights, we develop a CAM-based permutation engine for efficient parallel search and a softmax engine with hybrid token- and expert-wise calculation skipping to minimize inference latency. Further details are discussed in Section IV.

III. Software Optimization

To mitigate the all-to-all communication bottleneck in MoE inference, this section presents a predicted-popularity-aware expert mapping strategy, which is aimed at optimizing bandwidth usage and minimizing communication latency.

A. Expert Popularity Prediction

As illustrated in Fig. 4(a), for a 2×2 chiplet group with experts 0-3 arranged clockwise, each chiplet needs to send five tokens. However, with an optimized expert mapping scheme, each chiplet only sends three tokens, as more tokens remain on the original chiplet where their target experts reside. Thus, by considering the popularity of experts on each chiplet, an optimal mapping can be derived to either reduce inter-chiplet data transfers or minimize transmission hops, significantly lowering communication costs.

However, as routing decisions in MoE layers are dynamically determined at runtime, adjusting expert mapping based on the real-time gating results hinders time-overlapped weight loading, ultimately extending overall execution time. Therefore, predicting expert popularity in advance is essential for early expert mapping and prefetching. To this end, we track the routing decisions of 200,000 input tokens from the C4 dataset [25] as they traverse consecutive MoE layers and analyze the conditional probabilities of expert selection across various MoE models. Fig. 4(b) shows a heatmap of conditional probabilities for the Switch-base-16 model, revealing that expert selection across consecutive MoE layers is correlated. Therefore, expert popularity $\tilde{P}_c(E_{n,i})$ can be predicted as:

$$\tilde{P}_c(E_{n,i}) = \sum_{j=0}^{E-1} P_c(E_{n-1,j}) \times P(E_{n,i}|E_{n-1,j}) \qquad (1)$$

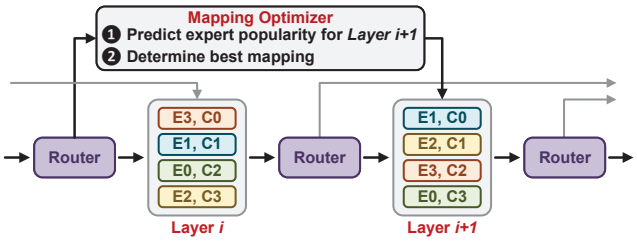

Fig. 5. Illustration of popularity-aware expert mapping.

In this equation, $P_c(E_{n-1,j})$ represents the real-time frequency of tokens assigned to expert j in layer $n-1$ for chiplet c, while $P(E_{n,i}|E_{n-1,j})$ represents the prior conditional probability of selecting expert i in layer n when expert j was selected in the previous layer $n-1$. This conditional probability-based prediction method enables the optimization of expert mapping.

B. Expert Mapping Algorithm

Building upon the expert popularity predictions presented in Section III-A, we develop an optimized expert mapping strategy, as shown in Fig. 5. Based on the prior conditional probability and the real-time routing decision in layer i, the expert mapping for layer $i+1$ can be determined. We first introduce a communication cost model tailored for multi-chiplet architectures, converting the problem into the following optimization task:

Given the expert popularity prediction $\tilde{P}_c(E_{n,i})$, the objective is to determine an optimal mapping between experts $\{E_{n,0}, E_{n,1}, ..., E_{n,E-1}\}$ and chiplets $\{C_0, C_1, ..., C_{C-1}\}$, where $n \in \{0, 1, ..., L-1\}$, $i \in \{0, 1, ..., E-1\}$ and $c \in \{0, 1, ..., C-1\}$. The mapping should minimize the following cost function:

$$\sum_{n=0}^{L-1} \sum_{c=0}^{C-1} \sum_{i=0}^{E-1} h(i,c) \times \tilde{P}_c(E_{n,i}) \qquad (2)$$

Here, L and C represent the number of MoE layers and chiplets, respectively, while $h(i,c)$ quantifies the communication cost between the chiplet hosting expert i and chiplet c. This cost is approximated as the sum of the minimum horizontal and vertical hops in the interconnect topology.

To solve the above combinatorial optimization problem, we employ a simulated annealing algorithm, as detailed in Algorithm 1. The algorithm is deployed on the mapping solver in Hydra chiplet. During inference for layer n, the external memory interface retrieves the experts for layer $n+1$

based on the pre-computed mapping scheme from the solver. This approach mitigates all-to-all communication overhead and overlaps computation with memory access, effectively reducing latency and improving overall system throughput.

Algorithm 1 Expert Mapping using Simulated Annealing

```

        bestCost ← newCost
    end if
    Temp ← Temp × CoolingRate
end while
return bestMapping, bestCost
```

IV. Hardware Design

In this section, we present the detailed hardware implementation of Hydra, designed to enhance computational efficiency for MoE inference.

A. Overall Architecture

Fig. 6(a) illustrates the architecture of the Hydra multi-chiplet system, composed of a 2×2 Hydra chiplet array coupled with high-bandwidth memory. Similar to Simba [8], these Hydra chiplets are organized in a 2D grid and connected via ground reference signals (GRS), supporting 100 Gb/s bandwidth in each direction. This scalable configuration allows for expansion to larger chiplet arrays, enabling the deployment of MoE models with varying sizes and diverse computational demands. Fig. 6(b) details the design of a single Hydra chiplet, which comprises 16 processing element (PE) arrays, a global SRAM buffer, an auxiliary unit, a top controller, a mapping solver, a softmax engine, a CAM-based permutation engine, and die-to-die interconnects.

B. CAM-based Token Permutation Engine

The (un)-permutation stage employs sparse matrix multiplication to rearrange data. While crucial for all-to-all communication and FFN computation, (un)-permutation incurs significant computational overhead. Therefore, we introduce a CAM-based solution to establish a mapping between the token and expert to achieve equivalent data layout transformation with reduced complexity.

We adopt a conventional 9T NAND-type CAM design [26], which is implemented by incorporating additional NAND logic outside the basic 6T SRAM cell to facilitate the search operation. When all bits in a row of the CAM array match the search key, the match result remains at a high level. As this

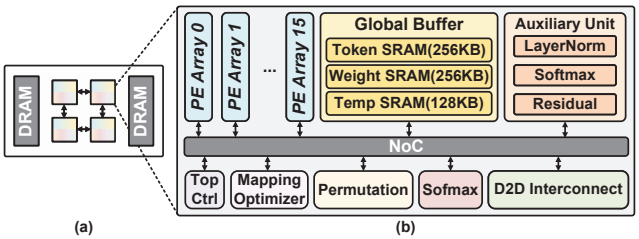

Fig. 6. (a) Overall architecture of Hydra MCM and (b) Hydra chiplet design.

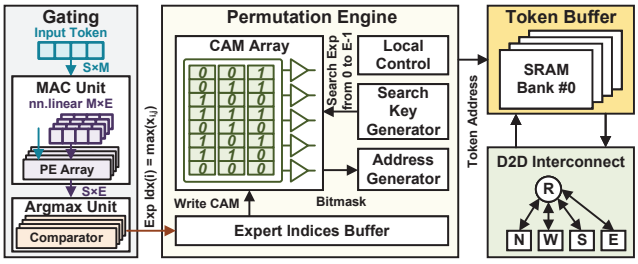

Fig. 7. CAM-based token permutation engine.

matching process is applied across all rows of the memory array, CAM enables rapid parallel searching.

The proposed CAM-based permutation engine is depicted in Fig. 7. Initially, the input tokens pass through a small linear layer. The output projection matrix is then passed to the *argmax* unit to identify the target expert, with corresponding expert indices stored in the CAM. The search key in the CAM is then sequentially set from 0 to $E-1$, with the match results forming a bitmask to indicate the positions of the relevant input tokens in memory. The address generator uses this bitmask to produce address indices for token retrieval, after which the tokens are fetched from the token buffer for participation in all-to-all communication. Following the completion of the FFN computation, the tokens are returned to the original chiplet through the interconnection network and stored back into the token buffer according to the bitmask.

The complexity of the parallel search operation in the CAM-based token permutation scheme is only $O(E)$. Given that CAM is far more energy-efficient in parallel search compared to conventional digital circuits, the overhead of this search is negligible relative to the extensive MAC operations in MoE inference. Thus, the token-to-expert mapping table is established at a minimal cost. Based on this mapping table, Hydra can complete the data layout transformation with just S data moves, achieving token permutation (or un-permutation) while eliminating the sparse matrix multiplication operations and minimizing intermediate results storage. This significantly reduces MoE inference latency and improves energy efficiency.

C. Redundant-Calculation-Skipping Softmax Engine

Fig. 8 illustrates the proposed softmax engine with hybrid token- and expert-wise calculation skipping. During probability calculation, exponential values for each element in the $S\times E$ output projection matrix of the linear layer are first computed and summed row-wise. The probability $S(x_{i,j})$ is subsequently derived through a division operation, which is implemented as a subtraction in the logarithmic domain.

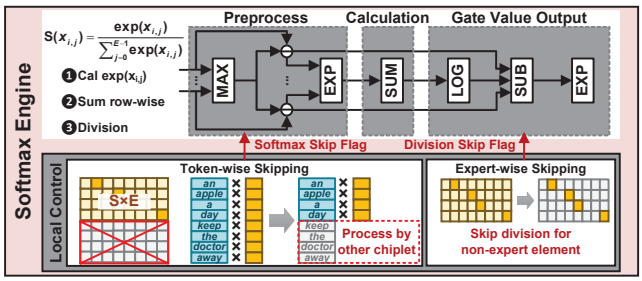

Fig. 8. Softmax engine with hybrid token-wise and expert-wise skipping.

The proposed token-wise skipping strategy targets redundant operations introduced by attention layers. Under model-parallelism, all-reduce communication occurs between chiplets that hold different weight tensor slices. As a result, input tokens across chiplets in the same model-parallel group are identical when entering the MoE layer. Thus, the local control unit instructs each chiplet to compute probabilities for only $1/M_P$ of tokens, with the remaining softmax operations assigned to other chiplet in the same group. Here, M_P is the degree of model parallelism. Expert-wise skipping strategy, on the other hand, aims at eliminating unnecessary division operations caused by the sparse gating mechanism. Once the *argmax* unit identifies the target expert, the local control unit skips the division operations for non-target experts, significantly reducing computational overhead.

The aforementioned token-wise skipping strategy is statically defined by the parallel configuration established during model deployment, while the expert-wise skipping strategy is dynamically determined by the routing decisions. As the proposed softmax skipping approach neither depends on data sparsity nor relies on approximate calculations, it offers an efficient, lossless computational optimization that eliminates redundancies arising from the inherent characteristics of the MoE algorithm and the parallelism framework.

V. Evaluation

A. Experimental Settings

Models and datasets. We evaluated the performance of Hydra using the Switch Transformer model [4], a state-of-the-art large-scale MoE model based on the encoder-decoder architecture. Specifically, we focused on switch-base-8 and switch-base-16 (with 8 and 16 experts per layer), as they are representative and highlight Hydra's scalability. The FP16 data type was employed. To verify that Hydra does not introduce any accuracy loss, we compared the negative log perplexity on a masked language modeling task against a GPU baseline using the C4 dataset.

Implementation. We evaluated a Hydra accelerator with a 4×4-chiplet configuration, using the Intel Xeon Gold 6242 and NVIDIA Geforce RTX 3090 as CPU and GPU benchmarks, respectively. The CAM array was implemented with custom circuits and simulated in Cadence Virtuoso. Power and area for inter-chip interconnects were scaled from previous 2.5D accelerator designs [8], consuming 2.4 pJ/bit. The rest of the digital modules were synthesized using Synopsys Design Compiler at 500 MHz under a 22 nm node. Table I shows the area and power breakdown. At 500 MHz, each Hydra chiplet occupies 10.49 mm^2 and consumes 934.65 mW of power.

TABLE I
Area and Power Breakdown of Hydra at 500MHz

Module	Area (mm^2)	Power (mW)
PE Arrays	5.77	643.98
Permutation Engine	0.01	0.86
Softmax Engine	0.14	19.36
Auxiliary Unit	0.26	35.43
Global Buffer	3.76	203.99
D2D Interface	0.06	4.38
Others	0.49	26.65
Total	**10.49**	**934.65**

Methodology. We used the s-tui tool [27] and NVIDIA System Management Interface to monitor the CPU and GPU, respectively. For the Hydra chip, we developed a behavioral-level simulator that was validated against the RTL implementation. At the chiplet level, we modified Noxim [28] to simulate inter-chiplet data transmission patterns, assessing both latency and power. For a thorough comparison, batch sizes of 1-4 were tested with various input-output token length combinations, where input lengths ranged from 64 to 1024 and output lengths from 16 to 256, reflecting typical user requests.

B. Performance

Inference latency and power consumption. Fig. 9(a) illustrates the normalized execution time of a single MoE layer across various input and output token lengths. The results show that Hydra achieves an average speedup of 14.2× over the GPU and 42.4× over the CPU. This significant performance improvement can be attributed to several key factors. First, Hydra optimizes expert mapping strategies, effectively reducing all-to-all communication latency. Additionally, Hydra leverages the CAM array and supports softmax skipping, minimizing the latency of the permutation operation and lowering the computational overhead of the gating stage. Fig. 9(b) presents the normalized power consumption of Hydra. The results demonstrate that Hydra achieves average power savings of 169.1× over the GPU and 357.5× over the CPU.

Multi-GPU implementation. Since multi-GPU systems also support expert parallelism, we deployed the MoE model on 4 to 8 NVIDIA A100 GPUs to compare the performance of Hydra with multi-GPU inference. Fig. 10 shows the normalized throughput and energy efficiency of Hydra under different batch sizes. The results indicate that, compared to implementations on 4 GPUs and 8 GPUs, Hydra achieves throughput improvements of 11.0× and 11.2×, respectively, along with energy efficiency improvements of 312.2× compared to 4 GPUs and 588.1× compared to 8 GPUs. The observed superiority of the 4 GPU implementation over the 8 GPU implementation may be attributed to increased communication overhead and resource contention, which can diminish the benefits of additional computational resources.

Ablation study. To evaluate the contribution of each proposed technique, we conduct ablation experiments. The work-

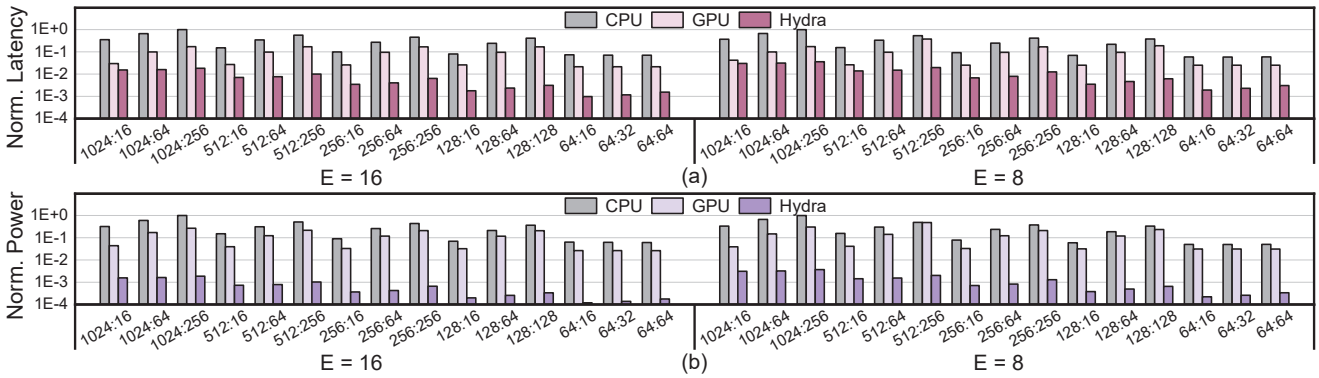

Fig. 9. (a) Inference latency and (b) power of Hydra compared to GPU and CPU. $E = 8$ refers to switch-base-8, and $E = 16$ refers to switch-base-16.

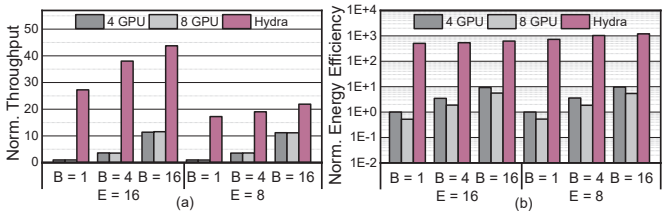

Fig. 10. Comparison with multi-GPU.

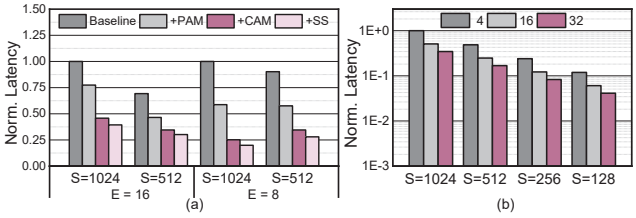

Fig. 12. (a) Ablation study. (b) Scalability evaluation.

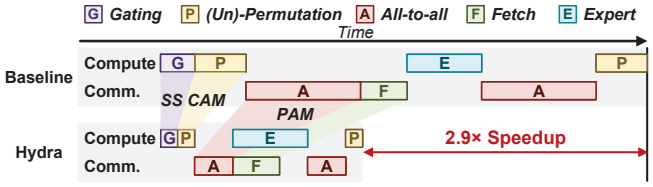

Fig. 11. Execution timeline. SS: softmax skipping; CAM: cam-based permutation; PAM: popularity-aware expert mapping.

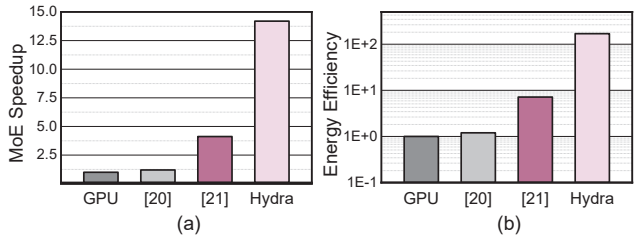

Fig. 13. (a) Inference speedup and (b) energy efficiency improvement of Hydra over other state-of-the-art works.

flow of Hydra with regard to the baseline is depicted in Fig. 11, and the results are displayed in Fig. 12(a). The optimized weight mapping strategy significantly reduces inference latency by 1.49× while introducing only a 1.2% increase in hardware overhead due to the mapping solver. Additionally, CAM-based permutation yields a 1.59× reduction by efficiently realizing token reordering, while the softmax-skipping technique further provides an additional 1.22× speedup. The above results demonstrate that each technology of Hydra has made significant contributions to inference acceleration.

Scalability. Fig. 12(b) demonstrates the performance scalability of Hydra when running the switch-base-16 model across different numbers of chiplets. When $C \leq E$, each chiplet holds E/C experts. Conversely, the MoE layer adopts a hybrid expert-model parallelism strategy, where each expert is distributed across C/E chiplets. While inter-chiplet communication costs generally limit the performance gains in chiplet-based systems, our expert mapping strategy efficiently optimizes bandwidth usage and minimizes all-to-all communication latency, thereby enabling Hydra to scale effectively.

Comparison with other accelerators. We compared Hydra to two state-of-the-art MoE acceleration schemes, Pre-gated MoE [20] and FLAME [21], both of which leverage memory offloading for single-device inference acceleration. Fig. 13 illustrates the speedup and energy efficiency results on the switch-base-8 model. Hydra achieves 14.2×, 11.8×, and 3.5× speedups over GPU-only, Pre-gated MoE, and FLAME, respectively, demonstrating the capability of a chiplet-based architecture in addressing MoE model memory requirements while alleviating latency bottlenecks from all-to-all communication through optimized expert mapping. Hydra also realizes energy efficiency improvements of 169.1×, 141.1×, and 18.9× over GPU-only, Pre-gated MoE, and FLAME, respectively.

VI. Conclusion

This work presents Hydra, a software/hardware co-design developed to address the communication and computational bottlenecks in MoE model deployment. By predicting expert popularity and dynamically adjusting expert mapping, Hydra significantly optimizes all-to-all communication. By incorporating a CAM array for (un)-permutation operations and eliminating redundant softmax calculations, Hydra further enhances computational efficiency. Hydra achieves significant reductions in latency and power, with average improvements of 14.2× and 169.1× over the NVIDIA RTX 3090 GPU, highlighting its effectiveness in accelerating MoE inference.

***Abstract*—Data-Free Knowledge Distillation (DFKD) enables the knowledge transfer from the given pre-trained teacher network to the target student model without access to the real training data. Existing DFKD methods focus primarily on improving image recognition performance on associated datasets, often neglecting the crucial aspect of the transferability of learned representations. In this paper, we propose Category-Aware Embedding Data-Free Knowledge Distillation (CAE-DFKD), which addresses at the embedding level the limitations of previous rely on image-level methods to improve model generalization but fail when directly applied to DFKD. The superiority and flexibility of CAE-DFKD are extensively evaluated, including: *i.)* Significant efficiency advantages resulting from altering the generator training paradigm; *ii.)* Competitive performance with existing DFKD state-of-the-art methods on image recognition tasks; *iii.)* Remarkable transferability of data-free learned representations demonstrated in downstream tasks.**

***Index Terms*—Knowledge Distillation, Representation Learning, Transfer Learning, Contrastive Learning.**

I. Introduction

KNOWLEDGE distillation (KD) transfers knowledge from high-capacity teacher networks to compact student networks, enabling comparable performance with reduced computational costs. Although effective for various computer vision tasks (e.g., image classification [1], object detection [2], [3], and semantic segmentation [4], [5]), traditional KD requires access to real training dataset (Figure 1 **(a)**), presenting privacy concerns. Data-free knowledge distillation (DFKD) [6] addresses this by reconstructing training data from the given pre-trained teacher network (Figure 1 **(b)**), are broadly categorized into optimization-based [7], [8] and generator-based views. This paper focuses on generator-based DFKD [9]–[12], where a trainable generator network synthesizes proxy dataset guided by the pre-trained teacher that as the non-updatable discriminator.

Despite advances in generator-based DFKD for image recognition [13], [14], a key research gap remains to understand and improve the transferability of learned representations to new downstream tasks and datasets. Furthermore, existing DFKD explorations also suffer from two key limitations: ***i)*** the teacher category prediction preferences introduce distributional shifts in the synthetic dataset, leading to inconsistent synthetic image quality across categories [15]–[17]; ***ii)*** the generator network training process can suffer from pattern collapse, leading to numerous noisy or worthless synthetic images. As shown in Figure 2 **(a)**, the synthetic images on CIFAR-100 exhibits significant difference across categories in low-confidence proportion from the teacher view ($\leq$ 0.1 highest probability), indicating inconsistent synthetic image quality and potential category imbalance. Figure 2 **(b)** visualizes the lack of clear semantic content in low-confidence synthetic images. Consequently, existing methods for improving model generalization or task adaptability, such as high-intensity data augmentation or auxiliary supervised objectives, directly applying methods such as Mixup or contrastive learning to synthetic images, can negatively impact student network performance (Table I), as transformations applied to semantically ambiguous synthetic images further degrade their usefulness (Figure 2 **(c)**).

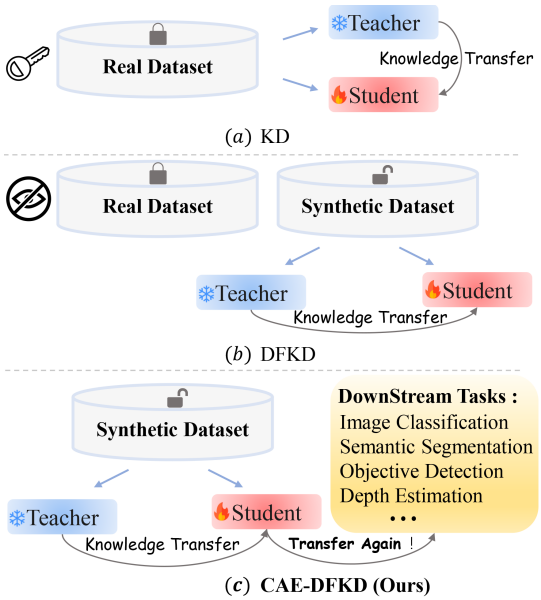

Fig. 1. **From KD to CAE-DFKD.** (a) The traditional paradigm of knowledge distillation (KD) has access to the real dataset. (b) Data-Free Knowledge Distillation (DFKD) is unaware of the read dataset and employs synthetic datasets for knowledge transfer. (c) The goal of CAE-DFKD is to continually transfer the knowledge acquired under data-free setting to downstream tasks.

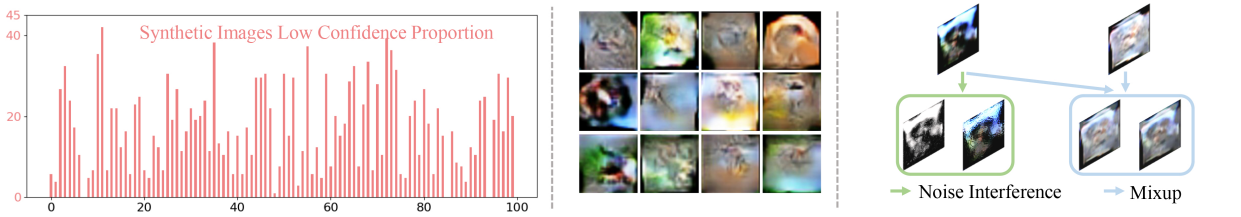

TABLE I
DIRECTLY APPLYING CONTRASTIVE LEARNING OR MIXUP, WHICH ARE DESIGNED FOR IMAGE-LEVEL, TO DFKD SYNTHETIC IMAGES YIELDS ADVERSE EFFECTS. SETTING: CIFAR-100, RESNET-34 → RESNET-18.

Method	**Top-1 Acc.(%)**
Vanilla	77.54
+ Mixup	77.13↓
+ Contrastive Learning	76.38↓

This paper addresses these limitations by shifting from image-level operation to embedding-level operation for DFKD, promoting more robust and transferable feature learning. By operating in the embedding space, our **Category-Aware Embedding Data-Free Knowledge Distillation (CAE-DFKD)** method mitigates the adverse effects of quality inconsistencies in synthetic images, and contributions are as follows:

- **Category Embedding Noise Diffusion (CEND) Layer**: Unlike

(***a***) CIFAR-100 Synthetic Dataset Quality Inconsistency (***b***) Low-Quality Synthetic Images (***c***) Negative Effects of Image-level Augmentation

Fig. 2. **Quality Difference in Synthetic Images.** (a) The proportion of low-confidence (≤ 0.1 highest probability) synthetic images within the corresponding categories. (b) The generator inevitably produces semantically ambiguous, low-quality synthetic images. (c) Applying image-level noise interference or high-intensity data augmentation to uncertain images renders their semantics more abstract and difficult to exploit.

native DFKD setting that sample generator embedding inputs from unstructured Gaussian noise, we introduce a structured embedding space with category priors using pre-trained language models. The proposed CEND layer applies multi-source noise to dynamically diffuse category embeddings, enriching the structured embedding space, and contributes to the fast convergence of the generator.

- **Category Noise Contrastive Learning (CNCL)**: CNCL is an embedding-level contrastive learning method designed for DFKD that exploits the generator network to *indirectly* produce positive-negative contrastive pairs, encouraging the student network to focus on domain-invariant category features with stronger generalization.
- **Effective Data-Free Transferability**: CAE-DFKD integrates the advantages of the CEND and CNCL components, enabling effective data-free knowledge transfer to various downstream tasks (Figure 1 (c)), surpassing the adaptability and practicality of existing DFKD methods.

II. Related Work

1) ***Data-free KD (DFKD):*** DFKD transfers knowledge from the given pre-trained teacher to the target student network using synthetic images, avoiding access to the real training dataset. Generator-based DFKD methods [13]–[15], [18], the focus of this paper, adversarially train a generator network and a student network under the guidance of the given teacher network that as the un-trainable discriminator. The generator synthesizes images to maximize the divergence between student and teacher predictions, while the student learns to align its predictions with the teacher in these synthetic images [9], [11], [18].

However, generator-based DFKD faces a key challenge: synthetic dataset quality. These generated images often do not fully capture the diversity and complexity of real data, and their quality is heavily influenced by the teacher network prediction preferences [15], [16]. Existing DFKD methods attempt to address this limitation through various strategies. Some optimize generator features to promote diversity (e.g. SpaceShipNet [14]), while others incorporate causal inference (KDCI [15]), leverage open-world data (ODSD [16]), implement curriculum learning (AdaDFKD [19]), or employ diffusion-based augmentation (DDA [17]). NAYER [13] periodically re-initializes the generator for improved diversity.

Although these methods improve image recognition performance on the corresponding real dataset by improving synthetic image quality, their effectiveness on broader downstream tasks remains largely unexplored. In other words, it remains unknown whether the representations learned following the data-free setting possess transferability. This paper fills this gap by introducing an embedding-level paradigm to DFKD, enabling data-free and privacy-preserving knowledge transfer for a wider range of real-world applications.

2) ***Contrastive Learning:*** Self-supervised learning exploits pretext tasks on unlabeled data to obtain robust and discriminative representations [20]–[23]. Among these pretext tasks, contrastive learning [24]–[27] outperforms many downstream tasks by bringing semantically similar data closer to the latent space while pushing apart differing data. However, the effectiveness of contrastive learning is highly dependent on how positive and negative pairs are defined [24]. Conventional methods generally produce these contrastive pairs at the image level [20], [22], but under the DFKD setting, this strategy risks introducing greater noise or more marked semantic ambiguity, thus increasing uncertainty in the optimization objective of the student network, as discussed in Section I.

In this paper, we exploit the synthesizing ability of the generator-based DFKD to address this issue. Instead of constructing positive-negative contrastive pairs at the image level, we introduce embedding-level design that avoids the potential degradation resulting from low-quality synthetic images, allowing the student model to focus on more generalizable domain-invariant features.

III. Method

A. Problem Formulation and Overview

1) ***KD $\rightarrow$ DFKD:*** Given a training dataset $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{\mathcal{I}}$, where $\mathcal{I}$ represents the length of $\mathcal{D}$, and each image $x_i \in \mathbb{R}^{3\times h\times w}$, where $h \times w$ are the input resolution, $y_i \in \{1, 2, \cdots, K\}$ denotes its corresponding hard label. Knowledge distillation (KD) aims to transfer knowledge from the given pre-trained teacher network $\mathcal{T}(x;\theta_T)$ to the smaller target student network $\mathcal{S}(x;\theta_S)$. The objective is for the student to approximate the teacher network output logits on $\mathcal{D}$ through the following optimization:

$$\min_{\theta_s} \mathbb{E}_{(x_i,y_i)\in\mathcal{D}} \Big[\mathcal{L}_{\text{KL}}\left(\mathcal{S}(x_i;\theta_S), \mathcal{T}(x_i;\theta_T)\right) + \lambda\mathcal{L}_{\text{CE}}\left(\mathcal{S}(x_i;\theta_S), y_i\right)\Big], \tag{1}$$

where λ is used as a hyperparameter to balance the Kullback-Leibler divergence ($\mathcal{L}_{KL}$) and cross-entropy loss ($\mathcal{L}_{CE}$).

By comparison, data-free knowledge distillation (DFKD) seeks to train the student network without access to the real training dataset $\mathcal{D}$. Generator-based DFKD achieves this by employing adversarial training, in which a generator G produces synthetic images used to train the student:

$$\min_{\theta_S}\max_{\theta_G} \mathbb{E}_{z\sim\mathcal{N}(0,1)}\left[\mathcal{L}_{KL}\left(\mathcal{S}(\hat{x};\theta_S), \mathcal{T}(\hat{x};\theta_T)\right)\right], \tag{2}$$

where $\hat{x} = G(z, y;\theta_G)$ is a synthetic image produced by the generator G, and z is embedding vector sampled from the Gaussian distribution.

2) ***Motivation:*** The goal of existing DFKD methods is to improve image recognition performance on the corresponding real dataset, yet there is insufficient exploration on whether the performance gains obtained through data-free paradigm can benefit other downstream tasks.

3) ***CAE-DFKD Framework:*** Figure 3 demonstrates how our proposed CAE-DFKD flexibly incorporates into the existing DFKD framework. During the generator network update, we replace the native unstructured Gaussian noise sampling with the initial category

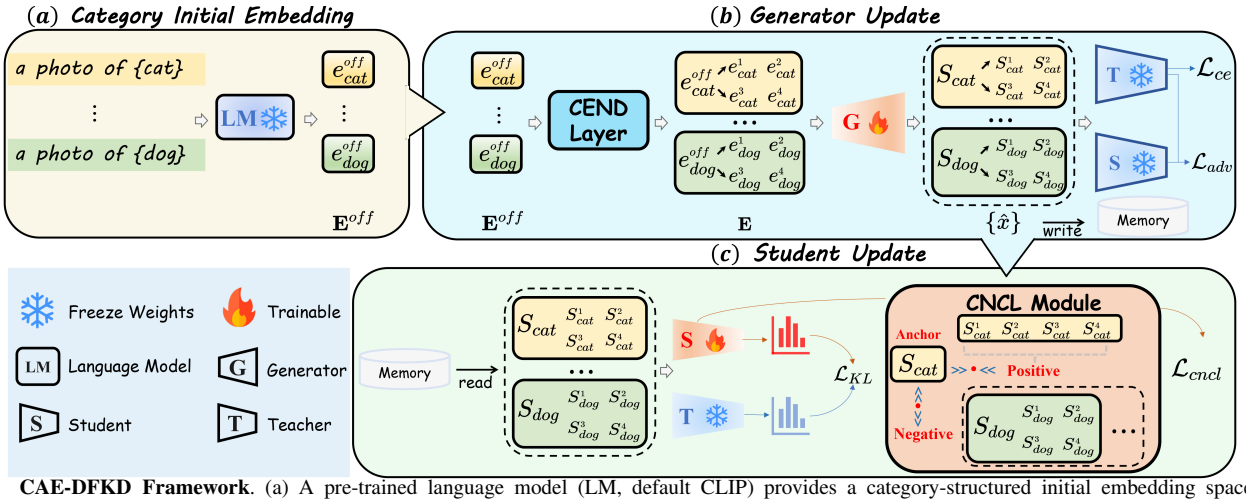

Fig. 3. **CAE-DFKD Framework**. (a) A pre-trained language model (LM, default CLIP) provides a category-structured initial embedding space, $\mathbf{E}^{\text{off}}$, contrasting with the un-structured Gaussian noise used in native DFKD, this process is performed offline and does not cause any training burden; (b) During generator updates, the Category Embedding Noise Diffusion (CEND) layer addresses $\mathbf{E}^{\text{off}}$ sparsity and lack of diversity. CEND samples from noise sources with distinct pre-set distributions, dynamically diffusing category embeddings to induce a diverse embedding space, $\mathbf{E}$. synthetic images, written to memory, are fed to teacher and student networks to compute cross-entropy ($\mathcal{L}_{ce}$), adversarial ($\mathcal{L}_{adv}$), and batch normalization ($\mathcal{L}_{bn}$) losses for generator updates; (c) During student updates, classic logit knowledge distillation ($\mathcal{L}_{kl}$) is performed on synthetic images read from memory. Further, Category Noise Contrastive Learning (CNCL) constructs embedding-level positive-negative pairs, optimizing towards $\mathcal{L}_{cncl}$.

embedding $\mathbf{E}^{\text{off}}$, and employ the Category Embedding Noise Diffusion (CEND) layer to construct a diffusible multi-source, category-structured embedding space $\mathbf{E}$. The synthetic images are then generated and stored in memory, with the generator network optimization details given in Section III-D. During the student network update, synthetic data from memory is fed into both the teacher and student networks. In addition to traditional logit knowledge alignment, the Category Noise Contrastive Learning (CNCL) module encourages the student network to focus on robust domain-invariant category features beneficial to strong generalization.

B. Initial Category Embedding and Noise Diffusion

Unlike native DFKD, which samples unstructured Gaussian noise as the generator embedding inputs, we employ a pre-trained language model (LM) to introduce structured initial category embeddings. Specifically, as illustrated in Figure 3 **(a)**, we construct prompts of the form "*a photo of* {*class*}" as input to the LM, where "{*class*}" can be the class name or class index (further explored in Section V-5). For example, for the class "cat", we input *"a photo of cat"* into the LM, obtaining the corresponding initial category embedding $\mathbf{e}^{\text{off}}_{\text{cat}} \in \mathbb{R}^D$ where D is the embedding dimension. This process is repeated for all K categories, forming the initial category embedding space $\mathbf{E}^{\text{off}} = \{\mathbf{e}^{\text{off}}_k\}_{k=1}^K$, where $\mathbf{E}^{\text{off}} \in \mathbb{R}^{K\times D}$ and "off" indicate that this operation takes place offline and is only performed once throughout the entire DFKD process, without introducing any additional training overhead.

Although $\mathbf{E}^{\text{off}}$ exhibits the initial category structure compared to Gaussian noise, it remains sparse and lacks the embedding space richness. To address this, we introduce the **Category Embedding Noise Diffusion (CEND)** layer, detailed in Figure 3 **(b)** or Figure 4. CEND takes $\mathbf{E}^{\text{off}}$ as input and samples from N noise sources (illustrated with $N = 4$). Each noise source, denoted as $\mathbf{NS}_n$ for $n \in \{1, 2, \ldots, N\}$, follows a distinct pre-defined noise distribution, generating the corresponding noise vectors $\mathbf{q}_n \in \mathbb{R}^D$, which guides $\mathbf{E}^{\text{off}}$ to diffuse into diverse latent embedding spaces. For the "cat" category, we sample noise vectors $\mathbf{q}_n$ from each $\mathbf{NS}_n$ and perform element-wise calculation to diffuse the initial category embedding $\mathbf{e}^{\text{off}}_{\text{cat}}$:

$$\mathbf{e}^{n}_{\text{cat}} = \mathbf{e}^{\text{off}}_{\text{cat}} \oplus (\mathbf{M}_n \odot \mathbf{q}_n), \quad n \in \{1, 2, \ldots, N\} \tag{3}$$

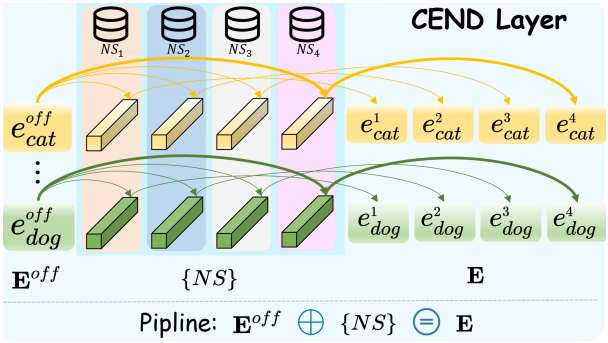

Fig. 4. **Category Embedding Noise Diffusion (CEND).** We leverage a pre-trained language model to initialize category embeddings ($\mathbf{E}^{\text{off}}$) with structure, in contrast to the unstructured Gaussian noise used in native DFKD. However, $\mathbf{E}^{\text{off}}$ suffers from sparsity and lacks diversity. Our proposed CEND layer introduces N noise sources ($\{NS\}$), each following a distinct pre-defined distribution (illustrated here with N=4), sampling from each $NS_n (n = 1, \cdots 4)$ and element-adding it to $\mathbf{E}^{\text{off}}$ enables dynamic diffusion of the initial embeddings, resulting in a richer embedding space $\mathbf{E}$.

where $\mathbf{M}_n$ is the magnitude of noise perturbation from source $\mathbf{NS}_n$, $\oplus$ denotes the element-wise addition and $\odot$ represents element-wise multiplication. The same process is applied for all K categories, producing diffused embedding space $\mathbf{E}$, as shown in Figure 4, which serves to enrich the category-structured embedding space.

C. Contrastive Pairs Construct: Image-Level → Embedding-Level

Traditional contrastive learning constructs positive-negative pairs at the image level, however, as analyzed in Section I (both quantitatively and qualitatively), this native design provides limited benefit to the student network in DFKD. We propose an embedding-level method that exploits the synthesizing ability of the generator network to indirectly construct positive-negative contrastive pairs, thereby avoiding direct comparisons among often lower-quality synthetic images.

We introduce the **Category Noise Contrastive Learning (CNCL)** module, which uses the initial category embeddings $\mathbf{E}^{\text{off}}$ and the diffused noise embeddings as generator input to produce anchor synthetic images and corresponding positive contrastive pairs. For example, as shown in Figure 3 **(b)**, the initial embeddings $\mathbf{e}^{\text{off}}_{\text{cat}}$ and $\mathbf{e}^{\text{off}}_{\text{dog}}$ generate anchor images $S_{\text{cat}} = G(\mathbf{e}^{\text{off}}_{\text{cat}})$ and $S_{\text{dog}} = G(\mathbf{e}^{\text{off}}_{\text{dog}})$,

respectively. The diffused embeddings $\mathbf{e}^n_{\text{cat}}$ generate $S^n_{\text{cat}} = G(\mathbf{e}^n_{\text{cat}})$, which serve as positive pairs for S_{cat}. As shown in Figure 3 **(c)**, anchor images of other categories (e.g., S_{dog}) and its corresponding noise-perturbed versions ($S^n_{\text{dog}} = G(\mathbf{e}^n_{\text{dog}})$) constitute negative pairs for S_{cat}. This leads to the CNCL loss:

$$\mathcal{L}_{cncl} = -\frac{1}{K}\sum_{k=1}^{K}\sum_{S_k^+ \in \mathcal{P}_k} \log \frac{\exp(\text{sim}(S_k, S_k^+)/\tau)}{\sum_{S' \in \mathcal{P}_k \cup \mathcal{N}_k} \exp(\text{sim}(S_k, S')/\tau)} \tag{4}$$

where K is the number of categories, τ is the temperature parameter, S_k is the anchor image for category k, $\mathcal{P}_k = \{S^n_k | n = 1, \ldots, N\}$ is the set of positive samples generated from the diffused embeddings of category k, $\mathcal{N}_k = \{S^n_{k'} | k' \neq k, n = 1, \ldots, N\}$ is the set of negative samples from other categories, and $\text{sim}(\cdot, \cdot)$ denotes the cosine similarity function.

D. Optimization

1) ***Generator Optimization****:* The generator network is trained using the following loss function (Figure 3 **(b)**):

$$\mathcal{L}_G = \mathcal{L}_{CE} + \lambda_{bn}\mathcal{L}_{BN} + \lambda_{adv}\mathcal{L}_{adv} \tag{5}$$

where $\mathcal{L}_{CE}$ is the cross-entropy loss between the teacher network's predictions on synthetic images and its corresponding ground-truth labels, $\mathcal{L}_{BN}$ is a batch normalization loss for numerical stability (commonly used in DFKD), and $\mathcal{L}_{adv}$ (Eq. 2) is the adversarial loss. The hyperparameters λ_{bn} and λ_{adv} balance these losses.

2) ***Student Optimization****:* The student network is trained using a combination of the classical knowledge distillation objective and our proposed contrastive learning method (Figure 3 **(c)**). The loss function is:

$$\mathcal{L}_S = \mathcal{L}_{KL} + \alpha\mathcal{L}_{cncl} \tag{6}$$

where $\mathcal{L}_{KL}$ is the KL divergence between the teacher and student logits (for knowledge distillation), $\mathcal{L}_{cncl}$ is the embedding-level category noise contrastive learning loss (introduced in Section III-C), and α controls the contribution of the contrastive loss.

IV. EXPERIMENTS

A. Experimental Setup

Datasets: We comprehensively evaluate the performance of the proposed CAE-DFKD method across image recognition datasets with various input resolutions. For smaller resolutions of 32×32, we evaluate CAE-DFKD on CIFAR-10 and CIFAR-100, which contain 10 and 100 categories, respectively. For medium resolutions of 64×64, we employ Tiny-ImageNet, which comprises 200 categories. For larger resolutions of 224×224, we conduct evaluations on ImageNet-1K.

Configuration Details: Evaluation procedure is performed across various teacher-student combinations, including ResNet [35], WideResNet (WRN), and VGG [36] models, without access to the real dataset. The generator network is optimized using the objective function defined in Eq. 5, with the Adam optimizer and an initial learning rate of 0.001. For the student network, we employ the objective function defined in Eq. 6 and optimize it using the SGD optimizer with an initial learning rate of 0.1 and training epochs of 300. Additionally, cosine annealing scheduling is applied to adjust the learning rate throughout the training process. All experiments are performed on the NVIDIA RTX 3090 GPUs.

B. Main Results

1) ***Comparison with State-of-the-art Methods****:* Tables II, III, and IV present the experimental results[1] conducted at progressively increasing resolutions: smaller (32×32), medium (64×64), and larger (224×224), respectively. "Teacher" and "Student" denote the results obtained using the data-accessible setting. In Table II, focusing on the smaller resolution corresponding

[1]Top three methods in descending order: 1_{st}, 2_{nd}, 3_{rd}

TABLE IV
LARGER RESOLUTION EXPERIMENTS. RESNET-50→RESNET-50. SYMBOL [$^\lambda$] INDICATES THAT THE RESULT IS FROM [13].

Methods	Data Available	ImageNet-1K Top-1 Acc. (%)
Teacher	✓	75.45
Student	✓	75.45
FM$^\lambda$ [18]$_{AAAI'22}$	✗	57.37
DeepInv$^\lambda$ [30]$_{CVPR'20}$	✗	68.00
NAYER [13]$_{CVPR'24}$	✗	68.92
CAE-DFKD (Ours)	✗	**69.33**

to CIFAR-10 and CIFAR-100, CAE-DFKD consistently outperforms other methods, except for the ResNet-34 → ResNet-18 combination on CIFAR-10. At medium resolution for Tiny-ImageNet, most current DFKD methods [13], [14], [37] select the ResNet-34 → ResNet-18 setting for testing, as shown in Table III, where our CAE-DFKD surpasses SOTA NAYER [13] (64.17% → 64.72%). In Table IV at the larger resolution for ImageNet-1K, due to efficiency constraints, existing DFKD methods rarely report results. We follow the classic ResNet-50 → ResNet-50 setting [13], [18], [30], using PyTorch-provided pre-trained weights for the teacher ResNet-50.

*2) **Generalization Performance Comparison**:* We conduct extensive experiments to validate the transferability of learned representations by student networks. Specifically, we perform the evaluation under both data-accessible and data-free settings across a range of downstream tasks, including semantic segmentation, depth estimation, surface normal prediction, and object detection. The evaluation metrics for each task are detailed as follows:

- NYUv2: A benchmark for scene understanding, NYUv2 employs distinct metrics for each subtask. Semantic segmentation evaluation via Mean Intersection over Union (mIoU) and Pixel Accuracy (pAcc). Depth estimation evaluation using absolute and relative error. For surface normal estimation, we consider the mean absolute error (Mean), median absolute error (Median), and percentages of pixels with angular errors within 11.25, 22.5, and 30 degrees.
- ADE-20K: Serving as a benchmark [40] to evaluate scene parsing capabilities, relies on semantic segmentation and employs pAcc and mIoU, consistent with NYUv2 evaluation. Training and evaluation are conducted using the open-source framework.
- COCO-2017: A large-scale image recognition dataset, COCO-2017 [41] includes various subtasks. We focus on evaluating transfer capabilities within the object detection subtask. Metrics include the mean Average Precision (mAP) at different IoU thresholds (50, 75) and detection behavior across object sizes, categorized as small (s), medium (m), and large (l).

In addition, CAE-DFKD and the other compared methods perform complete data-free knowledge distillation on CIFAR-100, and the obtained Student weights are then **fine-tuned** for downstream tasks.

Tables V and VI present the evaluation results for downstream tasks, comparing the proposed CAE-DFKD with state-of-the-art (SOTA) DFKD methods like CMI [32], SpaceShipNet [14], and NAYER [13], "Student" denotes data-accessible settings. Although SOTA DFKD methods might achieve comparable or marginally superior accuracy against the data-accessible setting on the real image recognition dataset, this advantage does not consistently extend to broader tasks, falling short of the data-accessible "Student". Notably, our method, in addition to maintaining comparable performance on the real image recognition dataset, prioritizes learning generalizable and transferable category representations. CAE-DFKD not only exceeds existing SOTA DFKD methods, but also outperforms data-accessible "Student" settings in certain scenarios, including absolute error (AErr) in depth estimation, the 11.25° setting in surface normal prediction, and COCO-2017 with small and medium object (mAP$^{bbox}_s$, mAP$^{bbox}_m$).

V. ABLATION EXPERIMENTS

*1) **Ablation Study of CEND and CNCL**:* Table VII uses CMI [32] as the base method to validate the effectiveness of our proposed CEND layer and CNCL module under the data-free setting. It is observed that the category-structured embeddings introduced by CEND, compared to the un-structured Gaussian noise embeddings commonly used in DFKD, introduce embedding-level richness and alleviate the convergence burden of the generator, which helps produce high-quality synthetic images. Additionally, CNCL constructs positive-negative contrastive pairs at the embedding level to mitigate the issue of significant difference in synthetic image quality, and encourages the student network to focus on category representations with strong domain generalization, thereby benefiting downstream tasks, as shown in Figure 5.

*2) **Effect of Noise Sources Number (N) on Generalization**:* In CEND, we introduce the noise diffusion method into the initial category embeddings to enrich the embedding space, which is influenced by the noise diffusion source number N. In addition, N also affects the construction of positive-negative contrastive pairs in CNCL. In Table VIII, we present the impact of different N on the performance of the student network in downstream tasks. When N is relatively small (< 4), CEND struggles to introduce sufficient richness to the embedding space $\mathbf{E}$. In contrast, when N becomes too large (> 4), an excessive number of positive and negative pairs is generated for CNCL, which decreases training efficiency and increases the difficulty of semantic contrast for noisy images, thus placing a heavier burden on the optimization process of the student network. Despite this, our CAE-DFKD significantly outperforms the base method under different values of N, with the most robust performance achieved when $N = 4$.

*3) **Efficiency Advantage of CEND**:* Under native DFKD generator network update setting, which samples Gaussian noise and is required to project into highly structured dataset structures ("**un-structured → structured**"), faces extreme difficulties, particularly in the data-free setting where no real images are available to provide discriminative information. In contrast, our CAE-DFKD approach introduces rich structured embeddings through CEND, transforming the generator update process into "**structured → structured**", significantly alleviating the convergence burden on the generator. Table IX reports the efficiency gains made by CEND.

*4) **LMs on Generalization**:* In Section III-B, we employ a pre-trained LM to provide structured category information for the generator embedding inputs. In Table X, we report the impact of different LMs on the downstream task of COCO-2017 object detection. It can be observed that, compared to the base, the specific choice of LM (doc2vec, CLIP, SBERT) shows little sensitivity, as all lead to significant performance improvements. However, CLIP yields superior performance.

*5) **Limitation**:* Data-free settings involve the absence of the real dataset. In scenarios demanding heightened privacy, access to class names might be restricted, or pre-trained language models may lack corresponding category priors. Unlike the discussion in Section III-B, which exploits *"a photo of {class name}"* as the default prompt, we explore a more general prompt design: *"a photo of {class index}"*. The experimental results in Table XI demonstrate the effectiveness of both prompt designs, with the more general

VI. CONCLUSION

In this paper, we propose **CAE-DFKD**, which rethinks the existing DFKD framework from the embedding-level view. For technical contributions: ***i)*** CAE-DFKD incorporates a category-aware prior, enriching the structured embedding space and alleviating the generator convergence burden; ***ii)*** Through embedding-level contrastive learning, CAE-DFKD addresses the ineffectiveness of image-level generalization methods for DFKD. For application contributions: CAE-DFKD extends the data-free knowledge transfer potential beyond widely focused image recognition to more diverse downstream tasks. Extensive experiments demonstrate the superiority and flexibility of CAE-DFKD.

***Abstract*—Advanced integrated circuit (IC) systems increasingly utilize chiplet-based packaging with complex 2.5D/3D structures and dense Through-Silicon Via (TSV) arrays. While the Finite Element Method (FEM) provides high-fidelity thermal simulation for these systems, its computational efficiency degrades significantly when generating and optimizing meshes for intricate geometries. To address these performance limitations while preserving simulation accuracy, we present NeuralMesh, a novel framework that accelerates thermal analysis of chiplet-based ICs. Our approach integrates deep learning and geometric analysis to optimize mesh generation without the need for iterative refinement steps. NeuralMesh first employs an enhanced segmentation model to predict thermal distributions based on geometric, material, and power parameters. These predictions, combined with key geometric features, guide the optimization of an initial coarse FEM mesh. By eliminating traditional iterative mesh refinement, our framework achieves up to 45.00× mesh generation speedup while maintaining thermal accuracy within 0.8% of commercial COMSOL simulations. It reduces the number of mesh elements in unimportant areas, which represents a speed improvement of the subsequent thermal simulation. This advancement enables rapid yet precise thermal analysis essential for modern IC package design.**

***Index Terms*—Chiplet, Thermal Simulation, Finite Element Method, Mesh Optimization, Segmentation Model**

I. Introduction

As semiconductor scaling approaches fundamental physical limits in the post-Moore era, traditional manufacturing process improvements yield diminishing returns in integrated circuit (IC) performance and power efficiency [1]. This challenge has driven the emergence of chiplet-based integration as a promising direction for the IC industry. This approach, illustrated in Fig. 1, employs advanced 2.5D/3D packaging to combine separately manufactured functional chiplets into integrated systems. By enabling the use of different manufacturing processes for different chiplets, this methodology overcomes single-process limitations while reducing defect rates and manufacturing costs [2], [3].

However, the increasing power density and decreasing feature sizes in modern chiplet-based designs have intensified thermal management challenges [4]. Localized hot spots significantly impact chip performance and reliability [5]. Furthermore, temperature gradients combined with mismatched thermal expansion coefficients generate thermal stress that can cause mechanical failures such as delamination, warping, and peeling in chiplet structures. These challenges necessitate precise and efficient thermal simulation methods for optimizing integrated chip designs.

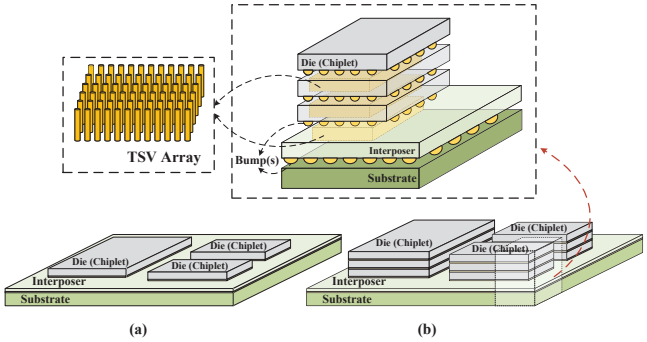

Fig. 1. The structure of integrated chips. **(a)** is the 2.5D packaging and **(b)** is the 3D packaging. The differences between them are: In 3D structure, the lower dies are also embedded with TSVs, and there are micro-bumps between the lower dies and the upper dies.

Current thermal simulation approaches fall into two categories: analytical and numerical methods [6]. While analytical methods offer closed-form solutions, they are generally limited to simple geometries and inadequate for complex integrated chip structures. Numerical methods, particularly the finite difference method (FDM) and finite element method (FEM) discretize heat conduction equations into systems of algebraic equations. Advanced-standard tools implementing these approaches include the FDM-based Hotspot [7] and 3D-ICE [8], and the FEM-based solutions like Manchester Thermal Analyzer (MTA) [9], Celsius [10] and COMSOL [11].

The geometric complexity of modern integrated chips, characterized by intricate stacking structures, redistribution layers (RDL), and dense through-silicon via (TSV) arrays, poses significant challenges for traditional FEM approaches [12]. *Mesh generation and optimization consume a substantial portion of the simulation time when applying FEM to integrated chip thermal analysis*. Recent research has explored

neural networks to accelerate the solution of discrete thermal equations [6], [13]. However, these deep learning approaches struggle with generalization across varied chip structures, and their end-to-end thermal predictions often fall short of simulation requirements [14].

FEM theory demonstrates that properly constructed meshes converge to exact solutions of the original differential equations through progressive refinement [15]. Traditional FEM mesh optimization relies on computationally intensive iterative refinement based on posterior error analysis. Recent active optimization strategies employing graph convolution networks (GCN) [15], machine learning [16], and reinforcement learning [17] have shown promise in improving efficiency. However, these methods focus primarily on 2D mesh optimization and fail to adequately address crucial regions of high temperature and large thermal gradients in integrated chip thermal simulation.

Recognizing that thermal gradient predictions can guide efficient mesh optimization for accurate simulation, we present NeuralMesh, a novel FEM mesh optimization framework that significantly reduces mesh generation time for integrated chip thermal simulation while maintaining accuracy. Our framework leverages segmentation model characteristics for rapid thermal distribution prediction and combines this information with critical geometric features to guide mesh optimization. Our research makes three primary contributions to the field:

- We pioneer a novel mesh optimization framework, NeuralMesh, that for the first time leverages deep learning-based thermal predictions to guide FEM mesh generation to replace traditional iterative refinement with neural network-guided mesh optimization.
- We develop an enhanced segmentation network architecture that achieves relatively high accuracy in thermal distribution prediction on the fly while maintaining real-time performance. The unique structure of our network preserves critical thermal gradient information essential for identifying regions requiring precise mesh refinement, enabling targeted optimization impossible with conventional approaches.
- We introduce an adaptive mesh refinement parameter that unifies thermal gradient data with geometric boundary information to precisely control element density. This innovation enables automatic identification and refinement of thermally critical regions, reducing mesh element count by 44% while maintaining simulation accuracy within 0.8% difference of commercial tools.

II. Background

A. Thermal Simulation of Integrated Chip by FEM

The thermal behavior of integrated chips is governed by the heat conduction equation, which simplifies to a Poisson equation for steady-state analysis:

$$k_x \frac{\partial^2 T}{\partial x^2} + k_y \frac{\partial^2 T}{\partial y^2} + k_z \frac{\partial^2 T}{\partial z^2} + Q_s = 0, \tag{1}$$

where Q_s represents volumetric power dissipation, $\frac{\partial T}{\partial \mathbf{n}} | \mathbf{n} = x, y, z$ denotes temperature gradients along principal axes, and $k_{\mathbf{n}}$ represents directional thermal conductivity. FEM discretizes the solution domain into three-dimensional elements, typically tetrahedra or hexahedra. Within each element, temperature is interpolated using shape functions $N_i(\mathbf{x})$, yielding the approximation $T(\mathbf{x}) = \sum_{i=1}^{s} N_i(\mathbf{x}) T_i$.

At chip-air interfaces, convective heat transfer is modeled using the Robin boundary condition:

$$-k \frac{\partial T}{\partial n} = h(T - T_\infty), \tag{2}$$

where h denotes the convective heat transfer coefficient and T_∞ represents ambient temperature. This convection term contributes to the heat source vector through the boundary integral:

$$F_i = \int_{\Gamma_h} N_i h (T - T_\infty) \, d\Gamma, \tag{3}$$

where Γ_h represents the convective boundary surface.

B. FEM Mesh Optimization

The quality and efficiency of FEM analysis depend critically on mesh characteristics, which are determined by model geometry, feature relationships, and thermal behavior [18], [19]. In integrated chips, geometric features such as device boundaries, inter-feature distances, and small structures like TSVs directly impact mesh requirements. Regions of high temperature or steep thermal gradients demand locally refined meshes to ensure simulation accuracy. For each tetrahedral element e, mesh quality is quantified using the aspect ratio metric:

$$Q_e = \alpha \frac{V_e}{h_e^3} \tag{4}$$

where V_e is the element volume, h_e is the longest edge length, and α is a normalization constant. The a posteriori error estimator η_e for thermal analysis is defined as:

$$\eta_e^2 = h_e^2 |R(T_h)|0, e^2 + \frac{1}{2} h_e |J(T_h)|0, \partial e^2 \tag{5}$$

where $R(T_h)$ is the element residual and $J(T_h)$ represents the jump in temperature gradient across element boundaries. Element subdivision uses the refinement criterion:

$$h_{new} = h_{old} \sqrt{\frac{\eta_e}{\eta_{target}}}, \tag{6}$$

whereas mesh reconstruction generates new elements based on the size function:

$$h(\mathbf{x}) = \min(h_{max}, \max(h_{min}, \beta |\nabla^2 T|^{-1/p})), \tag{7}$$

where β controls refinement intensity and p is the polynomial order. r-refinement optimizes node positions by minimizing the energy functional:

$$E(\mathbf{x}) = \int_\Omega |\nabla T|^2 d\Omega + \gamma \sum_e Q_e^{-2} \tag{8}$$

The selection of the optimization method depends on the specific requirements for accuracy, computational efficiency, and mesh quality constraints in the thermal simulation.

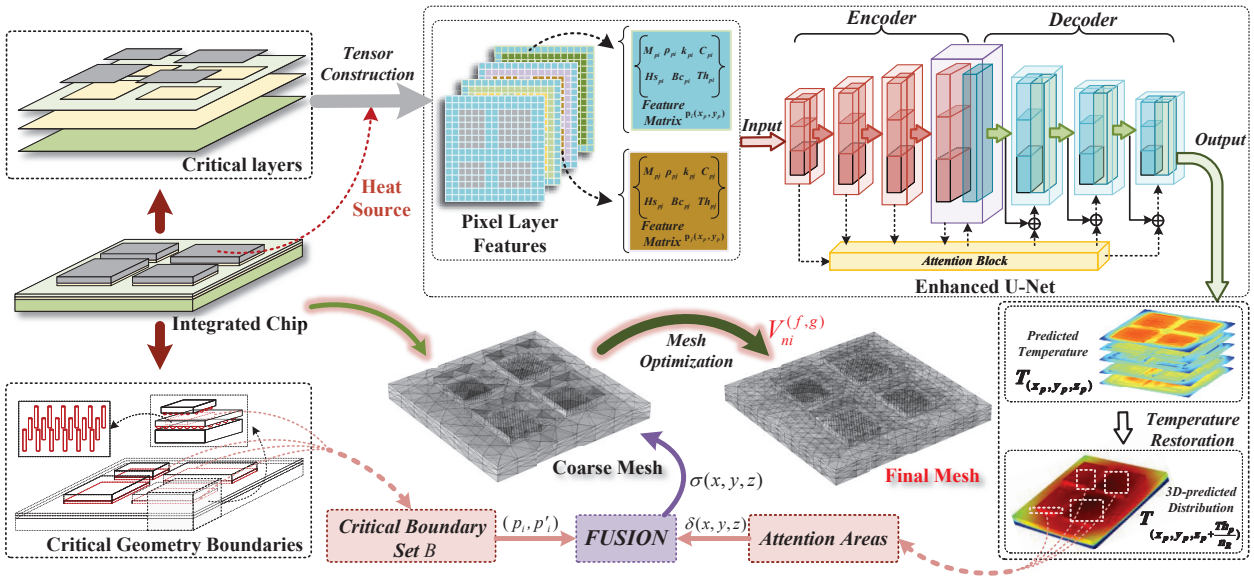

Fig. 2. The mesh optimization framework NeuralMesh for getting final refined FEM mesh.

III. Proposed Methodologies

Our NeuralMesh framework accelerates FEM mesh generation for integrated chip thermal simulation while maintaining accuracy. As illustrated in Fig. 2, the framework comprises three key stages: (1) geometric and thermal feature extraction through tensor construction, (2) temperature distribution prediction via an enhanced U-Net architecture, and (3) intelligent mesh optimization guided by predicted thermal gradients and geometric constraints.

A. Model Input and Tensor Construction

The framework integrates two critical information sources: geometric boundaries and predicted thermal distributions. For geometric boundaries, we define the edge set $E = \{e_i(p_i, p_i')\}, i = 1, 2, ..., N$, where each edge e_i connects points $(p_i, p_i') = [(x_i, y_i, z_i), (x_i', y_i', z_i')]$. Component volumes form the set $V = \{v_i^{(comp)}\}, i = 1, 2, ..., M$, and $comp = \{TSV, die, ..., substrate\}$. Critical boundaries are

$$f_{crit}(e) = e \in [v_i^{comp(i)} \wedge v_j^{comp(j)}], i \neq j \tag{9}$$

where $v_i^{comp(i)}$ and $v_j^{comp(j)}$ are the volumes of component i and j respectively. Yielding the boundary set $B = \{e_i\}$ where $f_{crit}(e_i) = True$. For thermal prediction, we decompose the 3D structure into critical layers based on material transitions. Each layer forms a 2D plane P_i with feature tensors encoding local physical properties:

$$\mathbf{p}(x_p, y_p) = \left[M_p, \rho_p, k_p, C_p, Hs_p, Bc_p, Th_p\right]^\top \tag{10}$$

where M_p, ρ_p, k_p, C_p, Hs_p, Bc_p, and Th_p represent material properties, density, thermal conductivity, heat capacity, heat source, boundary conditions, and Z-axis thickness respectively. The complete plane tensor is:

$$\mathbf{P} = [\mathbf{p}(x_p, y_p)]_{x=1,...,W;,y=1,...,H} \in \mathbb{R}^{W \times H \times C_f}, \tag{11}$$

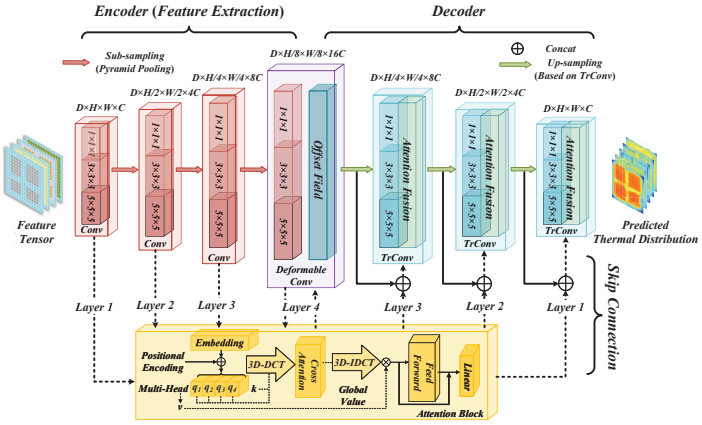

Fig. 3. The Enhanced U-NET for Temperature Prediction

where C_f is the number of channels of the feature. The tensor P is used as the input of the enhanced U-Net network proposed in this paper, which will be completely described in the next section, to predict the temperature distribution.

B. Temperature Prediction based on Enhanced U-NET

Our method first aims to predict the accurate temperature distribution of integrated chips based on the feature tensor constructed in the previous section. This segmentation model is implemented based on the enhanced U-Net architecture (illustrated in Fig. 3), which extends the traditional encoder-decoder structure with multi-scale convolution and pyramid pooling to capture diverse structural features. The network comprises three key components:

1) Encoder Structure: The encoder is the key feature extraction component in the U-NET, which is designed to capture the thermal characteristics of the integrated chip from local to global. In the encoder component, the following strategies are made to improve the extraction of the plane feature:

- **Multi-scale Convolution Layer:** Since the structure of the integrated chip is layered into plane tensors, it is

necessary to capture the local detail and wide-area thermal features of the integrated chip in a single layer. The multi-scale convolution strategy with various sizes convolution kernels (1×1×1, 3×3×3 and 5×5×5) in parallel can capture structural information from fine (TSV) to coarse (substrate). This design allows the U-Net to more comprehensively understand the thermal characteristics of the integrated chip, hereby improving the representation ability of the features.

- **Pyramid Pooling:** After the Multi-scale convolution layer, the sub-sampling based on pyramid pooling can enhance the spatial capture capability of U-Net by applying different sizes of pooling windows. It not only improves sensitivity to different-scale features but extracts more global thermal information.
- **Deformable Convolution:** Since different areas of a material respond differently to heat conduction, after the 3 layers of multi-scale convolution and pyramid pooling, the deformable convolution enables the U-Net more flexible to the heterogeneity of integrated chips.

2) Attention Block-based Skip Connection: Skip connection can effectively avoid the gradient disappearance in the enhanced U-Net training process. The attention block with multi-head attention mechanism-based skip connection can enable the decoder to reconstruct and refine the specific details of the temperature distribution in the large temperature gradient changed area. The 3D discrete cosine transform (3D-DCT) is applied to convert spatial features into the frequency domain, and the 3D inverse discrete cosine transformation (3D-IDCT) transforms the frequency branch back into the spatial domain to enrich the semantic content. This method effectively improves the efficiency of feature reuse and increases the accuracy of the enhanced U-NET.

3) Decoder Structure: The decoder is responsible for up-sampling the chip features, which are extracted by the decoder, to the original resolution. And then generating the temperature distribution prediction map of the integrated chips.

- **Transposed Convolution (TrConv):** The transposed convolution is the up-sampling strategy of the decoder part. It enables the output details of each layer to gradually closer to the high-resolution temperature map of the integrated chips.
- **Attention Fusion:** After each up-sampling, the features of the corresponding encoder layer are concat with the output of the current decoder layer after passing through the skip connection based on the attention block. By fusing the attention feature from the Attention block, the attention fusion module in the decoder performs weighted processing on each feature, which can give priority to focusing and refining the areas with large temperature gradient changes and concentrated hot spots.

Through the design of the above structure, the enhanced U-Net can effectively extract key features from the 2D tensor structure slices of complex integrated chips and perform precision temperature distribution prediction.

C. Mesh Optimization

While our U-Net provides accurate thermal predictions, further refinement is needed for simulation-grade accuracy, which is essential for an industrial standard of thermal simulation. To this end, we utilize the predicted temperature distribution to optimize the coarse FEM mesh based on the critical boundaries and the temperature distribution prediction.

1) 3D Temperature Field Reconstruction: The initial thermal predictions exist on discretized planes corresponding to material interfaces. To obtain a continuous 3D temperature field, we must first reconstruct the full volumetric distribution. Within regions of consistent material properties, the temperature field satisfies the steady-state heat equation:

$$\nabla \cdot (k \nabla T) = -q \tag{12}$$

where k is the thermal conductivity tensor and q represents volumetric heat generation. Given this governing equation and the assumption of piece-wise constant material properties between layers, we employ a physics-informed interpolation scheme:

$$T_{(x_p,y_p,z_p+\frac{Th_p}{n_R})} = (1-\frac{1}{n_R})T_{(x_p,y_p,z_p)} + \frac{1}{n_R}T_{(x_p,y_p,z_p+Th_p)} \tag{13}$$

where n_R determines the interpolation resolution along the z-axis. This approach preserves thermal continuity while respecting material boundaries.

2) Thermal-Geometric Refinement Parameter: The effectiveness of mesh refinement depends critically on identifying regions requiring higher resolution. We propose a novel refinement parameter that couples thermal behavior with geometric features. The thermal contribution is captured through a normalized parameter:

$$\lambda(x_p, y_p, z_p) = \frac{T_{(x_p,y_p,z_p)} - T_{min}}{T_{max} - T_{min}} \cdot \frac{|\nabla T_{(x_p,y_p,z_p)}|}{|\nabla T_{(x_p,y_p,z_p)\max}|} \tag{14}$$

This formulation balances absolute temperature magnitude with local gradients, addressing both hot spots regions and areas of rapid thermal variation. The inverse transformation:

$$\delta(x_p, y_p, z_p) = \frac{1}{1-\lambda(x_p, y_p, z_p)} \tag{15}$$

provides appropriate scaling for mesh refinement decisions. To incorporate geometric features, we transform the thermal parameter from discretized coordinates to the continuous geometric domain:

$$\delta(x, y, z) = \delta(x_p, y_p, z_p) \cdot \wp[\frac{\mathbf{n}p}{\mathbf{Ln}}|\mathbf{N}|\mathbf{n}_{p-1} : \mathbf{n}_{p+1}] \tag{16}$$

where $\wp[\cdot]$ represents a neighborhood interpolation function, $\mathbf{L_n}$ denotes directional pixel counts, and $|\mathbf{N}|$ gives physical dimensions. The final refinement parameter synthesizes thermal and geometric information:

$$\sigma(x, y, z) = \frac{e \cdot \delta(x, y, z)}{1 + [\sqrt{|(x, y, z) - p_i|^2 + |(x, y, z) - p_i'|^2}]_{min}} \tag{17}$$

TABLE I
DETAILS OF BENCHMARKS AND THE COMPARISON OF DIFFERENT MESH GENERATION METHODS

Average	-	-	-	-	-	-	-	-	-	18.00×	29.91×

This formulation ensures enhanced resolution near material interfaces and in regions of significant thermal activity while maintaining smooth transitions in element size.

3) Adaptive Tetrahedral Refinement: For tetrahedral elements, we employ an edge-based refinement strategy. Given an element m_{i0} with vertices $[(x, y, z)_f, f = 1, 2, 3, 4]$, the number of new vertices along edge (f, g) is determined by:

$$V^{(f,g)}ni = \Lambda[\sigma(x, y, z)_f + \sigma(x, y, z)_g] \tag{18}$$

where $\Lambda[\cdot]$ represents the ceiling function. The positioning of new vertices follows an exponential distribution governed by local σ values, ensuring smooth size transitions while maintaining element quality.

This approach satisfies several key theoretical properties including: (1) Element quality bounds are preserved through controlled vertex placement, (2) Mesh size transitions remain gradual, preventing numerical artifacts, (3) Refinement naturally concentrates in regions of high thermal gradient, (4) Material interfaces receive appropriate resolution enhancement.

The validation demonstrates that this algorithm achieves significant computational efficiency while maintaining accuracy. For complex 3D integrated chips, our framework demonstrates up to 51× acceleration compared to conventional approaches, with thermal prediction errors remaining below 0.8% relative to commercial FEM solvers.

IV. EXPERIMENTS AND RESULTS

In this section, We evaluate the NeuralMesh design and present our evaluation results. We first introduce the experimental setup. And then, in order to assess the efficiency of the NeuralMesh framework, we compare the mesh generate time and the number of mesh elements among the NeuralMesh, COMSOL [11] and the wild-used open source software Gmsh [20]. Finally, we verify the thermal simulation accuracy of different mesh refine algorithm by comparing the heat distribution from SOTA commercial software COMSOL.

A. Experimental Setup

Benchmark: Our evaluation employs seven industrial-grade integrated circuit test cases derived from Cadence reference designs, encompassing both 2.5D and 3D packaging architectures. The vertical stack comprises a substrate layer, C4 bumps, TSV-embedded interposer layer, micro-bumps, and dies. Test cases feature varied chiplet configurations randomly distributed across different substrate scales. TSV and micro-bump arrays follow local-uniform distribution patterns beneath chiplets, with specifications detailed in Table I.

Methodology and Platform: We conducted all experiments on an AMAX X12SPA-TF server equipped with an NVIDIA RTX 3090 (24GB VRAM) and Intel Xeon Gold 6336Y CPU (2.40GHz, 256GB RAM). The enhanced U-Net was pre-trained using thermal distributions from COMSOL simulations as ground truth. We evaluate mesh generation efficiency through element count and generation time metrics, comparing NeuralMesh against COMSOL and Gmsh implementations, which implement the SOTA mesh generation methods.

B. Effectiveness of Final Mesh Generation

We conducted a comprehensive evaluation comparing the proposed NeuralMesh against advanced-standard COMSOL and open-source Gmsh across diverse test cases which are mentioned above. The number of mesh elements and the mesh generation time of the final optimized FEM mesh are presented in Table I.

The number of mesh element reductions achieved by NeuralMesh ranges from 30.5% (Chip_2.5D_20_4) to 57.3% (Chip_2.5D_10_2) compared to COMSOL, with average reduction rate of about 44%, and is reduced averagely by about 25% compared to Gmsh. This efficiency stems from the ability of our framework to selectively refine thermally critical regions while maintaining coarser meshes elsewhere. The reduction in the number of elements directly translates to computational savings during the subsequent thermal simulation.

The running time of mesh generation based on NeuralMesh achieves significant improvement both compared to COMSOL and Gmsh, especially in the complex integrated chips. According to the improvements in mesh generation time, there is a super-linear scaling with the complexity of test cases. For simpler 2.5D structures (Chip_2.5D_10_2), NeuralMesh achieves 3.00× speedup versus COMSOL. And for the complex 3D structures (Chip_3D_10_6), this advantage increases dramatically to 45.00×. It is indicated that our segmentation model guided approach becomes increasingly effective as geometric complexity grows. And the performance gain primarily derives from eliminating redundant refinement iterations through predictive thermal distribution.

C. Accuracy of Thermal Simulation

In order to validate the thermal simulation accuracy of the FEM mesh obtained by NeuralMesh, we performed thermal simulation using COMSOL as the solver across FEM meshes generated by NeuralMesh, Gmsh and COMSOL. All the simulations are equipped with identical power distributions

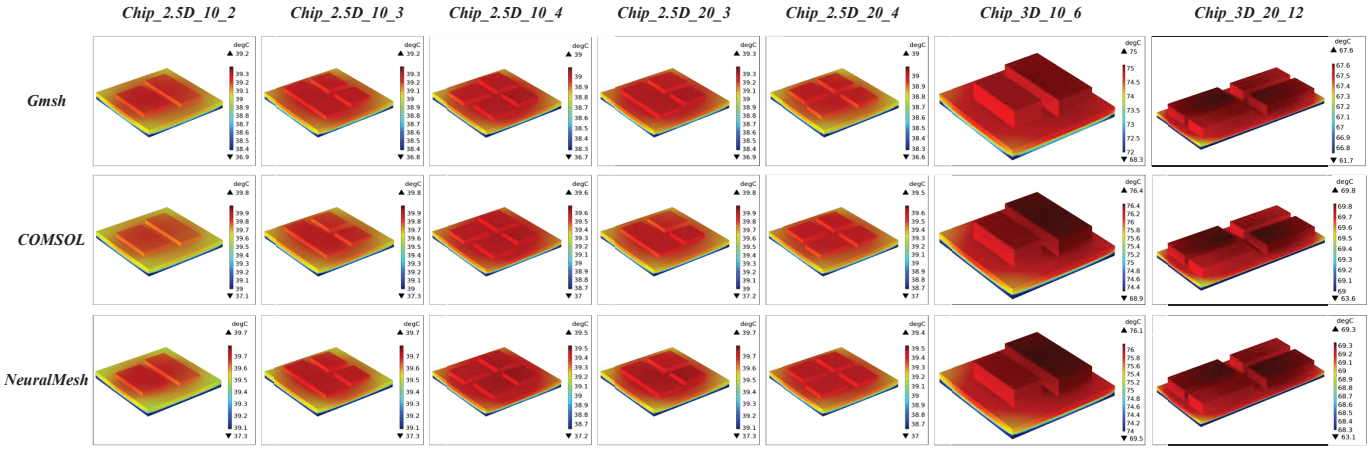

Fig. 4. Thermal Maps of Integrated Chips from Different FEM Mesh Generation Method

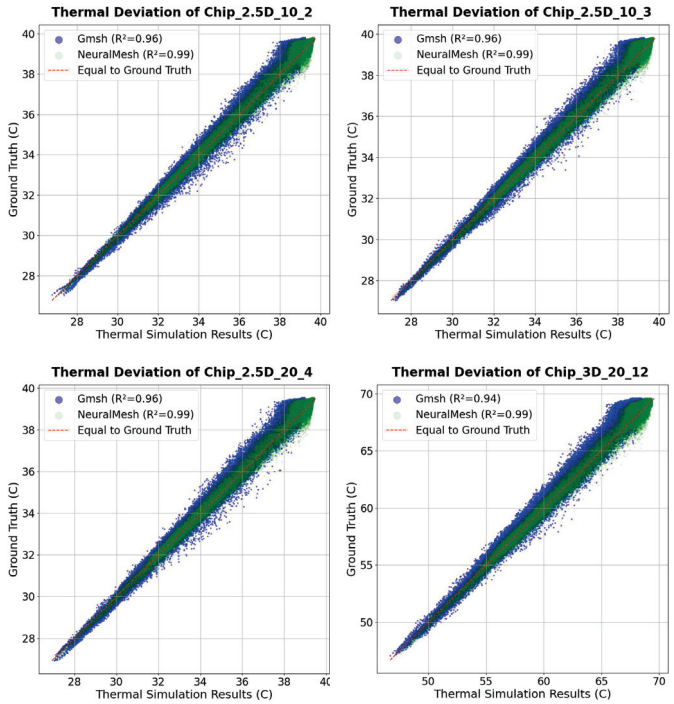

Fig. 5. Thermal Deviation of Representative Benchmarks

and boundary conditions. The Fig.4 presents the thermal maps of benchmarks from different FEM mesh generation methods, with the results of COMSOL serving as the golden reference.

The thermal distribution of the integrated chip main body with the maximum and minimum values of the temperature in Fig.4 directly illustrates the agreement of NeuralMesh and golden reference (COMSOL). The maximum difference in temperature ranges from 0.2 degC to 0.5 degC, which is from the simplest test case (Chip_2.5D_10_2) to the most complex test case (Chip_3D_20_12), and the error percentages are kept within 0.8%. Moreover, according to the comparison between the thermal results from Gmsh and the proposed NeuralMesh, it can be concluded that the thermal simulations based on NeuralMesh are more accurate than the Gmsh-based.

Furthermore, in order to more intuitively compare the accuracy of thermal simulation results based on NeuralMesh and Gmsh, we plot the thermal deviation images of four representative benchmarks including the temperature of the surrounding air field, which are illustrated in Fig. 5. According to the Coefficient of Determination R^2, it can easily obtain that the thermal distribution results based on Gmsh are more scattered than those based on NeuralMesh because their index R^2 are more deviated from *1*.

All these analysis above demonstrate that NeuralMesh achieves substantial computational efficiency without compromising thermal accuracy. The preservation of thermal gradients, particularly in critical regions, validates our approach of coupling neural prediction with geometric refinement criteria.

V. Conclusion

This paper presents NeuralMesh, a novel finite element mesh optimization framework that accelerates the thermal simulation of integrated circuits by combining neural network-based thermal prediction with geometric analysis. Our approach achieves up to 45× speedup in mesh generation while maintaining thermal accuracy within 0.8% of commercial solutions, demonstrating particular efficiency gains for complex 3D packaging structures. While the framework requires significant computational resources for initial training and currently focuses on steady-state analysis, these limitations are outweighed by the dramatic reduction in mesh generation time. The effectiveness of the proposed framework in selectively refining thermally critical regions while minimizing element count represents a significant advancement in thermal-aware IC design, though future work should address dynamic thermal analysis and broader packaging architectures. Despite these constraints, NeuralMesh establishes a new paradigm for efficient thermal simulation of integrated circuits, enabling rapid design iteration without compromising accuracy.

***Abstract*—In this work, we aim to address the computational overhead challenge in quantum optimal control while reducing circuit latency. We propose a novel approach combining ZX-Calculus, circuit partitioning, and circuit synthesis for pulse generation. By implementing finer granularity in pulse generation and exploring equivalent circuit representations, we achieve increased parallelism and decreased latency. Our method demonstrates a 31.74% reduction in latency compared to previous work and a 76.80% reduction compared to gate-based pulse generation methods, while minimizing computational overhead.**

***Index Terms*—quantum optimal control, quantum compilation, quantum circuit optimization**

I. Introduction

Quantum computing has emerged as a promising paradigm with the potential to outperform classical computers in various domains [1], including chemistry [2], machine learning [3], and physical simulations [4]. However, the current Noisy Intermediate-Scale Quantum (NISQ) era [5] presents significant challenges, such as limited qubit count, short coherence times, and high error rates [6]. To exploit the power of NISQ devices effectively, it is crucial to develop efficient quantum circuit optimization techniques that mitigate the impact of noise and errors [7]. The coherence time determines the duration and depth of quantum circuits that can be successfully executed on real quantum hardware. The term "quantum volume" has been proposed to quantitatively describe this property, which takes into account both the number of qubits and the depth of the quantum circuit that can be reliably executed on a given quantum device [8].

A typical quantum program compilation workflow starts with implementing quantum algorithms as quantum circuits. As shown in Figure 1, these circuits undergo compilation passes to become compatible with the hardware topology, including decomposition into basis gates and mapping to the target architecture [9]. Once expressed in basis gates, the gates are converted into physical signals applied to the qubits [10]. For superconducting quantum computers, these physical signals are modulated microwave pulses sent to transmons [11]. The modulated pulses are generated with an envelope that determines their function and a carrier signal.

In the final step of the compilation process, where basis gates are translated to pulses, quantum optimal control (QOC) [12] is used to find optimal control pulses that implement desired unitary operations, minimizing noise and errors [13]. However, QOC has significant computational overhead, limiting its scalability [14]. Previous works have proposed methods to accelerate QOC, such as utilizing GPUs, pre-compilation techniques, and improved circuit libraries [15], [16], [17]. These pulse generation frameworks focus on generating pulses from unitary matrices directly derived from quantum circuits without exploring equivalent representations, thus overlooking optimization opportunities by not adopting coarse-grained methods.

By coarse-grained methods, we refer to existing frameworks such as AccQOC [18] and PAQOC [19], which perform circuit partitioning at the gate level. These methods first group the quantum gates in the circuit and calculate the corresponding unitary matrices for each

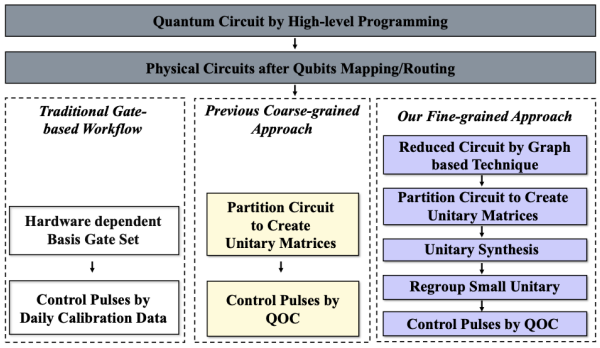

Fig. 1: The diagram compares the traditional gate-based workflow for creating quantum circuits with our novel fine-grained approach.

group. QOC is then applied to these unitary matrices to generate the optimized control pulses. While this approach can provide some benefits in terms of pulse optimization, it is limited by the inherent gate structure of the quantum circuit. If the depth of the circuit blocks does not match, leading to mismatched pulse latencies, the utilization rate of the qubit lines, where the pulses are applied, may not be optimal. This can result in suboptimal performance and longer overall execution times.

In this paper, we aim to propose a fine-grained approach in contrast to the previous coarse-grained methods and traditional workflow, as depicted in Figure 1. Thus, we introduce EPOC, a novel approach that combines ZX-calculus [20], circuit partitioning, and circuit synthesis with QOC to enhance pulse generation. Our main contribution is the development of a finer-grained method for generating quantum pulses, which results in increased parallelism and reduced latency. This is accomplished by partitioning circuits into blocks, computing their corresponding unitary matrices, and applying synthesis techniques to identify equivalent circuits composed of unitary gates. By breaking down relatively large circuit blocks into smaller unitary gates, we create additional opportunities for optimization, enabling more efficient and effective pulse generation. However, directly applying QOC to these small unitary gates, which are the products of synthesis, presents a challenge. The issue arises because these blocks are typically too small to fully leverage the advantages of QOC. To address this, we need to aggregate these blocks to achieve a suitable size that allows for effective application of QOC techniques. Therefore, we introduce a regrouping process for the unitary gates, where different unitary gates and two-qubit gates like CNOT are aggregated into a single unitary matrix. This regrouping technique allows us to further trade classical computational power for quantum computational power while limiting the size of the resulting matrices to avoid excessive computational overhead [18].

Finally, we apply QOC to the regrouped unitary matrices to obtain the optimized microwave pulses for the qubits. By combining QOC

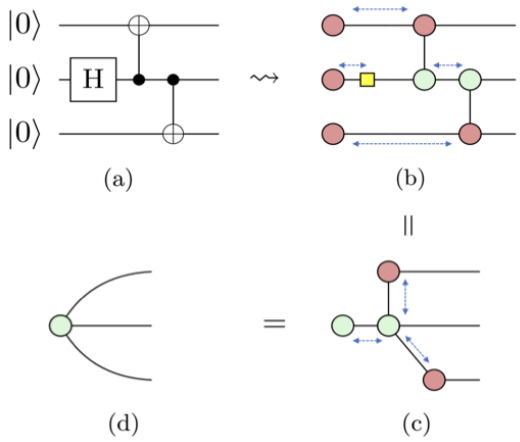

Fig. 2: ZX-Diagram of a GHZ-state preparation circuit. (a) Quantum circuit for preparing a 3-qubit GHZ state $(|000\rangle + |111\rangle)/\sqrt{2}$. (b) Corresponding ZX-diagram. Simplifications are made using rewriting rules such as spider fusion, which is indicated by dashed double-arrow lines for contractable spiders. (c) Further simplification. (d) Final compact representation of the GHZ state [21].

with the synthesized and regrouped unitary matrices, we generate highly optimized and robust quantum circuits tailored to the specific characteristics of the target quantum hardware.

The main contributions can be summarized as follows:

- We propose EPOC, a framework that identifies the optimal circuit size for combining QOC with synthesis techniques to enable efficient pulse generation while managing compilation overhead.
- We introduce a regrouping strategy that combines quantum gates into optimally-sized (not smallest but balanced) unitary matrices to achieve a balance between synthesis optimization potential and QOC benefits.
- We demonstrate through extensive benchmarking that this balanced approach achieves significant improvements in circuit latency and compilation efficiency compared to existing methods.

The remainder of this paper is organized as follows. Section I provides an introduction, followed by the background information in Section II. We introduce our proposed framework, EPOC, in Section III. The evaluation of EPOC is presented in Section IV. Section V discusses related work, and we conclude the paper in Section VI.

II. Background

A. ZX-Calculus

The ZX-calculus, developed by Bob Coecke and Ross Duncan [22], [23], offers a graphical language tailored for representing quantum states and operations on qubits. It utilizes the formalism of string diagrams, with Pauli-X and Pauli-Z matrices as representing basis, thus termed ZX-diagrams. ZX-diagrams represent the topological configuration of quantum circuits, allowing transformations that do not alter qubit connections due to their topological invariance. The calculus includes a set of graphical rewrite rules, collectively known as the ZX-calculus rules. Fundamentally, ZX-diagrams are composed of building blocks called "spiders", which represent various quantum computing elements such as isometries, states, unitary operations, and measurements in specific bases. These diagrams feature nodes colored in green and red, where green nodes correspond to the computational basis states $|0\rangle$ and $|1\rangle$, and red nodes represent the Hadamard-transformed basis states $|+\rangle$ and $|-\rangle$. Additionally, Hadamard nodes are depicted as yellow boxes. Connections in the diagram are made by wires, which can curve, cross, and contract. In Fig. 2, we give an example showing the ZX-diagram of a GHZ state which illustrates the ZX-Calculus and the rewriting rule for circuit simplification.

The theoretical foundation of ZX-Calculus is rooted in the field of dagger compact categories [24], a discussion of which is beyond the scope of this paper but can be explored in further readings [25]. ZX-calculus has found application in various domains of quantum information and computation, including measurement-based quantum computation [26], quantum error correction [27], [28], and quantum circuit optimization [29]. The application of ZX-calculus to quantum circuit optimization is particularly relevant to ours.

B. Synthesis

Quantum circuit synthesis plays a crucial role in quantum computing by generating efficient and optimized quantum circuits from high-level mathematical descriptions of quantum algorithms. Synthesis techniques aim to decompose unitary matrices, representing quantum transformations, into a sequence of elementary quantum gates that can be directly executed on quantum hardware [30]. The quality of synthesized circuits is typically evaluated based on the number of gates, particularly the count of expensive two-qubit gates like CNOT, as well as the overall circuit depth [31]. Shorter circuits with fewer gates are highly desirable, especially for NISQ devices characterized by limited coherence times and noisy operations. Effective synthesis methods can significantly reduce the computational overhead and improve the reliability of quantum algorithms on real hardware [32], [33]. Moreover, quantum circuit synthesis enables hardware design exploration, algorithm discovery, and circuit optimization. Existing synthesis approaches can be broadly categorized into top-down methods, which employ rule-based decomposition techniques, and bottom-up methods, which utilize numerical optimization and search strategies to construct circuits incrementally.

C. Quantum Optimal Control

In the context of a closed quantum system, the dynamics can be described by a Hamiltonian, given as:

$$H(t) = H_0 + \sum_{j=1}^{n} u_j(t) H_j, \tag{1}$$

where H_0 represents the drift Hamiltonian that accounts for the intrinsic evolution of the system, and H_j are the control Hamiltonians modulated by time-dependent control signals $u_j(t)$. The temporal evolution of the quantum state $|\psi\rangle$ in this system is governed by the Schrödinger equation:

$$\frac{d}{dt}|\psi(t)\rangle = -iH(t)|\psi(t)\rangle, \tag{2}$$

assuming the initial state of the system at time $t = 0$ is $|\psi(0)\rangle$.

QOC aims to determine the optimal control signals $u_j(t)$ that transition the system from an initial quantum state to a desired target state. This control strategy is particularly critical in achieving precise state transformations while considering system constraints and minimizing operational errors. To optimize the control signals, QOC employs a cost function, typically defined in terms of the fidelity between the achieved unitary transformation induced by the applied control signals and a desired unitary goal. This fidelity metric quantifies the accuracy of the state transformation. Advanced algorithms such as Gradient Ascent Pulse Engineering (GRAPE) [34] and Chopped

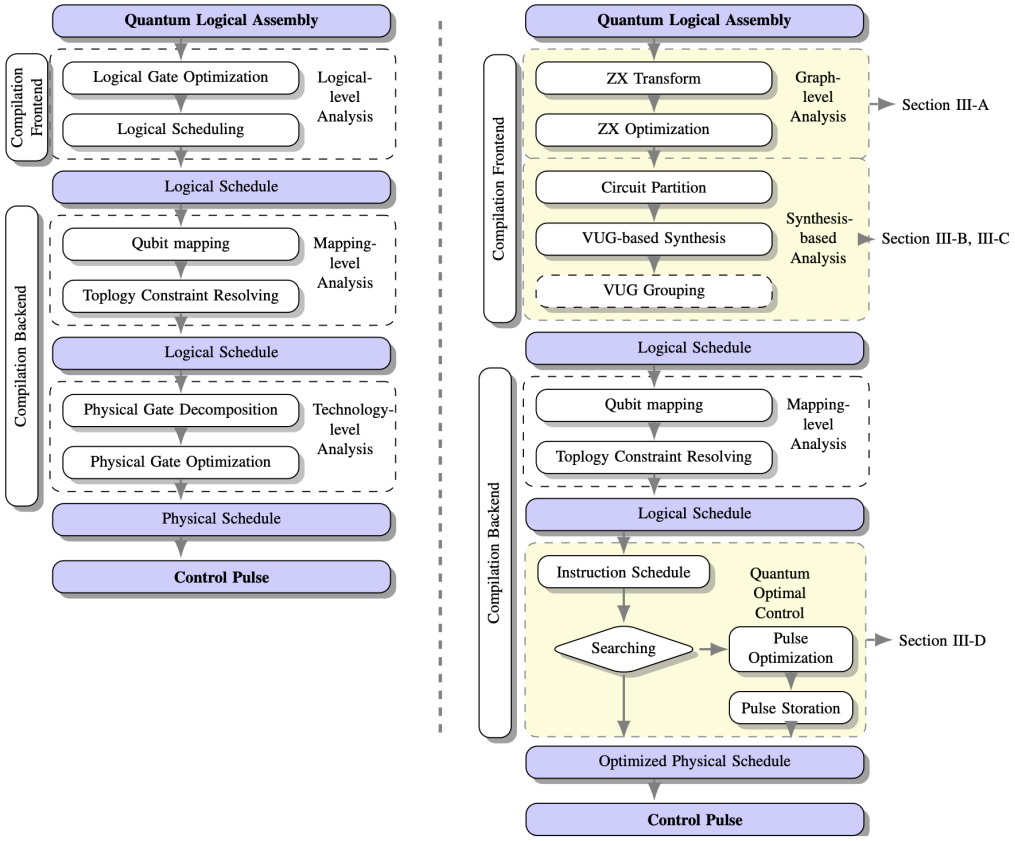

Fig. 3: The comparison between standard gate-based compilation (left) and our approach (right). The colored areas highlight the differences.

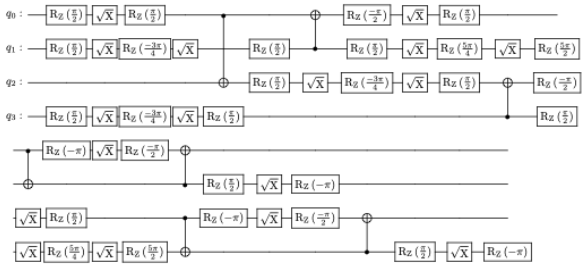
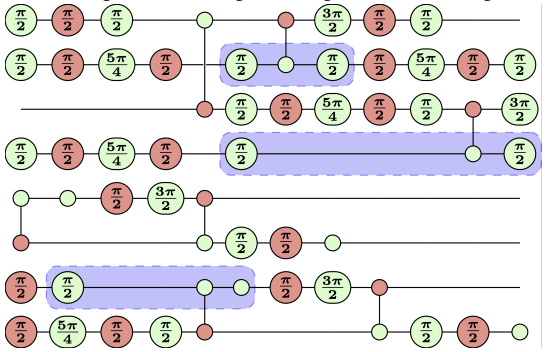
Random Basis (CRAB) [35] are utilized to systematically solve the QOC problem. These methods iteratively adjust the control signals to maximize the fidelity, ensuring that the final quantum state closely approximates the target state.



III. Methodology

In this section, we present the methodologies employed in EPOC to accelerate pulse generation. As shown in Figure 3, EPOC consists of several steps, each of which will be discussed in detail throughout this section. We will provide a comprehensive explanation of the techniques and algorithms used in each stage of the EPOC process, highlighting their contributions to improving the efficiency and effectiveness of pulse generation.



A. Graph-based Depth Optimization

After converting the input circuit into a ZX graph, the gates in the circuit are analyzed to determine if they can be delayed and potentially cancelled against future gates or combined with other gates. This process, known as gate commutation, allows for circuit optimization and depth reduction. For instance, a NOT gate can be placed on either side of a CZ gate for both control and target qubits without altering the gate's functionality. Similarly, a Z gate on the control qubit can be commuted through a CNOT gate if a Z gate also appears on the target qubit, and a NOT gate on the target qubit can be commuted through a CNOT gate if a NOT gate also appears on the control qubit. However, a Hadamard gate cannot be commuted through a CZ gate or a CNOT gate due to its non-commutative properties. Gate commutation enables the aggregation of gates, leading to a reduction in circuit depth. For example, a NOT gate and a Hadamard gate can be combined into a Z gate, while a Z phase gate can be aggregated with a NOT gate, Z phase gate, or T gate by adjusting the rotation phase. Additionally, a pattern consisting of a Z phase gate between two Hadamard gates is transformed into a Hadamard gate between two Z phase gates with negative phases to enhance commutativity and aggregation capabilities. Such a process is simplified with ZX graphs, as in a ZX graph, nodes in the same color are commutative and can be combined into a single node. Apart from gate commutation and gate aggregation, other ZX-calculus rules such as spider fusion are applied to simplify the circuit representations and further reduce the complexity of the quantum circuit. In our work, we utilize PyZX [36], a Python library designed for simplifying ZX-diagrams and optimizing quantum circuits.

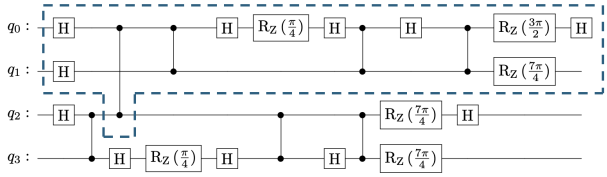


Figure 4 demonstrates a concrete example of the transformation and optimization process. In this example, we consider a bell state preparation circuit with four qubits. The first step involves transforming the original circuit into a ZX graph representation, under the rules provided by ZX-calculus. Once the quantum circuit has been represented as a ZX graph, we can employ optimization methods to simplify the circuit. As shown in Figure 4b, the nodes in the blue boxes of the same color are commutative and can be aggregated into a single node. We iteratively search for such patterns in the graph, ultimately resulting in a simplified and shallower quantum circuit. The optimized ZX graph can then be transformed back into a quantum circuit representation, and the circuit depth is reduced from 23 to 14, resulting in a more efficient and compact version of the original bell state preparation circuit. This example highlights the power of using ZX-calculus and graph-based optimization techniques to simplify quantum circuits. Furthermore, we remark that ZX-calculus for optimization is generally universal for most quantum circuits. For 34 randomly selected circuits, an average depth reduction of 1.48 times is observed as indicated in Figure 5. On extreme occasions, the circuit depth of a variational quantum eigensolver (VQE) is reduced from 7656 to 1110.

Fig. 4: Graph-level optimization steps of the Bell state preparation quantum circuit.

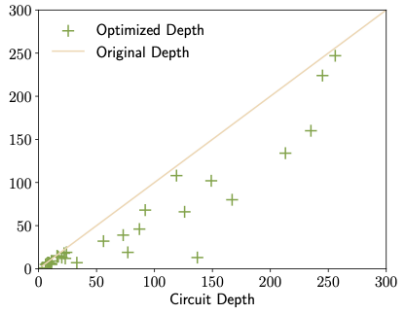

Fig. 5: ZX optimization results for 34 randomly selected quantum circuits. An average depth reduction of 1.48 times is observed across the selected circuits.

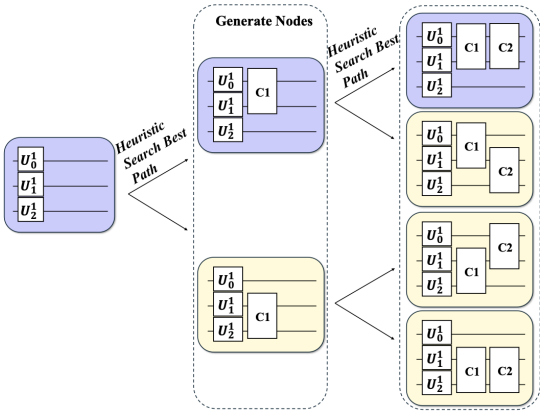
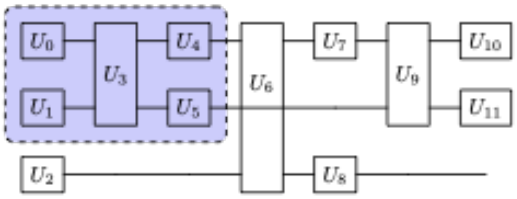
B. Greedy Circuit Partition

After processing the circuit using ZX-calculus, we employ a greedy partitioning algorithm to divide it into smaller blocks for synthesis. The algorithm begins with horizontal cutting, grouping qubits together to form initial blocks, followed by vertical cutting to fill each block with as many gates as possible up to a predetermined size limit. By filling the blocks with gates, we ensure each block contains enough operations to benefit from synthesis, with minimal overhead introduced by vertical cutting. The prior ZX-calculus optimization enhances the effectiveness of the greedy partitioning algorithm. ZX-calculus simplifies the circuit by reducing it to a small gate set, resulting in a more uniform structure. This uniformity makes the circuit particularly suitable for the greedy partitioning approach, allowing for a balanced and efficient distribution of gates among the blocks. Figure 4c illustrates the partitioning process, showing a typical circuit block enclosed within a rectangular region after partitioning. These blocks are now ready for the subsequent circuit synthesis process, which will further optimize and transform them into a more compact representation. By combining ZX-calculus optimization with greedy circuit partitioning, we effectively decompose large quantum circuits into smaller, more manageable blocks.





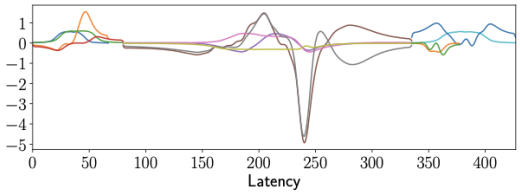


Fig. 6: Illustration of the quantum circuit synthesis process. The synthesis begins with an empty circuit and iteratively generates new nodes by inserting gates at different positions. Each node represents a candidate quantum circuit. The search for the optimal circuit follows the A algorithm, which evaluates nodes based on a cost function that measures the distance between the target unitary matrix and the unitary matrix of the synthesized circuit. The search continues until a circuit that accurately approximates the target unitary matrix with minimal size is found. The resulting synthesized circuit consists of variable unitary gates (VUGs) and CNOT gates.

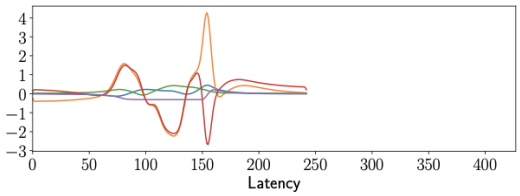
C. Circuit Size Optimization: Balancing Synthesis and QOC



After the greedy circuit partitioning, we obtain a list of grouped gates. We then calculate the unitary matrices of these grouped gates. Since we limit the size of the groups, the computational overhead here is negligible and totally acceptable. In fact, we note that the overhead to compute the unitary matrices remains manageable even with very deep circuit blocks, as long as the number of qubits is moderate. Once we have the unitary matrices of circuit blocks, we leverage insights from QSearch [37] to develop our VUG-based circuit synthesis approach within the BQSKIT [38]. Our synthesis process generates a quantum circuit composed of VUGs and CNOT gates, as illustrated in Figure 6. The synthesized circuit shown in Figure 7a achieves a depth reduction from 11 to 7 compared to the original circuit in Figure 4c. However, a key observation emerges: while traditional synthesis approaches aim to minimize circuit size, this may not be optimal when combining synthesis with QOC. Our analysis reveals that fine-grained VUGs limit the potential benefits of QOC. This insight led us to develop a strategic regrouping approach that creates optimally-sized unitary matrices for QOC processing. Figures 7b and 7c demonstrate the significant impact of this approach: direct pulse generation from individual VUGs results in higher circuit

(a) The synthesis result of the partitioned circuit in the blue box of Fig 4c.

(b) Illustration of the Pulse generation for each gate within the purple box in Fig 7a.

(c) Pulse generation for the entire purple box in Fig 7a, treating all gates as a single grouped unitary.

Fig. 7: The comparison between circuit synthesis + QOC before regrouping strategy and after implement regrouping stratey.

latency, while our regrouping strategy (purple box in Figure 7c) substantially reduces pulse latency. This finding emphasizes the importance of identifying the sweet spot in circuit size that maximizes the combined benefits of synthesis and QOC.

D. Pulse Generation

In our proposed framework EPOC, our methodologies are built upon prior works AccQOC [18] and PAQOC [19]. We employ QOC techniques to generate a pulse library, which essentially serves as a lookup table. The indices of the table are unitary matrices, and each entry stores the corresponding microwave pulses. The techniques in AccQOC and PAQOC involve a binary search to determine a short pulse latency for a given unitary matrix as input. Specifically, the QOC we employ is implemented using the GRAPE algorithm [34], where pulses are divided into segments or time slots with constant values, forming a pulse sequence. The GRAPE method optimizes the time slots according to a cost function, often defined as the fidelity between the pulse unitary and the target unitary, adjusting pulse strengths during each time slot based on gradients. However, pulse simulation and optimization are computationally expensive, which limits the scalability of QOC; thus, we limit the size of the unitary matrices input to the QOC algorithm. Once we have obtained the pulse library, we can accelerate future QOC processes by directly fetching pre-existing pulses for unitary matrices already present in the library. During this process, we also consider the global phase when comparing unitary matrices. In contrast to the previous works on accelerating QOC, EPOC supports the detection of unitary similarity with global phase, allowing us to identify more matched unitary matrices, similar to having a higher cache hit rate.

IV. Evaluation

The experiments were conducted on a Linux-based system with Debian 5.10.179-1 operating system, using 8 nodes. Each node is equipped with 32 cores and 256GB of RAM.

As the first to introduce synthesis into the workflow of QOC, we compare the results from: (1) applying QOC directly on the synthesized circuits and (2) grouping the synthesized results before running QOC. As shown in Figure 8, Figure 9 and Figure 10, we demonstrate although both settings have similar compilation times, our method with an extra grouping step significantly reduces circuit latency and increases circuit fidelity. We evaluate our methods using 17 benchmarks from QASMBench [39], showcasing the effectiveness of incorporating the grouping step in the QOC workflow.

The fidelity is calculated as the accumulated fidelity of each quantum pulse. Specifically, we calculate the fidelity of each pulse and then multiply these fidelities together for all the pulses in the circuit. The fidelity of each individual pulse is determined by the distance between the unitary matrices before and after QOC. This calculation can be described by the following equation:

$$ESP = \prod_{i=1\ldots n} (1 - |U_i - H_i(t)|) \tag{3}$$

where ESP represents the estimated total fidelity of the quantum circuit, n is the number of pulses, U_i is the target unitary matrix for the i-th pulse, and $H_i(t)$ is the unitary matrix achieved by the optimized pulse after applying QOC. The term $|U_i - H_i(t)|$ calculates the distance between the target and optimized unitary matrices for each pulse, and $(1 - |U_i - H_i(t)|)$ represents the fidelity of the i-th pulse. The product of these pulse fidelities gives the overall fidelity of the entire quantum circuit.

Across the 17 benchmarks from QASMBench [39], our method achieves an average reduction of 51.11% in pulse latency with only a 7.11% increase in compilation time by incorporating a regrouping step after synthesis in the QOC workflow. Furthermore, our approach manages to increase the circuit fidelity by an average of 33.77%. These results demonstrate that the regrouping step is necessary and beneficial for reducing circuit latency without introducing significant overhead, highlighting the effectiveness of our proposed method in enhancing the performance of quantum circuits.

We compare our results with both PAQOC [19] and AccQOC [18], two recent works on quantum optimal control. As shown in Table I, our approach achieves significant latency reductions: 31.74% compared to PAQOC and 71.23% compared to AccQOC. Moreover, we consistently report higher fidelity values compared to both approaches - our method achieves an average fidelity of 0.974, surpassing AccQOC's average of 0.890 across all circuits, while also outperforming PAQOC's reported fidelities where data is available. This dual improvement in both latency and fidelity demonstrates the effectiveness of our framework. We attribute these improvements to our novel circuit synthesis process, which effectively optimizes quantum circuits before the QOC step, resulting in reduced latency and increased fidelity. While our synthesis process adds extra computational workload compared to both PAQOC and AccQOC, it mainly involves local entanglement and unitary calculations that can be executed in parallel. Therefore, our approach maintains scalability while significantly reducing pulse latency. We validated our framework by testing it with a large and deep 160-qubit quantum program, obtaining meaningful results. Although this data point isn't in our table due to the lack of comparable data from other methods, it confirms the feasibility and scalability of our approach.

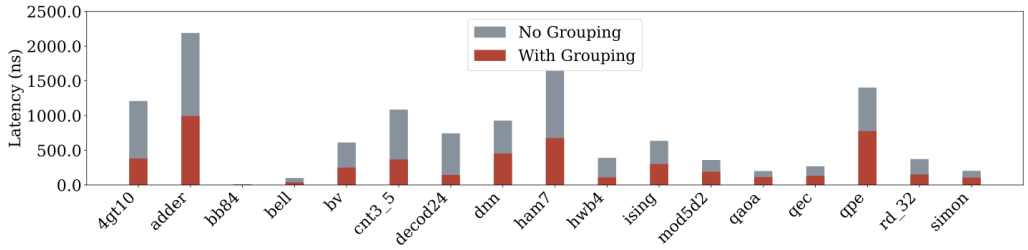


Fig. 8: The latency before and after grouping. We show through the results that the grouping can reduce the circuit latency.

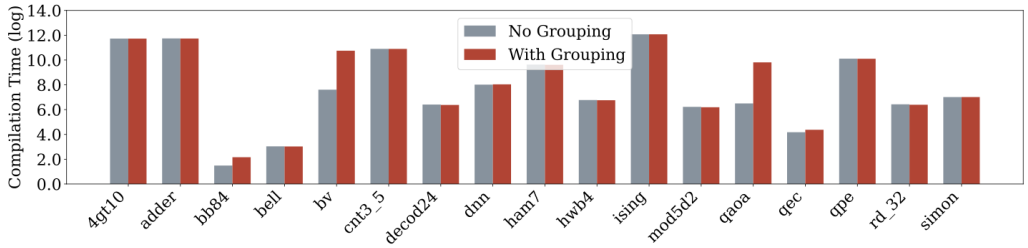

Fig. 9: The compilation time with and without grouping of quantum gates before the final QOC step. This indicates that the latency reduction benefits can be achieved through grouping without incurring a significant increase in compilation time.

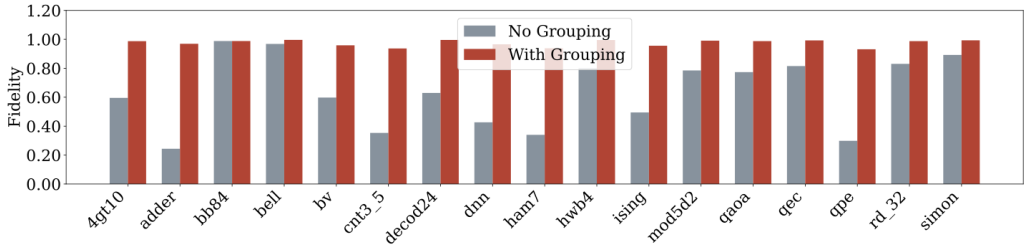

Fig. 10: The fidelity of quantum circuits with and without grouping. The results can be attributed to the fact that the no-grouping approach operates at a very fine granularity, which can lead to the accumulation of errors during the QOC process.

Circuit	Latency (ns)				Fidelity			
	Gate-based	AccQOC [18]	PAQOC [19]	EPOC	AccQOC [18]	PAQOC [19]	EPOC
simon	469	175.22	141.23	**92**	0.91	-	**0.984**
bb84	56.5	24.07	13	**10**	0.659	0.981	**0.988**

ham7	5238.5	1553.09	1186.5	**675.5**	0.920	-	**0.938**

TABLE I: Comparison between AccQOC [18], PAQOC [19], and EPOC (our approach) for 7 widely applied quantum circuits. In most scenarios, EPOC returns a generation result with shortened latency and increased fidelity. On average, our approach achieves a 31.74% reduction in latency compared to PAQOC [19] and a 76.80% reduction compared with the gate-based method to create pulse sequences. The '-' indicates PAQOC returns fidelity as 0 for the corresponding task.

V. Related Work

A recent work AccQOC [18] employs a novel approach by segmenting the quantum circuit into small, uniform subcircuits, each comprising two qubits. It then builds a pulse database for these subcircuits, storing previously generated pulses for efficient reuse. To streamline this process, AccQOC utilizes a similarity graph that maps the distances between different fixed-size subcircuits, including those not currently in the database. The Minimum Spanning Tree (MST) of this graph is then calculated to optimize the order in which control pulses are constructed for the subcircuits. This method significantly enhances the efficiency of pulse compilation, reducing overall time requirements. A more recent work, PAQOC [19], is automatically detecting common gate patterns through subgraph mining for expanded search space exploration. It also systemically constructs customized gate-sets based on their impact on overall program latency and quickly adapts to system recalibrations with its small-scale pattern-based gate generation. However, all the aforementioned compilation strategies generate pulses directly from the partitioned circuit group. Therefore, the group size is constrained due to the unmanageable overhead of pulse generation for large unitaries.

VI. Conclusion

In this paper, we introduced the EPOC framework, integrating ZX-calculus, circuit partitioning, and synthesis techniques with QOC to enhance pulse generation efficiency in quantum circuits. EPOC employs refined granular optimization to significantly reduce circuit latency and computational overhead while increasing parallelism. By strategically regrouping unitary matrices and optimizing their configurations, EPOC improves the scalability of QOC processes and demonstrates considerable performance enhancements in NISQ devices. We achieve notable improvements in pulse generation speed and circuit performance, including an average 31.74% reduction in circuit latency over PAQOC and 71.23% compared to AccQOC. These results indicate significant potential for applying EPOC in practical quantum computing scenarios.

***Abstract*—Boolean decomposition is a powerful technique in logic synthesis that breaks down Boolean functions into simpler components. Decomposition-based logic synthesis yields high-quality results and is particularly effective when combined with small-window optimization methods in Gate-Inverter Graphs (GIG). However, the efficiency limitations of current methods have constrained their applicability in handling large and complex logic. To address this challenge, we propose a novel framework, called *EDGE*, which leverages modern database techniques to accelerate Boolean decomposition, thereby achieving improved synthesis results while maintaining high efficiency. Experimental results demonstrate a runtime speedup of up to 21× and an overall reduction in node count of at least 15% compared to state-of-the-art synthesis methods.**

I. INTRODUCTION

The transformation from a two-level Sum-of-Product (SOP) to a multi-level logic is a key process that affects the area of synthesized circuits. The modern workflow of the transformation process, as shown in Figure 1①, simplifies the input SOP and optimizes it by extracting divisors [1]. From the optimized SOP, a Gate-Inverter Graph (GIG), a data structure used to represent multi-level logic implementations, is generated. A series of small-window optimization methods are subsequently applied to the GIG. This workflow is efficient and generally effective. However, it lacks control over the GIG structure, creating a gap between simpler SOPs and simpler GIGs. Despite some factoring methods intended to enhance logic sharing, these methods are coarse-grained and rely heavily on structural hashing for more localized sharing [2], which is insufficient. Moreover, internal Don't Cares (DCs) are ignored during the transformation and must be recomputed during small-window GIG optimization. To address these issues, Boolean decomposition has been proposed for the transformation [3].

Boolean decomposition is a powerful but time-consuming technique to break down a complex Boolean function into simpler sub-functions. For a given input subset, i.e. the bound set, it extracts a minimal sub-function from the original function, effectively utilizing Don't Cares (DCs) and discovering logic sharing. Figure 1② shows a typical decomposition-based transformation workflow, where the function is repeatedly decomposed until each sub-function is at the gate level, and is converted into a GIG. To improve efficiency, many approaches use single-output disjoint support decomposition (DSD) with binary decision diagrams (BDDs) [3], [4]. BDDs limit the solution space and ignore logic sharing among primary outputs which leads to larger GIGs. Additionally, gate-level decomposition on BDDs is unnecessary, as decomposing small functions is generally less effective compared to SOP-based transformation.

Considering the above limitations, we adopt multi-output Boolean decomposition and propose the transformation flow as shown in Figure 1③. We use multi-output decomposition to break down large functions into small-size sub-functions ($\leq$ 6 inputs) and then synthesize them using the SOP-based workflow. This pipeline allows us to control the overall multi-level structure while achieving effective GIG implementations for each sub-function. To realize this workflow, we face two main challenges:

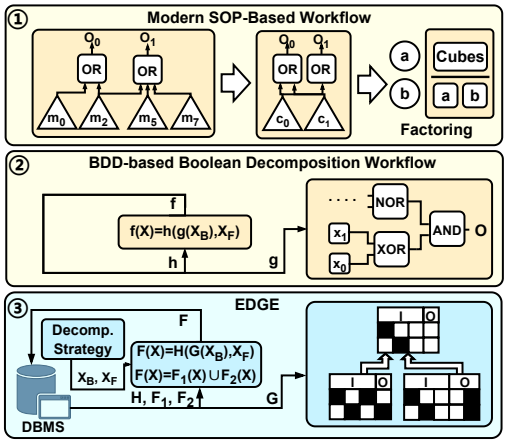

Fig. 1: Comparison of different transformation workflows. ***EDGE*** is our proposed workflow.

1. Multi-output Boolean decomposition faces efficiency challenges due to its NP-hard nature, which limits the size of functions to be processed. Existing solutions use set algebra to form the decomposition process [5], [6], but this approach is difficult to implement and fails to address the runtime problem.
2. The solution space for decomposition grows exponentially with the size of the input set. To the best of our knowledge, there is no framework that can effectively make decisions for a long decomposition chain.

To tackle these challenges, we present the following contributions and results:

- We improve the efficiency of Boolean decomposition using a Database Management System (DBMS). By formulating the decomposition as relational query operations, we optimize its time complexity and leverage various DBMS techniques to accelerate the process.
- We propose a novel Bool**E**an decomposition-based **D**BMS-accelerated **G**IG synth**E**sis framework, ***EDGE***, to manage the continuous decision process of decompositions and schedule the synthesis of each sub-function.
- We propose multiple decomposition strategies for different types of functions. To implement these strategies, we design two heuristic output clustering algorithms for parallel decomposition and introduce an efficient bound set search method for filtering high-quality decompositions.
- We conduct extensive evaluations on ***EDGE***. The results demon-

strate that our framework achieves up to 21× speedup in multi-output decomposition compared to existing methods, while reducing the total GIG size by at least 15% compared to state-of-the-art (SOTA) SOP-based transformation methods.

II. PRELIMINARIES

A. Definitions

Boolean Functions. A Boolean function maps a set of Boolean variables to a single Boolean output, denoted as $y = f(X)$, where y is the *output variable*, f is the *Boolean function*, and $X = \{x_0, x_1, \dots\}$ is the set of *input variables*. When multiple Boolean functions share the same input set X, they can be represented as $Y = F(X)$, where $Y = \{y_0, y_1, \dots\}$ is the set of output variables and $F = \{f_0, f_1, \dots\}$ is the corresponding set of Boolean functions. In this case, F is called a *multi-output Boolean function*. For the remainder of this paper, we use "Boolean functions" to refer to both single-output and multi-output Boolean functions.

Truth Tables. A truth table records the input-output relationships of Boolean functions in a tabular form. A specific combination of input or output values is called a *pattern*. In logic synthesis, due to the presence of *don't cares* (DCs) in designs, a truth table may omit some input patterns, resulting in an *incompletely specified* truth table. **Sum of Products** (SOP) is a compact representation of a truth table with DC values in input and output combinations. Each row in the SOP is called a cube.

Boolean Network. A Boolean network is a directed acyclic graph (DAG) representing Boolean functions [7]. A **Gate-Inverter Graph** (GIG) is a type of Boolean network. A GIG consists of a single type of logic component, and each node has a fixed in-degree (typically 2). Logic NOT gates can be placed on the edges. Common types of GIGs include AND-Inverter Graphs (AIGs), XOR-Inverter Graphs (XIGs), and Majority-Inverter Graphs (MIGs) [8].

Boolean Decomposition. Boolean decomposition is a technique used to break down a Boolean function into simpler sub-functions. Given a Boolean function $Y = F(X)$, there are two types of Boolean decomposition operations [5]:

- *Serial Decomposition.* A serial decomposition extracts a sub-function from a subset of input variables. The decomposition $Y = H(G(X_b), X_f) = F(X)$ is a serial decomposition of F, where $X = X_b \cup X_f$, X_b is the *bound set*, X_f is the *free set*. H and G are sub-functions of Y, and the set $X_s = X_b \cap X_f$ is called the *shared set*. If $X_s = \emptyset$, the decomposition is a *disjoint support decomposition* (DSD). G can be a multi-output Boolean function, and its number of output variables is denoted as $|G|$. For a bound set X_b and a free set X_f in the same serial decomposition, we refer to (X_b, X_f) as a *bound-free pair*.
- *Parallel Decomposition.* A parallel decomposition splits the output set into new sub-functions. If $Y = Y_0 \cup Y_1 \cup \dots$ is a disjoint split of Y, where $Y_i \cap Y_j = \emptyset$ for any $i \neq j$, then $Y_0 = F_0(X), Y_1 = F_1(X), \dots$ is a parallel decomposition of Y, where $F_0, F_1, \dots$ are sub-functions of F.

Relational Algebra Operators. The relational algebra operators used in this paper are listed below [9]:

- σ_θ (select): filtering rows in a relation based on the specified condition θ.
- $\times$ (cartesian-product): producing a relation that is the combination of every tuple in two relations.
- Π_A (project): extracting the specified column set A from a relation, with duplicates removed.
- $\bowtie_\theta$ (join): combining tuples from two relations based on a matching condition θ.

B. Related Works

The inspiration for this work primarily comes from multi-output Boolean decomposition on SOPs [5], [6] and support-reducing decomposition synthesis [3], [4].

In the studies on multi-output decomposition, two basic operations were defined for SOPs: serial decomposition and parallel decomposition [5], [6]. To unify operations on DCs and 1s and 0s, complex set systems were used to build the serial decomposition process, making it difficult to implement and resulting in inefficiency. However, in practice, simplified SOPs do not always have significantly fewer rows than truth tables. Thus, for ease of implementation and optimization of efficiency, we adopt truth tables instead of SOPs. Additionally, no prior work provided a decomposition strategy suitable for modern-scale functions, which motivated us to design ***EDGE***.

In the study on BDD-based DSD for GIG small-window optimization [3], the potential of Boolean decomposition to discover good GIG structures was demonstrated. However, limited by BDD, an inefficient and complex process for logic sharing was required, restricting the window size to 30 nodes and 8 inputs, which reduced the overall effectiveness. In another study [4], the same technique was applied on a larger scale, focusing on reducing the LUT count after mapping rather than optimizing the GIG area. In the process, small-window optimizations were combined to improve the quality of results, but single-output decompositions ignore logic sharing among primary outputs, limiting the effectiveness.

Based on the strengths and addressing the weaknesses of these existing works, we aim to accelerate multi-output Boolean decomposition and extend its applicability to 16 inputs, thereby achieving a better structure on a larger scale and reducing overlap with small-window optimization for improved results.

This work is also influenced by other decomposition-related algorithms, including LUT network optimization [10]–[12] and decomposition method acceleration [13]–[15].

III. *EDGE*

EDGE is a novel framework that utilizes Boolean decomposition for logic synthesis, integrating a DBMS [9] to facilitate large-scale multi-output Boolean decompositions. However, as the scale of processed Boolean functions increases, the solution space grows exponentially, posing substantial challenges to scalability improvements. Therefore, a framework is necessary to evaluate solutions, reduce the search space, and manage the synthesis process. The architecture of ***EDGE***, as depicted in Figure 2, is specifically designed to meet these requirements. Below, we outline the workflow of ***EDGE*** and provide detailed explanations of each component involved.

Workflow. The input truth table is initialized as a Truth Table Unit, which then becomes the root unit node of the Decision Tree, denoted as U_0, and is recorded in the Edge Node Pool. The Decomposition Manager starts working by extracting U_0 from the pool and finding potentially valuable decompositions for the truth table. The selected operations are applied to the unit to generate sub-functions and update the Decision Tree.

The sub-functions are then initialized as new Truth Table Units. If a sub-function's input set size is below a predefined threshold, the unit is marked as terminal and passed to an external GIG synthesis tool [16] for implementation. Non-terminal nodes are added to the Edge Node Pool, and the process repeats until the pool is empty and all edge nodes in the Decision Tree are terminal.

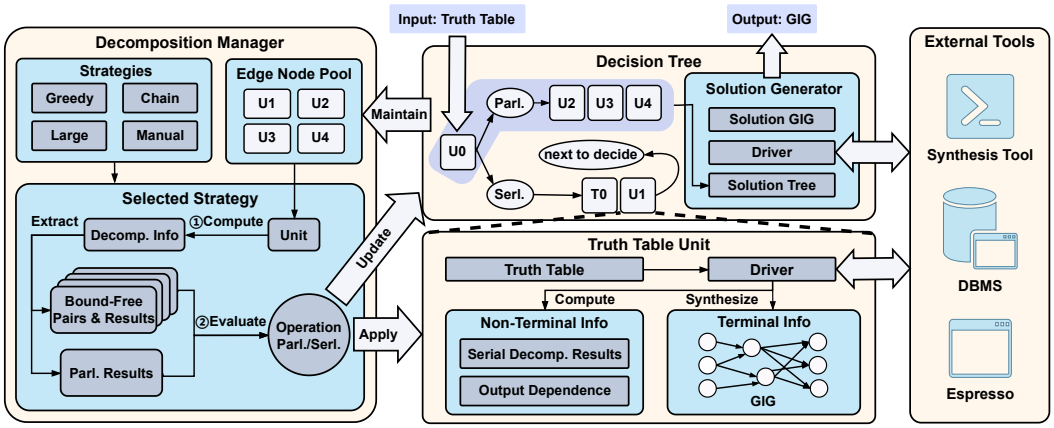

Fig. 2: Architecture of ***EDGE***. Parl. and Serl. are short for parallel and serial decomposition operation nodes. **T** for terminal nodes, **U** for truth table unit nodes.

The Decision Tree can record multiple decomposition-based synthesis solutions, each corresponding to a subtree known as a Solution Tree. By using Solution Trees, the GIGs of sub-functions can be composed, with small-window optimizations performed via the external synthesis tool, resulting in the final GIG output.

Truth Table Unit. The Truth Table Unit serves as the foundational structure in ***EDGE***. It stores the truth table and provides interfaces for decomposition operations and GIG implementation. The truth table is managed within the DBMS, which greatly reduces memory usage and accelerates decompositions. Espresso [17] is used to compute each output's support set for clustering during parallel decomposition.

A unit is marked as terminal when its truth table size is below a specified threshold. This approach is based on the observation that combinations of GIG small-window optimization methods can achieve near-optimal implementation for truth tables with up to 6 inputs in a very short time.

Decision Tree. The Decision Tree serves two main purposes: tracking the synthesis process and generating the final GIG output. Each truth table unit is considered a unit node in the tree.

For a function, there are many possible decomposition paths; the Decomposition Manager strategically selects a small subset of these paths to minimize the solution space. After each decomposition, multiple sub-functions are produced, and the Decision Tree records this entire process.

A sub-tree of the Decision Tree, called the Solution Tree, tracks a complete decomposition-based synthesis process. By traversing the operation nodes of a solution tree in the reverse topological order, the solution GIG is composed. Finally, the GIG implementation of the root node is obtained. Each solution tree yields a different root GIG, and the optimal one is selected as the final output.

Decomposition Manager. The Decomposition Manager determines the decomposition type and details (bound set, free set, or output split) for the nodes from the Edge Node Pool.

Different types of Boolean functions require different strategies to ensure high-quality decomposition. The strategy begins by testing a set of potential decomposition results. These results are then evaluated to determine the final operations. Multiple algorithms are proposed to support the strategies. Details are provided in Section IV.

IV. TECHNIQUES

A. Database-Accelerated Serial Decomposition

Serial decomposition is the core algorithm in ***EDGE*** and is executed many times within a transformation process, thus requiring high efficiency. However, it involves solving an NP-hard problem, and the demand for accuracy makes it hard to approximate the process. Existing works rely on complex set systems, which are challenging to implement and introduce unnecessary computation. To tackle these problems, we use relational algebra query operators to build the algorithm. The algorithm is divided into two stages: Prepare and Commit. For a serial decomposition $Y = F(X) = H(G(X_b), X_f)$, the Prepare phase computes the G sub-function, and the Commit phase computes the H sub-function.

Prepare Phase. The Prepare phase is illustrated in Algorithm 1. Before explaining the process, we first introduce several key concepts and a lemma:

- **Bound / Free / Output Pattern.** The pattern represents a specific set of Boolean variable assignments for the bound set, free set, and output set, respectively.
- **Conflict Pair.** A conflict pair is defined as a tuple of two bound patterns, $\langle X_{bi}, X_{bj} \rangle$, derived from two rows in a truth table, denoted as r_0 and r_1. If r_0 and r_1 have the same free pattern but different output patterns, then the bound patterns of r_0 and r_1 are said to be in *conflict*, forming a conflict pair.

Lemma 1 *Given a serial decomposition $F(X) = H(G(X_b), X_f)$, the decomposition is valid if and only if, for every conflict pair $\langle X_{bi}, X_{bj} \rangle$, it holds that $G(X_{bi}) \neq G(X_{bj})$.*

Proof *Assume $F(X) = H(G(X_b), X_f)$ is a valid decomposition, where there exists at least one conflict pair $\langle X_{bi}, X_{bj} \rangle$ such that $G(X_{bi}) = G(X_{bj})$. By the definition of a conflict pair, X_{bi} and X_{bj} have the same free pattern, i.e., $X_{fi} = X_{fj}$. Since $G(X_{bi}) = G(X_{bj})$ and $X_{fi} = X_{fj}$, it follows that: $H(G(X_{bi}), X_{fi}) = H(G(X_{bj}), X_{fj})$. This contradicts our definition of the conflict pair. Thus, our initial assumption must be false, proving Lemma 1.*

Lemma 1 provides the condition for a valid serial decomposition. Thus, the first task in Algorithm 1 is to identify conflict pairs (line 1). According to the definition of conflict pairs, we can write the following relational algebraic expression to find them:

$$C \leftarrow \Pi_{F_1.Bound, F_2.Bound}\big(\sigma_{F_1.Free=F_2.Free} \big(\sigma_{F_1.Output \neq F_2.Output}(F_1 \times F_2)\big)\big) \tag{1}$$

where F_1, F_2 are aliases of F, and $Bound, Free, Output$ are short for bound, free and output patterns. This is an equivalent method to the SOP-based one in the previous work [6]. Given X as the input set, this query has a time complexity of $O((2^{|X|})^2)$. Although existing

Algorithm 1 Serial Decomposition Phase Prepare

Input: Truth Table F, Bound Set X_b, Free Set X_f
Output: Truth Table G
1: Conflict Pairs $C \leftarrow \mathsf{LookupConflictPairs}(F, X_b, X_F)$;
2: Graph $\mathcal{G}_C \leftarrow (\Pi_{X_b}(F), C)$; ▷ $\mathcal{G}_C$: (Nodes, Edges)
3: Map $M \leftarrow \mathcal{G}_C.\mathsf{Coloring}()$; ▷ M : Bound Pattern → Color ID
4: Map $P \leftarrow \mathsf{AssignPattern}(M)$; ▷ P : Color ID → New Pattern
5: $G \leftarrow M \bowtie P$; ▷ M joins P on Color ID
6: **return** G;

Algorithm 2 Bound-Free Set Pair Search

Input: Truth Table F, Flag $allow_share$, Search Range $[l, u]$
Output: Map M ▷ M: bound set size → truth table array
1: Let X, Y be the input and output variable set of F;
2: Set $C \leftarrow \bigcap_{y \in Y} \mathsf{Supports}(y)$;
3: Integer $\langle lower,\ upper \rangle \leftarrow \langle l, \mathsf{Min}(u, |C| - 1) \rangle$;
4: **for** integer $k \in [lower,\ upper]$ **do**
5: **for** set $X_b \in \mathsf{Combinations}(C, k)$ **do**
6: Truth Table $G \leftarrow \mathsf{SerialPrepare}(F, X_b, X \setminus X_b)$;
7: $M[k] \leftarrow M[k] \cup \{\langle G, X_b, X \setminus X_b \rangle\}$;
8: $M[k].\mathsf{sort}()$;
9: **if** $allow_share$ **then**
10: $\mathsf{ExtendSharedSet}(M)$;
11: **return** M;

methods are applied to cubes, they still rely on expanding DCs to identify conflict pairs, resulting in the same time complexity.

To improve efficiency, we propose the following optimizations:

1. **Join Rewriting.** By adjusting the selection order, we can rewrite the cartesian-product into a conditional join, which greatly reduces the operation cost.
2. **Symmetry Elimination.** Due to the symmetry in conflict relations and output pattern comparison, we can add constraints to the inner join and replace $\neq$ with $<$ in the selection, which halves the rows to scan.

After these revisions, we refine Equation (1) as follows:

$$C \leftarrow \Pi_{F_1.Bound, F_2.Bound}\big(\big(\sigma_{F_1.Output < F_2.Output} (F_1 \bowtie_{F_1.Free = F_2.Free \wedge F_1.Bound < F_2.Bound} F_2)\big)\big) \tag{2}$$

With these optimizations, the time complexity is reduced to $O(2^{\frac{2|X_b|+|X_f|}{2}})$. Additionally, executing the query in a DBMS provides several benefits [9]:

- **Sort-merge join.** For $F_1 \bowtie F_2$, the DBMS would use a sort-merge join rather than a double full table scan.
- **Multi-thread acceleration.** The DBMS splits the query operation into multiple independent subtasks and accelerates them through multithreading.
- **Storage optimizations.** These techniques are optimized for handling table data, reducing memory usage, improving storage efficiency, and speeding up queries.

After finding conflict pairs in Algorithm 1, we construct a valid minimal sub-function using graph coloring (lines 2-3). Each node represents a unique bound pattern, and each edge represents a conflict. After coloring, each color corresponds to a unique input pattern in the new function G. We assign each color a distinct pattern and construct G based on the coloring results (lines 4-5). Since graph coloring has near-linear time solutions under edge constraints [18], it is not a significant factor in efficiency.

Commit Phase. In the Commit Phase, we compute the sub-function H according to the sub-function G. Since G is a mapping from the X_b as a subset from X, then to obtain H, all we need to do is a natural join of G and F on X_b, denoted as $H = G \bowtie F$, which is a very fast process.

B. Search of Bound-Free Pair

In Section IV-A, we improve the efficiency of serial decomposition. However, for a truth table with $|X|$ inputs, there can be $O(2^{|X|})$ possible bound-free pairs, even for DSDs. To avoid the overhead of exhaustive search, we present Algorithm 2.

The search is conducted using the bound set length as the unit. In line 1, we find the intersection of output supports, as including output-irrelevant inputs is meaningless. In lines 4-7, we iteratively test the results of serial decomposition on bound-free pairs within the search range and store the result tuples in M. In line 8, we sort the results based on two metrics of G within the same bound set size: (1) the number of outputs, and (2) the number of unique output patterns. We retain only the top-K tuples in M, where K is a hyperparameter. In lines 9-10, an optional step allows for extending the free set to form shared sets.

Shared sets can enhance connections between sub-functions, benefiting GIG optimization. However, searching for suitable shared sets is costly, so it is provided as an optional action, executed only when time permits. The heuristic algorithm for extending the free set of a DSD is as follows:

S1. Denote the result tuple to extend as $\langle G, X_b, X_f \rangle$. Initialize a set $S = \{\{x\} \mid x \in X_b\}$.
S2. Pop X_S from S, and get $G_S \leftarrow \mathsf{SerialPrepare}(F, X_b, X_f \cup X_S)$. If $|G_S| = 1$ or $|G_S| - |X_S| \leq |G|$, update $T \leftarrow T \cup \{X_S \cup \{x\} \mid x \in X_b \setminus X_S\}$. Keep a record of the largest $X_S \in S$ as X_L.
S3. Repeat Step 2 until $S = \emptyset$. Return $X_L \cup X_f$.

Note that when the bound set size approaches the input size, the extension of free sets is less effective.

C. Heuristic Clustering of Parallel Decomposition

Parallel decomposition separates outputs with weak logical connections when serial decomposition struggles to find meaningful bound-free pairs, enabling the synthesis process to continue. We design two methods for parallel decomposition. The first method clusters output variables based on their support sets, and if this fails, we apply a second method that clusters outputs by unique pattern numbers.

By Support Set. When the support sets of a group of output variables differ significantly, serial decomposition will not yield meaningful results. To address this, we cluster the outputs based on their support sets. The Jaccard distance is used to measure the distance between two outputs:

$$D(y_i, y_j) = 1 - \frac{|\mathsf{Supports}(y_i) \cap \mathsf{Supports}(y_j)|}{|\mathsf{Supports}(y_i) \cup \mathsf{Supports}(y_j)|} \tag{3}$$

where $y_i,\ y_j \in Y$, $D(y_i, y_j)$ is the distance between y_i and y_j. Hierarchical clustering with average linkage is then used to adaptively determine the number of clusters.

By Unique Pattern. The process for this method is shown in Algorithm 3. The function $\mathsf{COUNT}(query)$ returns the number of rows in the query result. The goal is to minimize unique output patterns in the two sub-functions.

D. Decomposition Strategies

Decomposition strategies determine the appropriate decomposition for each input truth table after search and evaluation. To handle functions with various characteristics, we propose three automatic

Algorithm 3 Unique Pattern Based Parallel Decomposition

Input: Truth Table F
Output: Cluster C_0, C_1
1: Let Y be the output variable set of F;
2: **for** $y \in Y$ **do**
3: **if** $\frac{\mathsf{COUNT}(\Pi_{C_0 \cup \{y\}}(F))}{\mathsf{COUNT}(\Pi_{C_0}(F))+1} \leq \frac{\mathsf{COUNT}(\Pi_{C_1 \cup \{y\}}(F))}{\mathsf{COUNT}(\Pi_{C_1}(F))+1}$ **then**
4: $C_0 \leftarrow C_0 \cup \{y\}$;
5: **else**
6: $C_1 \leftarrow C_1 \cup \{y\}$;
7: **return** C_0, C_1;

Algorithm 4 Greedy Strategy

Input: Truth Table F, Termination Size t, Search Range r
Output: Operations Op
1: $F_R \leftarrow \mathsf{RemoveTrivialOutputs}(F)$;
2: Let X, Y be the input and output variable set of F_R;
3: **if** $|X| \leq t$ **then** ▷ Termination condition
4: $Op \leftarrow \mathsf{Terminate}$;
5: **return** Op;
6: $Results \leftarrow \mathsf{SerialPairSearch}(F, True, [|X|-r, |X|-1], k)$;
7: $Results \leftarrow Results \cup \mathsf{SerialPairSearch}(F, True, [2, 2+r], k)$;
8: **if** $|Y| = 1$ **then** ▷ Single-output situation
9: $Op \leftarrow \mathsf{EvaluateSingle}(Results)$;
10: **if** $Op = \emptyset$ **then**
11: $Op \leftarrow \mathsf{EarlyTerminate}$;
12: **else if** $|Y| > 1$ **then** ▷ Multi-output situation
13: $Op \leftarrow \mathsf{EvaluateMultiple}(Results)$;
14: **if** $Op = \emptyset$ **then**
15: $Op \leftarrow \mathsf{HeuristicParallel}(F)$;
16: **return** Op;

strategies: Greedy, Large, and Chain. Additionally, we provide a **Manual** mode for debugging and developing new strategies.

Greedy. The greedy strategy is designed to handle general cases. It prioritizes support-reducing serial decomposition, with parallel decomposition applied only if no good bound-free pair is found. The process is shown in Algorithm 4.

In line 1, RemoveTrivialOutputs preprocesses F by removing output variables whose support set contains 2 or fewer inputs, as these are easy to implement and could interfere with finding meaningful bound-free pairs. In lines 2-4, we check if the termination condition is met. If so, the Terminate operation is returned, and the truth table is passed to the GIG synthesis tool. In lines 6-7, bound-free pairs are searched within the specified range from both sides. Lines 8-15 evaluate single-output and multi-output Boolean functions using different criteria to decide the final operation. Elements of $Results$ are denoted as $\langle G = Y_G(X_b), X_b, X_f \rangle$ for subsequent use.

For single-output Boolean functions, the results of serial decompositions are first filtered based on the following conditions:

- **Not Support-reducing:** $|G| = |X_b|$.
- **No Logic Sharing:** $\mathsf{COUNT}(\Pi_{Y_G}(G)) = 2^{|X_b|}$.

The second condition comes from Shannon Decomposition:

$$f(X, x_i) = x_i \cdot f(X, 1) + \overline{x_i} \cdot f(X, 0) \tag{4}$$

which represents the worst-case result of a serial decomposition without any logic sharing, refined here to the pattern level.

If no valid tuple remains after filtering, EarlyTerminate is returned for F even if $|X| > t$. For the remaining decompositions, the following criteria are used to determine the best option, in order of priority:

1. **Is Single-Output:** $|G| = 1$.
2. **Estimated Area Sum:** $|G| \cdot 2^{|X_b|} + |F_R| \cdot 2^{|G|+|X_f|}$.

Algorithm 5 Chain Strategy

Input: Chained Truth Table F_C
Output: Operation Op
1: Let X, Y be the input and output variable set of F_C;
2: $y_0 \leftarrow \arg\min_{y \in Y} |\mathsf{Supports}(y)|$;
3: **if** $|\mathsf{Supports}(y_0)| \leq 2$ **then**
4: $Op \leftarrow \mathsf{ParallelByGroup}(Y \setminus \{y_0\},\ \{y_0\})$;
5: **else**
6: $Op \leftarrow \mathsf{SerialPrepare}(F, \mathsf{Supports}(y_0), X \setminus \mathsf{Supports}(y_0))$;
7: **return** Op;

3. **Bound Set Scale:** $\mathsf{COUNT}(\Pi_{Y_G}(G))$.

For multi-output decompositions, similar steps are followed, but with differences in filtering conditions and evaluation criteria:

- **No Logic Sharing:** $|G| = \sum_i |G_i| \wedge \mathsf{COUNT}(\Pi_{Y_G}(G)) = 2^{|G|}$, where $G_i = \mathsf{SerialPrepare}(\Pi_{X, \{y_i\}}(F), X_b, X_f)$, $y_i \in Y$.

If no valid tuple remains after filtering, a parallel decomposition is selected as the operation on F. The evaluation criteria are similar to the single-output case, but **Is Single-Output** and **Estimated Area Sum** are modified as follows:

- **Is Single-Output:** $|G| \leq |F|$.
- **Estimated Area Sum:** $\frac{|G|}{\sum_i |G_i| - |G|} \cdot 2^{|X_b|} + |F_R| \cdot 2^{|G|+|X_f|}$.

Here, an extra bias is introduced to prioritize logic sharing.

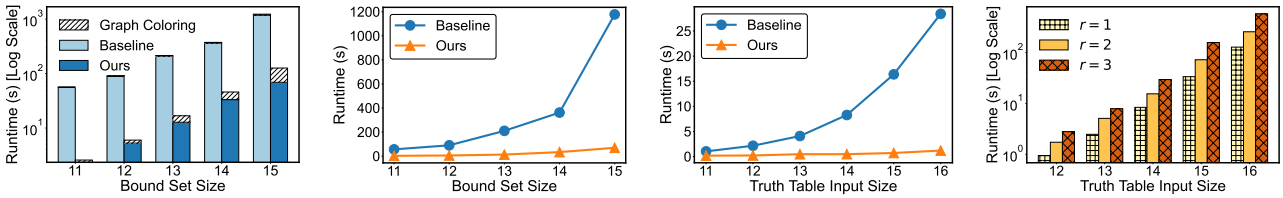
Large. The Large strategy is a variant of the greedy strategy, designed to reduce the runtime for large truth tables by avoiding searches of large bound sets. Adjustments include:

1. Bound-free pairs are searched only from the lower side instead of both sides (line 7 in Algorithm 4).
2. Pairs are searched step by step rather than over a range. Once a feasible serial decomposition is found, it is returned.
3. If the bound set size becomes large (≥ 12), EarlyTerminate or HeuristicParallel is selected as the operation.

These modifications may impact result quality, and users can choose the strategy according to the specific scenario.

Chain. The Chain strategy is designed for a special type of functions where $\mathsf{Supports}(y_0) \subseteq \mathsf{Supports}(y_1) \subseteq \mathsf{Supports}(y_2) \subseteq \cdots$ with all outputs logically related. The optimal structure of such functions forms a chain. In practice, these functions are identified based on their output support sets. The process of the chain strategy is shown in Algorithm 5. There is no need to search for pairs, as the optimal solution is obvious. Once the bottom-level output becomes trivial, it is separated from the function.

V. EXPERIMENTS



EDGE is implemented in Python, using *DuckDB* [19] as the DBMS and *NetworkX* [20] for graph algorithms support. All experiments are conducted on a server with an AMD EPYC 7742 CPU and on IWLS 2023 contest benchmarks.[1]

A. Efficiency of Serial Decompositions

This subsection evaluates the efficiency of our serial decomposition implementation under various settings. The original method based on Equation (1) could not complete within 3,600 seconds in our experiments. Consequently, we compare our approach exclusively with the complexity-reduced method based on Equation (2) without DBMS acceleration, which we will refer to as the baseline.

EXP-1: Comparison on 16-Input Truth Tables. In this experiment, we compare the total runtime of serial decomposition for 16-input

[1] https://www.iwls.org/iwls2023/2023_IWLS_Contest_Benchmarks.zip

(a) 16-Input Total Time (b) 16-Input Conflict Pairs Search (c) Varying-Input Total Time (d) Bound-Free Pair Search

Fig. 3: Efficiency of Serial Decomposition

truth tables with different bound set sizes. In Figure 3(a), "Baseline" and "Ours" represent the runtime of the conflict pairs search component in the baseline method and our approach, respectively, while "Graph Coloring" denotes the runtime associated with graph coloring. As can be seen, the pairs search component dominates the overall runtime. Our proposed approach achieves a reduction in the runtime of this component by 94-95% compared to the baseline method across different bound set sizes, as shown in Figure 3(b). Consequently, the total runtime using our approach is 10-21× better than that of the baseline method.

EXP-2: Comparison for Fixed Bound Set Size. In this experiment, we compare the runtime for different input sizes with a fixed bound set size of **10**. Figure 3(c) shows the runtime trend as the input size increases. While the initial improvement in runtime is 10× at an input size of 11, this enhancement grows exponentially as the input size increases, proving the scalability of our optimizations.

EXP-3: Evaluation of Bound-Free Pair Search. This experiment evaluates the efficiency of bound-free pair search with varying truth table sizes and different bound-free pair search ranges. We use 32 parallel threads to accelerate the search, without applying the Large strategy. Figure 3(d) shows that for a truth table with 16 inputs, the total runtime with $r = 3$ is the longest, reaching 576 seconds, while with $r = 1$, it takes only 127 seconds. This difference arises from two factors: (1) the number of bound-free pairs within the range, and (2) the runtime of decompositions for different bound set sizes. For a 12-input truth table, reducing 4 inputs results in a runtime of only 2.7 seconds for $r = 3$. This highlights the rationale behind our Large strategy: to quickly reduce truth table size while focusing on decomposition quality for smaller functions.

B. *Effectiveness of* ***EDGE***

EXP-4: Comparison of Synthesis Results. In this experiment, we evaluate and compare the GIG synthesis results of ***EDGE*** against SOTA SOP-based transformation processes. All input truth tables are considered random, with no specific optimizations for any instance. The termination size is set to 6 for truth tables with more than 8 inputs and 4 otherwise. The benchmarks are grouped based on the official information from the IWLS 2023 contest, and all synthesis results are verified by comparing the simulated truth tables. The quality of the synthesis is measured by the number of AIG nodes. We compare three methods implemented in ABC [16]. The sequence used for all methods includes reading truth tables, simplifying SOPs, and converting to AIGs: *read_truth -xf; collapse; sop;* [factorization command]*; strash;*. Original does not use a factorization command, while `fx` and `fxch` use *fx* and *fxch* commands, respectively.

Table I shows the node counts of AIGs after transformation. For each dataset, ***EDGE*** produces fewer initial AIG nodes than other methods, achieving an 18% reduction in the total node count compared to the best SOTA (`fx`) results. Although having fewer initial AIG nodes does not necessarily mean fewer nodes after optimization, a smaller initial size reduces the runtime of powerful but time-consuming optimization methods [3], [21]. The average runtime for ***EDGE*** per truth table is **230** seconds. Notably, for truth tables with 14 or more inputs and multiple outputs, the primary source of runtime is the Espresso computation for output supports.

TABLE I: Number of Nodes After Transformation

Benchmarks	Original	`fx`	`fxch`	***EDGE***
ex00-ex01	1,018	736	795	**654**
ex02-ex07	4,626	3,229	3,494	**3,074**
ex08-ex09	4,384	2,660	2,817	**2,452**
ex10-ex15	5,978	3,833	3,902	**3,523**

ex50-ex67	37,561	23,322	25,211	**16,526**
ex68-ex99	18,310	12,521	13,510	**9,986**
Total	111,617	73,222	78,419	**60,035**

TABLE II: Number of Nodes After GIG Optimization

Benchmarks	Original	`fx`	`fxch`	***EDGE***
ex00-ex01	704	669	704	**602**
ex02-ex07	3,408	2,959	3,147	**2,878**
ex08-ex09	2,958	2,474	2,574	**2,364**
ex10-ex15	4,122	3,443	3,485	**3,162**
ex16-ex27	13,984	12,571	13,007	**10,787**
ex28-ex49	13,341	11,893	12,658	**11,662**
ex50-ex67	25,704	21,313	22,791	**15,739**
ex68-ex99	12,489	10,936	11,649	**9,040**
Total	76,710	66,258	70,015	**56,234**

Table II shows the node counts of AIGs after transformation and optimization using a sequence of instructions: *fraig; resyn; resyn2; resyn2a; resyn3; drw; dc2; refactor;*, repeated 50 times to approach the optimization limit. Our method outperforms all SOTA methods across all datasets, achieving a 15% reduction in total node count compared to the best SOTA (`fx`) results. In 36 specific test cases, our method achieves more than a 10% reduction compared to the best SOTA results.

VI. CONCLUSION

In this work, we propose a two-level logic transformation process based on multi-output Boolean decomposition to enhance the quality of GIG synthesis. To improve efficiency, we have formulated the process as relational query operations and leverage DBMS techniques to accelerate computations and reduce redundancy. For better synthesis quality, we have proposed a decomposition framework, ***EDGE***, with tailored strategies to handle truth tables of varying characteristics. Experimental results demonstrate that ***EDGE*** achieves significant improvements in decomposition efficiency and higher-quality synthesis results compared to SOTA methods.

***Abstract*—Interlaced Magnetic Recording (IMR) drives have been regarded as promising hard disk drives (HDDs) to meet the ever-growing storage demand in the post-AI era. Among various technologies, IMR drives achieve increased storage capacity by overlapping tracks in an interlaced fashion; however, updating data on overlapped tracks necessitates rewriting up to two tracks, which can degrade performance. Previous strategies have attempted to reduce track rewrites by either delaying the timing of overlapping based on storage space usage or relocating frequently updated data to non-overlapped tracks through update-frequency-based hot/cold data separation. In contrast, this paper proposes a novel approach that leverages data deduplication as a natural solution to the rewrite challenge in IMR drives. Unlike conventional hot/cold separation, this paper utilizes deduplication metadata, specifically reference counts, as a direct indicator for data relocation. The rationale behind the proposed approach is that deduplicated data, which remains static unless reference counts drop to one, can be stored or migrated to overlapped tracks without inducing future track rewrites. The proposed approach diverges from traditional frequency tracking methods by leveraging data deduplication information to guide data placement and reduce rewriting. Evaluation results show that the proposed scheme effectively reduces the accumulated read/write latency by 37.57% on average compared with state-of-the-art data management on IMR drives with data deduplication enabled.**

***Index Terms*—IMR, deduplication, relocation, HDD**

I. Introduction

Owing to the explosive growth of digital data in the post-AI era, both hardware and software designs have been explored to either enhance the storage density or reduce the data volume without significantly changing existing file and storage systems. Among various hardware solutions, hard disk drives (HDDs) are favored for their low cost-per-gigabyte, high reliability, and long lifespan. While the superparamagnetic effect (SPE) [1] limits the storage density of existing conventional magnetic recording (CMR) HDDs, various new technologies, such as the shingled magnetic recording (SMR) [2–4] and interlaced magnetic recording (IMR) [5–7], have been widely studied. Although SMR has been commercialized [8], the shingled track layout leads to an excessive number of data rewrites under random workload and greatly limits the random write performance. Thus, SMR becomes less preferable and issues related to unpredictability of I/O performance have also been reported [3, 4, 9]. Recently, the advances of interlaced magnetic recording (IMR) technology have outperformed SMR and enables even-higher storage density with alleviated track rewrites.

Figure 1 compares CMR, SMR and IMR technologies. Unlike SMR that has multiple tracks overlapped on top of previous tracks, IMR organizes *top tracks* and *bottom tracks* in an interlaced fashion and each top track overlaps at most two adjacent bottom tracks. IMR achieves higher linear density by applying higher laser current to the wide bottom tracks and has narrow top tracks placed closer for higher areal density [10]. Such an interlaced layout enables top tracks to be updated freely and induces at most two track rewrites when updating bottom tracks if adjacent top tracks contain valid data. As a result, IMR is considered a more attractive alternative over SMR with the lowered number of track rewrites. To further alleviate the overhead when updating bottom tracks on IMR drives, space allocation strategies, including the rewrite-minimized data placement [11], the three-phase data management [12], and the Z-Alloc [13], are proposed to postpone the allocation of top track until all bottom tracks are in use. After top tracks are allocated, another perspective is to reduce updates on bottom tracks by either buffering updates on free top tracks, such as the top buffer [13] and selective track buffering [14], or relocating frequently-updated bottom tracks to non-overlapped top tracks. Examples of data relocation include the block swap [13], the track flipping [14], and the data hotness aware movement [15]. Nevertheless, *most existing mechanisms employ similar approaches to swap or relocate data blocks based on update frequency for hot/cold data separation.*

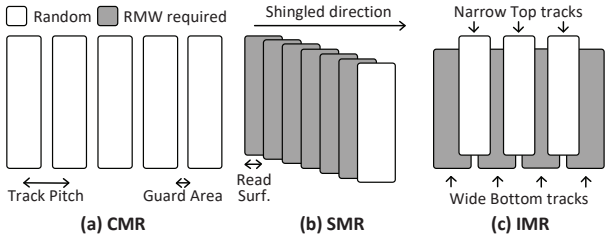

Fig. 1. Comparison of CMR, SMR, and IMR, in which the track pitch and the guard area indicate the distance between data tracks and the distance to avoid interference. For RMW-required tracks, read surfaces are reserved and exposed for the disk read head to retrieve stored data.

Examples of software solutions for enlarging usable storage space include the data compression and data deduplication techniques [16]. While data compression encodes the digital data using fewer bits, data deduplication eliminates duplicate copies of repeated data. Although both techniques can effectively lower data size, data compression has higher performance overhead since encoding and decoding are required during data writes and reads, respectively. In addition, owing to the decoding overhead, the *readahead*[1] [17] mechanism in existing file systems may induce additional decoding overhead if the access pattern prediction is incorrect. In other words, data deduplication is preferable with read performance consideration.

This work was supported in part by the National Science and Technology Council, Taiwan, under grant nos. 113-2221-E-A49-189-MY3, 111-2221-E-A49-198-MY3, and 113-2221-E-007-134.

*Corresponding author

[1]By predicting the access pattern, the readahead mechanism prefetches file data into main memory to reduce the latency of future access.

Data deduplication identifies and eliminates redundant copies of data, retaining a single instance at block- or chunk-level by (1) calculating the *cryptographically secure hash-based fingerprints* [16], (2) comparing fingerprints to identify duplication, (3) storing only one copy of the duplicate data, (4) maintaining mapping information between the stored data and those deduped chunks or files. Even though data deduplication techniques have been studied for over 20 years [16] and machine learning deduplication has also been proposed [18, 19], *the potential of leveraging data deduplication information to facilitate the IMR management received much less attention.*

Notably, instead of utilizing data deduplication information for tracking update frequency and separating hot/cold data, this paper is constructed based on the fact that *deduplicated data chunks*[2] *remain unchanged unless the reference count drops to one.* Specifically, deduplicated data chunks do not receive updates directly. Instead, updates are applied to new or unique chunks. If the reference count of a duplicated chunk drops to one, suggesting it is no longer shared, it may then become eligible for modifications or updates. This paper introduces a *deduplication-assisted data relocation* (DADR) scheme to reduce track rewrites by utilizing data deduplication information, specifically the reference count of each block or chunk, enabling effective data relocation and space allocation. Integrating data deduplication onto IMR drives requires sharing deduplication information between the host system (e.g., file systems) and the disk firmware (e.g., Interlaced Translation Layer (ITL) [14]). This is because, in the proposed scheme, fingerprint calculation is assumed to be conducted at the host system, as IMR drives are typically resource-constrained. The deduplication information is then maintained within ITL, based on details passed down from the host system as a *hint* via the ATA command set [20, 21].

The DADR scheme is threefold. First, after valid top tracks start overlapping bottom tracks, non-deduped bottom tracks are swapped with deduped top tracks during bottom track updates to reduce the number of track rewrites. Meanwhile, during track rewrites, deduped top tracks are actively relocated to invalid or non-deduped bottom tracks. Second, after fingerprint calculation is performed on the host system, the proposed DADR scheme actively relocates non-deduped and deduped data writes to top and bottom tracks. Notably, since the size of deduped blocks or chunks (i.e., 4 KB) is typically smaller than a IMR tracks (i.e., 2 MB), non-deduped and deduped data chunks are packed into non-deduped and deduped data tracks, respectively. Third, the DADR scheme delays the allocation of top tracks that are on top of non-deduped bottom tracks. Above measures are effective since deduped data chunks are static as long as the reference count is larger than 1, thus allowing the proposed scheme to effectively lower track rewrites on IMR drives. Another benefit of integrating data deduplication onto IMR drives is lowering the total amount of written data, thus further reducing the overall latency during data writes. The main contribution of this study lies in *leveraging the deduplication information to facilitate the IMR management, reducing track rewrites and enhancing performance.* Evaluation results show that the number of track rewrites and the accumulated latency are reduced by 41.34% and 37.75% on average compared with the state-of-the-art ITL [13] with data deduplication, Z-alloc, block swap, and top buffer enabled.

[2]Deduplicated data chunks refer to data chunks that have undergone the data deduplication process.

II. Background and Motivation

A. Interlaced Magnetic Recording (IMR)

Interlaced Magnetic Recording (IMR) technology achieves higher storage density by organizing data tracks in an interlaced layout, as shown in Figure 1(c). By placing narrower top tracks on at most two wider bottom tracks, IMR is capable of reading data from bottom tracks through the residual track surface. Nevertheless, due to the track overlap, writing data on bottom tracks destroys valid data on adjacent top tracks. To restore those destroyed data, the *read-modify-write (RMW)* operation is introduced. As illustrated in Figure 2(a), before $Track$ 1 is updated, data on $Tracks$ 8 and 9 are first read out. Then, after updates to $Track$ 1 are already merged, $Tracks$ 1, 8 and 9 are then written back. Inevitably, additional write traffic is induced due to track rewrites during the RMW operations and becomes performance overhead. To lower the amount of write traffic and the number of track rewrites, existing strategies can be categorized into 3 groups, including space allocation, track relocation, and track buffering [12–14]. Notably, these strategies are typically implemented in the interlaced translation layer (ITL) to manage IMR drives with a *logical-to-physical (L2P) mapping table*. For instance, based on the ratio of space utilization, the Z-alloc [13] has three phases of allocation, and the allocation direction is reversed when phases switch.

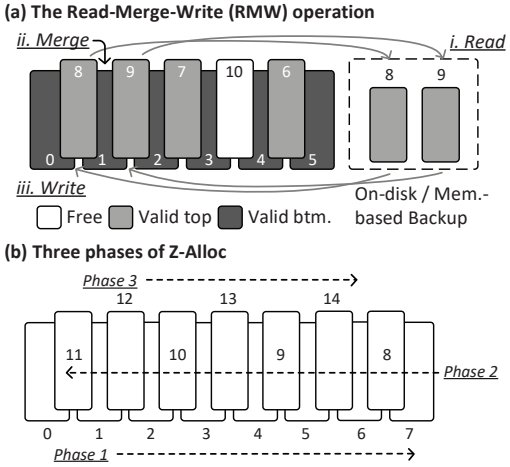

Fig. 2. Read-merge-write operation and Z-alloc of IMR drives, in which track indexes are labeled according to their allocation sequence.

As shown in Figure 2(b), the $Phase$ 1 of Z-alloc only allocates bottom tracks. Then, the $Phase$ 2 reverses the direction and only allocates every other top tracks. Finally, the $Phase$ 3 reverses the direction again and allocates those residual top tracks. Although Z-alloc can effectively delay the timing of allocating top tracks, *the possibility of storing frequently-updated data onto bottom tracks remains.* To relocate those frequently-updated data, data relocation, such as the block swap [13] and the data hotness aware movement [15], exchanges frequently-updated data on bottom tracks with infrequently-updated data on top tracks. In other words, update frequency tracking is required for hot/cold data separation. Nevertheless, *update frequency could change overtime according to locality and induce additional relocation overhead when the locality*

shifts. Lastly, an example of track buffering is the top buffering [13], which reserves a number of top tracks for buffering bottom track updates to delay or avoid the track swap. Even though previous strategies can effectively reduce the number of track rewrites on IMR drives, *the possibility of further reducing the amount of written data or facilitating IMR data management through data deduplication has received much less attention.*

B. Data Deduplication

Since 2000s, data deduplication techniques have been commercialized and widely adopted by cloud storage providers. For instance, Microsoft and EMC report that roughly 50% and 85% of data in their storage systems are duplicated [16]. The process of data deduplication can be summarized as Figure 3. First, data duplication are identified at either *block-* or *chunk-level*. For chunk-level deduplication, incoming data steams are divided into smaller data chunks via either fixed-size chunking (FSC) or content-defined chunking (CDC), where CDC can achieve higher deduplication ratio than FSC. Second, each data chunk is labeled with a fingerprint generated by hash functions, such as MD5 and SHA-256, and are compared with other fingerprints to check whether the data chunk is duplicate or not. The process of comparison is known as *fingerprint indexing*, which can be accelerated by Bloom filters [16].

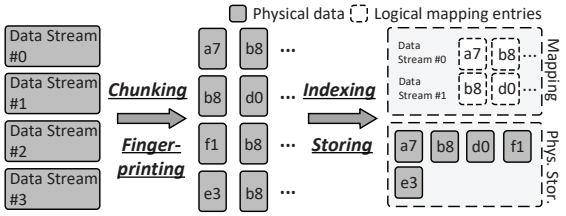

Fig. 3. The process of chunk-level deduplication, in which data streams go through the chunking, fingerprinting, indexing, and storing steps for data deduplication.

Finally, mapping entries are maintained between the stored physical copy of the data chunk and the logically deduplicated data chunks or files. In this study, data deduplication mapping entries are assumed to be maintained within the ITL after the host system conducts deduplication and passes the results through the reserved field in the ATA command set. This paper reveals that the reference count can be repurposed to indicate whether a data chunk will be updated. Notably, rather than using the reference count for access frequency prediction, data with a reference count greater than 1 remains static and receives no updates unless the reference count drops to 1. According to the investigation of this study, *such an indication from data deduplication techniques has not been explored to facilitate the data management of IMR drives.*

C. Motivation

This section provides an illustrative example to explain the existing inefficiency of the state-of-the-art space allocation and data relocation strategies, namely Z-alloc and block swap, on IMR drives. As shown in Figure 2(b), existing Z-alloc divides the track allocation into 3 phases based on the ratio of space utilization. However, as shown in Figure 4(a), in $Phase$ 1, all data, including frequently-updated data, can only be written to bottom tracks. If subsequent updates to the frequently-updated data happen during either $Phase$ 2 or $Phase$ 3, track rewrites or block swaps become inevitable and induce performance overhead, as shown in Figure 4(b). Such an unwanted overhead can be avoided if data that will not be updated, namely dedupled data chunks with reference count larger than 1, can be identified and proactively stored on bottom tracks. Consequently, the adjacent top tracks of bottom tracks containing deduplicated data chunks can be allocated for data that could be updated directly in $Phase$ 1.

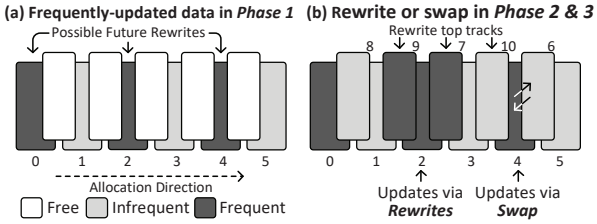

Fig. 4. Motivational example, in which frequently-updated data are written on bottom tracks in the Phase 1 of Z-alloc and induce track rewrites or swaps in Phase 2 and 3.

To relocate frequently- (*i.e.,* hot) and infrequently-updated (*i.e.,* cold) data, the existing block swap strategy needs to attain the hot and cold data information on the block basis. Typically, such hot/cold information is obtained from keeping the access count of each data block. Other strategies, such as Least Recently Used (LRU), can be also utilized; however, both the access count and LRU mechanism could be affected by temporal locality, leading to frequent block swaps under thrashing scenarios. The reference count in data deduplication techniques, on the other hand, provides a clear indication of whether a stored data chunk may be updated—specifically, stored data chunks with a reference count greater than 1 are static and receive no updates unless the reference count drops to 1. It would be beneficial if deduplication information could substitute for access count or LRU mechanisms, as this approach would reduce the influence of temporal locality while identifying blocks that remain static.

III. Deduplication-Assisted Data Relocation (DADR) Scheme

A. Overview

To facilitate the data management of IMR drives, this paper presents a deduplication-assisted data relocation (DADR) scheme with the goal of lowering the number of track rewrites by leveraging the data deduplication information. Figure 5 illustrates the system architecture, showing how deduplication metadata facilitates the DADR scheme in managing IMR drives. In the considered system architecture, the generation of deduplication fingerprint is conducted at the host system for the better processing capability. Then, deduplication index, the logical address, and the original data are passed through conventional write requests of ATA command. Under this implementation, a two-level mapping table is presented to keep track of both the L2P mapping entries of the original ITL and the data deduplication information. Logical addresses of stored data chunks are mapped to deduped entries based on the entry indices, and each deduped entry records the fingerprint, the reference count, and the physical address. As deduplication information is shared between the host system and the proposed scheme, deduped entries are cached onto the host system and periodically flush are conducted to ensure consistency. Alternatively, if a specialized

controllers or special intellectual property (IP) cores can be integrated into the IMR drives for fingerprint generation, the fingerprint could be generated within the ITL, eliminating the need to pass it down from the host system.

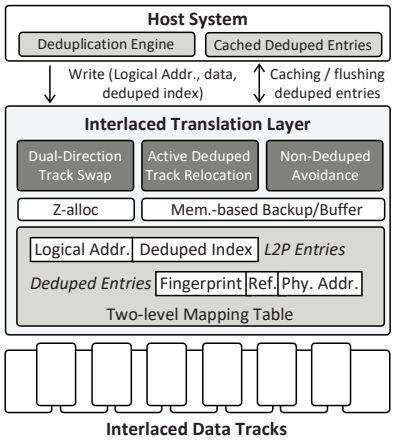

Fig. 5. The system architecture of DADR scheme, in which Z-alloc is utilized with the aids of proposed components.

Based on the two-level mapping table, the main components of the DADR scheme are illustrated below. First, the *dual-direction track swap* is proposed to swap to-be-updated bottom tracks with top tracks that have the largest deduped reference count. The main rationale behind the dedupe-based track swap is that the only physical copy of deduped data chunks remains static if it is referenced by more than one logical data chunk. In other words, this physical copy remains unchanged even when one of its logical data chunk is being updated, which either remaps to another deduped physical data chunk or triggers copy-on-write (COW) to create another new physical data chunk. Second, based on the state-of-the-art allocation method (*i.e.,* Z-alloc), the *active deduped track relocation* is included to actively relocate non-deduped and deduped data to the top and bottom tracks, respectively, during the $Phase$ 1 of IMR track allocation. Lastly, the *non-deduped avoidance* is included during $Phases$ 2 and 3 to skip allocation of those top tracks with their adjacent bottom tracks storing non-deduped data chunks (*i.e.,* reference count equals to 1), and introduces $Phase$ 4 to utilize those residual top tracks after $Phase$ 3. In summary, this paper presents a pioneering design that first integrates data deduplication on IMR drives and leverage deduplication information to facilitate data management.

B. Dual-Direction Track Swap

To avoid frequent track rewrites, previous studies [13, 15] have suggested that swapping hot bottom tracks with cold top tracks is an effective action after valid top tracks start overlapping valid bottom tracks. While most of the previous designs rely on the update frequency of each data track for identify hot/cold data, the proposed DADR scheme includes the dual-direction track swap to utilize the reference count of data deduplication mechanism for track swaps. Accordingly, the to-be-updated bottom tracks with the reference count of 1 are going to be swapped with the top track that has the highest reference count. In an extreme case where all top tracks have a reference count of 1, the RMW operation will be triggered to update the bottom tracks and preserve the overlapped valid top tracks. Nevertheless, according to our experimental results, such an extreme case has not been observed with real-world workloads. An example is given in Figure 6 to better illustrate the above procedure. In this example, an update request is made to $Track$ 2, and the overlapping $Track$ 9 and $Track$ 7 are buffered to prevent data loss. Data on $Track$ 2 are swapped with the top track with the highest reference count, which is the $Track$ 9. Subsequently, the original data on $Track$ 9 are relocated to $Track$ 9 and the original data on $Track$ 2 are merged with updates and stored to $Track$ 9.

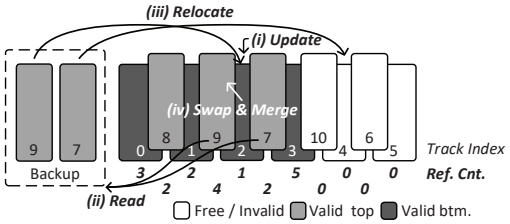

Fig. 6. Dual-direction track swap, which lowers the possibility of future rewrites by swapping and relocating tracks based on the deduped reference count.

Notably, in addition to proactively swapping non-deduped bottom and deduped top tracks, the proposed dual-direction track swap further leverages the deduped reference count to relocate adjacent deduped top tracks of the to-be-updated bottom tracks when the to-be-updated bottom track is swapped with a deduped top tracks. This is because, as shown in Figure 6, overlapping top tracks of to-be-updated bottom tracks are buffered. If those top tracks contains deduped data chunks, it would be beneficial to relocate the buffered top track to an invalid or a non-deduped bottom track since deduped data chunks (i.e., the reference count is larger than 1) remains static. Such an approach allows top tracks to be reserved for data that could possibility be updated. In Figure 6, during the swap of $Track$ 2 and $Track$ 9, the $Track$ 7 with a reference count of 2 is also read out. To fully utilize the track rewrite opportunity and avoid future rewrite overhead, the $Track$ 7 with the reference count of 2 is moved to a free bottom track, namely $Track$ 4, during the updates of $Track$ 2. Then, $Track$ 7 becomes free again for future allocation. Such an approach makes the rewrite overhead worthwhile and fully utilizes the track rewrite opportunity.

C. Active Deduped Track Relocation

Following the Z-alloc method on IMR drives, $Phase$ 1 of Z-alloc could force frequently-updated data to be stored on bottom tracks and leads to track rewrites or block swaps during $Phase$ 2 and $Phase$ 3. In other words, it would be beneficial if infrequently- and frequently-updated data can be redirected to bottom and top tracks during $Phase$ 1 of Z-alloc. In the proposed DADR scheme, the active deduped track relocation, as summarized in Figure 7, is included to relocate data according to their deduped reference count, which can be observed while data are buffered on memory before being stored permanently. Since buffering is widely used on HDDs to improve response time, the active deduped track relocation does not alter the existing data flow. Data with a deduped reference count greater than 1 are stored on bottom tracks, while non-deduped data with a reference count of 1 are proactively stored on the top tracks above them. Top tracks that are on top of bottom tracks containing deduped data chunks are referred to as allocatable top tracks. If allocatable top tracks do not exist, those non-deduped

data are still stored on bottom tracks since writing to top tracks on top of free bottom tracks leads to RMW operations while those free bottom tracks are allocated in the future. Notably, since deduped data chunks are typically smaller than a track of IMR drives, multiple data chunks are stored on the same tracks, which are non-deduped or deduped tracks. That is, data chunks are stored onto data tracks based on whether their reference count is larger than one or not. This is because the proposed scheme is designed based on whether a data block will be updated or not, and the ranking of the reference counts makes no difference.

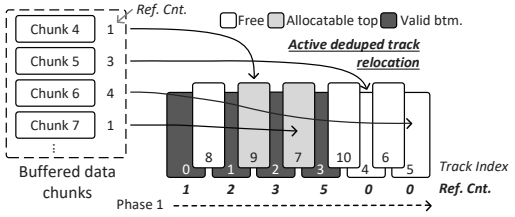

Fig. 7. Active deduped track relocation, which aims to avoid storing non-deduped data chunks onto bottom tracks in $Phase$ 1 of Z-alloc.

D. Non-Deduped Avoidance

To further leverage deduplication information to lower track rewrite overhead on IMR drives, the proposed DADR scheme introduces the non-deduped avoidance into the $Phase$ 2 and $Phase$ 3 of Z-alloc to delay the allocation of top tracks that are on top of bottom tracks containing non-deduped data chunks. Meanwhile, the allocation of those top tracks is delayed until a newly-included $Phase$ 4 after the $Phase$ 3 finishes. Such approach further reduces the possibility of track rewrites since those bottom tracks with non-deduped data chunks can still be freely updated without inducing track rewrites during $Phase$ 2 and $Phase$ 3. Notably, in this study, instead of completely replacing the state-of-the-art space allocation method on IMR drives, the proposed DADR scheme explores the merits of dedupication information to assist the data management of IMR drives and reduce the possibility of track rewrites. In other words, the components of the proposed DADR scheme can be integrated to other allocation methods on IMR drives, while integrating data deduplication to reduce the size of written data.

IV. Performance Evaluation

A. Experiment Setup

In this session, experiments are conducted to evaluate the effectiveness of the proposed DADR scheme in terms of reducing the accumulated read and write latencies, as well as the number of rewritten data tracks. Since the current implementation involves altering the ITL of IMR drives, both the existing Tracklace [13] approach and the proposed DADR scheme are implemented and simulated on an IMR simulator [6]. Notably, the Tracklace includes methodologies such as Z-alloc, block swap, and top buffer approaches. The evaluation uses three types of workloads: two real-world traces from the FSL-Dedup Traces dataset and one synthetic trace with a lower data deduplication ratio. The characteristics of each trace used in the experiment are detailed in Table I.

The two real-world traces, labeled *user000* and *user002*, provide valuable insights into the performance of storage systems under deduplication conditions. In the selection process for these two traces, the main consideration is the peak data chunk sizes and the aim to understand how data chunk size impacts the effectiveness of the proposed scheme. The peak chunk sizes for the two traces are near 0 bytes and approximately 250,000 bytes. Given that FSL-Dedup traces capture a snapshot of a deduplication-enabled storage system, additional data update requests were manually and randomly generated during this evaluation to simulate real-world usage. The synthetic trace, on the other hand, was generated with a normal distribution of data write sizes for each entry, using a mean of 128 KB and a standard deviation of 30 KB. This synthetic trace helps to model a scenario with different deduplication ratios for helping to understand the effectiveness and performance trend of the proposed scheme, thus providing a contrast to real-world traces.

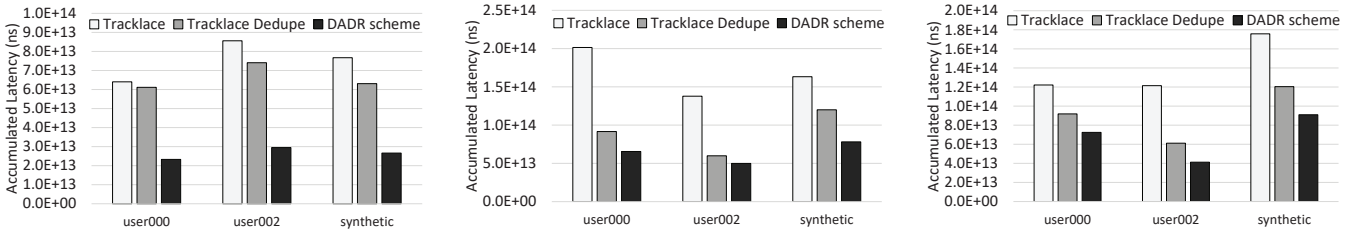

TABLE I
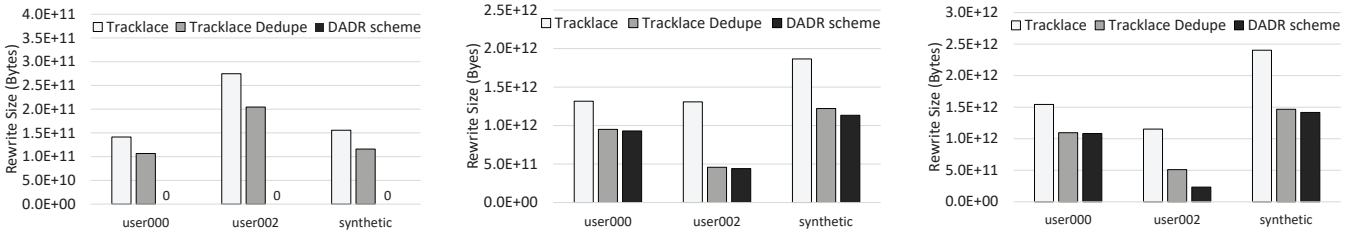
Workload characteristics.

Traces	Write Size (GB)	Dedupe (%)	Update size (GB)
user000	70.8	16.9	44.1
user002	210.9	27.2	128
synthetic	130.8	14.4	98.69

B. Experimental Results



To eliminate the effect of data deduplication and focus on investigating the effectiveness of data management of the DADR scheme, the improvement percentage shown in this paper is derived by comparing the proposed DADR scheme and the Tracklace with data deduplication enabled (*i.e.,* Tracklace Dedupe). The experimental results of Tracklace without enabling data deduplication are also included for completeness. In addition, to understand the capability of the proposed DADR scheme under different space utilization scenarios, three ratios of space utilization are chosen, which are 50%, 80%, and 90%. Accordingly, the accumulated latency comparisons are first shown in Figure 8. When the ratio of space utilization is 50%, the accumulated latency can be reduced by 59.96% on average when compared with Tracklace Dedupe. This is because the DADR scheme can actively relocate data to the bottom and top tracks based on the reference count of the deduplication mechanism to differentiate static data or data that could be possibly updated. Meanwhile, the reason why Tracklace performs worse than Tracklace Dedupe is that Tracklace already enters the Phase 2 of Z-alloc, the top buffer of Tracklace is enforced for every update to bottom tracks, thus inducing additional overhead.

After the ratio of space utilization grows up to 80% and 90%, the proposed scheme achieves latency reductions of 26.68% and 26.06% on average, respectively. The reason for the reduction drop is that the dual-direction block swap of the proposed scheme is triggered to relocate data due to updates to bottom tracks. Nonetheless, the reduction is still positive and up to 32% for user002 at 90% space utilization. On the other hand, as one of the design goals of the DADR scheme is to reduce track rewrites, the accumulated rewrite data size is reported in Figure 9. For 50% space utilization, the DADR scheme induces no track rewrites since the dual-direction block swap is not triggered. On the contrary, Tracklace requires RMW operations when flushing the top buffer to the bottom tracks. After the ratio of space utilization grows to 80% and 90%, the average reductions are 4.93% and 19.63%, respectively. The reason is

(a) 50% space utilization (b) 80% space utilization (c) 90% space utilization

Fig. 8. Comparison of accumulated latency under different space utilization, including the latency of data reads/writes for serving incoming requests and the latency of data rereads/rewrites during block swap for all three methods and top buffer flush, which is enabled for Tracklace and Tracklace Dedupe.

(a) 50% space utilization (b) 80% space utilization (c) 90% space utilization

Fig. 9. Comparison of accumulated rewrite size of block swaps under different space utilization. This comparison is included to show the number of track rewrites between each compared methods.

that, at 80% space utilization, the dual-direction block swap is constantly triggered. Then, at 90%, there are much fewer block swaps as most of the active updated data are relocated to top tracks. In other word, even when the space utilization is at 90%, the included active deduped track relocation is still effective in terms of reducing the amount of data rewrite.

V. Conclusion

To avoid the locality shifting issue of conventional data management on IMR drives, this study introduces a pioneering approach called the deduplication-assisted data relocation (DADR) scheme. The DADR scheme leverages data deduplication information to optimize data management on IMR drives and strategically relocates deduped data to the bottom tracks while moving non-deduped data with a higher likelihood of updates to the top tracks. Notably, instead of tracking updating frequency or trying to reflect updating frequency through the deduplication information, the proposed DADR scheme is designed based on the fact that deduped data remain static unless the reference count drop to 1. Accordingly, the DADR scheme actively redirects data to the bottom and top tracks and delays the allocation of top tracks on non-deduplicated bottom tracks. With the above mechanism, the DADR scheme demonstrates a significant reduction in both track rewrites and accumulated read/write latency. On average, it achieves a 41.34% reduction in track rewrites and a 37.75% reduction in accumulated read/write latency compared to the existing Tracklace approach with data deduplication enabled. By minimizing track rewrites, the DADR scheme presents a promising approach for managing IMR drives data deduplication.

***Abstract*—We present a quantum-inspired algorithm that utilizes Quantum Hamiltonian Descent (QHD) for efficient community detection. Our approach reformulates the community detection task as a Quadratic Unconstrained Binary Optimization (QUBO) problem, and QHD is deployed to identify optimal community structures. We implement a multi-level algorithm that iteratively refines community assignments by alternating between QUBO problem setup and QHD-based optimization. Benchmarking shows our method achieves up to 5.49% better modularity scores while requiring less computational time compared to classical optimization approaches. This work demonstrates the potential of hybrid quantum-inspired solutions for advancing community detection in large-scale graph data.**

I. Introduction

Quantum computing with the principles of quantum mechanics can process information in different ways from classical computers. This is because qubits can exist in superposition, and therefore can represent multiple states simultaneously [1]. This capability, combined with entanglement and interference, allows quantum algorithms to solve certain classes of problems, such as integer factorization and combinatorial optimization, more efficiently than classical methods. Therefore, quantum computing has lead to advancements in cryptography [2], optimization [3], machine learning [4], and materials science [5]. In parallel, quantum-inspired algorithms bring similar quantum concepts to classical computing, with principles such as tunneling, adiabatic transitions, and Hamiltonian dynamics to address complex problems without requiring quantum hardware. These approaches have demonstrated enhanced performance in areas like traffic routing and combinatorial optimization, where classical systems emulate quantum behaviors to achieve good efficiency [6].

Community detection is an important problem in network analysis, and it's essential for interpreting the structural and functional organization of complex systems [7]. An example is given in Figure 1. The overall goal is to identify communities—groups of nodes with denser connections among themselves than with the rest of the network [8]. In large-scale graphs, which are common in various real-world applications such as social networks, biological systems, and communication networks, effective community detection provides valuable insights into network behavior and properties, and can support applications like anomaly detection, network optimization, and information dissemination [9]. The impact of community detection is deep across many domains. In social networks, it enables the identification of groups with shared interests or behaviors, which can enhance recommendation systems and targeted marketing strategies [10], [11]. In biological networks, community detection reveals functional modules or protein complexes, and contributes to a better understanding of cellular processes and disease mechanisms [12], [13]. Additionally, fields like communication networks, financial systems, and transportation networks takes community detection to optimize efficiency, bolster security, and improve resilience against failures or attacks [14], [15].

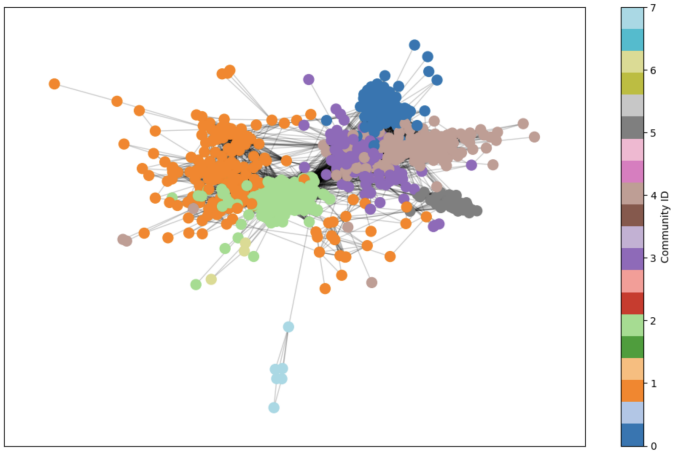

Fig. 1. Visualization of community structure in a complex network. The network consists of nodes grouped into communities, each represented by a different color.

Detecting communities in large-scale graphs presents substantial computational challenges. Traditional algorithms often struggle with scalability, resulting in increased processing times and high resource consumption as network size grows [16]. Furthermore, maintaining the accuracy and quality of detected communities becomes more complex with larger datasets due to the intricate network structures and the presence of noise [10]. These challenges call for the development of more scalable algorithms capable of handling large-scale graphs without compromising performance or accuracy [17].

Quantum-inspired algorithms inherit conceptions from quantum computing to enhance classical computational methods [18]–[22]. Quantum Hamiltonian Descent (QHD) [23], [24] is an algorithm designed to efficiently solve optimization problems by leveraging quantum tunneling effects to escape local minima, and therefore enhances performance in non-convex optimization scenarios. By simulating the behavior of quantum systems, Quantum Hamiltonian Descent can navigate complex energy landscapes to find optimal solutions more effectively than some traditional optimization techniques [25]. This makes it a promising approach for tackling the computational demands of large-scale community detection, where the formulation is not always convex.

Our approach involves formulating the community detection problem as a QUBO model as shown in Figure 2. The QUBO formulation is a versatile framework for representing combinatorial optimization problems where the objective is to minimize a quadratic function of binary variables [26]. By expressing community detection in this form, we can apply optimization algorithms like Quantum Hamilto-

nian Descent directly. In this way, the challenge of running graph algorithms on GPUs can be addressed by transforming them into a QUBO formulation, which allows for the deployment of GPU-accelerated algorithms. Quantum Hamiltonian Descent is particularly effective for solving QUBO models due to its ability to efficiently explore huge and complex solution spaces. By mimicking the dynamics of quantum systems, it can avoid becoming trapped in local minima and converge rapidly to high-quality solutions. This efficiency is essential for large-scale problems where traditional optimization methods may be too slow or require excessive computational resources.

To further improve efficiency and solution quality, we have developed a multi-level algorithm that iteratively refines community assignments. This algorithm alternates between QUBO formulation and Quantum Hamiltonian Descent solving at different levels of graph granularity. Starting from a coarse representation of the graph, it progressively refines the community structure by incorporating more detailed information in each iteration. This hierarchical approach helps in escaping local optima and enhances the overall accuracy of the community detection process.

Our method has been benchmarked against GUROBI [27], which is a leading commercial solver renowned for its optimization capabilities. On smaller problem instances, our algorithm matches GUROBI's performance, demonstrating its effectiveness and reliability. Notably, for larger problems exceeding 1,000 variables, our approach surpasses GUROBI. This performance advantage is crucial for practical applications involving large-scale graphs where computational resources and time are significant constraints. Recognizing the computational intensity of large-scale community detection, we have implemented our algorithm on multi-GPU architectures. GPUs offer massive parallel processing power, which accelerates the Quantum Hamiltonian Descent process and handles the extensive computations required for large graphs. Our implementation demonstrates excellent scalability and makes it feasible to analyze large networks in reasonable time budget. This efficient use of high-performance computing resources indicates the practicality of our approach for real-world applications.

Our contributions are:

- Developed a novel quantum-inspired community detection algorithm utilizing QHD optimization
- Formulated community detection as a QUBO problem with an iterative multi-level refinement approach
- Demonstrated competitive performance with GUROBI solver on small instances and superior scalability for problems exceeding 1,000 variables

The remainder of this paper is organized as follows. Section II provides the necessary background on community detection, QUBO problems, and quantum-inspired optimization techniques. In Section III, we present the formal mathematical framework of our approach, detailing the QUBO formulation. Section IV describes our implementation, including the multi-level algorithm design and QHD algorithm. We present comprehensive experimental results and performance analysis in Section V. Finally, Section VI concludes the paper with a summary of our contributions and directions for future research.

II. Background

A. Quantum Hamiltonian Descent

QHD introduces a new quantum counterpart to classical gradient descent methods, derived through path integral quantization of the continuous-time limit of gradient descent algorithms. Unlike conventional approaches that only quantize specific components of classical algorithms, QHD quantizes the entire dynamical system, resulting in a quantum evolution governed by a Hamiltonian $\hat{H}(t) = e^{\phi_t}(-\frac{1}{2}\Delta) + e^{\chi_t} f(x)$, where e^{ϕ_t} and e^{χ_t} are damping parameters controlling system energy flow. This formulation allows QHD to take advantages of quantum tunneling effects to escape local minima by considering all possible paths at the same time, including those prohibited in classical mechanics. The algorithm exhibits three distinct phases - kinetic, global search, and descent - and has demonstrated superior performance over both classical gradient-based methods and quantum adiabatic algorithms in solving non-convex optimization problems.

B. Community Detection

Community Detection (CD), also known as graph clustering or graph partition, is one fundamental task in graph theory and network science with the main goal of identifying groups of nodes within a graph that are more densely connected to each other than the rest. Applications of community detection span various fields, such as social network analysis [28], biology [29], computer networks, and recommendation systems [30]. Based on the definition of the nodes, applications, and the definition of a good partition. Various methods have been proposed, such as the modularity-based method [31], which aims to maximize modularity, which is a measure of the strength of the division of a network into communities, spectral clustering, which involves the use the eigenvalues and eigenvectors of matrices like the Laplacian derived from the graph to identify community structures based on the network's spectral properties and hierarchical clustering which use methods such as divisive clustering to build a hierarchy of communities either by progressively merging nodes (bottom-up) or recursively splitting larger communities (top-down) based on similarity measures.

III. Formalization

In this section, we introduce how we transform the CD problem into QUBO form and the main considerations of our formulations.

A. Modularity

Formally, the community detection problem with the goal of maximizing modularity can be formulated as follows: Given an undirected graph $G = (V, E)$ with $n = |V|$ vertices and $m = |E|$ edges, the task of community detection is to partition the vertices into k non-empty communities such that nodes within the same community are more densely connected while nodes in different communities are sparsely connected. One commonly used metric to measure how well the graph is partitioned is 'modularity' which is defined by:

$$Q = \frac{1}{2m} \sum_{i,j} \left(A_{ij} - \frac{d_i d_j}{2m} \right) \delta(c_i, c_j) \tag{1}$$

where A_{ij} is the element of the adjacency matrix, d_i and d_j are the degrees of nodes i and j. And $\delta(c_i c_j)$ is the Kronecker delta function that equals 1 if nodes i and j are in the same community and 0 otherwise.

Various heuristics have been proposed to address the community detection problem. Cut-based methods aim to minimize inter-community edges while maintaining balanced partitions [32]. Modularity-based methods focus on maximizing the density of intra-community edges relative to a null model [33]. Another approach involves using quantum annealing; however, this method introduces additional overhead due to the need to embed the problem instance onto the quantum annealer [34].

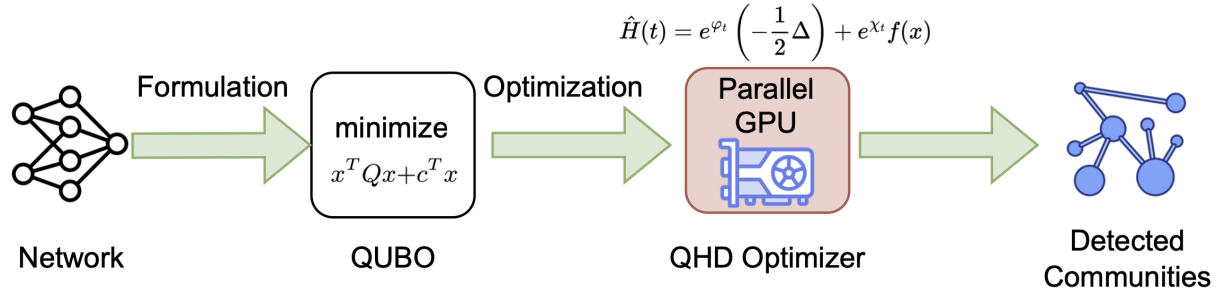

Fig. 2. Overview of our quantum-inspired community detection approach. The input network is reformulated as a QUBO optimization problem, which is then solved using QHD accelerated by parallel GPU computation. The QHD optimizer uses quantum-inspired dynamics to efficiently identify lowest cost function values in the complex landscape, and delivers superior scalability for instances with thousands of nodes.

B. QUBO Formulation for Community Detection

Inspired by previous classical and quantum methods, we propose a quantum-inspired method that takes Quantum Hamiltonian Descent to replace the original compute-intensive components of classical algorithms. This method first transforms the CD problem into a QUBO formulation, which is the first step for the use of both classical and quantum-inspired solvers that can be executed on GPUs without the need for direct embedding onto quantum hardware. The specific formalization is as follows.

Algorithm 1 QUBO Construction for Community Detection

Input:
n: number of nodes
k: number of communities
B: modularity matrix
$G(V, E)$: input graph
w_1, w_2, w_3: penalty weights
Output: QUBO matrix Q and linear terms b
Initialize $Q \in \mathbb{R}^{nk \times nk}, b \in \mathbb{R}^{nk}$ to zero
function IDX(i, c) **return** $i \cdot k + c$
end function
// Modularity term
$Q_{\text{idx}(i,c),\text{idx}(j,c)} \leftarrow -w_1 B_{ij}$
// Assignment constraints
$Q_{\text{idx}(i,c_1),\text{idx}(i,c_2)} \leftarrow 2w_2$
$b_{\text{idx}(i,c)} \leftarrow -w_2$
// Cut penalty
$i_c \leftarrow \text{idx}(u, c), j_c \leftarrow \text{idx}(v, c)$
$Q_{i_c,j_c} \leftarrow -2w_3$

1) Direct QUBO Formulation for Small Networks: To adapt the modularity optimization problem for QUBO solvers, we construct a QUBO objective function that encapsulates both the modularity measure and the necessary constraints for valid community assignments. Let binary variables $x_{i,c} \in \{0, 1\}$, where:

$$x_{i,c} = \begin{cases} 1 & \text{if vertex } i \text{ is assigned to community } c, \\ 0 & \text{otherwise.} \end{cases}$$

Assume a maximum of k communities, with $c \in \{1, 2, \ldots, k\}$. The modularity contribution can be expressed using the binary variables as:

$$Q_M = \frac{1}{2m} \sum_{i,j \in V} \left(A_{ij} - \frac{d_i d_j}{2m} \right) \sum_{c=1}^{k} x_{i,c} x_{j,c}. \tag{2}$$

. Different from the previous formalization, which only focused on maximizing modularity, we also added other terms. To ensure that each vertex is assigned to exactly one community, we impose the following constraint:

$$Q_A = \lambda_A \sum_{i \in V} \left(1 - \sum_{c=1}^{k} x_{i,c} \right)^2, \tag{3}$$

where λ_A is a penalty coefficient that enforces the constraints, and expanding the squared term ensures that derivation from the constraint incur a quadratic penalty. To prevent trivial solution where all vertices are assigned to a single community or most vertices are assigned to several communities and aim to provide a balance size of communities, we also introduce the constraints on the size of communities:

$$Q_S = \lambda_S \sum_{c=1}^{k} \left(\sum_{i \in V} x_{i,c} - \frac{n}{k} \right)^2, \tag{4}$$

where λ_S is the penalty coefficient for balancing community sizes and $\frac{n}{k}$ represents the desired average community size. Based on these, the complete QUBO objective function to be maximized can be formed as

$$Q = -Q_M + Q_A + Q_S, \tag{5}$$

where $-Q_M$ corresponds to the maximization of the modularity, Q_A enforces the constraint that each vertex will be in exactly one community, and Q_S enforces a balanced constraint, which is also a consideration in most CD formalization. In general, our formalization gives comprehensive objective functions that take multiple aspects into consideration instead of solely maximizing the modularity metric. More details are shown in Algorithm III-B.

2) Scale to Larger Networks: While previous direct QUBO formalization is effective for small to medium-sized networks($|V| \leq 1000$), larger networks require more scalable approaches. To address this and inspired by classical methods [35], we employ a hierarchical methodology that maintains solution quality while reducing computational complexity. More specifically, our method includes the following steps: Coarsening, initial partition, uncoarsening, and refinement. More details are shown in Algorithm III-B2.

Coarsening Phase: We iteratively reduce the graph size by aggregating vertices into super-nodes, thereby preserving the community structure at multiple scales. At each coarsening step, a heavy-edge matching strategy is utilized to select vertex pairs with strong connectivity:

$$w(e) = \alpha \frac{|N(u) \cap N(v)|}{|N(u) \cup N(v)|} + \beta \frac{A_{uv}}{\max_{e \in E} A_{uv}}, \tag{6}$$

Algorithm 2 Multilevel Community Detection

Input:
$G_0(V_0, E_0)$: input graph
k: number of communities
θ: coarsening threshold
Output: Community assignments $P : V_0 \to 1, \ldots, k$
function COARSEN(G_i)
    Match nodes in G_i to form super-nodes
    Combine matched nodes to create G_{i+1} **return** G_{i+1}
end function
function PROJECT(P_{i+1}, G_i)
    Map community assignments from level $i+1$ to i **return** P_i
end function
// Coarsening Phase
$i \leftarrow 0$
while $|V_i| > \theta$ **do**
    $G_{i+1} \leftarrow$ COARSEN(G_i)
    $i \leftarrow i + 1$
end while
$m \leftarrow i$ // Final level
// Initial Solution
$P_m \leftarrow$ SOLVEBASE(G_m, k)
// Uncoarsening Phase
for $i = m - 1$ **downto** 0 **do**
    $P_i \leftarrow$ PROJECT(P_{i+1}, G_i)
    $P_i \leftarrow$ REFINE(P_i, G_i, k)
end for
return P_0

where $N(u)$ denotes the neighborhood of vertex $u.\alpha$, and β are weighting coefficients that balance the contribution of neighborhood overlap and edge weight. This coarsening phase reduces the number of vertices while preserving the essential community structure.

Initial Partition: Once the graph is sufficiently coarsened to a manageable size, we apply the direct QUBO formulation (5) to partition the coarsest graph. This step provides an initial community assignment that captures the high-level structure of the original graph.

Uncoarsening and Refinement: After initial partitioning is found in the coarsest graph, the partitioning is then projected back to the original graph through the following steps:

1) **Projection**: Starting from the coarsest level, iteratively map the community from each coarsened graph G_i to the next finer graph G_{i-1}. This is based on the super-node correspondence established during the coarsening phase which can effectively transfer the high-level community structure to more detailed graph levels.
2) **Refinement**: At each level, we optimize the community assignments by iteratively reassigning nodes to communities that result in the highest gain in modularity. This involves evaluating potential moves for each node and updating its community assignment if the move improves the overall modularity. The refinement process continues until certain iterations of the threshold are met or no further improvement is achieved.

IV. IMPLEMENTATION

A. QHD on QUBO

QHDOPT [25] implements Quantum Hamiltonian Descent for solving nonlinear optimization problems. Its key innovation is implementing this optimization via quantum evolution governed by the time-dependent Schrödinger equation:

$$i\frac{\partial}{\partial t}\Psi(t,x) = \left(e^{\phi_t}\left(-\frac{1}{2}\Delta\right) + e^{\chi_t} f(x)\right)\Psi(t,x)$$

where Δ is the Laplacian operator and e^{ϕ_t}, e^{χ_t} control the energy distribution of the quantum system.

A significant computational advantage of this approach is that it requires only matrix multiplication operations, avoiding the need to solve linear systems (Ax=b). This makes the method particularly amenable to modern hardware acceleration. For practical implementation, QHDOPT employs a discretization and embedding strategy where the continuous Hamiltonian is discretized into an N^n-dimensional operator:

$$\hat{H}(t) = e^{\phi_t}\left(-\frac{1}{2}L_d\right) + e^{\chi_t} F_d$$

where L_d represents the discretized Laplacian and F_d encodes the objective function.

The method's matrix-multiplication-based formulation opens up possibilities for various compression techniques that can transform large sparse problems into smaller, denser ones. This includes techniques like tensor network compression [36], hierarchical matrix approximations [37], and randomized sketching methods [38]. Any additional constraints created during problem transformation can be efficiently handled through penalty-based methods, avoiding the need for complex constraint satisfaction algorithms.

When dealing with QUBO problems, QHDOPT can be efficiently accelerated using GPUs through careful implementation of the quantum Hamiltonian dynamics. The key is mapping the QUBO problem $\min_{x\in\{0,1\}^n} x^T Qx + b^T x$ to QHD's Hamiltonian framework in a way that exploits massive parallelism. Sparse operations can be particularly accelerated using specialized GPU packages like cuSPARSE [39] or MAGMA [40], which provide optimized implementations for sparse matrix operations. The time evolution can be implemented using GPU-optimized linear algebra operations, with the Laplacian operator Δ computed using parallel finite difference schemes and the potential term $e^{\chi_t} f(x)$ evaluated using batched matrix operations.

By leveraging frameworks like PyTorch [41] or JAX [42] that provide automatic differentiation and GPU acceleration, the quantum dynamics can be simulated efficiently - the gradient computations for the Hamiltonian evolution can be parallelized across the quantum state dimensions, and the time evolution steps can be batched for exploring multiple initial conditions simultaneously. The classical refinement step in QHDOPT can utilize GPU-accelerated optimizers to efficiently project solutions back to binary values. This hybrid quantum-classical approach combines quantum effects with massive parallel computing capabilities, making it particularly effective for large-scale optimization problems where traditional methods might struggle.

B. Multi-level Community Detection

This multilevel community detection algorithm is designed to efficiently handle large-scale graphs by employing a hierarchical approach. The algorithm operates in three main phases: First, in the coarsening phase, it repeatedly combines nodes to create a hierarchy of progressively smaller graphs while preserving the community structure. Once the graph is sufficiently small, it solves the community detection problem directly on this coarsened graph. Finally, in the uncoarsening phase, it progressively maps the solution

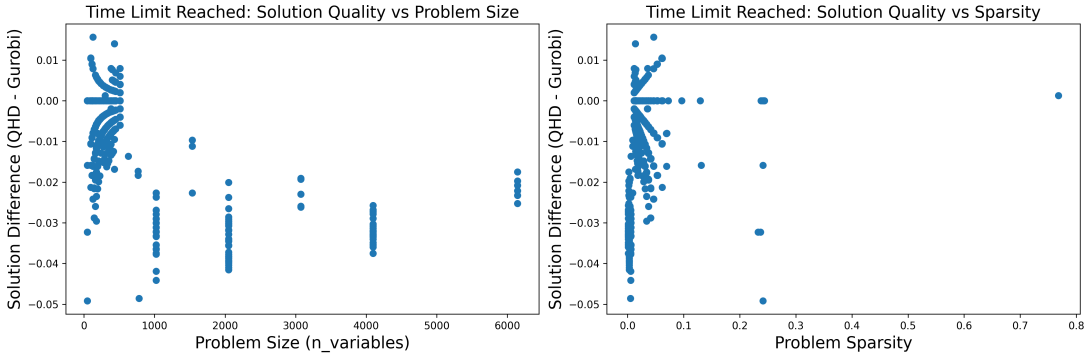

Fig. 3. Solution Quality Comparison When GUROBI Hits Time Limit: For 739 instances where GUROBI exceeded time limits (predominantly in larger problems), QHD found better solutions in 71.4% of cases. For larger-scale problems, QHD demonstrated superior performance by finding better solutions than GUROBI within the same time constraints. This advantage stems from QHD's inherent parallel processing capabilities, which can be further enhanced through additional GPU resources and optimized sparse matrix operations, suggesting even greater potential for scaling to larger problem instances.

back to finer levels while refining the communities at each step. This multilevel approach allows the algorithm to maintain both computational efficiency and solution quality by working with smaller problems during the initial solution while preserving the ability to make fine-grained adjustments during refinement.

V. Evaluation

A. Evaluation Setting

The experimental evaluation was conducted on a system running Debian Linux with kernel version 5.10.0-22-amd64. The computing platform features a dual 16-core CPU (32 cores total). The server is equipped with 251 GB of RAM. Implementation of QHD on QUBO is running with four NVIDIA A5000 GPUs and the comparison with GUROBI is conducted with CPUs as mentioned.

B. QUBO Solver with GUROBI and QHD

Comparing the computational performance between GUROBI and QHD presents unique challenges due to their different control parameters. While GUROBI can be configured with node exploration limits and termination times, QHD allows adjustment of sample sizes and iteration counts. To establish comparisons, we adopted a time-based benchmarking approach: first measuring QHD's execution time, then allocating GUROBI the same as its time limit. This methodology is justified because superior performance can be demonstrated either through faster execution at equal solution quality or through better solutions within equal time constraints. Our experiments focused on the latter approach, comparing solution quality between the two solvers under equivalent time constraints. The results demonstrate that QHD achieves higher solution quality while GUROBI cannot finish with status as OPTIMAL within the allocated time. It's worth noting that QHD's performance can be further enhanced with additional computational resources due to its inherent massive parallelism capabilities. The results in Figure **??** and Figure 3 demonstrate robust performance patterns across a substantial dataset of 938 instances. In the 199 cases where GUROBI found proven optimal solutions (typically smaller problems with mean size of 54 variables), QHD matched these optimal solutions in 75.4% of cases. More importantly, in the larger set of 739 instances where GUROBI hit its time limit (predominantly larger problems with mean size of 614 variables), QHD demonstrated superior performance by finding better solutions in 71.4% of cases and matching GUROBI's solutions in another 17.2%. While the time-limited instances show lower sparsity (mean 0.028 vs 0.157), this is primarily a characteristic of larger problem instances rather than a direct driver of performance difference. The results, based on this comprehensive dataset, strongly indicate QHD's effectiveness for larger-scale optimization problems where traditional solvers face computational limitations, regardless of sparsity.

C. Evaluation on Small Size Networks

Our experimental evaluation compared the Quantum Hamiltonian Descent approach with the GUROBI-based modularity optimization across a diverse set of network instances. As shown in Table I, the test bed has 10 networks ranging from a graph with (52 nodes and 146 edges) to an instance of (1,034 nodes, 26,749 edges), with edge densities from 3.4% to 15.2%. As shown in Fig. 5, the QHD-based method demonstrated robust performance, achieving higher modularity scores in 8 out of 10 instances compared to the GUROBI implementation. The average modularity difference of 0.0029 in favor of QHD suggests that quantum-inspired optimization can effectively match or slightly exceed traditional exact optimization approaches. This robust performance, where QHD achieves higher modularity scores in 8 out of 10 test instances while using only 20% of GUROBI's computational time with four GPUs, demonstrates its practical advantages over classical modularity optimization methods, with the potential for even greater efficiency gains through increased GPU parallelization.

TABLE I
Instance Properties and Modularity Scores

Instance	Nodes	Edges	Density %	GUROBI	QHD
0	333	2,519	4.56	0.4523	**0.4610**
107	1,034	26,749	5.01	**0.5290**	0.5241
348	224	3,192	12.78	0.3055	**0.3063**
414	150	1,693	15.15	0.5438	**0.5438**
686	168	1,656	11.80	0.3347	**0.3347**
698	61	270	14.75	0.5369	**0.5369**
1684	786	14,024	4.55	0.5528	**0.5640**
1912	747	30,025	10.78	0.5167	**0.5239**
3437	534	4,813	3.38	0.6724	**0.6784**
3980	52	146	11.01	**0.4619**	0.4619

D. Evaluation on Large Size Networks

Table II and Figure 6 of GUROBI and QHD performance across different networks reveal a significant density-dependent pattern. In the Facebook network (density 0.0108), QHD achieves a notable 5.49% higher modularity score (0.7512 ± 0.0258) compared to

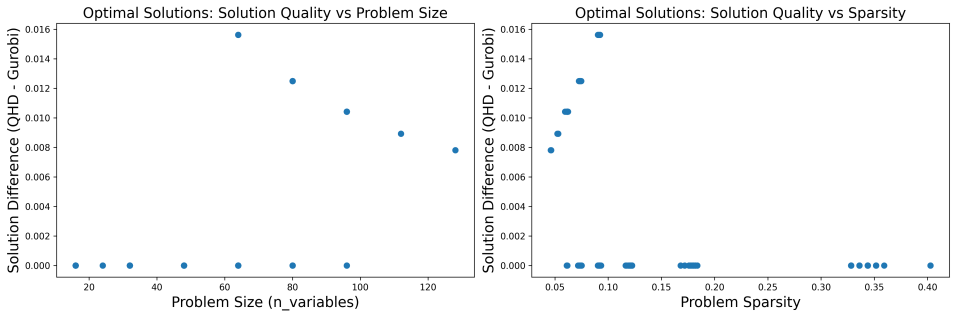

Fig. 4. Solution Quality Comparison When GUROBI Reaches Optimality: Among 199 instances where GUROBI found optimal solutions (predominantly in smaller problems), QHD achieved identical solutions in 75.4% of cases. In cases where QHD did not match GUROBI's optimal solutions (24.6% of optimally solved instances), the objective value differences remained within a 1.6% relative gap, primarily occurring in smaller instances where the absolute differences in objective values were minimal.

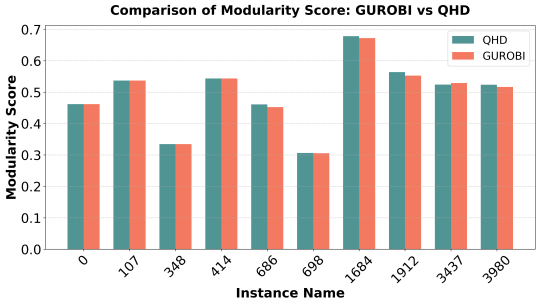

Fig. 5. Performance comparison between QHD and GUROBI on network instances ranging from 52 to 1,034 nodes. QHD achieves superior modularity scores in 80% of test cases with an average improvement of 0.0029, while requiring only 20% of GUROBI's computational time using four GPUs. Results demonstrate QHD's effectiveness across different network densities (3.4%-15.2%).

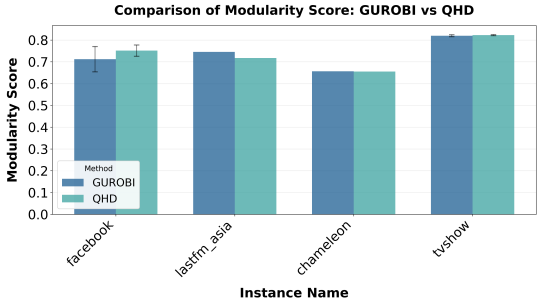

Fig. 6. The performance advantage varies with network density, from QHD's 5.49% improvement on Facebook (density 0.0108) to GUROBI's 3.79% advantage on sparse LastFM (density 0.0010). Both methods show comparable performance on medium-density networks.

GUROBI (0.7121 ± 0.0579), while also demonstrating better stability with lower variance. The densest network, Chameleon (density 0.0121), shows nearly identical performance between the methods, with only a 0.19% difference favoring GUROBI. The TVShow network, despite its lower density (0.0023), exhibits near performance from both methods, with QHD showing a marginal advantage of 0.33% (QHD: 0.8223 ± 0.0025, GUROBI: 0.8196 ± 0.0044) and both methods maintaining very low variance. Notably, in the sparsest network, LastFM (density 0.0010), GUROBI outperforms QHD by 3.79%. These results indicate that QHD's advantages are most pronounced in moderately dense networks. And GUROBI maintains good performance across network types, particularly in sparser networks, which is attributed to its branch-and-cut algorithm.

TABLE II
COMPARISON OF GRAPH PROPERTIES AND MODULARITY SCORES

Instance	Nodes	Edges	Density %	GUROBI	QHD
facebook	4,039	88,234	1.08	0.7121	**0.7512**
lastfm_asia	7,626	27,807	0.10	**0.7455**	0.7172
musae_chameleon	2,279	31,372	1.21	**0.6567**	0.6554
tvshow	3,894	17,240	0.23	0.8196	**0.8223**

VI. CONCLUSION

This work demonstrates the effectiveness of quantum-inspired optimization for community detection through our QHD-based approach. By reformulating community detection as a QUBO problem and leveraging GPU-accelerated quantum-inspired optimization, we achieve comparable or superior performance to traditional methods while reducing computational time. Our experimental results show strong performance on moderately dense networks, with up to 5.49% improvement in modularity scores and enhanced stability compared to GUROBI. The implementation of multi-GPU acceleration suggests further scalability potential for larger networks. These findings highlight the promising intersection of quantum-inspired algorithms and high-performance computing for complex network analysis tasks. Future work could explore extending this approach to other graph optimization problems and investigating additional acceleration techniques for handling ultra-large-scale networks. Better designed algorithms to formulate graphs into denser matrices can reduce the number of variables in QUBO, and combination with high-performance sparsity computation will also be helpful. Our results demonstrate that quantum-inspired methods, combined with modern computing architectures, offer a practical pathway for advancing the capabilities of community detection in real-world network analysis applications.

VII. ACKOWLEDGEMENT

JL is supported in part by the University of Pittsburgh, School of Computing and Information, Department of Computer Science, Pitt Cyber, PQI Community Collaboration Awards. And by NASA under award number 80NSSC25M7057. This research used resources of the Oak Ridge Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC05-00OR22725. RL is supported by NSF Grants 2322919, 2420632, 2426031, 2426940, 2114113, and DOE Grant DE-SC0022069. We thank Yuxiang Peng from University of Maryland and Jiaqi Leng from UC Berkely for their helpful and insightul discussions.

***Abstract*—Combinational Equivalence Checking (CEC) is a crucial technique in electronic design automation for verifying the functional equivalence of combinational circuits. Recently, combinational circuit design increasingly incorporates more complex arithmetic structures, commonly known as datapath circuits. However, existing state-of-the-art tools often exhibit subpar performance in solving datapath CEC problems. To further advance the exploration on datapath CEC process, this study introduces PDP-CEC (Parallel Dynamic Partitioning Combinational Equivalence Checking), a novel parallel CEC approach integrating circuit partitioning and dynamic task scheduling into the CEC process, enhancing the efficiency of CEC for datapath circuits. PDP-CEC introduces an innovative method for selecting critical nodes to split the search space of the CEC problem, facilitating the efficient generation of numerous independent subproblems. Meanwhile, a dynamic task scheduling strategy is implemented in PDP-CEC to ensure load balancing and prevent hard-to-solve subproblems from stalling the entire process. Compared to the most advanced tools such as ABC and Hybrid-CEC, PDP-CEC significantly accelerates CEC process, achieving speedups ranging from 5.11x to 125.27x, while effectively solving approximately three times more datapath CEC problems. With excellent scalability, PDP-CEC shows substantial improvements in combinational equivalence checking for datapath circuits, offering an efficient parallel approach to meet the demands of large-scale datapath CEC tasks.**

***Index Terms*—Combinational Equivalence Checking, parallel computing, circuit partitioning, dynamic task scheduling.**

I. Introduction

Combinational equivalence checking (CEC) involves verifying whether two combinational circuits are functionally equivalent. In contemporary circuit design processes [1], circuits are optimized through structural rewriting [2] or logic synthesis [3] after the RTL design stage. CEC is then employed to ensure that the circuit's functionality remains consistent before and after those optimizations. Its further applications cover various scenarios in electronic design automation (EDA) and digital integrated circuit design, including functional equivalence removal [4], computation of structural choice [5] and sequential equivalence checking [6].

Today, there has been a clear trend toward designing combinational circuits with increasingly complex arithmetic components [7]. Modern circuits are typically composed of fundamental arithmetic units, such as multipliers and multiplexers, collectively referred to as datapath circuits [8]. However, state-of-the-art CEC tools that are based on the SAT sweeping algorithm [9] [10] perform poorly when applied to datapath circuits.

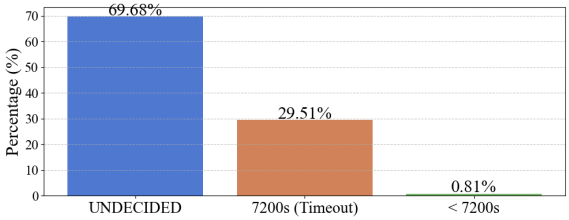

Fig. 1. Result distribution of ABC "&cec" on 742 industrial datapath circuits. "UNDECIDED" indicates the tool's inability to generate the result.

For example, 742 industrial datapath circuit cases were verified with the ABC "&cec" command [11], a widely used tool for logic synthesis and formal verification in both industry and academia, whose core is the SAT sweeping algorithm. As shown in Fig. 1, nearly 70% of the cases returned "UNDECIDED", while 29% produced no results after two hours. Only 1% completed verification within the time limit.

To improve the weak performance of these tools on datapath CEC problems, prior studies have predominantly concentrated on optimizing the CEC solving process, including more intelligent simulation methods [9] and unified representations [12]. As research on serial algorithms reaches saturation, it becomes crucial to explore universal parallel workflow for datapath circuits. There are two key challenges in parallelizing the datapath CEC process:

- **Ineffective partition** Circuits with high coupling and low locality, if divided naively, risk disrupting functional dependencies, which will create interdependent subcircuits. To generate independent subcircuits, the existing parallel approach [13] partitions circuits with Transitive Fan-In (TFI) cones of Primary Outputs (POs). Similarly, RepCut [14] employs hypergraph partition based on TFI levels. However, these partitioning methods that rely on TFI do not be well-suited for datapath circuits, which typically have a limited number of POs.

¶ Corresponding author

- **Load imbalance** Due to the inherent unpredictability of each subcircuit's workload, driven by the SAT solver at the core of CEC, efficiently balancing tasks in parallel execution becomes challenging. A parallel strategy [15] has been proposed in Satisfiability Modulo Theories (SMT) domain, with a binary tree to store subproblems' results and guide thread actions. However, this approach falls short for the parallel CEC workflow. Starting the execution from the root node's task can lead to significant thread stalling, particularly for the root problem and its nearby subproblems.

To overcome these challenges, we propose PDP-CEC (Parallel Dynamic Partitioning Combinational Equivalence Checking), a novel parallel CEC approach for datapath circuits that integrates circuit partitioning and dynamic task scheduling into the CEC process.

The circuit partitioning algorithm in PDP-CEC utilizes a distinctive node selection method to split the search space, effectively bypassing structural constraints and generating numerous independent subproblems. It incorporates a heuristic to estimate the complexity reduction achieved through partitioning, ensuring that removing assignment nodes propagated and inferred from the selected nodes substantially diminishes the circuit's overall complexity. To enhance this process, we integrate the Metis graph partitioning algorithm [16] and develop an approach for selecting suitable nodes in alignment with the circuit's structure.

Furthermore, PDP-CEC implements a recursive workflow based on a binary splitting tree to guide task scheduling during execution, which shows in Fig. 2. PDP-CEC employs the "master-worker" structure, comprising a master for expanding the binary splitting tree, a monitor for managing task scheduling, and workers for solving subproblems in parallel. With master pre-partitioning the circuit to initialize the tree, the task scheduling strategy helps PDP-CEC attain load balancing among workers, effectively reducing resource waste from idle workers and preventing hard-to-solve subproblems from stalling the entire process.

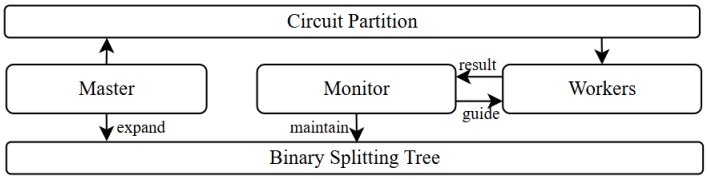

Fig. 2. The thumbnail of PDP-CEC's workflow.

In summary, we present PDP-CEC to fully exploit the potential of circuit structures, and our work makes the following contributions:

- We propose PDP-CEC, which integrates circuit partitioning and dynamic task scheduling to parallelize datapath CEC. With excellent scalability, PDP-CEC considerably outperforms state-of-the-art tools like ABC and Hybrid-CEC achieving speedups ranging from 5.11x to 125.27x with 128 threads in solving time and effectively resolving nearly three times more datapath CEC problems.
- We design a circuit partitioning algorithm for PDP-CEC that employs targeted node selection to split the search space, bypassing structural constraints and generating independent subproblems while ensuring that removing assignment nodes propagated and inferred from the selected nodes substantially decreases the circuit's overall complexity.
- We introduce a dynamic task scheduling strategy to attain load balancing during execution, avoiding resource waste from idle workers and preventing hard-to-solve subproblems from stalling the entire process.

Paper Organization Section II introduces the SAT sweeping algorithm. Section III presents the circuit partitioning algorithm and heuristic for selecting crucial nodes. Section IV details the workflow of PDP-CEC and gives an example of our dynamic scheduling strategy. Section V shows the experimental results, comparing PDP-CEC with state-of-the-art CEC tools. Finally, Section VI concludes the study and discusses future work.

II. Preliminaries

In this section, we introduce the typical CEC process which relies on the *SAT sweeping* algorithm and give an overview in Fig. 3.

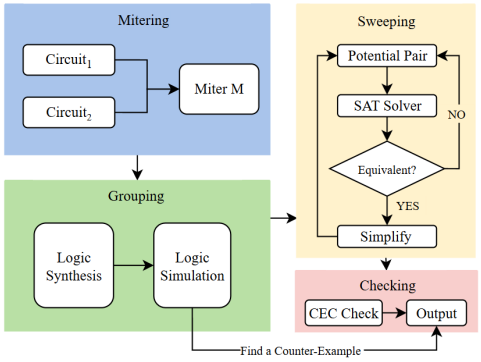

Fig. 3. The typical CEC process with SAT sweeping algorithm.

A complete CEC process typically involves four stages: constructing a miter circuit through mitering, grouping functionally potential-equivalent nodes by logic synthesis [17] and simulation, employing a SAT solver to identify potential-equivalent nodes and simplify the original miter circuit in a topological order through sweeping, and finally, checking the equivalence of the simplified circuit as the output.

Primarily suited for datapath CEC problems, Hybrid-CEC process [18] differs from traditional CEC in two key aspects: (1) it employs the ISD method [18] to reduce the number of pairs requiring verification by comparing TFI's structure with previously proven equivalent pairs, and (2) it partly replaces the SAT solver with the Exact Probability-based Simulation (EPS) method [19], which is better suited for solving low-

width pairs in datapath circuits. However, this method cannot serve as a comprehensive solution for all datapath circuits.

III. Circuit Partitioning Algorithm

Conventional graph partitioning methods often fail to yield parallelizable subcircuits because of high coupling within datapath circuits. To confront the structural intricacies of these circuits, we employ search space splitting to partition them into subcircuits for the following two main reasons:

- Structural information is lost when circuits are sent to the SAT solver. Search space partitioning on circuit level allows for better use of this information.
- Search space splitting avoids the intricate connectivity between gate nodes, focusing on dividing the search space instead of the structure.

In an And-Inverter Graph (AIG), each node represents an AND gate (or an XOR gate after preprocessing in PDP-CEC) with a maximum fan-in of 2 and a minimum fan-out of 1, except for output gates. Given the inherent characteristics of the circuit, each gate can only take values of 0 or 1, corresponding to low or high voltage levels. When assigning 0 or 1 to a gate, the search space of the original circuit is effectively divided into two independent regions. Based on the assignment, forward inference along the input direction and backward propagation along the output direction will be performed to assign new nodes through the property of gates. Removing those gates with assignments modifies the circuit structure, resulting in two smaller, independent subcircuits that each cover half the search space of the original circuit. We refer to this process of partitioning through assignment propagation as circuit incremental partitioning.

Algorithm 1 IncrementalPartitioning

1: **Input:** $TreeLevel\ L, Miter\ M(AIG)$
2: **Output:** $BinaryTree\ BStree$
3: Insert M into $BStree$
4: $Queue\ BSque$
5: $BSque.push(M)$
6: **while** $BStree.level \leq L$ **do**
7: $u \leftarrow BSque.pop()$
8: $x \leftarrow$ NodeSelecting(u)
9: $C_0 \leftarrow$ AssignValue$(u, x, 0)$
10: $C_1 \leftarrow$ AssignValue$(u, x, 1)$
11: Insert C_0 and C_1 into $BStree$
12: Push C_0 and C_1 into $BSque$
13: **end while**
14: **return** $BStree$

The Algorithm 1 describes the process of generating a binary splitting tree $BStree$ with a specified level L from the input miter circuit M. As the tree unfolds layer by layer, each parent node branches into two child nodes, representing an equal partitioning of the problem space. This partitioning process continues until it reaches the setting level L, which is determined by the circuit complexity and the number of threads available for parallel execution.

A. Subcircuits Creation

In lines 9 and 10 of Algorithm 1, the *AssignValue* function is invoked to partition circuit $C(V, E)$ into two subcircuits, $C_0(V_0, E_0)$ and $C_1(V_1, E_1)$ by assigning the gate x to 0 and 1, respectively. In the circuit topology, signals assigned to one gate can propagate in two directions. The term *inference* describes backward propagation along the input direction; for instance, if an AND gate's output is 1, both inputs must also be 1. Conversely, forward propagation occurs along the output direction, referred to as *propagation*. In this case, an AND gate's output of 0 will cause the output of the subsequent gate to be 0 as well, unless an inverter is present between them. Removing the assigned gates divides the circuit into two subcircuits with a combined search space equivalent to that of the original. In an AIG, this removal may create single-input gates, which can be simplified to wires, effectively reducing the overall circuit complexity.

Uncertain gates are stored as constraints. For instance, if an AND gate is assigned a 0, the constraint is that both inputs cannot simultaneously be 1, represented as (x_1,x_2,TT). These constraints serve as unique properties of the subcircuits and are subsequently converted into CNF expressions for SAT solver.

B. Nodes Selection

In line 8 of Algorithm 1, the *NodeSelecting* function is called to select appropriate nodes for first assignment. The selection of nodes is critical for the efficiency of the parallel execution process, as we aim to always choose nodes that significantly reduce circuit complexity during partitioning. Before introducing the algorithm for node selection, we first present the heuristic formula used to estimate the complexity of datapath circuit for SAT solving, which is evaluated by counting the number of XOR and AND gates, as expressed in the following formula:

$$\text{Complexity} = 3\log_2(\textit{num}_x) + \log_2(\textit{num}_a), \tag{1}$$

where $\textit{num}_x$ and $\textit{num}_a$ represent the number of XOR and AND gates, respectively.

In datapath circuits, components like multipliers and multiplexers are primarily built from adders, where XOR gates calculate sums and AND gates generate carries. Thus, the number of XOR gates, as a key indicator of the number of adders, carries more weight in (1) while AND gate count reflects circuit size. After partitioning, the number of removed nodes helps estimate subcircuit complexity using (1). However, calculating the exact impact of each node is time-consuming, so we further propose the following heuristic formulas to estimate the extent to which the selected nodes reduce overall circuit complexity:

$$\text{NC} = \frac{\textit{edge}_b - \textit{edge}_b \cdot \left(p_t \cdot \alpha \cdot (1 - \textit{rate}_x)\right)^{\textit{level}}}{1.0 - p_t \cdot \alpha \cdot (1 - \textit{rate}_x)}, \tag{2}$$

$$\text{Eval} = 3\log_2(\text{NC} \cdot \textit{rate}_x) + \log_2(\text{NC} \cdot (1 - \textit{rate}_x)). \tag{3}$$

The heuristic formula (2) for estimating the reduction in node count (NC) after partitioning is based on the geometric

series sum formula. The first term, $edge_b$, represents the number of different types of output edges, as edges with opposite signal assignments can aid propagation. The common ratio is $p_t \cdot \alpha \cdot (1 - rate_x)$, where p_t is the probability of a positive output edge, α is the average number of outgoing edges from a node, and $rate_x$ is the probability of XOR gates in the circuit. The variable *level*, representing the node's distance to the circuit's PO, helps gauge the propagation range. The 0 signal will continue to propagate through positive output edges after one round of propagation, so we use the probability of a positive output edge in the common ratio. By splitting NC into AND and XOR gates with $rate_x$, and applying (1), we can calculate the complexity reduction (Eval) for each node in (3). The node with the highest evaluation score (Eval) is chosen as the initial assignment node for partitioning, whose details are described in Algorithm 2.

Algorithm 2 NodeSelecting

```
Input: Circuit C
Output: Node N
Array Nodes ← GetPotentialNodes(C)
for node ∈ Nodes do
    h_0 ← EvalCompute(node, 0)
    h_1 ← EvalCompute(node, 1)
    node.sum_h ← h_0 + h_1
end for
best_node ← max_sum_h(Nodes)
return best_node
```

Algorithm 2 first identifies the range of potential optimal nodes in the circuit. For circuits solved with EPS, the range of selection is limited to the primary inputs (PI), as the number of PIs is a key factor influencing the speed of EPS. Since XOR chains pose a challenge for SAT-based methods [18], the Metis algorithm is applied to identify a cut set containing most of the XOR gates, aiming to reduce the number of XOR gates through incremental partitioning for circuits solved with SAT. The node that yields the greatest complexity reduction is then selected as the initial assignment node.

IV. Dynamic Task Scheduling Workflow

In PDP-CEC, potential equivalent pairs are directed to either SAT or EPS, depending on the width of miter circuit formed by the pairs' TFI cones. Once the solving method is determined, the original CEC problem will be divided into subproblems, which are then solved in parallel by threads within a thread pool. However, uneven distribution of subproblems across threads can lead to load imbalances. To prevent this issue, PDP-CEC incorporates a dynamic task scheduling workflow, including a binary splitting tree to guide task scheduling.

The workflow of PDP-CEC is illustrated in Fig. 4. Benefiting from the independence of the subproblems generated by partitioning, the framework adopts a "master-worker" structure. Avoiding complexity in control logic, we designed three types of threads: the master thread, the monitor thread, and worker threads in the thread pool.

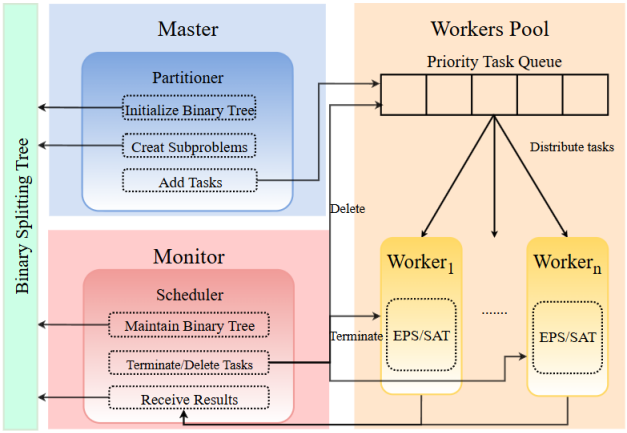

Fig. 4. The Workflow of PDP-CEC.

Master thread initializes the binary splitting tree with the help of the partitioner. In situations where the task queue has gaps, it identifies unresolved leaf nodes, generates new subproblems via the partitioner, adds these to the task queue, and facilitates the growth of the binary splitting tree.

Monitor thread serves as a central control mechanism for managing task scheduling within the workflow. It works alongside the master thread to oversee the node information stored in the binary splitting tree, controls the states of tasks, propagates information about nodes throughout the tree, and removes UNSAT node tasks from the task queue or instructs the threads currently handling those tasks to terminate.

Worker threads solve subproblems in the task queue concurrently, utilizing the solver designated for the original problem. A priority queue within the thread pool ensures that subproblems of lower complexity are solved first, with results being relayed to monitor thread for timely updates to the node information in the binary splitting tree.

A. Binary Splitting Tree

The binary splitting tree is primarily updated when Monitor thread receives new result information, which involves two main operations:

- **Inference towards the root node:** If a node is determined to be UNSAT, and its sibling node has also been proven UNSAT, then their UNSAT results can infer that their parent node is UNSAT. This process proceeds up towards the root node.
- **Propagation towards the leaf nodes:** If a node is UNSAT, then all its descendant nodes in that branch are also UNSAT.

B. Dynamic Task Scheduling Strategy

In the parallel process, each node in the tree has four states: unsubmitted, waiting, running, and completed. Initially, all nodes are in the "unsubmitted" state. Master thread sorts the leaf nodes according to (1), then adds them to the task queue where node's state is "waiting". Tasks in the queue are assigned to Worker threads, which update the nodes' states to

"running" before solving. After obtaining the results, Monitor thread retrieves the task IDs and updates the corresponding node's state to "completed".

We present an execution example in Fig. 5 that demonstrates our scheduling method. Five Worker threads are used, and the left side of the figure shows the binary splitting tree at an intermediate stage. After node 6 is completed and its UNSAT result is passed to Monitor thread, it infers node 3 as UNSAT since both nodes 6 and 7 are UNSAT. Node 2, the sibling of node 3, is subsequently pushed into the task queue and picked up by an idle thread. The propagation from node 6 triggers the termination of the corresponding worker for node 10 and marks node 11 as UNSAT. Since there are still idle threads available, Master thread identifies the next unresolved leaf node, node 8, splits it, and appends nodes 12 and 13 to the tree. Both nodes 12 and 13 are then queued for execution, with the idle Worker thread taking on node 12, while node 13 remains in the task queue.

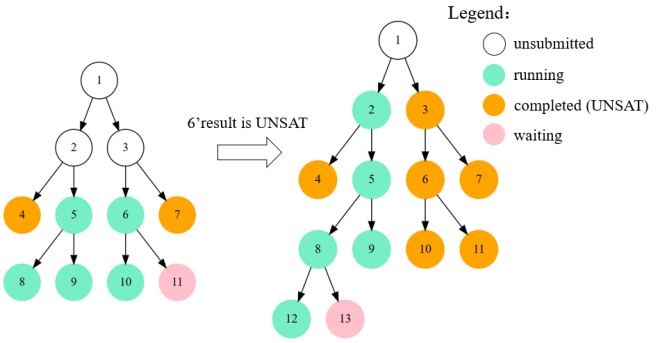

Fig. 5. A running example of our dynamic task scheduling strategy.

V. Experimental Results

In this section, we present the experimental setup and compare PDP-CEC with current representative CEC tools, such as ABC and Hybrid-CEC. Then we identify the factors contributing to the superior performance of PDP-CEC compared to Hybrid-CEC. Finally, we analyze the scalability of PDP-CEC.

A. Experimental Setup

All experiments were performed on a server with 128 Intel Xeon Platinum 8153 cores (2.00 GHz) and 2048 GB of memory, running CentOS 7. PDP-CEC is implemented in C++ and compiled with GNU g++ (version 9.3.1), with all competing methods compiled and executed under the same conditions. Our implementation utilizes the Metis [20] library for graph partitioning and the standard library for parallelism.

The benchmarks used in our experiments are derived from the Integrated Circuit EDA Elite Challenge 2022 [21] with modifications. We select 24 datapath circuits, featuring various sizes and high widths (higher than 32), including multipliers and adders. Each of the 24 instances consists of two functionally equivalent circuits in AIG format and has only a single PO, making parallel method [13] that depends on TFI unsuitable for these benchmarks.

For each experiment, the running time limit for each instance is set to 7200 seconds, and 'TO' means timeout. The unit of running time is seconds, and experiments were conducted with 128 threads by default.

B. Assessment of Datapath Benchmarks

We compare the performance of PDP-CEC with three other CEC tools in Table I:

- OPCEC: A simplified PDP-CEC version without pre-partitioning or the monitor's task submission strategy.
- ABC-SP: The split-based parallel CEC command in ABC, using "&splitprove -P 100 -L 7" for comparison.
- H-CEC: The Hybrid-CEC, a serial solution for datapath CEC.

TABLE I
Performance Comparison of Different CEC Methods on Datapath Benchmarks

Instance	Gates	PDP-CEC	OPCEC	ABC-SP	H-CEC
dpath_1	735	**9.63**	10.54	120.35	200.56
dpath_2	1034	**417.44**	523.08	1415.43	TO
dpath_3	1037	1386.46	**1172.67**	1377.82	TO
dpath_4	6905	**7.57**	8.97	TO	265.01
dpath_5	8003	**2771.45**	TO	TO	TO
dpath_6	6218	**7.21**	8.65	TO	298.92
dpath_7	7073	**12.39**	18.33	TO	1552.04
dpath_8	7994	**2917.33**	TO	TO	TO
dpath_9	6227	**7.25**	8.30	TO	156.46
dpath_10	7076	**14.32**	17.94	TO	490.71
dpath_11	7997	**4162.91**	TO	TO	TO
dpath_12	7079	**15.04**	17.86	TO	585.54
dpath_13	8000	**3180.89**	TO	TO	TO
dpath_14	8063	**4138.11**	TO	TO	TO
dpath_15	8087	**4158.53**	TO	TO	TO
dpath_16	8078	**4940.52**	TO	TO	TO
dpath_17	8066	**3926.71**	TO	TO	TO
dpath_18	8075	**4774.12**	TO	TO	TO
dpath_19	8072	**4134.73**	TO	TO	TO
dpath_20	8081	**4863.37**	TO	TO	TO
dpath_21	8084	**5108.63**	TO	TO	TO
dpath_22	8069	**3891.60**	TO	TO	TO
dpath_23	8090	**3788.22**	TO	TO	TO
dpath_24	9134	TO	TO	TO	TO
Best		22	1	0	0
Solved		23	9	3	7

The comparison results in Table I show that PDP-CEC is consistently the fastest among all methods. Compared to H-CEC, PDP-CEC solves 23 out of 24 instances within 7200 seconds, about 3x more than H-CEC. For instances completing within the time limit, PDP-CEC achieves speedups ranging from 5.11x to 125.27x over H-CEC, with the greatest benefits observed in larger circuits.

PDP-CEC also outperforms ABC-SP, whose search-space splitting strategy resembles PDP-CEC's. However, with the *NodeSelecting* algorithm, PDP-CEC generates more efficient subproblems, while its dynamic task scheduling strategy enables faster subproblem resolution, which results in more solved instances and reduced running time compared to ABC-SP. Finally, PDP-CEC outperforms OPCEC on all other in-

stances except dpath_3, where OPCEC performs better. This is because the key subproblems for dpath_3 are located in the lower levels of the binary splitting tree, a common occurrence in smaller circuits. Overall, the results highlight PDP-CEC's advantage due to its effective task scheduling and partitioning approach.

C. Comparative Analysis of PDP-CEC and Hybrid-CEC

TABLE II
PERFORMANCE COMPARISON OF SAT AND EPS BETWEEN H-CEC AND PDP-CEC WITH 128 THREADS.

Instance	Gates	T_{SAT}		T_{EPS}	
		PDP-CEC	H-CEC	PDP-CEC	H-CEC
dpath_14	8063	4120.48	TO	9.33	331.04
dpath_15	8087	4138.71	TO	9.82	339.92
dpath_16	8078	4939.53	TO	10.99	836.79
dpath_17	8066	3906.93	TO	9.78	423.97
dpath_18	8075	4754.60	TO	9.52	452.88
dpath_19	8072	4113.94	TO	10.79	1685.97
dpath_20	8081	4843.47	TO	9.90	1570.13
dpath_21	8084	5088.58	TO	10.05	1369.43
dpath_22	8069	3871.51	TO	10.09	355.38
dpath_23	8090	3768.02	TO	10.20	454.33

PDP-CEC also makes acceleration on Exact Probability-based Simulation (EPS), which is the key method in H-CEC. Table II shows the performance comparison between PDP-CEC and H-CEC on SAT and EPS. In this experiment, we extract 10 instances from the benchmark set, which H-CEC cannot solve. These results highlight that H-CEC struggles to handle these instances because of its insufficient SAT component. In contrast, PDP-CEC successfully resolves pairs identified as intractable SAT problems, which is critical for solving more complex datapath circuits. Additionally, PDP-CEC achieves speedups ranging from 35.48x to 158.60x over H-CEC for EPS. While the speedup is expected to be linear with the number of threads, slight deviations occur as a result of the overhead associated with the thread pool and graph partitioning. Remarkably, superlinear speedups are possible with sufficient system support.

D. Scalability Analysis of PDP-CEC

TABLE III
EXECUTION TIME WITH VARIOUS THREADS FOR PDP-CEC.

Instance	PDP-CEC				
	8t	16t	32t	64t	128t
dpath_1	33.62	26.75	16.38	13.74	9.63
dpath_4	16.49	8.52	7.25	8.30	7.57
dpath_6	14.49	8.67	9.92	8.69	7.21
dpath_7	48.59	31.23	20.84	19.37	12.39
dpath_9	19.03	11.12	9.45	8.29	7.25
dpath_10	55.20	31.64	19.47	18.92	14.32
dpath_12	56.26	30.20	22.30	19.94	15.04
average	34.81	21.16	15.09	13.89	10.49

We assess the scalability of PDP-CEC by varying the thread count from 8 to 128. The instances selected for this experiment, listed in Table III, were solved by PDP-CEC across

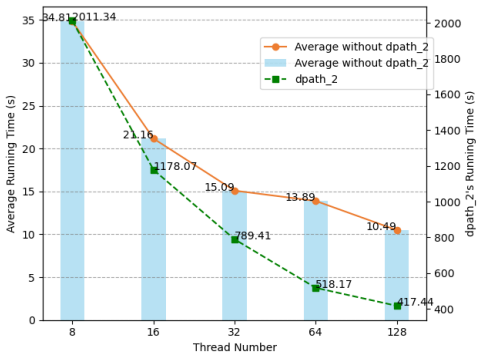

Fig. 6. The line-bar chart of execution time with various threads for PDP-CEC. Average data is come from Table III. The instance dpath_2 is separately illustrated.

different thread configurations. To minimize estimation errors caused by the extended running time of instances dpath_2, we report the average running time of other instances in Fig. 6, with dpath_2 shown separately as a distinct line. At lower thread counts, both average line and dpath_2 line show a near-linear speedup. However, the running time converges more gradually as threads increase, due to additional overhead from thread management and graph partitioning. In summary, the results showcase PDP-CEC as a scalable solution with strong potential for adaptation to distributed systems, supporting application to even larger datapath circuits.

VI. Conclusion

This study introduces a novel Parallel Dynamic Partitioning CEC approach, PDP-CEC, breaking the limitations of existing CEC methods, particularly in solving datapath CEC problems. By exploiting the inherent properties of circuits, PDP-CEC employs search space splitting in circuit partitioning for datapath CEC problem. An algorithm is designed in PDP-CEC for selecting assigned nodes and generate massive subproblems efficiently without dependencies. PDP-CEC applies a dynamic task scheduling strategy to manage the parallel execution of subproblems, preventing stalled workers and ensuring efficient resource utilization. Compared to three other CEC tools, PDP-CEC demonstrates superior performance, solving more instances and reducing overall running time. In conclusion, PDP-CEC demonstrates strong capability in solving datapath CEC problems, providing a scalable and efficient solution that surpasses the performance limitations of existing methods.

Future research will aim to extend PDP-CEC to distributed systems, further enhancing scalability and enabling applications on larger datapath circuit designs.

***Abstract*—In recent years, cloud providers are dedicated to enabling FPGA multi-tenancy to improve resource utilization, but this new sharing model introduces power side-channel threats, where attackers detect voltage fluctuations from co-located circuits. This paper proposes LeakyDSP, a novel on-chip sensor that maliciously configures DSP blocks to sense fine-grained voltage fluctuations but is overlooked by existing studies. Our experimental results show that LeakyDSP achieves high sensitivity to voltage fluctuations and strong robustness to different placements. Besides, we apply LeakyDSP to extract full AES keys with 25 k-78 k traces and build covert channels with a high transmission rate of 247.94 bit/s.**

I. Introduction

In recent years, leading commercial cloud service providers such as Amazon AWS [3], Alibaba [2], and Microsoft Azure [24] have introduced remote access to high-performance Field Programmable Gate Arrays (FPGAs) [6]. To maximize FPGA utilization efficiency, both academia and industry have focused their efforts on enabling the co-residence of FPGA circuits by independent tenants, referred to as multi-tenant FPGAs. For example, researchers have proposed different end-to-end frameworks to virtualize FPGA resources in the cloud environment [15], [18], [20], [21], [33], [38]. Besides, Xilinx has integrated Stacked Silicon Interconnect [36] and Dynamic Function eXchange [35] into advanced FPGAs to facilitate multi-tenant FPGAs.

While this new sharing model has attracted considerable attention from both academia and industry, it introduces new security risks, notably power side-channel leakages [13], [39], [42]. Specifically, different users' circuits on a multi-tenant FPGA share the same power delivery network (PDN) [6]. Consequently, transient voltage fluctuations in the shared PDN, induced by computing activities of a victim circuit, can be sensed by a co-located attack circuit. Leveraging this capability to sense voltage fluctuations, various remote power side channel attacks have been proposed to extract cryptographic keys [14], [32], [42], build covert channels [42], fingerprint computation workloads [13], and steal DNN model architectures [41] or inputs [25].

To sense voltage fluctuations, prior studies have proposed various malicious circuit designs that exploit combinations of traditional FPGA logic resources, i.e., Look-up Tables (LUTs) [14], [31], [32], [42], carry chains (CARRY) [10], routing resources [28], and flip-flops (FFs). For instance, time-to-digital converters (TDCs) [10] chain CARRY resources as a long delay line and connect each CARRY output precisely to an FF within the same slice. Besides, the ring oscillator (RO) circuits configure LUTs to implement *combinational loop* that generates oscillating signals, which are then captured by FFs.

In response, several countermeasures have been proposed to prevent the deployment of such circuits on multi-tenant FPGAs [4], [10], [30]. First, as TDC circuits require a long delay chain placed in continuous vertical areas, they can be mitigated by restricting access to such areas [10]. Second, as RO circuits inherently contain combinational loops and some TDC circuits [12] include latch structures, bitstream checks targeting these key structures have been introduced [4], [30]. Although there are new sensor designs [14], [28], [31], [32] that bypass these placement constraints and bitstream checks, all these designs are crafted by configuring traditional FPGA logic resources that are in the primary focus of bitstream checks [17]. Outside the scope of traditional FPGA resources, the DSP blocks dedicated to complex mathematical operations remain unexplored. To this end, we are interested in the following research questions:

Can voltage fluctuations be sensed through maliciously configuring DSP blocks? If so, what attacks can be launched, and what information might be leaked?

In this paper, we propose LeakyDSP, a new on-chip sensor that is built by configuring DSP blocks to sense fine-grained voltage fluctuations without requiring any traditional FPGA logic resources. In a multi-tenant FPGA environment, DSP blocks are partitioned into separate virtual areas, allowing each tenant exclusive access to their DSP blocks [21]. Our key observation is that each dedicated DSP block has three

† Co-first authors. * Corresponding authors.

main sub-components, i.e., a pre-adder, a multiplier, and an arithmetic logic unit (ALU). The signal delay incurred by either sub-components is sensitive to voltage, resulting in different signal propagation delay between output and input of a DSP block when different voltage fluctuations occur.

To this end, we craft LeakyDSP as follows. *First*, we amplify the effect of voltage variations on the output of DSP blocks by maximizing the signal propagation delay. This is achieved by creating a chain within a single DSP block that links the aforementioned sub-components without intermediate registers. Then, multiple configured DSP blocks are connected in series to accumulate their signal delays. To capture and store the resulting flipped bits, the output register of the final DSP block is instantiated. *Last*, we employ the `IDELAY` primitive to dynamically adjust the initial delay of DSP blocks after this sensor is deployed onto an FPGA board. This post-deployment calibration enhances LeakyDSP's robustness to different FPGA placements.

To demonstrate the viability of LeakyDSP, we first characterize the sensitivity of LeakyDSP in two experiments. In each experiment, the TDC [10] (i.e., the most studied circuits to sense voltage fluctuations) is re-implemented as a baseline and compared against LeakyDSP regarding their sensitivity. Specifically, we put LeakyDSP (resp., TDC) under a given placement and measure its sensitivity to voltage fluctuations caused by different victim activities. *Further*, considering that PDN influences its circuits unfairly, we evaluate the impact of spatial proximity to a given victim circuit on LeakyDSP (resp., TDC) by placing it onto different FPGA locations. Both experimental results show that LeakyDSP achieves fine-grained sensitivity to voltage fluctuations and strong robustness to different placements.

We then demonstrate the security implications of LeakyDSP by mounting two end-to-end case studies. First, we perform a correlation power analysis (CPA) against an AES-128 module running on FPGA, with 25 k-78 k traces for extracting the full AES key under 8 different placements of LeakyDSP and 4 operating frequencies of the AES circuit. Second, we use LeakyDSP to establish a covert channel with a high transmission rate of 247.94 b/s and low error rate of 0.24%.

Summary of contributions: The main contributions of this paper are as follows:

- We propose LeakyDSP, a new on-chip sensor design on multi-tenant FPGAs. To the best of our knowledge, we are the first to identify the information leakage through DSP blocks.
- We perform a comprehensive evaluation of LeakyDSP's capabilities. Experimental results show that LeakyDSP achieves high sensitivity to voltage fluctuations and strong robustness to different placements.
- We demonstrate the security implications of LeakyDSP, including extracting full AES keys and building covert channels.

The source code to reproduce the experiments is released at https://github.com/jjzou2002/LeakyDSP.

II. Background and Related Work

A. Power Side Channels on Multi-tenant FPGAs

FPGAs offer significant advantages for customized computation due to their inherent re-programmability and high-performance capabilities [26]. In recent years, the emergence of multi-tenant cloud FPGA environments, attracting prominent interest from both industry and academia [6], promotes flexible and cost-effective access to advanced FPGA functionalities. Specifically, a single FPGA instance is shared among numerous cloud tenants simultaneously, maximizing resource usage efficiency and potentially escalating performance. However, the sharing of an FPGA by multi-tenants, unfortunately, opens the door for various types of side channel leakages, particularly power side channels [13], [14], [28], [31], [32], [42]. Various security implications have been demonstrated via power side channels, including extracting cryptographic keys [14], [32], [42], building covert channels [8], [9], [42], fingerprinting victim computations [13], and stealing DNN model architectures [41] or inputs [25].

One key challenge in these attacks is to craft an on-chip sensor whose output is affected by its own supply voltage and to co-locate it with the victim circuit. In a multi-tenant FPGA scenario, this sensor can sense the voltage fluctuations caused by a victim circuit sharing the same PDN. All existing on-chip sensors exploit the malicious connection of traditional FPGA resources (e.g., LUTs, carry chains, wires, and FFs). As the most studied one, TDC-based circuits [10], [13] use the FPGA carry chain as a delay unit to construct a delay line, with each output connected to an FF that samples the signal traversing through the delay line. Besides, RO [41], [42], VITI [32], PPWM [31], and 1LUTSensor [14] initialize LUT and FF in their own ways. Last, RDS [28] freely places several FFs to abuse the delay incurred by routing resources, e.g., wires.

B. Digital Signal Processing Blocks

As FPGAs have transitioned from prototyping systems to deployable systems (e.g., BrainWave [22] and Catapult [23]), manufacturers have integrated digital signal processing (DSP) blocks into FPGA boards. Unlike traditional FPGA logic resources, which consume substantial area and power for complex mathematical calculations, DSP blocks offer a specialized hardware solution that significantly enhances both performance and efficiency, though at the cost of a degree of re-programmability. Accessed through dedicated hardware

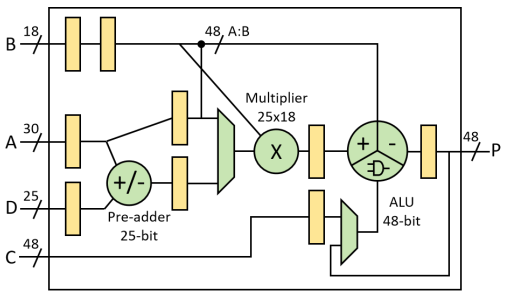

Fig. 1: Structure of the Xilinx `DSP48E1` primitive [27].

primitives, these DSP blocks can be configured for a wide range of arithmetic and logic operations [27].

For instance, starting with the Virtex-6 and 7-series architectures, the `DSP48E1` primitives are dedicated to the efficient processing of high-bitwidth data, enabling complex functions such as multipliers and filters to be implemented without relying on traditional FPGA resources. Figure 1 shows a simplified representation of the `DSP48E1` primitive. It has four inputs with different lengths and is composed of three main sub-components, i.e., a pre-adder, a multiplier, and an arithmetic logic unit (ALU). The pre-adder is a 25-bit addition/subtraction unit that operates on input D and the lower 25 bits of input A. The multiplier multiplies the lower 25 bits of input A or the result of pre-adder with the 18-bit input B. The ALU performs addition, subtraction, and logical operations using the output from the multiplier, input C, concatenated inputs A and B, or the previous output of the DSP block. These sub-components can be flexibly configured to allow the DSP block to perform a range of functions.

III. LeakyDSP

A. Threat Model

We focus on a multi-tenant FPGA scenario where different tenants' circuits are co-located on the same FPGA. Aligned with previous FPGA power side channels [10], [13], [14], [28], [31], [32], our only assumption is that the FPGA tenant applications effectively utilize the shared PDN to optimize resource allocation and bolster overall operational efficiency. To ensure robust logical isolation, each tenant is allocated physically separate FPGA regions to deploy their circuits. The cloud service providers empower tenants with the flexibility to implement a diverse array of FPGA circuits, except those containing combinational loops [4]. Additionally, tenants can define precise placement and routing constraints tailored to the unique requirements of their own designs.

B. LeakyDSP Design

The main idea behind LeakyDSP to sense on-chip voltage fluctuations is to design a malicious DSP function that inherently responds to variations in the supply voltage. Our key observation is that the dedicated DSP blocks in FPGAs are composed of three main sub-components: a pre-adder, a multiplier, and an ALU (discussed in Section II-B). The signal propagation delay through these components is sensitive to voltage changes, leading to signal delay variations between their input and output under different voltage levels.

We note that despite the limitations in configurability compared to traditional FPGA logic resources, DSP blocks still offer sufficient flexibility to construct a voltage-sensitive function. Specifically, each of the inputs for these sub-components can be responded asynchronously without intermediate registers (i.e., flip-flops). If we connect the three components in series, their delay will be accumulated and their computation results will also have dependencies. Further, the DSP architecture supports the cascading of multiple DSP blocks. This capability allows LeakyDSP to be composed of an arbitrary number of DSP blocks, much like how a single TDC instance can utilize an arbitrary number of CARRY structures.

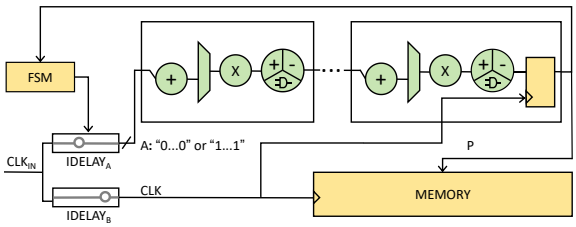

Fig. 2: An overview of LeakyDSP.

Figure 2 shows the overview of the proposed LeakyDSP sensor. Specifically, LeakyDSP contains two parts. First, we carefully configure the DSP blocks to make the signal propagate through the sub-components that are marked as green. The input of the first block (A) consists of multiple bits, and each of the bits equals the delayed CLK_{IN}. Second, we leverage `IDELAY` primitive to introduce a calibration design and dynamically adjust the phase difference between input signal A and the clock signal of the flip-flop within the last DSP block CLK. By doing so, LeakyDSP's output is sensitive to voltage fluctuations and adaptive to different placements.

Malicious DSP function: In this paper, we pick the simplest function that can be instantiated by DSP blocks to analyse the information leakage of LeakyDSP, i.e., $P = A$, where A is varying between '00...0' and '11...1'. To achieve this, we first configure the pre-adder to add a constant '0' to the input (A), and pass the result $(A + 0)$ to the multiplier for further computation. Second, we set the other input of the multiplier to '1', ensuring the multiplication result $(A + 0) \times 1$ remains consistent with the original input A. Third, we configure the ALU as an adder and set the second input as a constant '0', producing a result of $(A + 0) \times 1 + 0$. Last, we configure the output mode based on the position of the DSP block. If it is the last DSP block in a LeakyDSP instance, the output of ALU passes through a register before being stored in memory. Otherwise, the lower bits of output are fed directly into the next DSP block as its input.

Extracting the intensity of the voltage fluctuations: When the PDN is idle, LeakyDSP's outputs remain stable with only a few bit flips. However, in the case of a busy PDN, the number of flipped bits increases in response to fluctuating voltage. Taking `DSP48E1` as an example, its output is 48-bit wide, enabling a fine-grained quantization to voltage levels. To this end, LeakyDSP converts each raw sampled value into a numerical representation based on its Hamming weight [10], [28], referred to as the *readout*.

Calibration: Aligned with existing crafted circuits [10], [14], [28], [31], [32], LeakyDSP contains a calibration part to ensure that the bit-flip number from LeakyDSP's outputs changes accordingly when the voltage in PDN starts fluctuating. To dynamically adjust the initial delay, LeakyDSP incorporates two `IDELAY` components, which are part of the SelectIO resources and designed for signal timing adjustment in FPGA devices. Each `IDELAY` can generate a runtime-adjustable delay of up to

the half of the period of its connected clock signal (i.e., $T/2$) on the signal passing through it. By connecting them to the input signal A and clock signal CLK respectively, LeakyDSP can achieve a phase difference ranging from $-T/2$ to $T/2$ between A and CLK. We adopt a straightforward calibration procedure for LeakyDSP. Specifically, we iteratively increase the initial clock delay by changing the configuration of the two `IDELAY` units, until the readouts of LeakyDSP reach the maximum variation between two consecutive adjustments.

Implementation: Though LeakyDSP can be instantiated with an arbitrary number of used DSP blocks (i.e., n), the optimal choice of n is influenced by the resource budget and sensitivity to voltage fluctuations. In this paper, we select $n = 3$, an empirical value that provides a balance of high sensitivity, acceptable resource usage, and ease of calibration. Besides, we use the `DSP48E1` primitive to map the configuration of DSP blocks on 7-series FPGA boards and `DSP48E2` on Zynq Ultrascale+ FPGAs. For delay configurations, we employ `IDELAYE2` on 7-series FPGAs and `IDELAYE3` on Zynq UltraScale+ FPGAs.

IV. Evaluation

Machine settings: To perform the characterization and AES key extraction attack, we use a Basys3 board connected to a Huawei MateBook 14 laptop via UART and powered through the USB interface. To evaluate the covert channel, we use an ALINX AXU3EGB board, which has the similar architecture as the AWS EC2 instance (i.e., Xilinx UltraScale+ VU9P FPGA) [3]. To deploy hardware code onto the FPGA platforms, we use Vivado version 2020.1 for synthesis, implementation, and bitstream generation.

A. Characterizing LeakyDSP

To show the sensitivity of LeakyDSP to voltage fluctuations, we opt for power virus circuits as a victim to generate varying voltage fluctuations, aligned with [42]. The power virus circuit consists of a number of instances that are implemented as RO circuits. Specifically, within the power virus circuits, each RO circuit consists of a single inverter, an AND gate, and an FF. The output of the inverter is controlled by configuring the enable signal, determining whether it is active to make the output signal frequently switch between '0' and '1'. These switching activities can cause a voltage fluctuation in PDN.

LeakyDSP's sensitivity under different victim activities: Our first experiment is to characterize the readout change of LeakyDSP to various victim activities. Specifically, we create 8,000 instances of power virus to cover over 33.3% routing places of our Basys3 board and activate about 46% of available LUT resources. We then divide them into 8 groups and each group has 1000 evenly-distributed instances. When we activate a varying number of these groups, the voltage varies from 9 levels. For each level, we collect 2,000 readouts from LeakyDSP and take the average of them as the final result to compute Pearson correlation coefficient and regression coefficients. Pearson correlation coefficient is used to assess the strength and direction of the linear association,

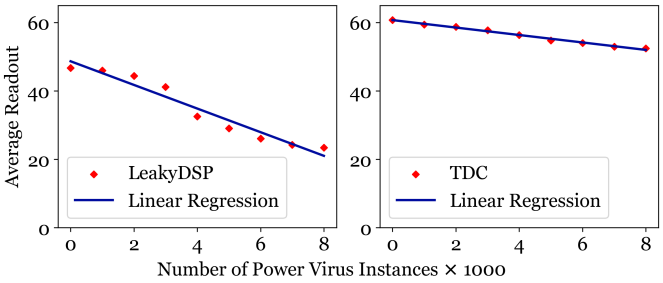

Fig. 3: The sensitivity of LeakyDSP and TDC in the same placement under different victim activities. Note that we implement TDC with 128 FFs, resulting in a 128-bit output, while LeakyDSP produces a 48-bit output.

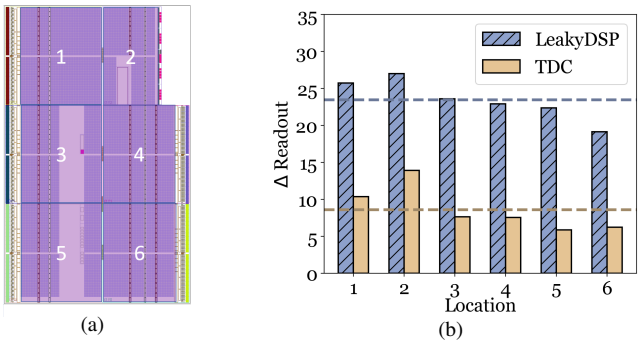

Fig. 4: The sensitivity of LeakyDSP and TDC [10] under different placements. The index as the x-axis in Figure 4(b) corresponds to the region index in Figure 4(a). The dashed line indicates the average value of a sensor.

while the regression coefficient measures the impact of these two values in a linear regression model.

Figure 3 shows the relationship between these readouts (i.e., the number of unflipped bits in LeakyDSP's output) and the number of activated power virus instances. These two values of LeakyDSP exhibit a roughly linear relationship with a Pearson correlation coefficient of -0.974, while TDC achieves -0.996. The close proximity of these correlation coefficients to -1 indicates a strong linear relationship, demonstrating that all the evaluated voltage levels fall within the observable range of LeakyDSP and can be accurately estimated using its readout. Furthermore, compared with the most studied on-chip sensor (i.e., TDC), LeakyDSP achieves a high regression coefficient of -3.45, while TDC achieves -1.09. This indicates that LeakyDSP provides finer granularity under the given sensor placement.

LeakyDSP's sensitivity under different placements: In a multi-tenant FPGA, spatial proximity between a crafted circuit and a victim's circuit is beyond the attacker's control. As such, we characterize the readout change of LeakyDSP with respect to their spatial proximity to victim logic that consumes power. Specifically, we instantiate 8,000 instances of the power virus, and constrain the placement of the power virus to region 1 and region 2 in Figure 4(a). Subsequently, we put LeakyDSP

(resp., TDC) in each of the 6 FPGA regions via a `Pblock` constraint with all the 8,000 power virus instances off and on. We sample 2,000 readouts under each setting and calculate their average.

As shown in Figure 4, although LeakyDSP is influenced by the unevenness of the FPGA's power supply design, it can still sense the given voltage fluctuation under all the above placements. Specifically, LeakyDSP achieves the best performance when it is placed in region 2. Further, when LeakyDSP is placed under the worst-case placements (i.e., region 5 and region 6 which are far away from the victim circuit), its readouts are still sensitive to voltage fluctuations.

B. Stealing Cryptographic Keys

As the most widely adopted symmetric-key cryptographic algorithm, AES has been implemented in different devices, including hardware circuits on FPGA platforms [1], [19], [37]. However, prior work has demonstrated that a remote attacker can extract the full secret key of AES circuits via CPA attacks [7]. These attacks leverage the Pearson Correlation Coefficient [5] to detect linear dependencies between voltage fluctuations during AES circuit execution and hypothetical power calculated from the ciphertext with a guessed key. To achieve this, attackers first use the Hamming weight and Hamming distance power models to estimate the power consumption for each possible key value. Then, they use their own side channel to obtain the power-related information. Last, they sort each guessed value according to its correlation coefficient to determine the ground-truth key value.

Experimental setup: Our end-to-end attack is built upon the open-source code of RDS [28], which implements an AES-128 module [1] that co-resides with the attack circuit on the Basys3 board. By default, the clock frequencies of the attack circuit and the AES are set to 300 MHz and 20 MHz, respectively. Please note that 20 MHz is exactly aligned with the victim setting in VITI [32] and RDS [28], and we just aim to show the general possibility of leakage. Unless otherwise stated, we collect 60 k power side-channel traces for each setting. In each trace collection, we transmit the key `K` and the plaintext `PT` to the AES core, and record the LeakyDSP's readouts obtained during AES encryption. To avoid plaintext repetition, we employ the current ciphertext as the subsequent plaintext. To simplify the process, we utilize the start encryption signal to trigger the collection of a sensor trace. To evaluate the performance of LeakyDSP, we run the key extraction attack under 8 placements and 4 different AES clock frequencies.

Aligned with previous AES key recovery attacks [14], [28], [31], [32], we use the key rank (KR) estimation metric, which evaluates the number of key candidates that an attacker needs to test. Specifically, the key rank is presented as a narrow range with an upper and lower bound, due to the bounded error in current key rank estimation algorithms. For instance, in the absence of any side-channel information, the upper key rank corresponds to the entire key space, which is 2^{128} for AES-128. Conversely, when the full key is compromised, the lower bound of the KR reduces to one, while the upper bound tightly constrains the range, indicating that the correct key can be deduced with minimal guessing. In such scenarios, attackers can arrange each guessed byte value based on correlation coefficient to obtain the genuine AES key. To speed up computation, we employed the open-source analysis tool [7] for conducting our CPA analysis on an NVIDIA GeForce RTX 3090 GPU.

TABLE I: Number of traces required to break the full AES 128-bit key for different sensor placements.

Setting	Traces to Extract Full Key (×1000)									
	P1	P2	P3	P4	P5	P6	P7	P8	Average	Baseline
LeakyDSP	55	43	58	28	48	25	37	41	41	51

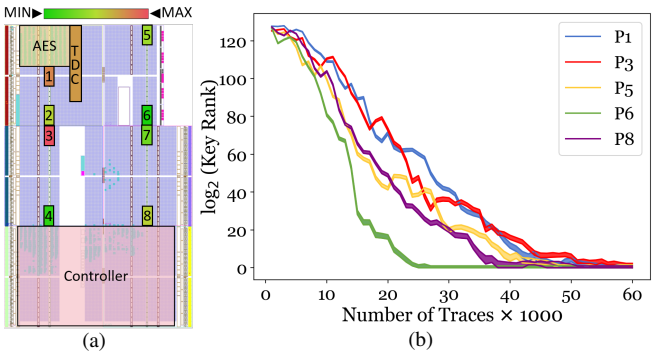

Fig. 5: Key rank estimation for LeakyDSP. The curves in Figure 5(b) are named after the number on each placement shown in Figure 5(a).

Experimental result: Figure 5 shows the average upper and lower bounds of the key rank estimation metric to evaluate the impact of the placement of LeakyDSP. Figure 5(a) is a color gradient that rates all 8 placements based on their key rank with 20 k power traces, revealing that the performance of a power analysis attack relies on the placement of LeakyDSP. This observation aligns with the findings reported in [28], [32], where the location-dependent sensitivity is attributed to the non-uniformity of the PDN across the FPGA board. Moreover, Figure 5(b) shows the key rank variability of LeakyDSP across 5 selected placements out of the total 8 placements, including the best and worst-case placements, as well as the placement closest to the victim circuit. Each placement is identified by its corresponding number, as indicated adjacent to them in Figure 5(a). The full results are summarized in Table I. Compared to TDC, which requires 51 k traces to extract the full key, LeakyDSP achieves a comparable efficiency with 25 k-58 k traces needed. We do not claim that our LeakyDSP is better than TDC in terms of the attack performance, as we only evaluate TDC in one setting. As our LeakyDSP does not use any traditional logic resources inside configurable logic blocks, we cannot place LeakyDSP and TDC in the same position for a solid comparison [28], [32].

We then evaluate the impact of the AES frequency on our attack, utilizing the best-case placement for attackers (i.e.,

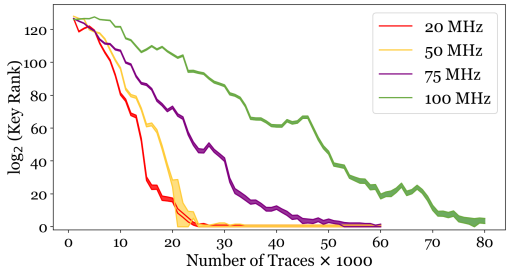

Fig. 6: The impact of the AES frequency on our attack. The efficiency of key extraction decreases as the frequency of the victim circuit increases.

P6). Figure 6 illustrates the corresponding key rank outcomes. We note that the performance of the attack is dependent on the frequency. The efficiency of our key extraction decreases as the frequency of the victim circuit increases. At a high frequency of 100 MHz, the 128-bit AES key cannot be fully recovered even with all 60 k traces. To address this, we collect an additional 20 k traces, achieving full key recovery with a total of 78 k traces.

C. Establishing Covert Channels

Aligned with existing work [9], [12], we apply the covert channel for assessing the bandwidth of our side channels, where the attacker has complete control over both the sender and receiver. We assume the colluding sender and receiver operate on the same FPGA. To induce the voltage fluctuations for the sender, we opt for power virus circuits as to generate varying voltage fluctuations. To transmit a '1', the sender sets its enable signals to '0', making all the power virus instances idle. To transmit a '0', a sender activates all the controlled power virus instances to plunder the voltage of receiver circuits. The receiver is a LeakyDSP-based circuit and loops to monitor voltage level via its readouts. By comparing the averaged readouts to a predefined threshold, the receiver distinguishes between the transmitted bits, '0' or '1'.

Experimental setup: To assess the performance of our covert channel, we vary the time for sending one bit from 2 ms to 7.5 ms and send 10 kb of random data in each configuration. Besides, we employ two metrics that are widely used in previous covert channels [40]: transmission rate (TR) and bit error rate (BER). TR measures the amount of data transmitted per unit time, while BER represents the proportion of received bits incorrectly interpreted relative to the sent bits.

Experimental result: Figure 7 shows the end-to-end results across 10 runs. The experimental results show a negative correlation between the BER and the time for sending a bit. When the sending time is greater than 3.5 ms, the BER stabilizes below 1%. When the sending time is less than 3 ms, the BER gradually increases with the decreasing of sending time due to the limited accuracy of the receiver in distinguishing data. The smaller the time for sending a bit, the greater the TR. So we recommend the sending time of 4 ms with a BER of 0.24%. With such setting, the TR of a single transmission is 247.94 b/s.

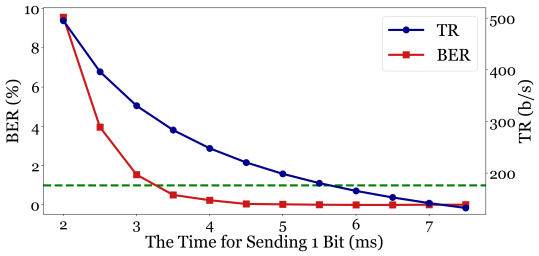

Fig. 7: The performance impact of timing parameters on LeakyDSP-based covert channel.

V. Discussion

Mitigation: Similar to existing on-chip sensors, LeakyDSP relies on precise voltage information from a shared PDN. While enhancing the PDN could mitigate such attacks, this approach is limited by current production technologies [29], [34] and does not protect already-deployed products. An alternative countermeasure is to inject noise into the PDN [11], [16], which obscures power patterns but introduces performance overhead. Besides, the developers can modify their circuits as constant-power implementation with some efforts. Last, after identifying the threats from DSP blocks, cloud providers can prevent the deployment of LeakyDSP by enforcing synchronized inputs or mandatory timing checks on DSP configurations. However, we note that both approaches limit benign tenants' flexibility in DSP reconfiguration. Besides, timing violation checks can be bypassed using programmable clock-generating circuits, as discussed in TDC [10] and RDS [28].

Future work: This paper demonstrates that DSP blocks can indeed be exploited for power analysis attacks through a comprehensive evaluation on two FPGA boards with different architectures. However, while LeakyDSP's readouts vary with voltage levels monotonously, this change is not absolutely uniform. Due to the *black-box* nature of DSP blocks' internal design, we cannot entirely explain LeakyDSP's leakage behavior at this stage. Besides, the number of DSPs within a single LeakyDSP sensor is an empirical value ($n = 3$). We leave the exploration of DSP operating principles and the optimal selection of n as future work.

VI. Conclusion and Acknowledgments

In this paper, we propose LeakyDSP, a novel on-chip sensor that maliciously configures DSP blocks to sense voltage fluctuations on multi-tenant FPGAs. Our characterization shows that LeakyDSP is highly sensitive to voltage fluctuations and robust across different placements. The viability of LeakyDSP is demonstrated by two case studies, which extract full AES keys under various placements of LeakyDSP and operating frequencies of victim circuits, and build FPGA-to-FPGA covert channels with a high transmission rate of 247.94 b/s.

We thank the anonymous reviewers for their feedback. In addition, we thank Yuhui Zhang for her valuable comments that helped us to improve the work. ***Abstract*—The logic synthesis optimization flow is crucial to the quality of results (QoR), which applies a sequence of transformations to a design. Recently, there has been a growing focus on the automatic optimization of synthesis flows to improve QoR, utilizing techniques such as Bayesian optimization and reinforcement learning, which may fall short in efficiency due to the exponentially large search space. In contrast, continuous optimization offers notable efficiency advantages by leveraging the explicit gradient. However, despite its potential, several significant concerns remain to be addressed. On one hand, it is essential to obtain a reliable gradient. On the other hand, a major challenge arises from the fact that searching within a continuous space can yield solutions that deviate from feasible ones. In this paper, we propose an efficient approach to optimize synthesis sequences within a continuous latent space. Specifically, the gradient information is derived from a QoR surrogate model, while the discrepancies between solutions and feasible transformations are minimized by a diffusion model. Experimental results on extensive benchmarks demonstrate that the proposed method not only achieves lower area and delay but also improves efficiency by 5X to 130X, compared with previous methods.**

I. Introduction

Logic synthesis is an important process that transforms circuits from register-transfer level design to gate-level netlist. Previous works usually represent circuits as AIG (And-Inverter Graph) [1] or similar boolean networks like MIG [2]. Then the synthesis process applies a sequence of logic optimization transformations like *rewrite*, *restructure* to circuits [1], [3]. For the same circuit, different sequences can lead to a variation in quality-of-result (QoR) of up to 40% [4]. Thus, it is imperative to optimize those synthesis sequences to improve the quality of synthesized netlists.

Previous works are devoted to optimizing sequences with techniques like reinforcement learning (RL) [5]–[7], multi-arm bandit (MAB) [8], and discrete Bayesian optimization (BO) [9]. Both RL and MAB methods treat the sequence optimization task as a sequential decision-making problem. They explore the probability of which transformation to take by updating the Q-function, policy function, etc. The discrete BO [9] has to sample sequences by discretely altering the transformations for evaluating the acquisition function. While automated methods yield significant QoR improvements over general heuristics, their dependence on extensive discrete searches and iterative nested updates leads to considerable overhead and inefficiency during the optimization process, particularly as the number of transformation options increases and the sequence lengthens. This raises a pertinent question: Can we directly optimize sequences without searching in the discrete space to achieve faster turnaround time?

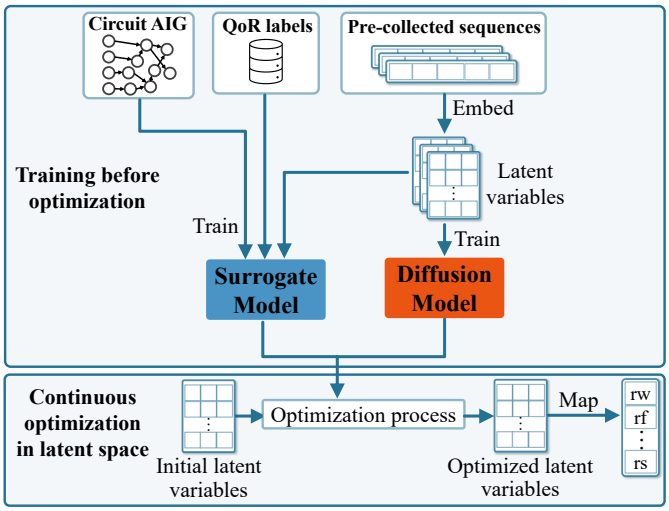

Fig. 1 Overview of the proposed framework. Upper part: Pre-training a surrogate model and a diffusion model. Lower part: Continuous optimization of sequence in latent space.

In contrast to discrete search, continuous search transforms the discrete search space into continuous latent space and leverages numerical optimization techniques like gradient descent to directly optimize the objective function guided by the gradient from a surrogate model [10]. Upon convergence, the final solution is retrieved by mapping the latent representation in continuous latent space back to the original space.

For synthesis sequence optimization, a deep learning-based surrogate model should first be built, which takes the circuit and sequence embeddings as input and predicts the QoR. However, it is observed that solely relying on the gradient from the surrogate model is problematic [11], [12]. Note that the final sequence for synthesis should be retrieved based on the optimized sequence embedding in the latent space. Unfortunately, even though the continuous optimization converges in the first phase, the sequence may hardly be retrieved due to a large discrepancy between the obtained embeddings and the feasible transformation embeddings. Some previous works explored to

*Equal contribution
†Corresponding author

conduct an additional mapping based on a distance metric [13] or a neural network-based decoder [14]. Nevertheless, neither of these methods can achieve the desired performance, as revealed in [15]–[17], since the additional mapping operation is already out of the optimization loop, offering no assurance against performance degradation. Therefore, to facilitate the retrieval of final transformations from continuous space, it is essential to ensure that the embedding discrepancy between the final solutions and feasible transformations is minimized, such that the final optimized sequence can be instantly retrieved.

To address the above challenges, we incorporate a novel generative diffusion model together with a surrogate model into the continuous logic optimization framework. The overview of it is shown in Fig. 1. Particularly, the diffusion model is designed to minimize that discrepancy. Different from the previous two-stage workflows, the proposed method can seamlessly integrate the two stages into a unified stage. Moreover, all the computations are within the optimization loop, which provides a higher level of assurance regarding the quality of the final solution. The discrepancy is minimized explicitly through a series of denoising steps, each of which is performed together with a gradient descent step. Upon convergence, the discrepancy between the optimized embedding and the feasible embedding is minimized, and thus the final optimized sequence can be retrieved instantly without degrading QoR. Our contributions are as follows:

1) To the best of our knowledge, it is the first work to propose a continuous optimization approach for the discrete logic sequence optimization problem.
2) We optimize the QoR together with the discrepancy between optimized embeddings and feasible transformations to achieve a unified framework.
3) We leverage the gradient obtained from a surrogate model for QoR optimization and the denoising steps based on a diffusion model for discrepancy minimization.
4) Experimental results demonstrate that the proposed continuous optimization framework achieves substantial improvements in runtime and QoR compared with previous baseline methods on logic optimization.

II. Preliminaries

Some frequently used notations are shown in TABLE I for a clearer illustration.

A. Logic Synthesis Sequence Optimization

In logic synthesis, a sequence of logic transformations is applied to the circuit to achieve a better QoR. A sequence $\boldsymbol{s}$ with length L is composed of transformations $[s_1, \dots s_L]$, where each transformation s_i belongs to an available set $\mathbb{S}$, i.e., $s_i \in \mathbb{S}$. In our work, $\mathbb{S} = \{\texttt{rw}, \texttt{rwz}, \texttt{rf}, \texttt{rfz}, \texttt{rs}, \texttt{rsz}, \texttt{b}\}$. These transformations have different effects on circuits represented in AIG by reducing the number of nodes and reducing the levels. Although ABC [1] is a relatively fast synthesis tool, the exponentially increasing search space ($|\mathbb{S}|^L$) still hinders efficient optimization. Given the fact that longer sequences may not necessarily lead to better QoR [8], we focus on finding a sequence with a fixed length L that leads to minimal area or delay, or both. It is formulated as:

$$\begin{aligned} \min_{\boldsymbol{s}} \quad & F(\boldsymbol{s}) \\ \text{s.t.} \quad & s_i \in \mathbb{S}, \quad i = 1, 2 \dots, L. \end{aligned} \tag{1}$$

TABLE I Notations in this work.

Notation	Explanation
$\boldsymbol{s}$	A sequence of discrete transformations with length L.
$g(\cdot)$	The function that embeds sequence into latent space.
$\boldsymbol{x}$	The sequence of transformation embeddings.
$\boldsymbol{x}_t$	The sequence of latent variables at denoising step t. We use $t = T$ to denote the start of denoising steps and $t = 0$ as the end to align with notations in diffusion models.
$\hat{F}(\cdot)$	Surrogate model to predict QoR.
$\boldsymbol{\epsilon}_t$	The added noise at the t-th step in diffusion process.
$\boldsymbol{\epsilon}_\theta(\cdot, t)$	The predicted noise at the t-th step by the diffusion model.
$\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma}^2)$	A Gaussian distribution with mean $\boldsymbol{\mu}$ and variance $\boldsymbol{\sigma}^2$.
$\boldsymbol{\sigma}_t, \boldsymbol{\alpha}_t$	Some constants dependent on t in the diffusion model.

B. Diffusion Models

Diffusion models have become the mainstream generative models [18]–[20]. Such popularity is mainly due to their extraordinary ability to capture the distribution of training data and then generate data with a similar distribution as the training data. Specifically, diffusion models will convert the training data into pure Gaussian noise by gradually adding Gaussian noise $\boldsymbol{\epsilon}_t$. Then they will learn to restore the data from pure Gaussian through denoising steps by removing noise $\boldsymbol{\epsilon}_\theta(\boldsymbol{x}, t)$ predicted by a neural network parameterized with θ.

III. Methodologies

Our continuous optimization framework involves two models, including a surrogate model to predict QoR and a diffusion model to learn the distribution of feasible transformation embeddings. The optimization process will optimize latent variables with both the gradient from the surrogate model and the denoising update from the diffusion model. Finally, it maps optimized latent variables back to discrete transformations. We illustrate the details in the following sections.

A. Training Surrogate Model

Since QoR after logic synthesis cannot be analytically formulated, a surrogate model is required to bridge the gap. Moreover, it is imperative that the surrogate model can generate the gradient information to enable continuous optimization. Recently, various works have investigated deep learning-based QoR prediction for logic synthesis [4], [21], [22]. Generally, these frameworks will first encode the sequence into an embedding in the latent space, i.e., $\boldsymbol{x} = g(\boldsymbol{s})$. Then a deep neural network is trained to predict the QoR. For each design, given a dataset comprising N data points that include sequences and QoR labels, the surrogate model is trained by minimizing the mean squared error between the predicted values and the corresponding labels as shown in the following equation:

$$\min \mathcal{L} = \frac{1}{N} \sum_{j=1}^{N} (\hat{y}^{(j)} - y^{(j)})^2, \tag{2}$$

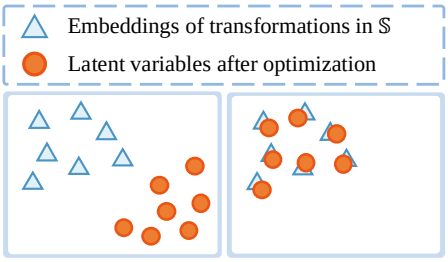

Fig. 2 (a) Latent variables optimized only w.r.t QoR. (b) Latent variables optimized w.r.t QoR and discrepancy.

where the $\hat{y}^{(j)}$ and $y^{(j)}$ are the predicted QoR and the label of the sample j, respectively.

B. Optimizing Sequences in Continuous Space

After a surrogate model is trained to predict the delay and/or area after synthesis, we can minimize the predicted delay or area by finding a sequence embedding in the latent space. For simplicity, we use $\hat{F}(\cdot)$ to represent the surrogate model, and $\boldsymbol{x}$ to represent the embedded sequence to be optimized.

$$\boldsymbol{x}^* = \underset{\boldsymbol{x}}{\operatorname{argmin}}\, \hat{F}(\boldsymbol{x}). \tag{3}$$

Since the surrogate model is based on a DNN, we can get the gradient by back-propagation. However, relying on gradient may lead to a large discrepancy between optimized latent variables and embeddings of feasible transformations. Fig. 2 presents an illustrative example that visualizes the embeddings in latent space by t-SNE [23]. It poses a great challenge for sequence retrieval, i.e., mapping the embedding in latent space to the real sequence for logic synthesis, given the results with large discrepancy shown in Fig. 2(a).

In this work, we propose to bridge the gap by introducing another auxiliary objective $H(\boldsymbol{x})$ that minimizes the discrepancy. Specifically, minimizing $H(\boldsymbol{x})$ implies that the optimized embedding $\boldsymbol{x}^*$ follows the same distribution as valid transformation embeddings so that we can eliminate the additional yet intricate mapping to retrieve the sequence, as depicted in Fig. 2(b). To this end, we reformulate our optimization problem in the latent space as:

$$\boldsymbol{x}^* = \underset{\boldsymbol{x}}{\operatorname{argmin}}[\hat{F}(\boldsymbol{x}) + H(\boldsymbol{x})], \tag{4}$$

where $H(\boldsymbol{x})$ represents the discrepancy between an embedding $\boldsymbol{x}$ and the valid transformation embeddings in latent space.

A widely used option for $H(\boldsymbol{x})$ is the negative log-likelihood (NLL). It is a commonly used objective to be optimized in generative models to ensure the generated data follows the same distribution as the training data. If minimized, the optimized latent variables should be in the distribution of the feasible transformation embeddings and the discrepancies between them are minimized. Ideally, we can directly compute the gradient of the objective in Equation (4) w.r.t $\boldsymbol{x}$, i.e., $\nabla_{\boldsymbol{x}}\hat{F}(\boldsymbol{x}) + \nabla_{\boldsymbol{x}}H(\boldsymbol{x})$.

The gradient $\nabla_{\boldsymbol{x}}\hat{F}(\boldsymbol{x})$ is easy to obtain since it can be computed via back-propagation. However, minimizing NLL through gradient descent leads to tractability issues for computing $\nabla_{\boldsymbol{x}}H(\boldsymbol{x})$. Instead, a variational bound is optimized [24], which is the mainstream approach to train generative models, including diffusion models [18]. Therefore, minimizing $H(\boldsymbol{x})$ can be resolved through training a diffusion model.

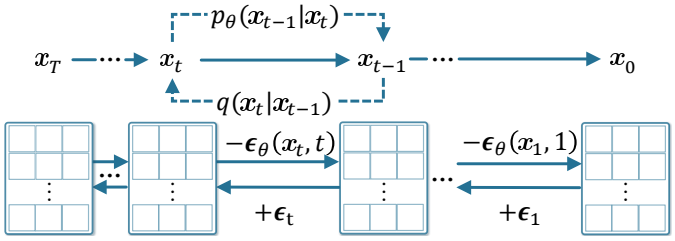

Fig. 3 The diffusion process (from right to left) and denoising process (from left to right) of a diffusion model.

C. Optimization with Diffusion Model

Diffusion models have shown extraordinary abilities in generating high-quality data in the training set distribution by minimizing a variational bound. The diffusion model encompasses a diffusion process and a denoising process as shown in Fig. 3. The diffusion process gradually adds noise to the feasible transformation embeddings as shown in Equation (5) with $\boldsymbol{\alpha}_t$ as some constants.

$$\boldsymbol{x}_t = \sqrt{\boldsymbol{\alpha}_t}\boldsymbol{x}_{t-1} + \sqrt{1-\boldsymbol{\alpha}_t}\boldsymbol{\epsilon}_t, \quad \boldsymbol{\epsilon}_t \sim \mathcal{N}(\mathbf{0}, \boldsymbol{I}). \tag{5}$$

This diffusion process converts the original data into pure Gaussian noise following the conditional distribution:

$$q(\boldsymbol{x}_t|\boldsymbol{x}_{t-1}) = \mathcal{N}(\boldsymbol{x}_t; \sqrt{\boldsymbol{\alpha}_t}\boldsymbol{x}_{t-1}, \sqrt{1-\boldsymbol{\alpha}_t}\boldsymbol{I}). \tag{6}$$

To generate in-distribution data, the denoising process tries to remove the same scale of Gaussian noise $\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t) \sim \mathcal{N}(\boldsymbol{\mu}_\theta(\boldsymbol{x}_t, t), \boldsymbol{\sigma}_t^2\boldsymbol{I})$ generated with a mean $\boldsymbol{\mu}_\theta(\boldsymbol{x}_t, t)$ parameterized by θ:

$$\boldsymbol{x}_{t-1} = \frac{1}{\sqrt{\boldsymbol{\alpha}_t}}(\boldsymbol{x}_t - \frac{1-\boldsymbol{\alpha}_t}{\sqrt{1-\bar{\boldsymbol{\alpha}}_t}}\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t)) + \boldsymbol{\sigma}_t\boldsymbol{z}, \tag{7}$$

where $\boldsymbol{\sigma}_t$ are some constants, $\bar{\boldsymbol{\alpha}}_t = \sum_{s=1}^{t}\boldsymbol{\alpha}_s$ and $\boldsymbol{z} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{I})$. This process follows the conditional distribution:

$$p_\theta(\boldsymbol{x}_{t-1}|\boldsymbol{x}_t) = \mathcal{N}(\boldsymbol{x}_{t-1}; \boldsymbol{\mu}_\theta(\boldsymbol{x}_t, t), \boldsymbol{\sigma}_t^2\boldsymbol{I}). \tag{8}$$

The objective of training the diffusion model is to minimize the variational bound over the negative log-likelihood through the denoising process, as shown in Equation (9).

$$\min \mathcal{L}_d = \mathbb{E}[-\log q(\boldsymbol{x}_T) - \sum_{t=1}^{T}\log\frac{p_\theta(\boldsymbol{x}_{t-1}|\boldsymbol{x}_t)}{q(\boldsymbol{x}_t|\boldsymbol{x}_{t-1})}] \geq \mathbb{E}[-\log p_\theta(\boldsymbol{x}_0)]. \tag{9}$$

Since the diffusion process with $q(\cdot)$ is irrelevant to parameters θ of the neural network, optimizing the loss function in Equation (9) is equivalent to learning a denoising process with parameters θ that can minimize the variational bound over the NLL. In practice, the diffusion model is trained by minimizing

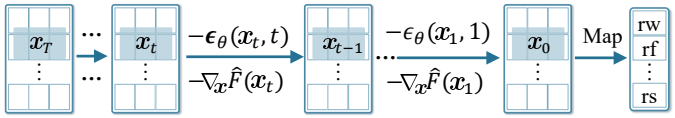

Fig. 4 The optimization process that gradually subtracts gradient from the surrogate model and noise from the diffusion model.

Algorithm 1 Training Diffusion Model

Input: N embedded latent sequences of transformations.
Output: A trained diffusion model parameterized by θ.

1: **repeat**
2: $t \leftarrow \text{Random}(1, T)$, $j \leftarrow \text{Random}(1, N)$.
3: $\bar{\boldsymbol{\alpha}}_t \leftarrow \sum_{s=1}^{t} \boldsymbol{\alpha}_s$.
4: $\mathcal{L}_d \leftarrow \text{Loss}(t, j, \boldsymbol{x}_0^{(j)})$. ▷ Equation (10).
5: $\theta \leftarrow \text{Update}(\theta, \mathcal{L}_d)$.
6: **until** Diffusion model converges.

the difference between the added noise and the predicted noise on the N pre-collected embedded sequences [18]:

$$\min \mathcal{L}_d = \mathbb{E}_{t,j,\boldsymbol{x}_0,\boldsymbol{\epsilon}_t}[||\boldsymbol{\epsilon}_t - \boldsymbol{\epsilon}_\theta(\sqrt{\bar{\boldsymbol{\alpha}}_t}\boldsymbol{x}_0^{(j)} + \sqrt{1-\bar{\boldsymbol{\alpha}}_t}\boldsymbol{\epsilon}_t, t)||^2], \tag{10}$$

where $\boldsymbol{x}_0^{(j)}$ means the original embedded sequence of sample j. The training details are also illustrated in Algorithm 1. The predicted noise $\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t)$ with a mean $\boldsymbol{\mu}_\theta(\boldsymbol{x}_t, t)$ that dependent on θ is updated by gradient descent on computed loss as shown in Line 5.

Given a well-trained diffusion model, the generated latent variable $\boldsymbol{x}_0$ through the denoising process should be in the distribution of embeddings of feasible transformations. The discrepancies between them in the latent space are also minimized. To minimize $\hat{F}(\boldsymbol{x}) + H(\boldsymbol{x})$ in Equation (4), the corresponding update rule can be calculated by back-propagation and Equation (7), respectively. Therefore, we can combine them as the optimization process starting from a sequence of initial latent variables following pure Gaussian distribution, i.e., $\boldsymbol{x}_T \sim \mathcal{N}(\mathbf{0}, \boldsymbol{I})$, and proceed with the iterative optimization in a continuous latent space as:

$$\boldsymbol{x}_{t-1} = \boldsymbol{x}_t - \eta(\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t) + \omega\nabla_{\boldsymbol{x}}\hat{F}(\boldsymbol{x}_t)) + \boldsymbol{\sigma}_t\boldsymbol{z}, \tag{11}$$

where the constant coefficients are combined into η and ω for brevity. This optimization process is also shown in Fig. 4. At each optimization step, we will subtract the predicted noise $\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t)$ computed by the diffusion model and the gradient w.r.t predicted QoR $\nabla_{\boldsymbol{x}}\hat{F}(\boldsymbol{x}_t)$.

Arguably, the surrogate model may not provide accurate prediction on a sequence consisting of *noisy* latent variables. Following [25], for each optimization step, we revert the *noisy* variables $\boldsymbol{x}_t$ to a noise-free version $\hat{\boldsymbol{x}}_t$ to obtain a more accurate gradient to optimize the QoR. This can be done by the reparameterization trick used in [25], [26]:

$$\hat{\boldsymbol{x}}_t = \frac{\boldsymbol{x}_t - (\sqrt{1-\bar{\boldsymbol{\alpha}}_t})\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t)}{\sqrt{\bar{\boldsymbol{\alpha}}_t}}. \tag{12}$$

Algorithm 2 Continuous Logic Optimization

Input: Trained surrogate model and diffusion model; target circuit.
Output: Optimized sequence for logic synthesis on the target circuit.

1: Randomly sample a sequence of latent variables from Gaussian noise: $\boldsymbol{x}_T \sim \mathcal{N}(\mathbf{0}, \boldsymbol{I})$.
2: **for** $t = T$ **to** 1 **do**
3: Run optimization step with Equation (13).
4: **end for**
5: Retrieve a sequence of transformations. ▷ Section III-D.

Combining Equation (12) and Equation (11), we can have the final update rule for solving the problem in Equation (4):

$$\boldsymbol{x}_{t-1} = \boldsymbol{x}_t - \eta(\boldsymbol{\epsilon}_\theta(\boldsymbol{x}_t, t) + \omega\nabla_{\boldsymbol{x}}\hat{F}(\hat{\boldsymbol{x}}_t)) + \boldsymbol{\sigma}_t\boldsymbol{z}. \tag{13}$$

This equation illustrates our idea of optimizing sequences in continuous space with the optimized variables in the distribution of valid transformation embeddings. It generates latent variables in a sequence to minimize QoR and prevent them from having large discrepancies from the feasible transformation embeddings. The optimization process is illustrated in Algorithm 2.

D. Retrieval of Optimized Transformations

Upon convergence of the above optimization, we obtain the optimized $\boldsymbol{x}^*$ in latent space. Owing to the denoising process involved, the separate embeddings in $\boldsymbol{x}^*$ will be almost aligned with the embeddings of feasible transformation from $\mathbb{S}$ with minimal discrepancy. Therefore, the final optimized transformation sequence can be retrieved instantly. Our framework can be concluded in Algorithm 1. This optimized sequence will be sent to ABC [1] for validating the actual QoR.

IV. Experimental Results

In this section, we demonstrate the efficiency of our continuous optimization method with several baselines in terms of QoR and runtime. We also ablate the effectiveness of our continuous optimization with different choices of surrogate models and the necessity of the diffusion model.

A. Experiment Setup

Target circuits are taken from EPFL15 and ISCAS89 benchmarks [27], [28]. The PDK for technology mapping is the open-source ASAP7 PDK [29]. Our surrogate model is an MTL-based from [22], which consists of a 2-layer GNN, an LSTM, and two 2-layer attention modules. It is trained by 20000 randomly generated sequences synthesized by ABC [1]. Our diffusion model has a 1-D U-Net structure [18], [30]. It has 500 diffusion/denoising steps. The experiments are conducted on a machine with two AMD EPYC 7543 32-core CPUs and one Nvidia RTX 3090 GPU. We target optimizing synthesis sequences with length $L = 20$. For each circuit, we train a corresponding surrogate model and a diffusion model, which takes about 11 minutes and is a one-time effort.

We choose several state-of-the-art methods of logic optimization as baselines, including DRiLLS [5], abcRL [6],

BOiLS [9], and FlowTune [8], all of which have open-source implementations. We spare all 64 CPU cores when running them for each circuit and one GPU if needed. We modify them meticulously so that both baseline methods and ours use the same set of transformations $\mathbb{S}$ to form a sequence with a length of 20 for a fair comparison. The numbers of optimization iterations of baselines are properly set according to their original papers. We repeat the evaluation 30 times for all methods and select the best sequence for comparison. For DRiLLS [5] and BOiLS [9], which support multi-objective optimization (delay and area), we evaluate them in a multi-objective scenario. For abcRL [6] and FlowTune [8], designed for single-objective optimization, we select the best results for area and delay separately.

B. QoR Comparison

Here we compare the delay and area after logic synthesis between our method and baseline methods. The results are shown in TABLE II. Note that the circuit scale in these benchmarks may vary significantly, and thus computing the mean value over all results may undermine the significance of small circuits (e.g., `ctrl`) and be biased towards large circuits (e.g., `hyp`). To mitigate this bias, we also list the geometric mean results, which reduce the disproportionate impact of substantially large values on the overall relative comparison. It can be seen that the proposed method can always dominate all baselines. Particularly, we can achieve a 4% to 13% reduction in the area and a 1% to 7% reduction in delay. This result validates that our continuous optimization is effective and can find superior sequences compared with baseline methods.

C. Runtime Comparison

For a fair comparison, for DRiLLS [5], abcRL [6], and BOiLS [9], we subtract the runtime of ABC [1] interleaved in the optimization loop so that the comparison is solely on the optimization algorithm itself. For our method, despite that model training may take time in our approach, it is a one-time effort. Therefore, the actual sequence optimization process in our approach is highly efficient. The runtime of our method compared with previous methods is shown in Fig. 5. It can be seen that the proposed continuous optimization method can achieve a 5X to 130X speedup compared with previous methods. In contrast, baseline methods like RL and Bayesian optimization require the model to be updated during the optimization process, and MAB searches a discrete space without explicit gradient information. Thus the efficiency of the baseline methods is not so high. The abcRL [6] is much slower as it requires building graphs from AIG being synthesized every after a transformation is applied. It is clearly shown that our continuous space optimization method is much more efficient than previous discrete optimization methods as it directly optimizes the sequence in a continuous space that avoids extensive discrete search.

D. Effectiveness of the Diffusion Model

We devise an ablation study to further validate the effectiveness of the diffusion model. To this end, we perform extensive

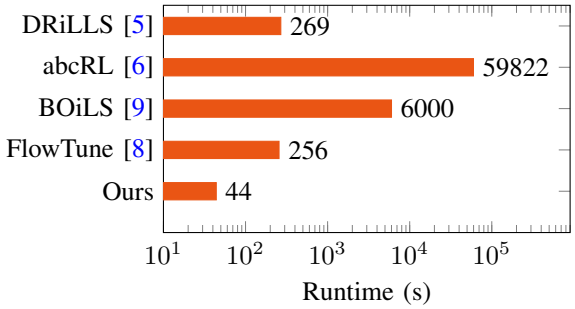

Fig. 5 Comparison of runtime.

validation not only on the MTL-based model [22], but also hybrid graph-based model (LOSTIN) [21] and convolutional neural network-based model (CNN) [4]. Regarding the counterpart without diffusion model, we perform the optimization using only the gradient from the surrogate model, i.e.,

$$\boldsymbol{x}_{t-1} = \boldsymbol{x}_t - \omega \nabla_{\boldsymbol{x}} \hat{F}(\boldsymbol{x}_t). \tag{14}$$

Fig. 6 presents the QoR results of continuous optimizations with various surrogate models, with and without the incorporation of the diffusion model. It can be seen that no matter which surrogate model we choose, incorporating the diffusion model can always result in a substantial performance improvement, which validates the general applicability of the proposed framework. Moreover, it is noted that solely utilizing a surrogate model to perform continuous optimization can hardly exceed the performance of baseline methods, e.g., FlowTune [8]. When the diffusion model is integrated, all the results can surpass the baselines. Please note that our continuous optimization method equipped with different surrogate models has approximately the same runtime (∼40 s) and is still much faster than baselines.

Next, we demonstrate a visualization of the optimized embeddings in latent space with t-SNE [23] in Fig. 7. With the diffusion model, the optimized variables are aligned with the embeddings of feasible transformations, allowing them to be mapped back to transformations instantly. The corresponding sequence in Fig. 7 is [`rw; rw; rsz; rfz; rw; rf; rf; rfz; b; rs; rw; rsz; rwz; rw; rw; rsz; rsz; rsz; rw; rsz`], which yields an area of 11900.00 μm^2. In contrast, without the diffusion model, optimized variables diverge from embeddings of feasible transformations. Mapping these latent variables back to the nearest feasible transformations with large discrepancies gives a sequence as [`rfz; rfz; rwz; rs; rs; rsz; rs; rs; rs; rs; rs; rwz; rs; rwz; rs; rs; rwz; rw; rwz; rwz`] and leads to an area of 22654.15 μm^2, which is 1.9 times larger than the area with a diffusion model.

V. Conclusion

In this paper, we propose to efficiently optimize logic synthesis sequences in a continuous space. The gradient-based optimization in continuous space alleviates the heavy runtime burden of extensive discrete search of transformations. We additionally incorporate a diffusion model to keep latent variables in feasible embedding distributions, allowing instant retrieval of feasible transformations without degrading QoR. Our experimental results show that our work is not only significantly faster than previous methods but also reaches better QoR.

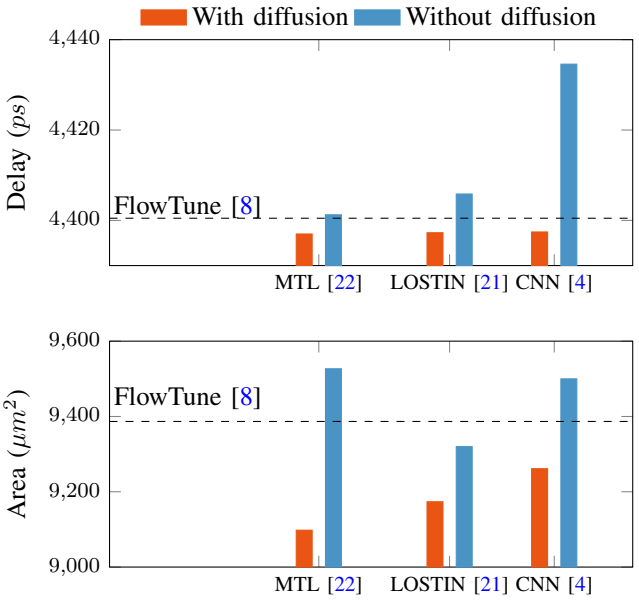

Fig. 6 Area and delay with and without diffusion model for various surrogate models.

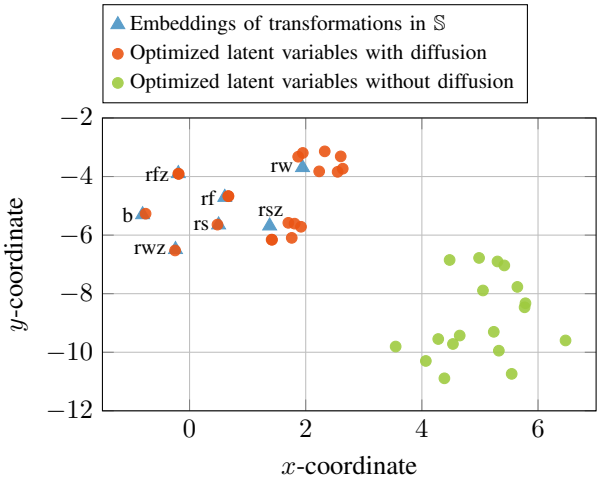

Fig. 7 The t-SNE projection of transformation embeddings from `div` design. The optimized latent variables without diffusion model deviate from feasible transformation embeddings.

***Abstract*—Cross-workload design space exploration (DSE) is crucial in CPU architecture design. Existing DSE methods typically employ the transfer learning technique to leverage knowledge from source workloads, aiming to minimize the requirement of target workload simulation. However, these methods struggle with overfitting, data ambiguity, and workload dissimilarity.**

To address these challenges, we reframe the cross-workload CPU DSE task as a few-shot meta-learning problem and further introduce MetaDSE. By leveraging model agnostic meta-learning, MetaDSE swiftly adapts to new target workloads, greatly enhancing the efficiency of cross-workload CPU DSE. Additionally, MetaDSE introduces a novel knowledge transfer method called the workload-adaptive architectural mask algorithm, which uncovers the inherent properties of the architecture. Experiments on SPEC CPU 2017 demonstrate that MetaDSE significantly reduces prediction error by 44.3% compared to the state-of-the-art. MetaDSE is open-sourced and available at this anonymous GitHub.

***Index Terms*—Design Space Exploration, Cross-workload, Prediction Model, Meta-learning**

I. Introduction

Design Space Exploration (DSE) is pivotal in modern CPU architecture design, enabling the optimization of configurations to balance multiple objectives like performance, power, and area (PPA) [1], [2]. The increasing complexity of CPU architectures has led to an exponential expansion of the design space, presenting significant challenges in efficiently identifying optimal configurations.

Prior DSE frameworks [3]–[11] have utilized learning-based surrogate models to expedite the DSE process, achieving substantial time savings compared to exhaustive simulations. However, these workload-specific DSE frameworks rely heavily on extensive simulations to generate sufficient data for training machine learning models, necessitating the evaluation of numerous design points. This approach can be exceedingly time-intensive, especially for complex architectural spaces.

To mitigate this challenge, various studies [12]–[18] have adopted the transfer learning technique to reduce simulation overhead. By leveraging previously collected data from source workloads, transfer learning enables the model to adapt to unseen target workloads, a process known as cross-workload DSE. Cross-workload DSE generally follows a two-stage training process: first, pre-training on data from source workloads, and then fine-tuning on limited data from the target workload. However, current cross-workload DSE frameworks have notable limitations in both upstream pre-training stage and downstream adaptation stage:

- **Upstream Pre-training Issues:** Existing methods typically rely on machine learning based surrogate models [12]–[14], [17], [18] combined with standard supervised learning, which are prone to overfitting the pre-training data. Additionally, the inherent data ambiguity across multiple workloads introduces optimization challenges for transfer learning, often hindering effective convergence.
- **Downstream Adaptation Issues:** Given the high cost of simulations, training samples for new workloads are often limited, leading most existing frameworks to rely on knowledge transfer for adaptation. However, these approaches typically assume workload similarity as a prerequisite [12], [15], [16], which is not always the case. When this assumption fails, the adaptation performance degrades significantly, limiting the effectiveness of traditional transfer learning methods in cross-workload CPU DSE tasks.

To tackle these issues, we rethink cross-workload CPU DSE as a few-shot problem and propose MetaDSE, an open-source framework featuring two key stages: upstream pre-training and downstream adaptation. **For the upstream pre-training stage,** we adopt a meta-learning approach [19]–[21], well-suited for addressing few-shot problems. Unlike normal supervised learning, meta-learning emphasizes "learning how to learn" across tasks, making it ideal for tackling data ambiguity in DSE. By treating each workload as a distinct task during meta-training, the model avoids overfitting to specific instances and instead captures shared patterns and relationships across tasks. **For the downstream adaptation stage,** we design an adaptation algorithm called the Workload-adaptive Architectural Mask (WAM). WAM provides a novel approach to knowledge transfer, emphasizing the inherent properties of the architecture rather than relying on workload similarity.

To summarize, we list our contributions as follows:

- We conduct a comprehensive analysis of existing CPU cross-workload DSE frameworks, identifying their limi-

*Runzhen Xue and Hao Wu contributed equally to this work.

tations in handling data ambiguity and enabling efficient knowledge transfer.
- We reframe the CPU cross-workload DSE task as a few-shot meta-learning problem, using the Model-Agnostic Meta-Learning (MAML) algorithm to enhance model adaptability with limited samples from new workloads.
- We introduce a novel adaptation algorithm named WAM, which captures inherent properties of the architecture, enabling efficient and generalized DSE framework across diverse workloads.
- Extensive experiments on the SPEC CPU 2017 benchmark suite show that our proposed MetaDSE framework significantly outperforms state-of-the-art methods, achieving 44.3% reductions in prediction errors across various workloads.

II. Background & Related Work

A. Cross-workload DSE framework

1) Taxonomy: Most cross-workload CPU DSE methods [12]–[18] use transfer learning [22], [23] to reduce sample requirements for new workloads by leveraging source knowledge, typically following three strategies. **Linear Fitting.** Work [18] uses linear regression to combine predictions from fixed source models, mapping them to the target workload label space using a few labeled samples. It merely builds a linear mapping between the source and target label spaces, relying heavily on the unrealistic assumption of identical distributions and linearity. **Data Augmentation.** Work [17] employs the Gaussian mixture model [24] to model the original data and perform augmentation. By swapping the coefficients of high-probability and low-probability Gaussian components, the method enhances rare data distributions, aiming for more balanced data augmentation while preserving the overall distribution. To some extent, this work stems from the premise of similarity in the distribution of workloads. **Similarity Analysis.** Studies [12]–[16] explore workload similarity for model adaptation using distinct strategies. [15], [16] leverage workload signatures, representing workloads during pretraining and identifying the most similar signature for downstream adaptation. This approach transfers knowledge through signature-based representation. In contrast, methods like TrEnDSE [12], TrDSE [13], and TrEE [14] adopt a data-driven approach. TrEnDSE uses Wasserstein distance [25] to measure workload similarity, while TrDSE clusters workloads using orthogonal array (OA) sampling and distributional features. TrEE further refines this with an OA-based foldover sampling strategy. These methods select similar samples from the pre-trained dataset to enhance downstream adaptation, directly integrating relevant upstream data without relying on explicit signature representation.

2) Re-evaluating Similarity-based Approaches: In this section, we examine the frameworks of incorporating data from source workload into downstream adaptation. One of the earliest works to apply this concept is TrDSE [13], which influenced subsequent frameworks such as TrEE [14] and TrEnDSE [12]. However, these methods always include a one-time training process using data from the target workload. Actually, concerns over data leakage make it uncommon and impractical to access pre-trained data in many real-world scenarios. These methods can be better described as data augmentation rather than transfer learning [23].

B. Few-shot Problem & Meta-learning

The few-shot learning problem involves training models to generalize effectively using only a small number of labeled samples [26], [27], typically just a few dozen. This scenario is common in situations where labeling data is costly. To address this challenge, meta-learning has emerged as a powerful approach. In meta-learning [20], [20], a model is trained across a diverse set of tasks and is optimized to generalize well over a distribution of tasks. Here, each task is associated with a dataset $\mathcal{D}$ containing features and labels, where the entire dataset acts as a single data sample. The goal of meta-learning can be formalized similarly to supervised learning, with the optimal model represented as $\theta^* = \arg\min_\theta \mathbb{E}_{\mathcal{D}\sim p(\mathcal{D})}[\mathcal{L}_\theta(\mathcal{D})]$.

As depicted in Fig. 1, the meta-learning model is trained on a variety of curated tasks from different datasets, where the supervised signal from these tasks guides the model to perform well across a wide range of unseen tasks. One common meta-learning technique is MAML [19], which aims to learn an optimal initialization of model parameters. This initialization enables the model to rapidly adapt to any new task with just a few gradient updates, providing efficient solutions for downstream few-shot problems.

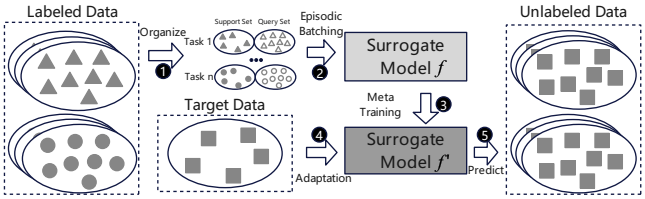

Fig. 1. Typical workflow of Model-Agnostic Meta-Learning.

III. Motivation

A. Limitations in Prior Arts

Current cross-workload DSE frameworks have notable limitations in both the pre-training stage and the adaptation stage.

1) Upstream Pre-training Issues: In the pre-training stage, the surrogate model is prone to overfitting the pre-training data and faces data ambiguity. For instance, previous methods [12]–[14] typically utilize machine learning based surrogate models, such as tree-based ones. These models tend to capture patterns specific to the source workloads and lead to overfitting with standard supervised training. However, due to the variability and ambiguity inherent in cross-workload CPU DSE scenarios, similar architectural configurations may yield vastly different performance metrics across workloads. This discrepancy leads the model to learn misleading or unreliable features during pre-training. Consequently, these features may not generalize well when the model is fine-tuned on new target workloads, resulting in poor predictive accuracy and limited adaptability.

2) Downstream Adaptation Issues: For the downstream adaptation stage, the primary challenge lies in the method of knowledge transfer. Many prior works assume that workloads are similar [12], [15], [16], employing methods like Wasserstein distance [25] to compare metric space distributions between source and target workloads, but this assumption does not always hold. In real-world scenarios, workloads exhibit significant variability in computational behaviors, data access patterns, and performance requirements, making this assumption unreliable.

For instance, our experiments on the SPEC CPU 2017 benchmark suite (as shown in Fig. 2) demonstrate that the similarities across workloads are inconsistent, with many showing substantial differences. This variability undermines the effectiveness of transfer learning methods like TrEnDSE when faced with diverse and complex workload characteristics. As a result, these methods may struggle to deliver accurate performance predictions for real-world DSE tasks, underscoring the need for a more adaptive, workload-independent approach to tackle the challenges of cross-workload CPU DSE.

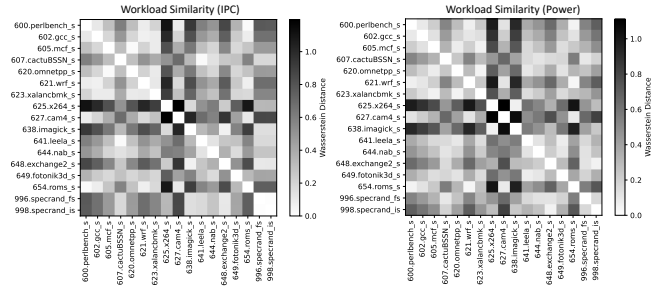

Fig. 2. Wasserstein distances among SPEC CPU 2017 workloads. The darker the color, the less similar the two workloads.

B. Rethinking Cross-workload CPU DSE

To overcome the limitations of prior arts, we introduce two innovative solutions tailored to the distinct stages.

For the pre-training stage, we address the challenges of overfitting and data ambiguity by reframing the task as a few-shot meta-learning problem. This perspective shift allows the model to be trained on a variety of tasks using only a small number of labeled samples, thereby reducing the risk of overfitting and improving its ability to generalize across different workloads. By leveraging the meta-learning technique, the surrogate model can capture shared patterns across workloads, eliminating the impact of data ambiguity.

For the adaptation stage, we recognize the limitations of conventional methods that rely on workload similarity for knowledge transfer. Instead, we propose shifting the focus from workload similarity to the intrinsic properties of the architectural design. To harness these inherent characteristics, we introduce the WAM algorithm. WAM uncovers key relations between architectural parameters and leverages them during adaptation. This novel approach enhances the model's robustness and adaptability, improving the overall effectiveness of cross-workload CPU DSE.

IV. Design of MetaDSE

A. Overview of MetaDSE

In this section, we introduce MetaDSE, a framework designed to enhance the efficiency of cross-workload CPU DSE. The workflow of MetaDSE, illustrated in Fig. 3, is divided into two main stages: pre-training (❶–❾) and adaptation (①–③). For the surrogate model f, we employ a transformer-based predictor, inspired by the strong performance of AttentionDSE [7] in CPU DSE tasks.

In the pre-training stage, the meta-training process begins by creating a copy of the surrogate model (parameterized by $\hat{\theta}$). This model is first fine-tuned on the support set of each task through a few gradient descents (❶, ❷). Subsequently, the fine-tuned model evaluates the loss on the corresponding query set (❸), and this computed loss contributes to the overall meta-loss (❹). The meta-loss is then used to update the parameters of the original surrogate model (parameterized by θ). After each training epoch, a meta-validation step is conducted to evaluate the model's performance and to identify the optimal parameters for downstream tasks. In the adaptation stage, the pre-trained surrogate model (parameterized by $\hat{\theta^*}$) undergoes fine-tuning with the WAM algorithm (②). WAM focuses on the inherent properties of the architecture, adjusting the model to emphasize relevant interactions between architectural parameters. Further technical details on the WAM adaptation process are elaborated in the subsequent sections.

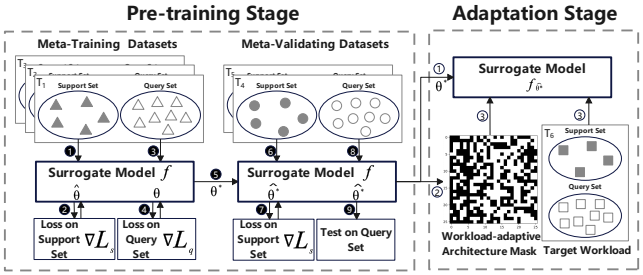

Fig. 3. The overview workflow of MetaDSE.

B. MAML-based Pre-training Stage

The pre-training stage in MetaDSE typically aims to build a model that performs well across a wide range of tasks. Instead, our MAML-based approach focuses on finding an optimal model initialization, θ, which can rapidly adapt to new downstream tasks using few data. This strategy allows the predictor to generalize effectively to diverse workloads without extensive retraining, tackling the core challenge of the few-shot problem in cross-workload CPU DSE.

Algorithm 1 describes the MAML-based pre-training process for the surrogate model. Before the training stage, each iteration begins by sampling tasks from the task distribution $P(T)$, representing different workloads. For each task, the model is trained using a support set S and evaluated on a query set Q. The training in MAML can be divided into two phases: the inner loop and the outer loop. The inner loop (from line 4 to line 12) focuses on task-specific adaptation, simulating the fine-tuning process during model deployment. Here, the model updates its parameters using the support set from a

Algorithm 1: The Pre-Training Procedure of Predictors

Input: f_θ: the predictor with random parameters; $P(T)$: task distribution of one workload; s, q: sample amount of support set and query set in one task, correspondingly; α, β: learning rate in inner and outer loop;
Output: f_{θ^*}: the meta-trained predictor

1 randomly initialize θ
2 **while** *not done* **do**
3 Sample tasks from some workloads' distribution $T_i \sim P(T)$
4 **for** *each task* t *in* T_i **do**
5 $\hat{\theta} = \theta$
6 Split out support set $S = (x_j, y_j)$ and query set $Q = (x_k, y_k)$ from t, $S, Q \leftarrow Spilt(t, s, q)$
7 **for** *each inner step* **do**
8 Evaluate $\nabla_{\hat{\theta}} \mathcal{L}(f_{\hat{\theta}})$ with respect to S
9 Compute adapted parameters with gradient: $\hat{\theta} = \hat{\theta} - \alpha \nabla_{\hat{\theta}} \mathcal{L}(f_{\hat{\theta}})$
10 **end**
11 Save Q and $f_{\hat{\theta}}$ temporarily
12 **end**
13 Evaluate and average meta gradients of every task from T_i, $\nabla_\theta \mathcal{L}(f_{\hat{\theta}})$ with respect to each Q in every t
14 Compute adapted meta parameters with meta gradient: $\theta = \theta - \beta \nabla_\theta \mathcal{L}_{T_i}(f_{\hat{\theta}})$
15 **end**
16 $\theta^* = \theta$
17 return final predictor f_{θ^*}

Algorithm 2: The Adaptation Procedure of Predictors

Input: f_{θ^*}: the meta-trained predictor; $P(T)$: task distribution of test workload; s, q: sample amount of support set and query set in one task, correspondingly; γ: learning rate during adaptation; M: workload-adaptive architectural mask.
Output: $f_{\hat{\theta^*}}$: the adapted predictor

1 Equip f_{θ^*} with M in its self-attention operator
2 Set M to learnable state: $M.required_grad = True$
3 Sample tasks from test workload's distribution $T_i \sim P(T)$
4 **for** *each task* t *in* T_i **do**
5 $\hat{\theta^*} = \theta^*$
6 Split out support set $S = (x_j, y_j)$ and query set $Q = (x_k, y_k)$ from t, $S, Q \leftarrow Spilt(t, s, q)$
7 **for** *each step* **do**
8 Evaluate $\nabla_{\hat{\theta^*}} \mathcal{L}(f_{\hat{\theta^*}}, M)$ with respect to S
9 Compute adapted parameters with gradient: $\hat{\theta^*} = \hat{\theta^*} - \gamma \nabla_{\hat{\theta^*}} \mathcal{L}(f_{\hat{\theta^*}})$
10 **end**
11 return adapted predictor $f_{\hat{\theta^*}}$
12 **end**

specific task. This phase aims to find temporary parameters $\hat{\theta}$ that adapt well to the current task. The update rule in this phase is: $\hat{\theta} \leftarrow \hat{\theta} - \alpha \nabla_{\hat{\theta}} \mathcal{L}(\hat{\theta})$. where α is the inner loop learning rate. This gradient descent adjusts the parameters to minimize the task-specific loss $\mathcal{L}$, effectively mimicking how the model would adapt when exposed to new data. The outer loop (from line 2 to line 15) aims to optimize the initial parameters θ by aggregating the feedback from multiple tasks. After the inner loop updates for each task, the model evaluates its performance on the query set to calculate the meta-loss. This meta-loss reflects how well the adapted model (with parameters $\hat{\theta}$) generalizes across different tasks. The meta-parameters θ are then updated based on the meta-gradient: $\theta = \theta - \beta \nabla_\theta \mathcal{L}_{T_i}(f_{\hat{\theta}})$ where β is the meta-learning rate. This outer-loop update ensures that the initial parameters θ are optimized to quickly adapt to new tasks with minimal data.

This two-level optimization process enables MetaDSE to efficiently adapt to new workloads. It ensures the pre-trained model generalizes well to diverse, unseen tasks, minimizing the need for extensive fine-tuning on large datasets.

C. Workload-adaptive Architectural Mask Adaptation Stage

In cross-workload CPU DSE tasks, workload dissimilarity poses a significant challenge for knowledge transfer. To tackle this, we propose WAM adaptation, which leverages inherent architectural properties to enhance the pre-trained model's generalization to unseen workloads.

A critical issue is that not all architectural parameters are fully correlated. Previous efforts [12]–[15], [18] have largely overlooked this, leading to noise from irrelevant parameter interactions and reduced prediction accuracy. To address this, we introduce an algorithm that generates a mask for the surrogate model, utilizing intermediate attention weights from the transformer-based predictor during pre-training. This mask filters out irrelevant parameter interactions, enabling the model to focus on key factors and improving prediction accuracy.

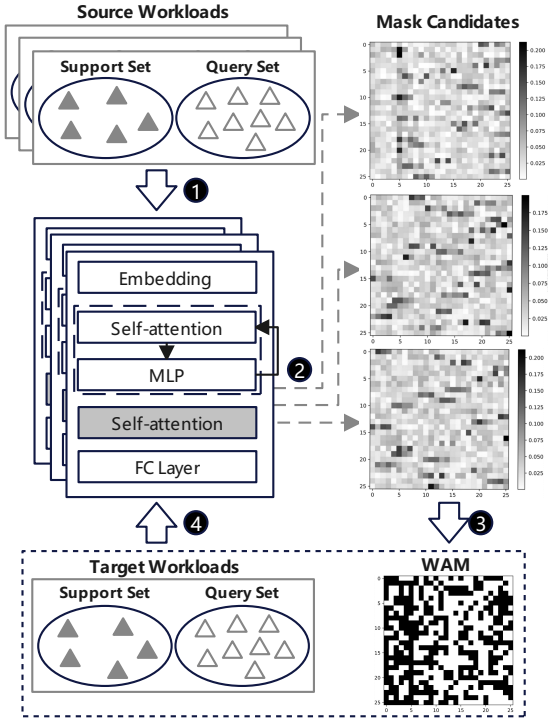

Fig. 4. The example of workload-adaptive architectural mask generation.

As Fig. 4 shows, we utilize attention weights obtained during the pre-training process to analyze the relationships between architectural parameters (❶, ❷). We extract all the attention weights from the last self-attention layer, referring to them as mask candidates. By identifying parameter interactions that frequently occur across diverse workloads, we construct a WAM (❸) that highlights high-frequency correlations, effectively filtering out less relevant interactions.

After the mask is generated, we leverage the mask and the target workloads to the adaptation stage (❹). The procedure is illustrated in Algorithm 2. The process also begins by sampling

tasks from the test workload's distribution $P(T)$. For each sampled task t, we initialize the adapted model parameters as $\hat{\theta}^* = \theta^*$ and split the task data into a support set S and a query set Q. During the adaptation process, we iteratively update the model parameters $\hat{\theta}^*$ using gradients computed based on the loss $\mathcal{L}$ evaluated on the support set S. The update rule $\hat{\theta}^* = \hat{\theta}^* - \gamma \nabla_{\hat{\theta}^*} \mathcal{L}(f_{\hat{\theta}^*})$ ensures that the model learns with mask M to minimize the error on the specific task at hand. Finally, the adapted predictor $f_{\hat{\theta}^*}$ is returned for each task, incorporating the updated parameters that better capture the features of target workloads.

WAM adaptation allows the surrogate model to focus on critical parameter interactions, reducing noise from irrelevant features and enhancing prediction accuracy. Moreover, it introduces a novel approach to knowledge transfer, prioritizing architectural properties over workload similarity.

V. Experimental Setup

Datasets Generation. We utilize GEM5 [28] as the timing-accurate simulator and McPAT [29] as the power modeling tool. We extend GEM5 using Python to generate different CPU cores with varying configurations. To bolster the credibility of our experiments, we employ SPEC CPU 2017 [30] as the evaluation benchmark. We utilize Simpoints [31] for each workload evaluation. Each workload is divided into at most 30 clusters, with each cluster containing ten million instructions.

For dataset splitting, we iteratively and randomly designated seven datasets for training, five for validation, and five for testing. This approach ensured balanced and robust training across various dataset combinations.

Baselines. We evaluate our proposed MetaDSE framework against several baselines from different perspectives. The first baseline is TrEnDSE [12], a state-of-the-art cross-workload CPU DSE framework. We then introduce TrEnDSE-Transformer, where the ensemble model in TrEnDSE is replaced with a Transformer-based predictor. Lastly, MetaDSE-w/o WAM is a variant of MetaDSE that excludes the WAM adaptation.

The Explored Design Space. The design space of the out-of-order processor is listed in Table I. The values in the third column are formatted as "start number: end number: stride". A two-level cache hierarchy with an 8192MB DRAM main memory configuration is employed.

Evaluation Metrics. The accuracy of the model is primarily measured using the Root Mean Squared Error (RMSE), which is calculated as:

$$\text{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2} \tag{1}$$

where y_i is the actual value, $\hat{y}_i$ is the predicted value, and N is the number of data points.

Additionally, other metrics such as Mean Absolute Percentage Error (MAPE) and Explained Variance (EV) are used for a more comprehensive evaluation:

TABLE I
Microarchitecture design space specification.

Parameters	Description	Candidate Value
Core Frequency	the frequency of CPU core in GHz	1/1.5/2/ 2.5/3

$$\text{MAPE} = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{\left|y_i - y_i^{\text{real}}\right|}{y_i^{\text{real}}}\right) \times 100. \tag{2}$$

$$\text{EV} = 1 - \frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{N}(y_i - \bar{y})^2} \tag{3}$$

where $\bar{y}$ is the mean of the actual values. Lower RMSE and MAPE values, and higher EV values, indicate better model performance.

VI. Experiment Results

A. Overall Analysis

The implementation of MetaDSE has two stages: upstream pre-training and downstream WAM adaptation. For pre-training, we run 15 epochs with 200 tasks per workload, each task having five support samples and forty-five query samples. Inner and outer loop learning rates are 1×10^{-5} and 1×10^{-4}, respectively. In each iteration, every model copy is optimized via five inner-loop steps on the support set using SGD, and the accumulated meta-loss is used to update the original model with the Adam optimizer. In the downstream stage, we fine-tune the pre-trained model using ten gradient steps with a

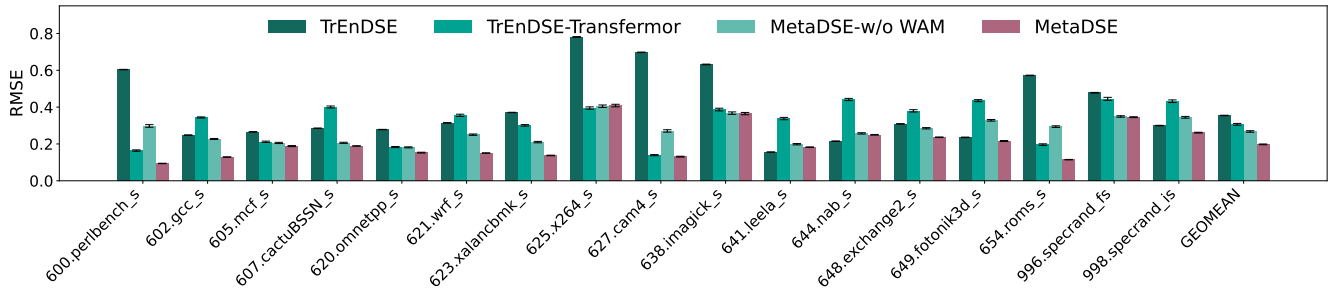

Fig. 5. Comparison of IPC RMSE per workload on SPEC CPU 2017 with the SOTA cross-workload CPU DSE framework (lower is better for RMSE).

TABLE II
THE OVERALL RESULTS, AVERAGED ACROSS FIVE DATASETS (600.PERLBENCH_S, 605.MCF_S, 620.OMNETPP_S, 623.XALANCBMK_S, AND 627.CAM4_S), ARE EVALUATED USING RMSE, MAPE, AND EXPLAINED VARIANCE.

learning rate of 1×10^{-5} and cosine annealing. We evaluate 1000 tasks per workload for mean and confidence intervals.

Fig. 5 illustrates the prediction accuracy comparison between MetaDSE and various baseline models on the SPEC CPU 2017 dataset. The last column presents the geometric mean (GEOMEAN) of prediction errors across all tasks. MetaDSE achieves a significant reduction in prediction error, lowering it by 44.3% compared to the state-of-the-art cross-workload CPU DSE framework, TrEnDSE. When comparing TrEnDSE with TrEnDSE-Transformer, we observe that simply replacing the ensemble learning model with a more powerful Transformer model provides some performance improvement. However, this improvement is relatively modest and inconsistent across different tasks. In contrast, within the meta-learning-based DSE framework, the inclusion of our proposed WAM adaptation technique leads to a substantial performance boost, reducing the average prediction error by 27%, and highlighting the effectiveness of adapting to workload-specific characteristics.

We further compare MetaDSE with several commonly used models in transfer learning for predicting IPC and power, including Random Forest (RF) and Gradient Boosting Regression Trees (GBRT), shown in Table II. Our results reveal that MetaDSE consistently outperforms TrEnDSE and other baselines across all evaluated workloads, demonstrating lower RMSE and MAPE values while achieving higher EV scores. These results further highlight the superiority of MetaDSE over traditional transfer learning approaches, emphasizing its enhanced ability to generalize and adapt effectively across different workloads in cross-workload CPU DSE tasks.

B. Exploring Data Impact

We further investigate the impact of pre-training and adaptation data on MetaDSE performance.

1) Sensitivity of Pre-training: For the upstream pre-training stage, we fix the downstream adaptation support set size to ten and change the support set size of the pre-training stage from five to forty. Fig. 6 illustrates that when the upstream and downstream data are aligned, the model achieves optimal transfer performance, with the highest EV and lowest RMSE. This improvement is attributed to the matched knowledge pattern and the higher learning efficiency when the data distribution is consistent across pre-training and adaptation phases, leading to better generalization and model adaptation.

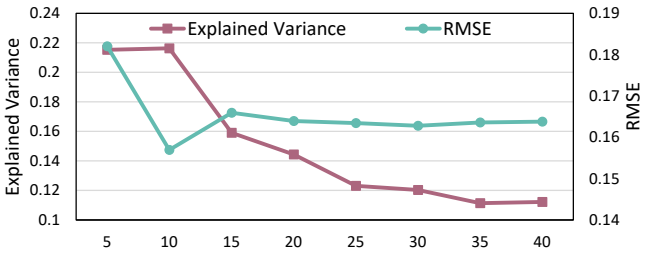

Fig. 6. The variation in explained variance and RMSE with respect to changes in the source sample size.

2) Sensitivity of Adaptation: We further investigate the impact of downstream adaptation data and compare MetaDSE to commonly used machine learning models, including RF, GBRT, and TrEnDSE. In this experiment, we fix the support set size of the upstream pre-training stage to ten while varying the adaptation support set size from five to forty. The results presented in Table III show that when the pretraining data size is fixed, increasing the adaptation data size results in modest performance improvements for MetaDSE. Notably, MetaDSE achieves high performance even with a smaller amount of adaptation data.

TABLE III
RMSE ON IPC PREDICTION AS THE DOWNSTREAM ADAPTATION SUPPORT SIZE (K) CHANGES.

Models / K	5	10	20	30	40
RF	0.4409	0.4397	0.4390	0.4386	0.4380
GBRT	0.2577	0.2390	0.2356	0.2321	0.2299
Baseline	0.2616	0.2397	0.2229	0.2147	0.2076
MetaDSE	0.1580	0.1562	0.1485	0.1471	0.1466

VII. CONCLUSION

In this work, we introduce meta-learning to cross-workload CPU DSE tasks and propose MetaDSE. MetaDSE utilizes the MAML and proposes the WAM algorithm to uncover the inherent architectural properties, offering a novel approach to prior knowledge transfer. Experiments on SPEC CPU 2017 benchmarks demonstrate that MetaDSE significantly reduces prediction errors compared to state-of-the-art methods, highlighting its effectiveness in improving model adaptability.

†*jiaqigu@asu.edu*

***Abstract*— Diffractive optical neural networks (DONNs), leveraging free-space light wave propagation for ultra-parallel, high-efficiency computing, have emerged as promising artificial intelligence (AI) accelerators. However, their inherent lack of reconfigurability due to fixed optical structures post-fabrication hinders practical deployment in the face of dynamic AI workloads and evolving applications. To overcome this challenge, we introduce, *for the first time*, a composable hybrid optical reconfigurable diffractive framework (CHORD), a physically composable architecture that unlocks a new degree of freedom and unprecedented versatility in DONNs. By leveraging full-system learnability, CHORD repurposes fixed fabricated optical hardware, achieving exponentially expanded functionality and superior task adaptability through the differentiable learning of system variables. Furthermore, CHORD adopts a hybrid optical/photonic design, combining the reconfigurability of integrated photonics with the ultra-parallelism of free-space diffractive systems. Extensive evaluations demonstrate that CHORD has digital-comparable accuracy on various task adaptations with 74× faster speed and 194× lower energy. Compared to prior DONNs, CHORD shows exponentially larger functional space with 5× faster training speed, paving the way for a new paradigm of versatile, composable, hybrid optical/photonic AI computing. Our code is open-sourced at link[1].**

I. Introduction

Emerging technologies promise efficiency and performance breakthroughs, and optical neural networks (ONNs) are at the forefront of this movement. They are poised to revolutionize next-generation AI computing by harnessing the inherent parallelism and speed of light. Diffractive ONNs (DONNs) [1], [2], [3], [4], [5] represent a compelling realization of optical AI hardware, employing free-space optical signal modulation, diffraction, and interference to achieve ultra-parallel intelligent information processing. Different from integrated photonic tensor cores (PTCs) [6], [7], [8], [9], [10], [11], [12] based on programmable photonic integrated circuits (PICs) designed for matrix-vector multiplication, free-space DONNs eliminate the dimension limitations of 2-D silicon chips and operate directly on light waves in 3-D free space, offering unprecedented parallelism through a global-view spatial linear operation.

However, DONNs face a significant challenge in their lack of reconfigurability after fabrication. The fixed manufactured phase masks limit their adaptability to new ML tasks, hindering their deployment in dynamic, real-world AI workloads [13], [14]. While research into reconfigurable phase masks based on tunable metasurfaces shows promise, these approaches remain in the immature stages. They struggle with limitations such as low endurance and reliability, which make them unsuitable for adoption in the near term.

To address these limitations, we shift our focus from device-level reconfigurability to system-level reconfigurability. Optical systems inherently feature adjustable parameters, such as wavelength, phase mask spacing, and element size, that significantly influence system behavior but are often manually determined based on experience in the early stage and fixed during the optimization process later. This raises a key question: **can these built-in hardware variables be automatically optimized for better expressivity?** However, for true task adaptation, adjusting these scalar variables alone lacks sufficient degrees of freedom. A fundamental system redesign is necessary to unlock the versatility needed for modern AI workloads. In this work, we address this challenge: **how to construct a versatile DONN system with exponentially many reconfigurable functionalities by re-purposing the same set of fabricated phase masks?** Furthermore, considering the strengths of both diffractive ONNs and integrated PTCs, we explore **how to hybridize free-space optics and integrated photonics organically** to leverage both the ultra-parallel processing capability of DONNs and the superior reconfigurability of integrated PTCs for joint NN acceleration.

[1]https://github.com/ScopeX-ASU/CHORD

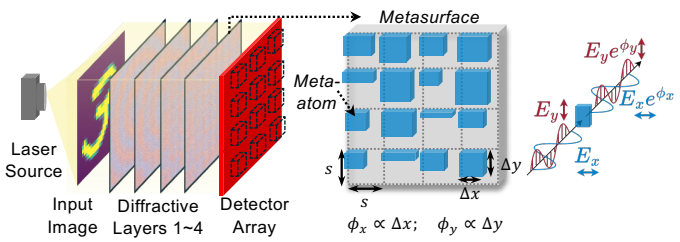

Fig. 1: Diffractive optical neural networks (DONN) based on metasurfaces with a pixel size of s. The rectangular meta-atom shape can be designed to realize a polarization-dependent phase shift for orthogonally polarized light.

To answer those questions, we investigate the intrinsic learnability of DONNs from the system level and propose a multi-dimensional reconfigurable hybrid DONN design paradigm, dubbed CHORD, with a physically composable architecture that can flexibly switch the orientation and placement order of phase masks for exponentially larger functional space. The main contributions are as follows,

- We present *the first* in-depth analysis of multi-dimensional learnability in DONNs, introducing a physically composable hybrid optical system CHORD for extreme multi-functionality.
- **Auto-Learned Multi-Dimensional System Variables**: we enable differentiable learning of DONNs across multiple dimensions (wavelength, spacing, orientation, permutation), exponentially enhancing expressivity and the functional space.
- **Hybrid Optical/Photonic System**: We explore the possibility of hybridizing free-space diffractive optics and reconfigurable integrated photonics for joint NN acceleration.
- **Superior Task Adaptability**: Extensive evaluations show that our system and differentiable learning algorithms enable digital-comparable task adaptation performance with 74× faster speed and 194× lower energy, outperforming prior DONNs with exponentially higher functional space and 5× higher training efficiency.

II. Background

A. Diffractive Optical Neural Networks (DONN)

As shown in Fig. 1, the main trainable parameters are weights on the phase mask, i.e., $\mathbf{\Phi} \in \mathbb{R}^{K\times K}$, where the phase shift of one unit cell is $\phi_{i,j} \in [0, 2\pi)$. When incident light X passes through the phase mask, it applies pixel-wise phase rotation, i.e., $e^{\Phi} \odot X$, where $\odot$ is element-

wise multiplication. Typically, to increase the number of trainable parameters, a DONN will have multiple cascaded phase masks, e.g., L layers [15]. Between two masks, the light will propagate in the free space with diffraction. This can be described using the Rayleigh-Sommerfeld diffraction, a dense linear transformation where each light on the output plane is the superposition of all light from the input plane with a distance-related intensity/phase modulation coefficient h. The transmission, including a phase mask and diffraction, is denoted as $X_{l+1} = \mathcal{H}(e^{\Phi_l} \odot X_l)$, formulated as [16]:

$$
\begin{aligned}
X_{l+1}(k_x^{l+1}, k_y^{l+1}) &= \sum_{k_x}^{K} \sum_{k_y}^{K} h_l(R, z, \lambda) \cdot e^{\phi_{k_x^l, k_y^l}} \cdot X_l(k_x^l, k_y^l), \\
h(R, z, \lambda) &= \frac{1}{2\pi} \frac{z}{R} \left(\frac{1}{R} - j\mathbf{k}\right) \frac{e^{j\mathbf{k}R}}{R}, \\
R &= \sqrt{((k_x^{l+1} - k_x^l) \cdot s)^2 + ((k_y^{l+1} - k_x^l) \cdot s)^2 + z^2}.
\end{aligned} \tag{1}
$$

In the diffraction coefficient h, $\mathbf{k} = \frac{2\pi}{\lambda}$ is the wave vector in free space, and λ is the wavelength, and z is the distance between two layers, $j = \sqrt{-1}$. R is the distance from the unit cell located at $(k_x{}^l, k_y{}^l)$ in the l-th layer to the unit cell located at $(k_x{}^{l+1}, k_y{}^{l+1})$ in the $(l+1)$-th layer. s is the pixel size of the phase mask unit cell.

As nanofabrication technology advances, a promising approach to implement DONN is using a sub-wavelength metasurface. Metasurfaces offer a compact solution, where each unit cell is called a meta-atom and consists of sub-wavelength nanostructures [2], [17], [18]. A typical meta-atom is a rectangular nano-pillar with precisely defined width, length, and thickness to achieve a specific phase shift, in Fig. 1. This structure is polarization-dependent and thus can induce independent phase changes in orthogonal light polarizations, e.g., ϕ_x for x-polarized and ϕ_y for y-polarized light. This is the foundation of our polarization-differential computing technique introduced later.

B. Integrated Photonic Tensor Cores

A different approach to implementing ONNs is through photonic tensor cores (PTCs). Unlike DONNs based on passive diffractive components, PTCs integrate photonic devices to actively modulate light to achieve high-speed matrix-vector multiplication (MVM) [6], [19], [20], [21], [11], [9], [10], [22]. DONNs are more natural for ultra-parallel low-energy spatial processing, while PTCs are more suitable in generic reconfigurable MVMs. This indicates complementary capabilities between the two hardware platforms for joint computing.

III. Related Works

Previous works have proposed solutions to build multi-functional DONNs. For instance, prior methods have introduced rotation into diffractive neural networks, enabling certain layers to be rotatable and thereby enhancing task adaptability [13], [14]. Prior work [18] also explored training different tasks on separate regions of the diffractive layer. This approach suffers from area limitations, constrained to a limited number of fixed functions (e.g., 2-3). Similarly, metasurface-based DONNs [17] leverage polarization-dependent phase responses to train multiple tasks, with each task corresponding to a different polarization state that the metasurface can distinguish. This approach faces limited expressivity as only a small number of orthogonal polarization states are supported by metasurfaces.

IV. Proposed Composable Hybrid Optical Reconfigurable Diffractive Framework CHORD

We introduce a hybrid DONN with multi-dimensional reconfigurability and physical composability, dubbed CHORD (see Fig. 2). By delving into the system-level learnability, CHORD introduces new degrees of freedom to overcome the reconfigurability limitations of traditional DONNs, enabling superior task adaptability and training efficiency.

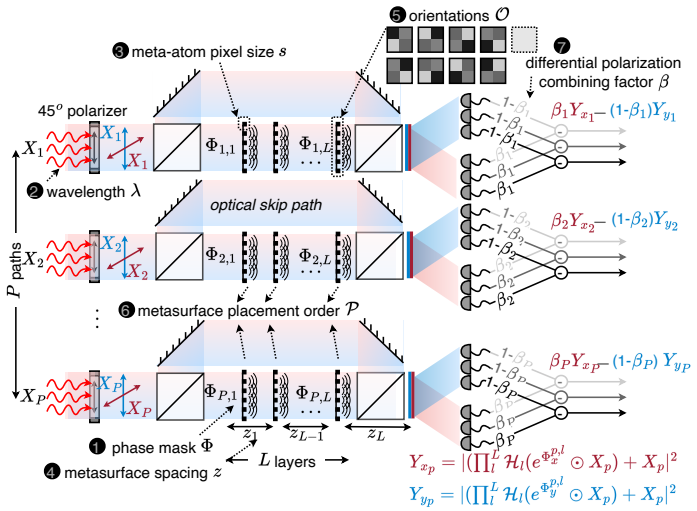

Fig. 2: Multi-path diffractive layer (DiffLayer) with P paths. Each has L cascaded metasurfaces and polarization-differential photodetection. Learnable parameters ❶-❼ are marked.

TABLE I: Parameter tuning mechanism (structural, electrical, mechanical) and reconfiguration frequency. ❶-❼ belong to diffractive optical hardware. ❽ is on integrated photonic chips.

Learnable System Parameters	Stru.	Elec.	Mech.	Reconfig. Freq.
❶ Phase Response Φ	√			Fixed after fab.
❷ Source Laser Wavelength λ		√		Tunable per task
❸ Meta-atom Pixel Size s	√			Fixed after fab.
❹ Metasurface Spacing z			√	Tunable per task
❺ Orientation $\mathcal{O}$			√	Tunable per task
❻ Placement Order $\mathcal{P}$			√	Tunable per task
❼ Differential Polarization Factor β		√		Runtime tunable
❽ Channel-Mixing Factors α_{pre}, α_{post}		√		Runtime tunable

A. Overview of Learnable System Parameters

For a generic expressive DONN, our CHORD is assumed to have a **multi-path** architecture with P parallel paths, each with L cascaded phase masks, shown in Fig. 2. We summarize programming mechanisms and properties of all variables in our CHORD architecture in Table I, including the *conventional* parameter phase masks Φ, and our **7 newly introduced dimensionalities**: light source wavelength λ, meta-atom pixel size s, diffraction distance between metasurfaces z, metasurface orientation $\mathcal{O}$, metasurface placement ordering $\mathcal{P}$, pre- and post-channel-mixing factor α_{pre} and α_{post}, and differential polarization combining factor β, visualized in Fig. 2.

1) ❶ Phase Masks Φ: Phase masks are the core parameters of DONNs. If phase elements (meta-atoms) are designed to be polarization-dependent, e.g., a rectangle, we can adjust meta-atom width/length to independently change its phase responses $\phi_x, \phi_y \in [0, 2\pi)$ for x- and y-polarized light. Once a phase mask is trained and fabricated, it is fixed and typically cannot be reconfigured.

2) ❷ Light Source Wavelength λ: The wavelength λ impacts the optical system's diffraction behavior $\mathcal{H}(\cdot|\lambda)$ while maintaining a near-constant phase response ϕ if using broadband meta-atoms. A reasonable range for λ is from 400 nm in the visible spectrum to 1600 nm in the near-infrared. Given a preferred λ, e.g., 532 nm, we consider local fine-tuning with $\pm$20 nm linewidth given the tunability of the current laser with a 0.1 nm tuning resolution.

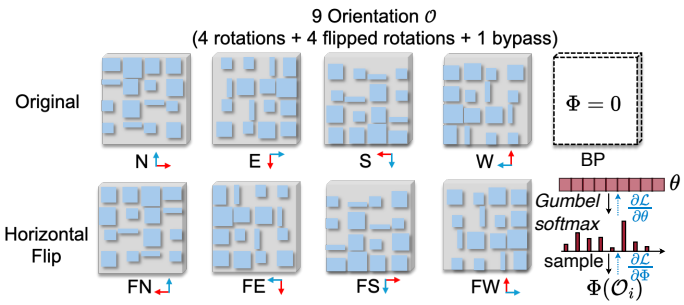

Fig. 3: 9 orientation states for each bi-directional phase mask, which can be learned differentiably using Gumbel-softmaxd.

3) ❸ *Meta-Atom Pixel Size s:* The diffraction operator $\mathcal{H}(\cdot)$ is a function of pixel size s, which is the period of the metasurface grid. Considering all metasurfaces have a shared scalar pixel size $s \in \mathbb{R}$, e.g., 300 nm, we are allowed to freely determine this variable during the initial design stage for better performance. The pixel size is lower-bounded by the meta-atom width required to realize 2π phase response plus minimum manufacturable linewidth, e.g., $s > s_{2\pi,\lambda_0} \cdot \lambda/\lambda_0 + \Delta s$. For example, given a reference λ_0=532 nm, the meta-atom width needs to be $s_{2\pi,\lambda_0}$=180 nm to realize 2π phase shift, then we assume a linear scaling w.r.t. λ. With a Δs=20 nm gap between pixels, the pixel period needs to honor the constraint $s > 200$ nm.

4) ❹ *Metasurface Spacing z:* The spacing between two phase masks determines the diffraction behavior of the light, i.e., $\mathcal{H}(\cdot|z)$ Intuitively, a small z passes the light directly to the next metasurface with weak diffraction and cross-pixel interactions, yielding a local linear operator with a nearly diagonal transfer matrix. A large spacing introduces all-to-all pixel interaction. However, most light spreads to spaces outside the next metasurface plane, which causes significant light energy loss and, thus, a dim and blurred image projected onto the next metasurface. Hence, a carefully optimized diffraction spacing z is critical to the receptive field and expressivity of the DONN. We explore a shared learnable spacing z for all layers and independently adjustable spacings $(z_1, z_2, \cdots, z_L)$ for different layers.

5) ❺ *Metasurface Orientation $\mathcal{O}$:* Before metasurface fabrication, the phase mask is freely optimized to realize an arbitrary phase distribution. After fabrication, the metasurface is fixed. Thanks to the physical composability of our CHORD design, the phase mask orientation becomes an additional degree of freedom to enrich the functionality while reusing the same piece of hardware, as shown in Fig. 3. The phase mask can be rotated at four angles, i.e., R0 (N), R90 (E), R180 (S), and R270 (W). Besides, a bidirectional phase mask can also be horizontally flipped to introduce chirality, i.e., shine the light reversely through the mask. Then, we can augment to another 4 states: FN, FE, FS, and FW, shown in Fig. 3. Replacing the phase mask with an identity mask $\Phi = 0$ is another allowable *bypass* state given the system flexibility, denoted as BP. Orientation reconfiguration can be implemented mechanically. Each metasurface can select its orientation out of 9 states. For a DONN with P parallel paths, each with L cascaded masks, there are 9^{PL} unique states. Though this approach might not be suitable for real-time frequent reprogramming, it is promising for less frequent task adaptation. It enables **exponentially many new system responses for potential lifelong hardware reusing**. Later, we will introduce how to learn the best state from discrete orientations in a differentiable way.

6) ❻ *Metasurface Placement Order $\mathcal{P}$:* To fully leverage the physical composability of our CHORD system, we further explore the location swapping of metasurfaces for extreme multi-functionality. Inspired by the concept of card shuffling, phase masks can be reordered and replugged to any valid slots. A permutation of all phase masks can be used to describe this placement ordering. In a $P \times L$ multi-path DONN, the total permutation reaches $(PL)!$, enabling an even larger design space than orientation.

7) ❼ *Differential Polarization Combining Factor β:* Polarization-multiplexed DONN [17] is previously demonstrated to map two tasks onto orthogonal polarization channels. Differently, we use two independent polarization directions in a **differential fashion to enhance the linear operation expressivity and realize full-range outputs**. Each forward pass through our CHORD system generates two non-negative outputs Y_x and Y_y for x(y)-polarized channel, respectively. We use balanced photodetection to obtain a full-range feature map $Y = \beta Y_x - (1-\beta)Y_y$ with *a non-negative combining factor* $\beta \in \mathbb{R}_+$. β is electronically implemented with low overhead and thus can be dynamically reconfigured in real time.

8) ❽ *Pre/Post Channel-Mixing Coefficients α_{pre} and α_{post}:* Simulating such systems in a multi-channel DONN layer is time-consuming and memory-hungry. With C_{in} input feature map channels and C_{out} output channels, it requires to simulate the P-path CHORD system by $C_{in}C_{out}/P$ times, which is not scalable. To make DONN training more scalable and efficient, we borrow the concept of depth-wise convolution, which performs **spatial-only channel-wise diffractive projection** without aggregating the computing results from C_{in} channels. To enable channel-wise feature extraction, we add a channel-mixing coefficient α_{pre} and α_{post} before and after the metasurface DONN layer, same as point-wise convolution. The pre-channel-mixing layer projects the features from C_{in}-channel to C_{mid}-channel. The DONN system forwards C_{mid} channels of images through the metasurface system and obtains C_{mid} output channels, which are further fed into α_{post} layer and projected to C_{out} channels.

As the channel-mixing operation only involves parallel MVM, it can be efficiently mapped to integrated PTCs for ultra-fast processing with real-time reconfigurability. By leveraging the ultra-parallel global-view spatial processing capability of diffractive optical systems and ultra-fast reconfigurable MVM power of integrated photonic accelerators, our hybrid optical-photonic CHORD system can realize **highly adaptable and efficient** optical computing. Meanwhile, this depthwise separable operation, with comparable expressivity to traditional multi-channel convolution-like DONN layers, **significantly lowers the training cost** of simulating diffractive layers.

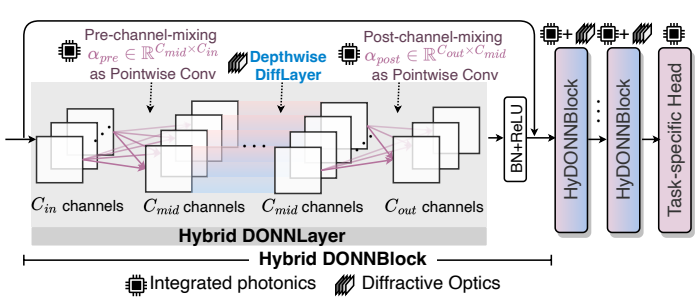

Fig. 4: Hybrid DONNLayer with pointwise Convolution mapped to integrated PTCs and depthwise diffractive layers mapped to free-space diffractive optics.

9) Hybrid DONNLayer: Figure 4 shows our hybrid DONNLayer with the channel-mixing operation mapped to integrated PTCs for ultra-fast point-wise Conv and diffractive layers (DiffLayer) in the middle

mapped to metasurface systems for ultra-parallel depth-wise spatial information extraction. `DONNResBlock` contains BatchNorm, activation, and a residual connection. Multiple `DONNResBlocks` construct the backbone of our `CHORD` system. The task-specific head at the end is mapped onto integrated PTCs.

B. Pre-Fab Training for Initial Task

In the initial training phase before metasurface fabrication, all system variables can be freely optimized. Note that since the phase response of the metasurfaces Φ can be freely adjusted, it is unnecessary to learn the orientation or placement order at this stage. The permutation $\mathcal{P}$ and metasurface rotation mask $\mathcal{M}$ will not be optimized during this phase. Therefore, we focus on optimizing parameters such as the Φ, α_{pre}, α_{post}, β, λ, z, and s on the initial machine learning task.

$$\min_{\Phi,\lambda,z,s,\alpha,\beta} \mathcal{L}((\Phi,\lambda,z,s,\alpha,\beta),\mathcal{D}_{init}). \tag{2}$$

C. Post-Fab Training for Tasks Adaptation

Once the first training is completed, DONN phase masks will be fabricated. Phases Φ and pixel size s are fixed. We now introduce how to enable fully-differentiable learning of the rest of the architecture variables to adapt the fabricated system to new tasks $\mathcal{D}_{adapt}$,

$$\begin{aligned} \min_{\lambda,z,\alpha,\beta,\mathcal{O},\mathcal{P}} \ & \mathcal{L}((\lambda,z,\alpha,\beta,\mathcal{O},\mathcal{P}),\mathcal{D}_{adapt}|\Phi^*,s^*) \\ \text{s.t.} \quad & \mathcal{P} \in \text{Permutation matrices} \\ & \lambda^* - \Delta\lambda \le \lambda \le \lambda^* + \Delta\lambda, \quad \beta \ge 0. \end{aligned} \tag{3}$$

1) Adapt Wavelength λ: Similar to the initial training, we allow local adjustment of wavelength with $\pm$20nm range to adapt the diffraction operation to new tasks.

2) Adapt Metasurface Spacing z: Similar to the initial training stage, we can either learn a shared spacing $z \in \mathbb{R}$ or a dedicated layer-wise spacing vector $\mathbf{z} \in \mathbb{R}^L$ with the standard gradient descent method.

3) Learn Metasurface Orientation $\mathcal{O}$ with Gumbel-Softmax Method: Selecting the orientation of metasurfaces is a highly discrete problem. We model the orientations of each metasurface as a 9-category parametric distribution. For the (p,l)-th metasurface, its probability of having orientation $\mathcal{O}_{p,l} \in \mathbf{O} = \{N, W, S, E, FN, FW, FS, FE, BP\}$ is

$$P_{\theta_{p,l}}(\mathcal{O}_{p,l} = \mathbf{O}[i]) = e^{\theta^i_{p,l}} \Big/ \sum_{i=1}^{9} e^{\theta^i_{p,l}}. \tag{4}$$

We employ Gumbel-softmax to learn the distribution parameter θ with a gradient-based method in Fig. 3. The phase mask Φ is the superposition of all 9 states weighted by a mask m, i.e., $\Phi_{p,l} = \sum_{i=1}^{9} m^i_{p,l}\Phi^i_{p,l}$, where the mask is sampled from the following distribution,

$$m^i_{p,l} = \texttt{GumbelSoftmax}(\theta^i_{p,l}|\theta_{p,l}) = \frac{e^{(\theta^i_{p,l}+g^i_{p,l})/\tau}}{\sum_i e^{(\theta^i_{p,l}+g^i_{p,l})/\tau}}, \tag{5}$$

where g and τ are the Gumbel noise and temperature. The final orientation $\mathcal{O}_{p,l}$ can be selected by $\mathcal{O}_{p,l} = \mathbf{O}[\text{argmax}_i\, \theta^i_{p,l}]$.

4) Learn Metasurface Placement Order $\mathcal{P}$ with Differentiable Permutation Learning: We introduce an automatic learning method to permute all PL metasurfaces in a differentiable way. Without loss of generality, we use the learning of a permutation across P metasurfaces as an example. Exploring the factorial permutation space is very challenging. Inspired by a differentiable circuit routing learning algorithm [23], as illustrated in Fig. 5, we use a $P \times P$ permutation matrix $\mathcal{P}$ to represent the mapping from metasurface indices to slot indices. A permutation matrix is a Boolean matrix $\mathcal{P} \in \{0,1\}^{P\times P}$ where each row and column only has one 1. $P_{ij} = 1$ means the i-th metasurface is placed at slot j. We convert the permutation constraint with its equivalent continuous format, i.e., the row-wise and column-wise ℓ_1-norm equals the squared ℓ_2-norm. We solve the constrained optimization problem with the augmented Lagrangian method (ALM) to relax the constraint as an objective term,

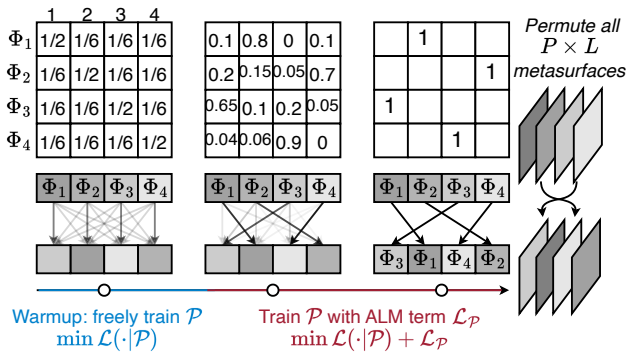

Fig. 5: Illustration of metasurface placement order permutation. Two-stage training is adopted with warmup training and ALM-based permutation learning.

$$\mathcal{L}_{\mathcal{P}} = \sum_{i=1}^{P} \mu^T_{i,r}\big(\Delta\widetilde{\mathcal{P}}^{i,:} + \frac{\rho}{2}(\Delta\widetilde{\mathcal{P}}^{i,:})^2\big) + \mu^T_{i,c}\big(\Delta\widetilde{\mathcal{P}}^{:,j} + \frac{\rho}{2}(\Delta\widetilde{\mathcal{P}}^{:,j})^2\big), \tag{6}$$

where $\mu^r \in \mathbb{R}^P$ and $\mu^c \in \mathbb{R}^P$ are row-wise and column-wise Lagrangian multipliers, and ρ is the quadratic penalty weight. $\Delta\widetilde{\mathcal{P}}^{i,:} = \|\widetilde{\mathcal{P}}^{i,:}\|_1 - \|\widetilde{\mathcal{P}}^{i,:}\|_2^2$. At every step when we update $\mathcal{P}$, we also perform the dual update on the multiplier $\mu \leftarrow \mu + \rho(\Delta\widetilde{\mathcal{P}}^{i,:} + \frac{1}{2}(\Delta\widetilde{\mathcal{P}}^{i,:})^2)$ to gradually increase the penalty to push it to a feasible permutation.

5) Train Task-specific Head Layers: After the backbone, task-specific head layers, such as the final linear classifier or convolutional regression layers, are re-initialized and trained on the new task.

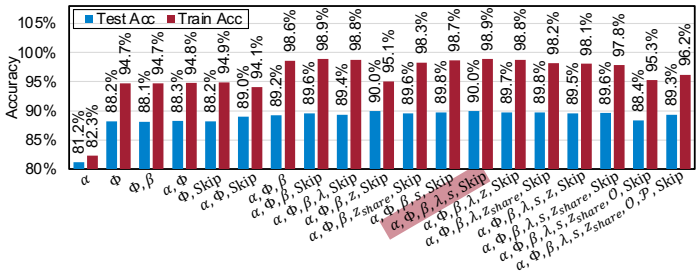
V. Evaluation Results

A. Settings

1) Model and Dataset: As a case study, we assume our `CHORD` system has up to 4 paths and up to 4 cascaded metasurface layers. The DONN model backbone based on this hardware contains two Hybrid `DONNBlocks`, with depthwise `DiffLayers` mapped to the same `CHORD` hardware. All structural and mechanical parameters that cannot be switched in runtime, i.e., λ, z, s, Φ, $\mathcal{O}$, $\mathcal{P}$, **are shared** across all `DiffLayers`. Runtime reconfigurable parameters, i.e., α_{pre}, α_{post}, and β, **are independently learned** for each `DiffLayer`. Each metasurface has 32×32 meta-atoms. The initial values for wavelength $\lambda = 532$ nm, meta-atom size $s = 400$ nm, and metasurface spacing $z = 8.42\ \mu m$ are typical values used in the literature [17]. We evaluate on three benchmarks:

- Pre-fab training on Fashion-MNIST [24] 10-class recognition and adapt the model to QuickDraw [25] 10-class image recognition. A classification head is used with AdaptiveAvgPool5-FC10.
- Pre-fab training on CIFAR-10 [26] and adapt the model to CIFAR-100 [26]. The classification head is Adaptive AvgPool5-FC10(100).
- Pre-fab training on Darcy flow [27] 1-channel PDE solving and adapt to Navier-Stokes [28] 10-channel PDE solving. A regression head is used with C64K3-BN-GELU-C1(10)K1.

2) Training Settings: General Setting: We train all DONNs for 100 epochs using the AdamW [29] optimizer with a learning rate (lr) of 1E-2, a cosine decay scheduler, a weight decay rate of 1E-2, and data augmentation techniques such as random cropping and flipping for both



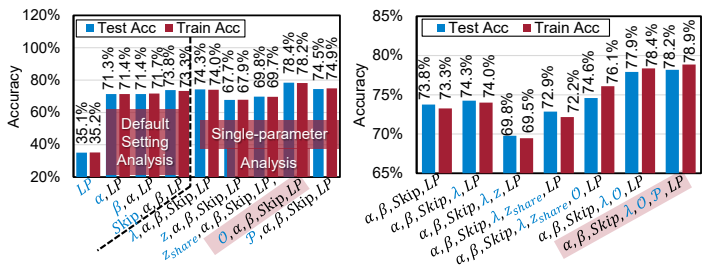


Fig. 6: Expressivity of different combinations of learnable system parameters. Training and test accuracy are shown on 2-layer DONN on FMNIST.

(a) (b)

Fig. 7: (a) Effectiveness of individual parameter (❷-❻) for task adaptation, LP: Linear Probing. (b) Effectiveness of progressively enabling parameters (❷-❻) in adaptation.

pre-fabrication training tasks and adaptation tasks. Weight decay is only applied to Φ, which is reparameterized in the range of $[-\pi, \pi)$.

Schedule τ in Orientation and ρ in Permutation: For orientation learning, to prioritize early-stage exploration and later-stage stable convergence, we apply exponential decay on the Gumbel-softmax temperature $\tau = \tau_{init} \cdot \gamma_\tau^{(epoch-1)}$, where τ_{init} is 5 and γ_τ is 0.956. To encourage early-stage free permutation optimization and gradually force the constraints, ALM quadratic penalty term ρ is scheduled as $\rho = \rho_{init} \cdot \gamma_\rho^{(epoch-warm\ up\ epoch)}$, with a warm-up period of 5 epochs, ρ_{init} set to 1E-5, and γ_ρ set to 1.2.

Parameter Quantization: λ can be adjusted within ± 20 nm around initial value, with 1 nm precision. To ensure that the meta-atom can generate a $-\pi$ to π phase response for a given λ, the pixel size's lower bound is calculated following Sec. IV-A3 equation: $s > \frac{\lambda}{\lambda_0} \cdot s_{2\pi,\lambda_0} + \Delta_s$, where $\lambda_0 = 532$ nm, $s_{2\pi,\lambda_0} = 300$ nm, and $\Delta_s = 20$ nm. The precision for z is set to 10 nm, while Φ is reparameterized $\in [-\pi, \pi)$ with a precision of 1°. We also employ learned step-size quantization-aware training [30]. A b_w=8-bit quantization is applied to weights and activations in layers utilizing PTCs, such as α and the final head.

Evaluation Metrics: Accuracy is used as the primary metric for the classification tasks. The Mean Squared Error (MSE) was utilized as the evaluation metric for PDE-solving tasks. Both training and test performance are shown to indicate each setting and parameter's contribution to the DONN's expressivity, trainability, and generalizability.

B. Ablation Study on CHORD's Learnable Parameters

1) Parameter Expressivity and Learnability in Pre-fab Training: In initial training, we conduct a thorough ablation study on parameters in Fig. 6. A single-path DONN is assumed ($P = 1$, $L = 4$). We train (α, Φ, β, λ, s) with the optical skip path enabled as the optimal default pre-fab training settings.

2) Individual Effectiveness of Params. ❷-❼ in Post-fab Task Adaptation: We explore the impact of each parameter on task adaptation

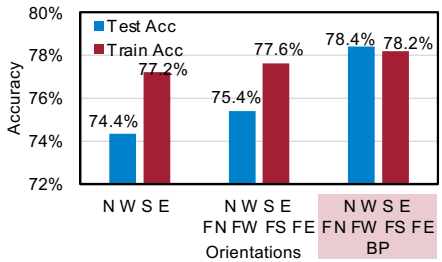

Fig. 8: Nine orientations show the best expressivity and accuracy on QuickDraw adaptation tasks.

TABLE II: Evaluate CHORD (P=4, L=4) on pre-fab initial tasks and post-fab adapted tasks. A 2-layer digital CNN (C32K3)$_{\times 2}$ is shown as a reference. In each group, DONN is trained on the first task and adapted to the second task. We use initial training results of the second task as a reference. For classification, test Acc. is shown. For Darcy/NavierStokes, MSE is shown.

Tasks	Digital 2-Layer CNN C32K3-C32K3	Pre-fab Initial Training P=4, L=4, α, Φ, β, *Skip*, s, λ	Post-fab Task Adaptation P=4, L=4, α, β, *Skip*, λ, $\mathcal{O}$, $\mathcal{P}$
FMNIST	0.9122	0.9014	-
Quickdraw	0.8978	0.8646	0.7992 (adapt from FMNIST)
CIFAR10	0.7633	0.6182	-
CIFAR100	0.4347	0.3815	0.2513 (adapt from CIFAR10)
Darcy	0.0466	0.055	-
NavierStokes	0.1085	0.1007	0.1753 (adapt from Darcy)

in Fig. 7(a). Simply training the head, called linear probing (LP), with the backbone frozen, is insufficient. As we enable the optimization of *electrically* tunable parameters (β and α), along with the optical skip path and linear probing, we observe a significantly enhanced accuracy.

Mechanically tunable parameters (λ, z, $\mathcal{O}$, $\mathcal{P}$) further improve task performance, with phase mask orientation $\mathcal{O}$ showing the largest impact due to its additional $9^4\times$ larger solution space. Permutation $\mathcal{P}$ also contributes positively to task adaptation, though not as impactful as orientation due to the 4! solution space with only 4 metasurfaces (single path), $273\times$ smaller than $\mathcal{O}$. The effectiveness of $\mathcal{P}$ is expected to factorially grow as the number of paths increases.

The diffractive distance z and z_{share} contribute less to performance, as they are too sensitive to be trained alongside other parameters, leading to an increase in training difficulty and thus impacting the overall optimality, which is not trained during adaptation.

3) Combinational Effectiveness of Params. ❷-❼ in Post-fab Task Adaptation: Building on the individual parameter analysis, we progressively enable these parameters to evaluate their combined effectiveness in task adaptation, as shown in Fig. 7(b). The results are consistent with those in Sec. V-B2, confirming that the diffractive distance z is highly sensitive and tends to reach suboptimal states when trained alongside other parameters. However, fixing z to its initial learned value significantly improves adaptation accuracy as additional parameters, λ, $\mathcal{O}$, and $\mathcal{P}$, are progressively introduced.

4) Orientation Effectiveness: Figure 8 provides strong evidence for the effectiveness of the 9-option orientations. Compared to 4-direction rotation [13], [14], the inclusion of 4 flipped states and the identity state improves test accuracy by +4%, demonstrating their significant contribution to CHORD's task adaptability.

C. Multi-Path, Multi-Layer Exploration

We investigate the impact of multiple parallel paths in CHORD, exploring a more generic design space to enable greater functionality.

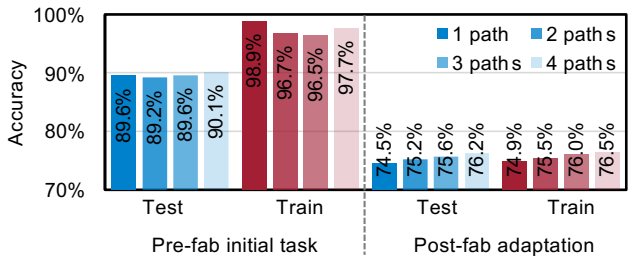

Fig. 9: Adapt four DONNs with L=4 and different paths P from pre-fab FMNIST task to post-fab Quickdraw task. Only permutation $\mathcal{P}$ is trained during adaptation to show the learnability gain by enlarging the solution space from 4! to 16!.

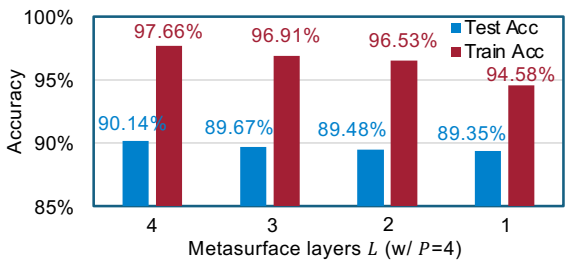

Fig. 10: Different layers L with P=4 on pre-fab FMNIST.

1) Number of Paths P in Pre-Fab Initial Training: In Fig. 9, we fix the layer count to L=4 and increase the number of diffractive paths P. Test accuracy on the initial task improves by approximately 0.5% with an increasing number of paths. However, fluctuations in training accuracy suggest that adding too many parallel phase masks, similar to large-kernel convolutions, introduces learning challenges.

2) Number of Paths P in Post-Fab Task Adaptation with Permutation: In Fig. 9(*Right*), we show task adaptation only with permutation learning enabled. By increasing the path from 1 to 4, the space of permutation increases from 4! to 16!, leading to a notable learnability boost and thus +1.7% improvement on test and training accuracy.

3) Number of Layers L in Pre-Fab Initial Training: We evaluate the impact of layer depth L on learnability by conducting pre-fab training with 4 parallel paths and varying the number of layers L. Figure 10 shows a significantly enhanced expressivity with more layers cascaded, demonstrating the clear benefit of deeper CHORD.

D. Main Results

We conduct three pre-fab training tasks on Fashion-MNIST, CIFAR-10, and Darcy, and transfer the CHORD system to new tasks, i.e., QuickDraw, CIFAR-100, and Navier-Stokes, respectively. Table II demonstrates that CHORD exhibits competitive expressivity compared to the digital counterpart in FMNIST and QuickDraw. However, we observe accuracy gaps on CIFAR-10 and CIFAR-100 due to the increased difficulty of those tasks. Notably, CHORD **excels in much harder PDE prediction tasks such as Darcy flow and Navier-Stokes. These tasks benefit from a global receptive field, aligning perfectly with the global spatial processing capabilities of diffractive ONNs**.

For task adaptation, when all system variables ❶-❽ are enabled to learn, we can largely resume the accuracy even when the major weights Φ are frozen. To understand the individual contribution of each variable to task adaptability, we show a detailed discussion below.

E. Discussion

1) Parameter Contribution to Adaptability: Figure 11 shows the insights of parameter contribution to adaptability.

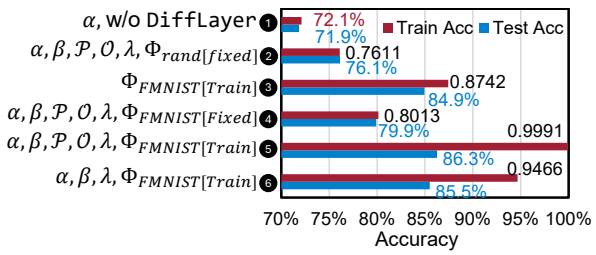

Fig. 11: Training different parameters during adaptation.

TABLE III: Device info in energy and latency calculation [12].

Device	8-bit ADC	8-bit DAC	TIA	MZM	PS	PD
Power (mW)	14.8	50	3	50	0.15	0

Compare (❶, ❹): Besides α_{pre}, α_{post} on integrated photonics, DiffLayers are also critical in DONN learning.

Compare (❷, ❹): The trained Φ from initial tasks carries transferable knowledge that helps new task learning.

Compare (❹, ❺): In the future, with advancements in *reconfigurable metasurfaces*, enabling Φ to be trainable on new tasks post-fabrication could significantly enhance performance, unlocking even greater potential for dynamic task adaptability and learnability.

Compare (❸, ❺): We want to highlight that even if Φ becomes trainable in the future, our introduced $\alpha, \beta, \mathcal{P}, \mathcal{O}, \lambda$ parameters can still enhance the network's expressivity and learnability.

Compare (❺, ❻): It validates that our introduced permutation $\mathcal{P}$ and orientation $\mathcal{O}$ effectively expand the solution space and are crucial for enhancing the model's adaptability.

2) Training Efficiency of Our Depth-wise DiffLayer: Our depth-wise DiffLayer achieves significant efficiency improvements over prior DONNs with 64-channel Conv-like diffractive layers, reducing memory by 29% (from 9807 MB to 6997 MB) and accelerating training by 4.92× per iteration (from 329.59 ms to 66.99 ms).

3) Energy and Speed Advantages of CHORD vs. Digital CNNs: Via behavior-level architecture simulation, on average, CHORD delivers 74× faster single-batch inference speed (1.48 ms to 0.02 ms) and consumes 194× less energy (134.9 mJ to 0.696 mJ) compared to a digital CNN on A6000 GPU. For the DONN part, we assume a photodetection (PD) speed of 10 GHz [31]. Given that P channels are processed in parallel, this results in an 8E-7 ms latency with 32/P=8 (P=4) cycles and 0.1 ns per cycle. Thus, the latency of the diffractive layer is negligible compared to the overall time.

For the PTC part, we employ a single-core 16×16 PTC design [12], with device power listed in Table III. The energy and latency are simulated using an open-source photonic accelerator simulator [20].

VI. Conclusion

We present the first in-depth analysis of multi-dimensional learnability in DONNs, introducing a physically composable hybrid optical/photonic system, CHORD. Our results demonstrate that CHORD with multi-dimensional learnable system variables provides digital-comparable accuracy on various task adaptations, especially challenging PDE-solving tasks, with 74× faster inference speed and 194× lower energy. Compared to prior DONNs, our hybrid CHORD shows exponentially larger functional space and extreme multi-functionality with 5× faster training speed. CHORD shows the potential to enable versatile and high-efficiency optical AI systems with repurposed hardware, paving the way for practical deployment in dynamic AI applications.

***Abstract*—Mixture-of-Experts (MoE) model parallelism is prevalent in training Large Language Models (e.g., ChatGPT). However, the intensive *all-to-all* collective communication of the MoE layer's intermediate computing results substantially degrades MoE training efficiency. In this paper, we propose BirdMoE, a novel load-aware communication compression technique with Bi-random quantization for MoE training with two core modules. Specifically, BirdMoE employs a lightweight Random Quantization (RQ) with expectation invariance property to efficiently map the floating-point intermediate computing results into integers while maintaining the MoE training quality. Additionally, BirdMoE utilizes a Mixed Precision (MP) strategy to dynamically balance the communication loads among expert nodes, significantly improving all-to-all communication efficiency for the MoE training system. Experiments on four typical MoE training tasks demonstrate that BirdMoE achieves higher 4.06×-10.44× total communication compression ratios and 1.18×-5.27× training speedup compared with the state-of-the-art compression techniques while maintaining the MoE training quality.**

***Index Terms*—Mixture-of-Experts training, communication compression, load balance.**

I. Introduction

The remarkable success of deep learning can be attributed to the combination of large-scale training datasets and increasingly expansive model architectures. For example, in domains like language generation, machine translation, and computer vision, augmenting model capacity significantly boosts model performance when datasets are suitably large [1]–[5]. However, dense neural networks process every sample using all parameters, resulting in escalating training costs. This includes increased demands on memory and computing power, proportionate to the growth in both model and dataset scales [6].

Mixture-of-Experts (MoE), a form of conditional computation technique, has recently proven effective in expanding model capacity with sub-linear cost [7]. Different from directly scaling small models to a large dense model, the MoE model consists of many small feed-forward networks (FFN), which are named *experts*. Training samples are dynamically selected by a trainable gate network and fed into different experts. Because experts are activated sparsely, MoE notably boosts the number of samples trained within the same time, improving model accuracy with lower computational expenses compared to conventional dense models [8]–[10].

(a) GPT-based MoE model trained on Wikitext103 (b) ViT-based MoE model trained on Tiny ImageNet

Fig. 1. The runtime breakdown per iteration of naive no-compression MoE training (left bar) and BirdMoE training (right bar).

Communication Bottleneck in MoE: Although the flexible MoE structure makes it more feasible to train a giant model beyond a trillion scale, the training process is still extremely costly. For instance, training a 600-billion-parameter MoE model requires 2048 TPUs and four days [11]. To improve training efficiency, *expert parallelism* is presented to distributedly train MoE models, where experts are partitioned into different workers (e.g., GPU nodes) and each worker processes a different batch of training samples in parallel. In MoE layers, the *intermediate computing results* of each worker are sent to different desired experts during the forward and backward propagation using '*all-to-all*' collective communication [11]. However, the distinct communication characteristics of MoE require the intermediate computing results to be intensively and unevenly transferred across workers in every iteration, making the imbalanced communication overheads a significant bottleneck in MoE training. To closely examine the communication bottleneck, we conduct four typical MoE training tasks on a cloud computing platform (detailed in Section IV). The left bars of Figure 1 indicate that communication times not only take up a large proportion but also increase significantly with the number of expert nodes.

Issues of Existing Solutions: To improve MoE training efficiency, several studies focused on modifying the MoE model architecture [8], [12] or optimizing the training workflow and resource scheduling [9], [10]. However, these works intrude on the standard MoE training workflow, potentially restricting their use in a wide range of practice scenarios. Additionally, as the MoE architecture scales up, the growth of the intensive traffic becomes explosive, making compressing the communication in MoE training a promising direction.

Recently, communication compression techniques, such as sparsification and quantization, have been successfully employed to reduce gradient volume in distributed learning due to the favorable compression ratios and scalability [13]–[20]. However, we noticed that the aforementioned distinct communication characteristics of MoE introduce three specific compression challenges to existing communication compression techniques: ❶ *Overhead Amplification Issue*: Forward and backward propagation of expert parallelism incurs intensive communication across multiple nodes demanding hundreds of compressions per iteration, dramatically amplifying the compression overhead up to 89.6% (as see Figure 2 (a)). ❷ *Error Propagation Issue*: Compression of intermediate computing results spans multiple MoE layers, causing information distortion to accumulate layer-by-layer during MoE training, significantly compromising 18.9%-66.7% training accuracy (as see Figure 2 (b)). ❸ *Communication Imbalance Issue*: existing communication compression techniques address all data uniformly without considering the imbalanced communication load among experts, thereby ineffective in resolving the dilemma of low resource utilization and congested all-to-all communication (as see Figure 2 (c)).

In this paper, we propose a novel load-aware **Bi-random** quantization technique tailored for **MoE** training system, named BirdMoE, to solve the aforementioned issue based on several observations and techniques as below.

To solve the **Overhead Amplification Issue**, we leverage the lightweight advantage of the random process and introduce a Probabilistic Thresholding-based Random Quantization (RQ) for MoE layer, which significantly reduces compression overheads by probabilistically mapping the floating-point intermediate computing results of the all-to-all communication into low-bit integers at a low $O(N)$ time complexity.

To solve the **Error Propagation Issue**, we exploit the convergence efficiency of unbiased representation [18], [19] and build the expectation invariance within RQ, which can preserve an unbiased estimation for the quantized intermediate computing results, thereby effectively reducing the information distortion and maintaining the MoE training quality.

To solve the **Communication Imbalance Issue**, we study the specific data routing characteristic of MoE layer and introduce a Mixed Precision (MP) strategy upon the above RQ, which can dynamically adjust the bit-widths of data routed to different experts, effectively balancing the communication load and improve efficiency to the overall MoE training system.

To the best of our knowledge, BirdMoE is the first compression technique designed for balancing and reducing the communication costs of intermediate computing results in all-to-all communication while maintaining model accuracy in the MoE training context. The right bars of Figure 1 indicate that BirdMoE successfully reduces communication costs at low overheads, making MoE training accessible in platforms with limited computing and communication resources. Our main contributions are summarized as follows:

- We identify three issues when applying communication compression techniques to MoE training: (*i*) Compressing the intensive communications incurs significant computational overhead; (*ii*) The compression error of intermediate results severely degrades the MoE training quality; (*iii*) Compression cannot address the low training efficiency caused by imbalanced communication loads.
- We propose BirdMoE, a novel load-aware MoE communication compression technique with two key modules: *Mixed Presicion* and *Random Quantization*, to dynamically balance and reduce all-to-all communication costs at low $O(N)$ time complexity. Additionally, we establish expectation invariance within BirdMoE to ensure the unbiasedness of the compressed intermediate computing results, effectively maintaining MoE training quality.
- We conduct comprehensive evaluations on mainstream MoE training tasks, involving multiple model structures and datasets at different scales. The evaluation demonstrate that compared with the state-of-the-art approaches, BirdMoE can achieve higher 4.06×-10.44× communication compression ratios with 1.18×-5.27× training speedup while maintaining the MoE training quality.

II. Background and Motivation

A. MoE Structure and observed Communication Bottleneck

MoE Structure: MoE is found to have a strong ability in modern large-scale pre-trained models. The key idea of MoE is to constitute numerous small sub-models, namely experts, to a large model, given the intuition that different small models are experts in different domains, and can be only activated when the data in its domain are input. The most common usage of MoE is to extend the MLP layer of the state-of-the-art sequences Transformer [1], [21], [22] by a large number of Feed Forward Network (FFN) (i.e., experts) [7], [11]. For each training iteration, samples are fed into a few experts, dynamically selected by a trainable gate network. because experts are sparsely activated, much computation is saved. Hence MoE can significantly increase the number of samples trained in the same period and improve the model performance compared with conventional dense models [7], [23].

Data Flow: As introduced in Section I, the MoE layer are shared across multiple worker devices (e.g., GPU), while all other non-MoE layers are replicated. To route the data (e.g., *tokens*) among expert nodes, the '*all-to-all*' collective communication is required to perform four times communication between MoE and non-MoE layers per training iteration. Specifically, during the Feed-Forward (FF) propagation, two all-to-all communications are employed to '*dispatch*' and '*combine*' the *feature activation* between source devices of data and target device of desired experts, according to the results of the *gate network*. In the Back-Propagation (BP) propagation, two reverse all-to-all communication are used to transfer the *feature gradient* of corresponding feature activation along the reverse trace. As mentioned before, these intensive and imbalanced communications dominate the overall runtime of MoE training, significantly degrading MoE training efficiency.

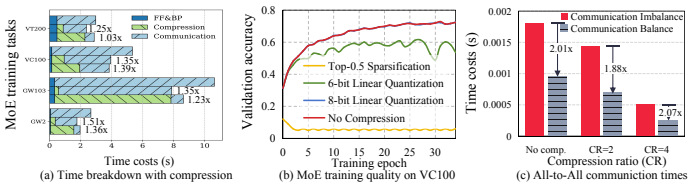

Fig. 2. Challenges of MoE communication compression. (a) Time breakdown of no-compression MoE training (top bar), linear quantization (middle bar), and Top-K sparsification (bottom bar). (b) Popular compression techniques degrade the model training quality to different degrees. (c) Compression with different levels cannot solve the communication imbalance issue.

B. Observed Compression Challenges in MoE

To examine the *Overhead Amplification* and *Error Propagation* issues discussed in Section I, we conduct various MoE training tasks on a distributed cloud-computing platform with 16 GPUs (detailed in Section IV-A). Then we apply two common communication compression techniques in distributed learning: Top-K sparsification and linear quantization, to reduce the communication costs of all-to-all stages during the MoE training.

Overhead Amplification issue: As illustrated in Figure 2 (a), time breakdown bars from up to bottom within a group represent the communication overheads of MoE training with no-compression, 8-bit linear quantization, and Top-0.1 sparsification. Experimental results show that sparsification reduces communication time by $63.5\% - 92.2\%$, but its naive implementation with $O(N \log K)$ complexity [24], [25] incurs significant compression overhead, yielding only a modest $1.03 \times - 1.39\times$ overall training speedup. Although 8-bit linear quantization has low computational overhead, it achieves a limited $4\times$ compression ratio, resulting in limited $1.25 \times - 1.51\times$ overall training speedup.

Error Propagation issue: Figure 2 (b) shows that even setting a high 0.5 sparsity for Top-K sparsification (Top-0.5), the MoE training collapse occurred, resulting in the model failing to converge. On the other hand, while low bit-width linear quantization (e.g., 6-bit) exhibits instability in training and reduced accuracy, sufficiently high bit-width (e.g., 8-bit) can ensure the MoE accuracy comparable to the no-compression counterpart (e.g., yet low compression ratio). This is because excessive compression error in intermediate computing results flow through the network, causing information distortion of feed and backward propagation.

Communication Imbalance issue: Popular expert nodes accept more data requiring longer communication time, thereby forcing other nodes to wait for synchronization and increasing the overall communication time. Figure 2 (c) shows the communication times with and without quantization in balanced and imbalanced expert communication loads. We observe that the ratio of balanced and imbalanced communication runtime remains similar under different compression ratios, indicating that evenly compress to all data does not alleviate the congestion in the imbalanced MoE communication.

C. Motivation of Our Solution

Driven by the above observations, we aim to solve the aforementioned issues by developing a load-aware communication compression technique, BirdMoE, tailored for the imbalanced and intensive all-to-all communication in MoE training based on the following motivations: ① Motivated by the lightweight computational advantages of random process and quantization operation, we introduce a lightweight random quantization algorithm to compress all-to-all communication by mapping the intermediate results to the closer ends of the quantization interval at a larger probability; ② Motivated by the convergence efficiency of unbiased gradient compression techniques in data parallelism context, we establish the expectation invariance within the above random quantization algorithm by maintaining the unbiasedness for the quantized intermediate computing results; ③ Motivation by the compression ratio of quantization is determined by the bit-width, we construct a mixed precision mechanism upon the above random quantization, which effectively improves the communication efficiency of the overall MoE training system by dynamically assigning different quantization bit-widths to the data routed to different expert nodes. The detailed methodology of BirdMoE are detailed in the next Section III.

III. Design and Implementation

A. Overview

In this paper, we propose BirdMoE, a load-aware Bi-random quantization technique for the MoE training with two key modules: *Mixed Precision* and *Random Quantization*.

1) *Mixed Precision (MP):* To balance the communication loads among expert nodes: (i) MP establishes a probabilistic negative correlation between bit-width and quantity of data routed to each expert. (ii) MP randomly assigns specific bit-widths to data routed to various experts according to a constructed probability distribution.
2) *Random Quantization (RQ):* For the intermediate computing results of experts in all-to-all communication: (i) RQ lowers compression overhead by randomly mapping the intermediate computing results to the closer integers at a larger probability. (ii) RQ maintains convergence efficiency of MoE training by building unbiasedness within the quantized intermediate computing results.

The detailed design and implementation of MP and RQ are introduced in the next subsections.

B. Mixed Precision (MP)

To balance the communication load in MoE training, MP assigns various bit-widths for the data routed to different expert nodes. The insight is that the quantization bit-width assigned to the data routed to a particular expert should be negatively proportional to the quantity.

Bit-width Assignment: For any expert node, assuming that a pre-set fixed bit-width is L (as in traditional fixed-precision quantization methods), the data quantity and bit-width routed to i-th node are N_i and L_i, respectively. As illustrated in

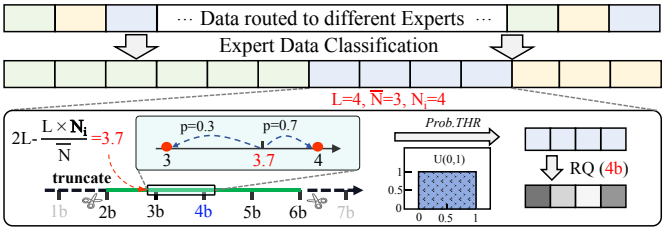

Fig. 3. A general example of Mixed Precision module.

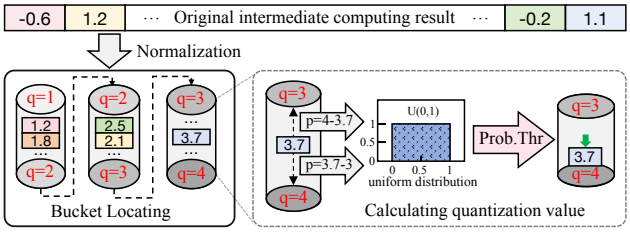

Fig. 4. A general example of Random Quantization module.

Figure 3, we first construct a bit-width intervals by expanding L to a bit-width range with multiple intervals as $\widetilde{L} \in \{1, 2, ..., L, ..., 2L-1\}$, centered at L. After that, MP randomly assigns L_i to the item of $\widetilde{L}$ by the following five steps: ① Calculating a scaler $s = \frac{N_i}{\overline{N}}$ to represent the factor of N_i relative to $\overline{N}$, where $\overline{N}$ is the average data quantity routed to all expert nodes. ② Determining the located bit-width interval $[b, b+1]$ within $\widetilde{L}$ according to s, where $b = 2L - floor(L \times s)$ is the left endpoint of the interval and $b+1$ is the right endpoint. As a result, a negative correlation is built between the data quantity routed to a specific expert node and the corresponding assigned bit-width. ③ Calculating the distance from $2L - L \times s$ to b and $b+1$ as $d_l = (b+1) - (2L - L \times s)$ and $d_{l+1} = (2L - L \times s) - b$, respectively, where $2L - L \times s$ is the location of N_i in the interval $[b, b+1]$. ④ Due to both d_l and d_{l+1} belonging to $[0, 1]$ while summing to 1, we can set the probability of assigning L_i to b and $b+1$ as the d_l and d_{l+1}, respectively. In doing so, L_i will be assigned to the closer endpoint (e.g., b or $b+1$) at a larger probability. ⑤ Assigning L_i to the specific endpoint as the bit-width by comparing the probability with a random number generated from the uniform distribution (i.e., *Probabilistic Thresholding (Prob. THR)* method) at a low computational cost. Notably, it can be derived that the average expectation of bit-width $\mathbb{E}[L_i] = L$ with $\forall N_i \leq 2\overline{N}$. Therefore, although data transferred to different nodes are randomly assigned with different bit-width, the average expectation of bit-width could be maintained at L.

Interval Truncating: In an extremely imbalance situation, data routed to one expert node may be very huge that $\exists N_i > 2\overline{N}$ (e.g., $N_1 = 3, N_2 = 5, N_3 = 1000$), thus the corresponding bit-width will be assigned to 1. While excessively low 1-bit quantization significantly reduces communication costs, it potentially degrades MoE training quality. To balance the communication costs and quantization error, MP bounds the lowest and highest bit-widths by truncating $\widetilde{L}$ as $\{L-\delta, ..., L-1, L, L+1, ..., L+\delta\}$. In doing so, we can flexibly balance communication costs and MoE accuracy while maintaining the average bit-width approximately equal to L. Note that the mixed precision strategy is degraded to the conventional fixed precision quantization if δ is set to 0.

Essentially, the Mixed Precision strategy balances the communication load at the cost of reducing the quantization precision of more data routed to several experts, thus there is a trade-off between δ values and MoE training quality. By evaluating multiple mainstream MoE training tasks, we notice that when δ is set to 2, the all-to-all communication congestion could be effectively eliminated without significantly compromising model training accuracy. After assigning the specific bit-width for the data routed to each expert, BirdMoE utilizes next RQ module to randomly quantize the original floating-point intermediate computing results to integers as follows.

C. Random Quantization (RQ)

As introduced in subsection II-B, lossy compression techniques potentially incur *Overhead Amplification* and *Error Propagation* issues. By exploiting the lightweight advantage of the random process and the convergence efficiency of the expectation invariance, we propose an unbiased Random Quantization (RQ) algorithm to efficiently compress the intermediate computing results of all-to-all communication in MoE layers. As illustrated in Figure 4, the insight of random quantization is to map the floating-point into the closer integer end of the quantization interval with a larger probability.

All-to-all Compression: Given the original floating-point intermediate computing result set $\mathcal{X}$ and the assigned bit-width L, the quantization counterpart of $\mathcal{X}$ is denoted by $\mathcal{Q}$. There is a natural range of quantization level $[1, 2, ..., L]$. A similar methodology as MP is employed to map the i-th elements x_i from $\mathcal{X}$ into $\mathcal{Q}$ as below: ① Calculating the normalized floating points as $f_i = \frac{|x_i|}{||\mathcal{X}||_\infty}$, which is used to reflect the proportion of x_i within the entire range of $\mathcal{X}$; ② Locating the bucket $[l, l+1]$ for x_i according to f_i, where $l = floor(f_i \times L)$ is the left endpoint of the bucket and $l+1$ is the right endpoint. ③ Calculating the distance from f_i to each endpoint as $d_l = f_i \times L - l$ and $d_{l+1} = l + 1 - f_i \times L$, where d_l and d_{l+1} are located in $[0, 1]$ while summing to 1. ④ Establishing a negative correlation between distance and probability by setting the probability of mapping x_i to $l+1$ and l as d_l and d_{l+1}, respectively. In doing so, x_i will be mapped to the closer endpoint (e.g., l or $l+1$) at a larger probability. ⑤ Quantizing x_i to the specific bucket endpoint (e.g., l or $l+1$) as the quantized value q_i using the *Probabilistic Thresholding* method with a low $O(N)$ computational complexity.

Unbiased Recovery: After the above random quantization, the sender node only needs to transfer (*i*) the signed quantized integer q_i, each element of $L+1$-bit; (*ii*) one floating-point factor $||\mathcal{X}||_\infty$, to the target expert node. The receiver node can recover the unbiased and trainable floating-point data with $\mathbb{E}[(\mathcal{Q})] = \mathcal{X}$. The convergence efficiency of similar algorithms has been theoretically proven in gradient compression of data parallelism scenario. Empirically evaluations suggest that RQ

module can effectively mitigate the *Error Propagation* issue in the compression of intermediate computing results using the recommended 3-5 bit-widths, thereby effectively maintaining the MoE training quality (detailed in subsection IV-B).

IV. Experiments

A. Experimental Setup

Tasks, Models, and Datasets: Our experimental workloads cover four typical MoE training tasks, which are trained on various models and datasets at different scales: ② GW2: Training a GPT-based MoE [22] model with 19.2 million parameters on WikiText2 [26] dataset using the Adam optimizer with a learning rate of 1e-2. ③ GW103: Training a larger GPT-based MoE model with 315.1 million parameters on WikiText103 [26] dataset using the Adam optimizer with a learning rate of 1e-2. ④ VC100: Training a ViT-based MoE model [23] with 19.0 million parameters on CIFAR100 [27] dataset using the Adam [28] optimizer with a learning rate of 1e-3. ⑤ VT200: Training a larger ViT-based MoE model with 181.3 million parameters on Tiny ImageNet [29] dataset using the Adam optimizer with a learning rate of 1e-3.

Baseline and compared methods: To demonstrate the superiority of our proposed BirdMoE, we select three popular state-of-the-art quantization-based communication compression techniques: QSGD [14], PWLQ [30], and ShapeShifter [31] to compare the MoE training quality, compression ratio, compression throughput, and training speedup across the above four MoE training tasks. Additionally, we also provide the performance of the original no-compression baseline to refer.

Experimental environment: We implement the MoE training environment upon a distributed cloud-computing platform with 16 GPUs within 4 nodes, and these nodes are connected by a limited 10 Gbps inter-node Ethernet. Within each node, 4 NVIDIA Tesla V100-SXM2-16GB GPUs are connected by a 400 Gbps intra-node NVLink. The compression operations of different methods are implemented using the `Pytorch v.2.2.1` [32] package in Python 3.8.13. The all-to-all communication is built on the collective communication of `torch.distributed` [32] package, utilizing the `NCCL v.2.19.3` backend.

B. Evaluation of MoE Training Quality

The most important premise in communication compression is to ensure that the model training quality remains unaffected significantly. Thus we first explore the superiority of BirdMoE in maintaining MoE training quality (i.e., model accuracy and convergence rate). To study the impact of our proposed mixed precision module on model training quality, we provide the evaluation results of BirdMoE with mixed and fixed precision (referred to as $\text{BirdMoE}_{\text{MP}}$ and $\text{BirdMoE}_{\text{FP}}$). For the sake of fairness, we first compare BirdMoE with the state-of-the-art quantization-based compression approaches QSGD, PWLQ, and ShapeShifter under the same bit-width as BirdMoE.

Figure 5 shows that when we assign different compression methods to the same bit-width, BirdMoE with fixed precision (i.e., $\text{BirdMoE}_{\text{FP}}$) achieves the best MoE training quality, which has a similar performance to the original no-compression MoE training solution. Specifically, ShapeShifter combines a global linear quantization with a lossless encoding to compress the flatten intermediate computing results without considering the distribution difference among data dimension, thereby failing to maintain the convergence stability of MoE training and degrading the model accuracy in GW103 and VT200 tasks. Although QSGD can compress gradients while maintaining the convergence efficiency in the data parallelism by preserving the expectation invariance of L_2-norm, the same measurement is ineffective for quantizing the intermediate results compression, thus causing a significant MoE training divergence. PWLQ employs a piece-wise quantization strategy to reduce the information distortion of intermediate computing results, effectively maintaining the MoE model training quality in GW2 and VC100 tasks. However, PWLQ cannot achieve a stable convergency in the other tasks with the larger model capacity due to its disregard for the distribution differences in data routed to different MoE layer. In contrast, BirdMoE with a Mixed Precision strategy (i.e., $\text{BirdMoE}_{\text{MP}}$) reduces the quantization precision of more data, slightly degrading model accuracy of $\text{BirdMoE}_{\text{FP}}$, while its craft unbiasedness enables it to achieve comparable and stable MoE training quality with further improving all-to-all communication efficiency.

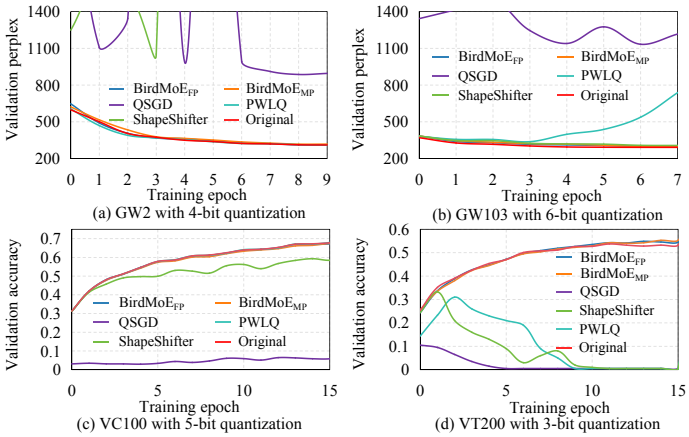

Fig. 5. $\text{BirdMoE}_{\text{FP}}$ and $\text{BirdMoE}_{\text{MP}}$ achieve better MoE training quality than other methods under the same bit-width.

C. Evaluation of Compression Ratio

Figure 6 (a) shows the communication compression ratio of different methods, calculated by the original communication costs of the no-compression solution divided by the compressed communication costs of each method under their **best practice**. Note that the best practice refers to the maximum compression ratio a particular method can achieve while maintaining the similar original MoE accuracy, given the same number of MoE communication rounds as the no-compression solution. Evaluation results indicate that $\text{BirdMoE}_{\text{FP}}$ achieves 5.3×-7.4× compression ratios in vision tasks, outperforming competing methods, while PWLQ and ShapeShifter have a comparable 2.2×-7.2× compression ratio in language tasks. This is because the compressibility of intermediate computing

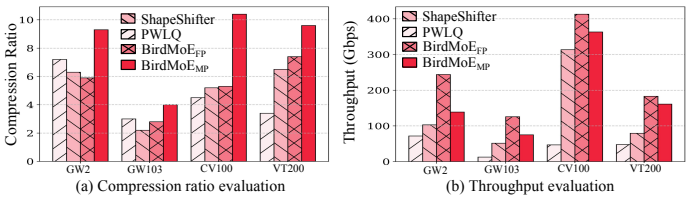

Fig. 6. The evaluation of communication compression ratio and compression throughput (Gbps) across various tasks.

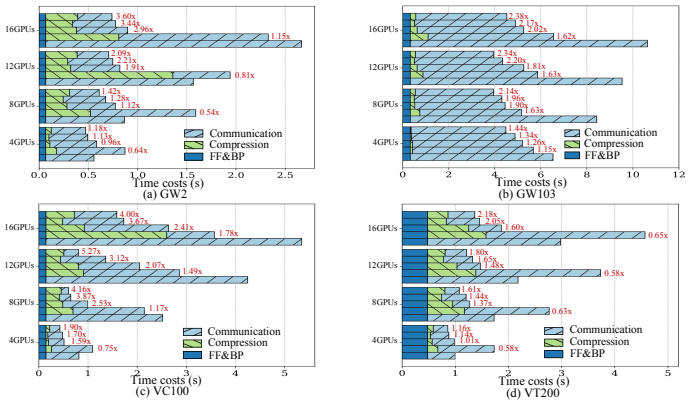

Fig. 7. The average time breakdowns per iteration on 4, 8, 12, and 16 GPU nodes. Bars from top to bottom are time breakdowns of BirdMoE$_{MP}$, BirdMoE$_{FP}$, ShaperShfter, PWLQ, and no-compression.

results differs among the various model structures, leading to different compression performances across tasks. In contrast, BirdMoE$_{MP}$ achieves superior 4.1×-10.4× compression ratios across all tasks by further reducing the bit-width of intermediate computing results with large quantities, thereby significantly increasing the overall compression ratio.

D. Evaluation of Throughput

Figure 6 (b) illustrates the compression throughput of different techniques, which is defined as $tp = \frac{CS}{CT}$, where CS is the amount of reduced data volume by compression, CT is the compression runtime. Compression throughput can effectively reflect the overall performance of an approach by comprehensively considering the compression overheads and gains. Experimental results suggest that although PWLQ and Shapeshifter can achieve a slightly higher compression ratio in partial tasks, their piece-wise calculation and lossless coding incur significant computational overheads, thereby limiting their compression throughput to 12.6-313.5 Gbps. In contrast, BirdMoE$_{FP}$ achieves the highest 125.7-612.8 Gbps compression throughput by employing lightweight random quantization to efficiently achieve a comparable compression ratio. On the other hand, BirdMoE$_{MP}$ utilizes MP module to further reduce the communication costs with an acceptable extra computational cost, achieving the second-best compression 75.1-363.2 Gbps compression throughput.

E. Scalability and Time Breakdown Evaluation

The essential purpose of communication compression is to speed up MoE training at different scales of nodes, thus we further deploy BirdMoE upon the MoE training environment containing various numbers of 4, 8, 12, and 16 GPU nodes. Then we validate our scalability superiority by comparing the average time breakdown and MoE training speedup performance with different compression methods.

Figure 7 illustrates the average time breakdown per iteration of the runtimes of forward and backward propagation (FF&BP), communication, and compression. The red values are acceleration rate (the runtime of the original no-compression MoE training divided by the runtime of MoE training with compression). Experimental results suggest that (*i*) the moderate communication compression ratio and significant compression overheads of PWLQ and Shapeshifter limit their training speedup performance and even prolong the training time to several tasks. Additionally, their inability to address the imbalanced communication load also limits the training speedup performance. (*ii*) BirdMoE$_{FP}$ achieves comparable compression ratio on different tasks at low computational costs, obtaining higher MoE training speedup of 1.13×-3.67×. (*iii*) BirdMoE$_{MP}$ further reduces the communication time by balancing the communication traffic among GPUs, obtaining the highest 1.18×-5.27× MoE training speedup. (*iv*) BirdMoE's training speedup performance improves with the increase of nodes. That is because increasing the number of nodes will increase the compressed communication volume without increasing the compression overhead due to the BirdMoE is deployed on different nodes and executed in parallel. Generally, the above results demonstrate that BirdMoE efficiently reduces communication costs and improves the efficiency of MoE training with different numbers of nodes. Therefore, the good scalability of BirdMoE not only advances research on MoE for resource-constrained platforms but also scales effectively to large-scale MoE training environments.

V. Conclusion and Future Work

In this paper, we propose a lightweight load-aware communication compression technique BirdMoE, which utilizes random quantization and mixed precision to compress the imbalanced and intensive communication of MoE training. Compared with the state-of-the-art approaches, experiments on mainstream MoE training tasks demonstrate that BirdMoE achieves higher 4.06×-10.44× communication compression ratio and 1.18×-5.27× training speedup while maintaining the MoE training quality. In the future, we aim to optimize the efficiency of BirdMoE with the CUDA and implement it into the all-to-all collaborative communication library.

***Abstract*—Modern GPUs typically segment Streaming Multiprocessors (SMs) into sub-cores (e.g. 4 sub-cores) to reduce power consumption and chip area. However, this partitioned design prevents potential task distributions across sub-cores, impairing overall execution efficiency. In this paper, we explore the performance benefit of sharing hardware resources among sub-cores and identify functional units (FUs) as critical components for compute-intensive applications. Moreover, our observations reveal that instructions residing in operand collectors can be obstructed by back-end FUs, but there is a high probability that unoccupied FUs are available in adjacent sub-cores during such blockages.**

In response, we introduce the adjacent computation resource sharing (ACRS) framework to efficiently utilize these unoccupied units among sub-cores. ACRS has two key modules: Shared FU Issue (SF_ISSUE) and Shared FU Write Back (SF_WriteBack). SF_ISSUE monitors the status of operand collectors and functional units, and offloads instructions from blocked sub-cores to unoccupied resources. Meanwhile, SF_WriteBack routes results back to the original sub-core.To minimize wiring overhead, each sub-core is assigned a fixed target core for sharing. We design a series of matching policies and finally filter out the most effective sequential method. Evaluation results show that ACRS improves performance by up to 46.4%, with an average of 14.1% over the traditional partitioned architecture, while reducing energy consumption by 8.3%. Besides, ACRS achieves an additional 12.3% performance improvement compared with the SOTA method.

I. Introduction

Modern GPUs have grown in complexity to meet the expansion of high-concurrency applications such as artificial intelligence and high-performance computing. To address the increases in power consumption and die size, GPU architectures now typically divide the main processing unit into homogeneous sub-cores [2]–[10], each equipped with its own control logic and computation resources.

However, partitioned architecture can significantly affect execution efficiency at runtime. Barnes et al. [11] revealed that partitioned architectures in streaming multiprocessors (SMs) cause performance drops when computing tasks are distributed among sub-cores with unbalanced workloads, as well as the increased opportunity of register bank conflicts. Our preliminary study further shows that there exists a large optimization space when integrating functional units (FUs), with an ideal improvement of 28.1%. Based on these works, we aim to explore a practical FU sharing strategy among sub-cores.

According to our observations, it is greatly effective to share FUs during the blockage of operand collectors (OCs). First, OCs often block the pipeline when functional units are unavailable. This is especially true for FUs with limited execution lanes and high occupancy rates. Second, there is a high probability of finding unoccupied FUs in neighboring sub-cores during these blockages. Our analysis shows that in 68.4% of blockage cases, at least one sub-core in the same SM has available FUs of the same type, indicating a significant potential for resource sharing.

However, the resource-sharing approach encounters challenges, particularly with global sharing within an SM. The challenge arises because resource isolation aims to reduce area and energy consumption. Introducing a crossbar-like network for data exchange among the sub-cores could lead to high overhead. Furthermore, integrating additional write-back paths into the register files requires a significant revision of the write-back logic. This integration could increase pipeline blockages, as data from multiple sub-cores would compete for the same write port. Additionally, adding more write ports would further complicate the issue by expanding the register files' size.

To address these challenges, we present adjacent computation resource sharing **(ACRS)** framework to enhance the utilization of separated functional units and effectively accelerate program execution. This design comprises two hardware components and one pairing strategy: an **SF_ISSUE** module to reroute blocked OC instructions to unoccupied FUs; an **SF_WriteBack** module at the FU exit that returns results to the correct register files via the sub-core identifier; and a **Matching Policy** to determine the sharing target sub-core. Specifically, to simplify control and transmission logic, we have shifted from a global sharing model to a more efficient one-to-one sub-core sharing scheme, significantly reducing the crossbar overhead. Moreover, we have implemented a four-entry write buffer at the register file's entrance to temporarily store write data from other sub-cores, thus avoiding the need for extra write ports and mitigating direct pipeline blockages.

The contributions of this paper include,

*Corresponding author.

- A performance analysis of the impact of sharing different resource types and demonstrate that integrating functional units provides the greatest performance boost.
- An ACRS framework that enables adjacent sub-cores to share unoccupied FUs, allocating available resources to busy operand collectors, thus improving load balancing.
- A comprehensive evaluation, which achieves performance improvement of up to 46. 4%, with an average of 14.1% over the traditional partitioned architectures, while reducing energy consumption by 8.3%.

II. Background

A. Partitioned Architecture of the SM

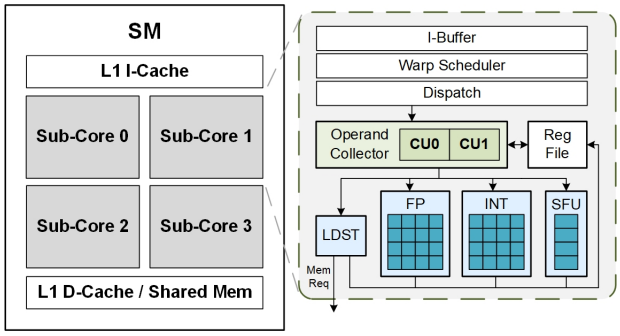

Fig. 1: Baseline SM architecture.

In contemporary GPU architectures, a hierarchical and homogeneous design paradigm is commonly adopted to streamline scheduling and control logic. The design principle is evident at the foundational hardware level, where each basic hardware unit is uniformly divided into four identical segments. For instance, NVIDIA divides a single Streaming Multiprocessor into four sub-cores [2]–[6], while AMD structures each Compute Unit with four SIMD units [7]–[10]. As illustrated in Figure 1, each quadrant of a divided SM possesses its own control and computation resources yet shares a unified L1 data cache and shared memory. Threads are organized into warps that operate synchronously. Once dispatched to a specific sub-core, a warp becomes one of several candidates, with its instructions stored in the I-buffer (instruction buffer) after the fetch and decode stages. Subsequently, an internal warp scheduler orchestrates the distribution of instructions to the operand collector, where they await the retrieval of operands from the register file. Upon readiness of the operands, the instruction is transmitted to either the functional units or the load/store units for further execution.

B. Blocking issues in FUs and OCs

Within each sub-core, multiple functional units process different data types and tasks, including floating point units (FP) for single-precision data, integer units (INT) for integer operations, and special function units (SFU) for complex functions like trigonometry. However, due to hardware limits, a sub-core often cannot process an entire warp simultaneously. For example, each sub-core in the RTX 2060 features 16 FPs and 4 SFUs, yet a warp consists of 32 threads [3]. Consequently, FP instructions require 2 consecutive cycles to be issued to the function units, while SFU instructions take at least 8 cycles.

TABLE I: Baseline simulation parameters.

SM Config	34 SMs, 1600 MHz
Per SM	4 sub-cores, Round-Robin sub-core scheduling
Per sub-core	8 warps, 2 CUs, Greedy-Then-Oldest warp scheduling, 64KB register files, 16 INTs, 16 FPs, 4 SFUs
Cache	128KB L1 I-Cache, 64KB L1 D-Cache/shared memory, 64KB Constant Cache, 4MB L2 Cache

TABLE II: Evaluated applications. The labels **C** and **M** in the Type column stand for compute-intensive and memory-intensive cases, respectively.

Suite	Abbr.	Type	Name
Rodinia [13]	LMD	C	Lava Molecular Dynamics
	KMS	M	K-means Clustering
Dragon-li [1]	JON	C	Dynamic Parallelism Join
Ispass [27]	RAY	C	Ray Tracing
Proxy [15], [16], [28]	XSB	C	XSBench
	RSB	C	RSBench
	LLS	M	Livermore Unstructured Lagrangian Explicit Shock Hydrodynamics
Parboil [14]	SPM	M	Sparse-Matrix Dense-Vector Product

This behavior, where a single instruction occupies multiple pipeline stages, can ultimately cause instruction blocking.

The core structure of the sub-core data flow is the operand collector [17], [18], shared by all functional units. The operand collector has multiple collector units (CUs) assigned by the dispatch logic. These units temporarily store instructions fetching operands and are designed to mitigate register file bank conflicts by processing multiple warp instructions concurrently. However, execution around the OCs can stall due to various issues. If no CU is available, the dispatch phase stalls. Additionally, if an instruction occupies multiple execution pipeline stages, especially SFU instructions, subsequent instructions requiring the same unit may stall at the OC exit, delaying execution and reducing efficiency.

III. Experimental Environment

We employ GPGPU-Sim 4.2.0 [12] to simulate a Turing-like architecture, modified from the RTX2060-S configuration provided. Table I presents the baseline parameters. We utilize four sub-cores per SM, mirroring the common 4-core architecture of mainstream GPUs. The methods described in this paper are applicable to architectures with more sub-cores. Additionally, we incorporate two collector units in each sub-core, as this configuration most accurately reflects the actual architecture [11]. This base architecture adeptly models the subdivision of a single SM into sub-cores, facilitating a detailed analysis of the enhancements proposed in this study. Table II presents the representative compute-intensive and memory-intensive applications we select from multiple benchmark suites, including Rodnia [13], Dragon-li [1], Ispass [27], Proxy-apps-doe [15], [16], [28], and Parboil [14]. The selection is based on the applications' characteristics and insights from prior works [21], [29],

trying to ensure a balanced representation of both categories. Previous research [19] indicates that the experimental results tend to converge after approximately 2 billion instructions are executed. We use the largest input sizes for each application and aim to execute each application either until completion or for a maximum of 4 billion instructions.

IV. Analysis

A. Impact of Multiple Partitioned Resources

Each sub-core exclusively possesses four key types of resources in the partitioned architecture: warp scheduler, register files, operand collector, and functional units. Unlike fully connected architectures, these monopolized resources are inaccessible to other sub-cores, even when they are underutilized or left idle. To evaluate the performance impact of individual resources, we share each type of resource within the SM modified from a partitioned structure and then measure the improvements in instructions per cycle (IPC) using the geometric mean, as shown in Figure 2. The following observations are made:

Observation 1: Among the four shared resources, the sharing of functional units and operand collectors both significantly boost performance, with functional units showing the most notable benefit in compute-intensive cases, resulting in an average IPC improvement of 28.1%.

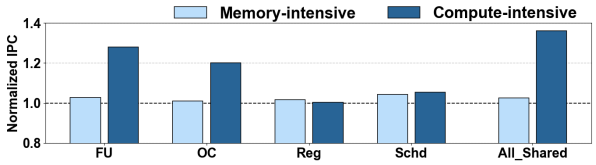

Fig. 2: IPC improvement from shared resources among sub-cores: warp schedulers(Schd), register files(Reg), operand collectors(OC), functional units(FU), and fully connected cores (All_Shared). The results are normalized to the 4-core baseline.

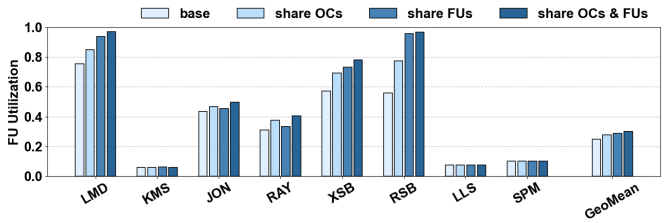

Fig. 3: Comparison of FU utilization for shared structures: shared operand collectors, shared functional units, and their combination, against the 4-core baseline.

Due to the close relationship between operand collectors and functional units, we further investigate whether sharing these two components offers similar benefits. We simultaneously share both operand collectors and functional units, demonstrating their impact on FU utilization as illustrated in Figure 3. FU utilization is defined as the proportion of cycles in which FU is active out of the total number of running cycles. From this figure, we make two main observations:

Observation 2: In memory-intensive cases (KMS, LLS, SPM), FU utilization remains below 20%, and sharing OCs and FUs offers virtually no benefit. This inefficiency stems from the substantial cache misses in these scenarios, which cause prolonged memory access delays and greatly impede the processing of subsequent instructions.

Observation 3: Simultaneously sharing OCs and FUs does not show a significant difference compared to integrating them separately. However, sharing FUs still outperforms sharing OCs. This is especially true in the cases of LMD, XSB, and RSB, where utilization is the highest among all applications.

Insights: The integration of functional units and operand collectors both significantly influences execution efficiency. Compared to sharing both, focusing solely on FUs achieves a similar impact. Additionally, it avoids the extra overhead associated with sharing OCs.

B. The Sharing Opportunity of Blocking Events

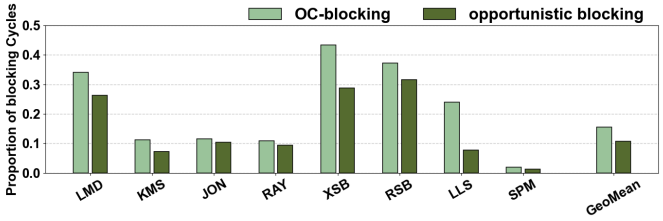

Fig. 4: The proportion of cycles for OC-blocking and opportunistic blocking relative to the total execution cycles.

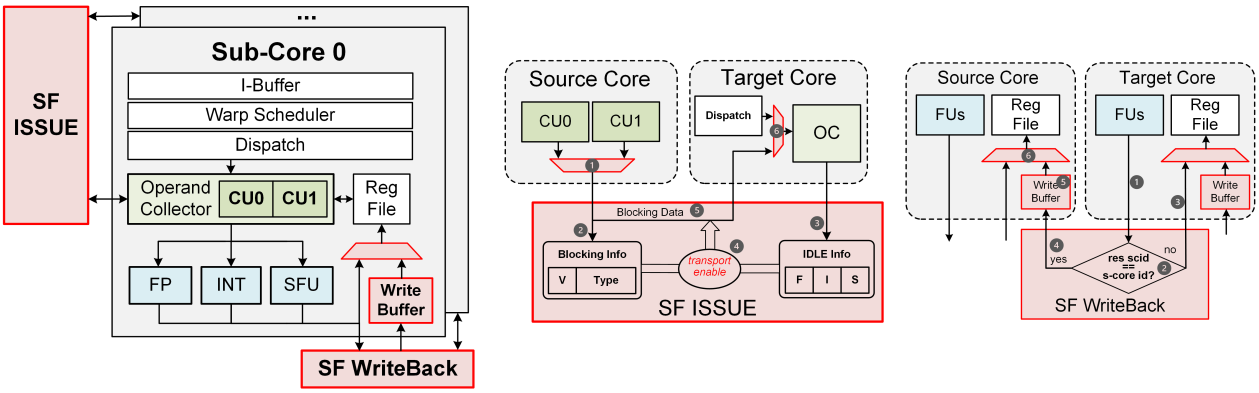

Pipeline blocking, as described in Section II-B, poses a significant issue in the partitioned architecture. We refer to situations where at least one CU in the OC is blocked as *OC-blocking*. OC-blocking not only diminishes the execution efficiency of the current instruction but also consumes OC resources, potentially hindering the dispatch of subsequent instructions and posing a broader threat to system performance. Figure 4 classifies OC-blocking into two categories: opportunistic and non-opportunistic, and provides statistics on their duration throughout the execution process. *Opportunistic blocking* refers to situations where other sub-cores have similar-type functional units available when the current sub-core experiences OC-blocking. To further understand the sharing potential during OC-blocking, we calculate the conditional probability of opportunistic blocking based on the following equation:

$$P(\text{opportunistic} \mid \text{OC-blocking}) = \frac{F(\text{opportunistic})}{F(\text{OC-blocking})} \quad (1)$$

where $F(*)$ represents the proportion of cycles observed in the total number of execution cycles. We make two key observations from the figure:

Observation 4: OC-blocking is quite prevalent, especially in compute-intensive cases. On average, the execution flow in the programs tested is disrupted by OC-blocking 15.5% of the time, with some tests (LMD, XSB, RSB) experiencing rates as high as approximately 40%.

Observation 5: In all applications tested, the average conditional probability of opportunistic blocking is 68.4%, reaching a peak of 90.5% in the RSB case. This suggests a high probability of reducing the frequency of OC-blocking by utilizing unoccupied units from other sub-cores.

(a) Overall structure (b) SF_ISSUE module (c) SF_WriteBack module

Fig. 5: The proposed ACRS framework.

Insights: OC-blocking is a common issue that impacts execution efficiency. However, there is substantial potential to mitigate these blockages by sharing computation resources. Specifically, if a sub-core can identify and utilize unoccupied execution units from other cores during OC-blocking episodes, overall performance can be greatly enhanced.

V. Design

A. ACRS Architecture

We propose the implementation of ACRS (adjacent computation resource sharing), which is designed to share computation resources among specific sub-core combinations within the SM, alleviating pipeline blocking and enhancing execution efficiency. Figure 5(a) illustrates the overall framework of ACRS where the red parts indicate modifications from the baseline architecture. To facilitate resource sharing, multiple additional data flows are introduced among the four sub-cores. The structure is divided into two main components: SF_ISSUE (Shared-FU Issue) and SF_WriteBack (Shared-FU Write Back), which respectively handle cross-sub-core data exchange before and after task execution. Additionally, a small write buffer is added at the write entrance to the register files to temporarily store results from other sub-cores.

Considering routing overhead, not all resources are made accessible to each core. For a specific sub-core, known as the Source Core (S-Core), when a blocking instruction that can be shared is encountered, the designated Target Core (T-Core) evaluates its ability to accept and process this instruction. The sharing relationship is fixed as one-to-one among the four cores to prevent the formation of an expensive crossbar. We explore various matching policies between S-Cores and T-Cores, which clearly affect the ultimate effectiveness of sharing.

SF_ISSUE. Figure 5(b) depicts the issue logic for a set of S-Core and T-Core. When S-Core experiences OC-blocking, a blocking instruction is first selected from two CUs using the loose round-robin strategy (❶), and its details are then sent to the SF_ISSUE module for arbitration. The transferred information consists of two components: the Blocking Info (❷) and the Blocking Data (❺). Specifically, the Blocking Info identifies the type and validity of each instruction. Instruction types are classified into F(FP), I(INT), and S(SFU) based on the back-end functional units. At the T-Core side, the operand collector consistently monitors the idle status of functional units and sends the information to the SF_ISSUE module. The IDLE Info (❸) consists of 3 bits corresponding to the three different function units. When no CU is idle, all three bits are 0. If there is an idle CU and the corresponding FU is also available, the respective bit is set to 1. Thus, the high status of IDLE Info bits indicates that the corresponding type of instruction can be promptly sent to the T-Core without further delay.

Once in possession of the Blocking Info from the S-Core and the IDLE Info from the T-Core, SF_ISSUE is able to employ comparison logic (❹) to determine their compatibility. The comparison leverages the type from the Blocking Info to examine the three bits of the IDLE Info. If the corresponding bit is set to 1 and the instruction is valid, the Blocking Data will be issued to the T-Core for execution. Data from the S-Core is given higher priority (❻) over data dispatched inside the T-Core and is directly accepted by the operand collector. The design rationale is that the transport enable signal is set high only when the execution flow of the S-Core is busy, while the execution flow of the T-Core is comparatively idle, allowing the T-Core to defer processing its own requests.

SF_WriteBack. When the S-Core instruction completes execution in the T-Core, the computation outputs need to be sent back via SF_WriteBack. As illustrated in Figure 5(c), the results (❶) from the functional units are directly forwarded to SF_WriteBack. The returned data includes the core ID, which identifies the type of the issuing core. If SF_WriteBack determines the T-Core as the issuing core (❸), it confirms local execution and allows direct write-back. Conversely, if the issuing core is the S-Core (❹), the results must be routed to the corresponding S-Core. By accurately routing the computation data, the integrity of the SF results is maintained.

The design augments the register write path with a route enabling data return from other cores. To avoid the substantial overhead associated with adding additional ports to the register file, SF_WriteBack incorporates a small WriteBuffer at the entrance to the register file (❺) to temporarily store computation results from other cores. The local write-back path and the WriteBuffer share a common write port. During arbitration (❻), the data with the earliest dispatch time is selected for

return to the register file. According to our experiments, a write buffer with a capacity of four entries is sufficient for collecting externally returned data.

Hardware Overheads. Compared to a crossbar used for global sharing, the structure proposed in this paper achieves a significant reduction in layout and routing overhead. The area complexity of a crossbar scales as $O((pw)^2)$ [42], while its scheduler incurs an additional overhead of $O(p^4)$ [43], where p denotes the number of ports and w represents the width of each port. By employing a fixed matching policy, the proposed approach reduces the overhead to $O(pw)$, effectively avoiding the exponential growth in area complexity. Apart from the wiring logic, the primary hardware overhead is the write buffer at the register file interface. Each buffer consists of four entries, with each entry capable of storing a 32-bit result for one warp, totaling 128 bytes. For 64-bit operations, each instruction occupies two buffer entries Consequently, the total size of the write buffer for each sub-core is 512 bytes, which is negligible compared to the 64KB register files.

B. Matching Policies

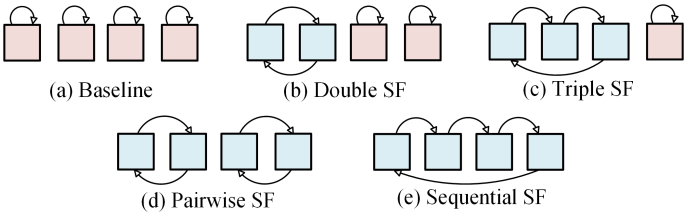

Fig. 6: Matching policies among four sub-cores. Each connection line represents a sharing relationship (from S-Core to T-Core). Blue squares are sub-cores participating in sharing, while red squares are not. We focus on the latter four policies.

Based on the structure proposed in section V-A, each sub-core is required to serve as both an S-Core and a T-Core. With four sub-cores in the SM, four sets of S-Cores and T-Cores are needed. Treating all four sub-cores as identical, we enumerate all possible matching policies for the shared functional units (SF) architecture based on topological principles, as illustrated in Figure 6. In the diagram, each square symbolizes a sub-core, and the connecting lines demonstrate the pairings from S-Cores to T-Cores. Figure 6(a) illustrates the baseline scenario with no sharing, where each core serves as its own S-Core and T-Core. Figure 6(b) shows the *Double SF* configuration, in which two cores share mutually, each acting as the T-Core for the other, while the other two cores remain unshared. Figure 6(c) depicts *Triple SF*, which divides the sub-cores into groups of three and one, with the trio employing a sequential sharing method and the single remaining core not participating in sharing. Figure 6(d), illustrating *Pairwise SF*, divides the four sub-cores into two pairs, with each pair of sub-cores serving reciprocally as T-Cores. Finally, as shown in Figure 6(e), *Sequential SF* policy organizes the sub-cores into a ring, where each subsequent sub-core serves as the T-Core for the previous one.

Notably, we treat all four cores as equivalent, therefore the division of match groups depends only on the number of cores, not on specific cores. For instance, given core IDs from 0 to 3 with parentheses indicating the division into sharing groups, the matching policy for the group (0 1) and (2 3) is considered the same as for the group (0 2) and (1 3), both classified as Pairwise SF. Consequently, the above four matching policies primarily differ in their scope of sharing. Within each group, cores are sequentially assigned a unique T-Core. Compared to the FU sharing method discussed in Section IV-A, referred to as *Ideal SF*, these one-to-one and fixed sharing relationships significantly reduce hardware layout and routing pressure.

VI. Evaluation

In this section, we evaluate the proposed optimization methods using benchmarks from Table II and simulator configurations from Table I as our baseline.

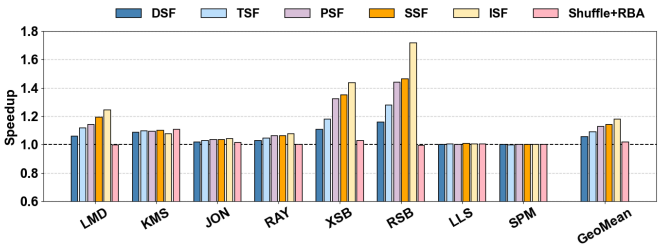

Fig. 7: IPC improvement over the baseline of Shuffle+RBA (SOTA) and our ACRS method with four candidate matching policies: DSF (Double SF), TSF (Triple SF), PSF (Pairwise SF), and SSF (Sequential SF), and the ideal scenario: ISF (Ideal SF).

Performance. Figure 7 illustrates the IPC improvement across all applications under the matching policies described in Section V-B. First, all four matching policies exhibit noticeable improvements in IPC, with larger scopes of sharing resulting in greater enhancements. The sequential matching policy (SSF) shows the largest increase, achieving an average IPC improvement of 14.1%, closely approaching the results of the ISF policy. Second, when all four sub-cores participate in sharing, significant performance improvements are observed across all sharing strategies, with minimal differences among them. The PSF strategy, for instance, achieves an average speedup only 1.3% lower than the best-performing SSF strategy. Third, compute-intensive applications benefit markedly from the shared structure, with the SSF strategy exhibiting up to 46.4% and an average improvement of 19.1%. As for memory-intensive applications, although the enhancements are modest, there are no adverse effects.

Compared with the Shuffle sub-core scheduler and RBA warp scheduler [11] that has a modest 1.8% average performance improvement, our ACRS with SSF matching policy achieves an additional 12.3% improvement, which demonstrates the effectiveness of our approach. The main reason lies in that Shuffle+RBA only focuses on front-end optimization, leaving OC-to-FU stalls unaddressed. The Shuffle scheduler mitigates inter-warp divergence by employing randomized sub-core scheduling patterns, while the RBA scheduler reduces register bank conflicts by sharing queue information of register file banks with the warp scheduler. However, both strategies are unable to resolve the FU separation challenges. In contrast, the ACRS architecture alleviates OC-blocking through FU sharing,

significantly improving pipeline efficiency by addressing back-end bottlenecks.

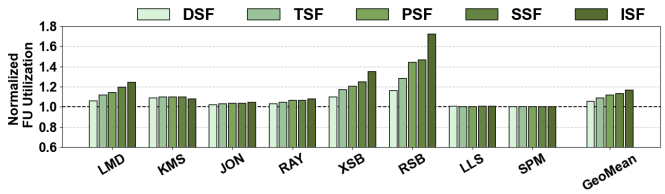

Fig. 8: FU utilization normalized to the baseline.

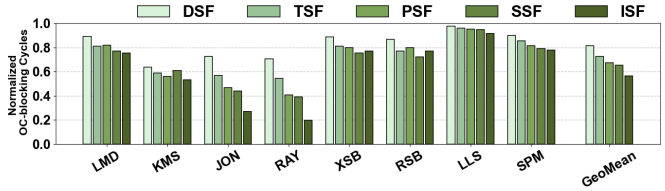

Fig. 9: OC-blocking cycles normalized to the baseline.

We further explore the root causes for the performance improvement and confirm it mainly comes from increased FU utilization and reduction of OC-blocking. Comparing Figure 7, 8, and 9 together, tests showing notable performance increases also exhibit a significant rise in FU utilization and a marked decrease in OC-blocking time. For instance, in the most effective RSB case, the SSF strategy increases FU utilization by 46.5% and reduces the OC-blocking cycles by 27.7%. This observation consistently holds for the top three effective compute-intensive cases (LMD, XSB, RSN). Interestingly, in cases like JON and RAY, although there is a notable reduction in OC-blocking time, the performance improvements are not substantial. This is because OC-blocking is relatively infrequent in these tests and does not represent a bottleneck in the compute pipeline. Therefore, reducing the frequency of OC-blocking has minimal impact on performance in these cases. As for memory-intensive cases (LLS, SPM), their performance is limited by long-latency memory accesses, with memory stalls dominating execution. Consequently, FU utilization remains largely unchanged, and while OC-blocking may be alleviated to some extent, it does not substantially affect overall efficiency due to its minor role in these cases.

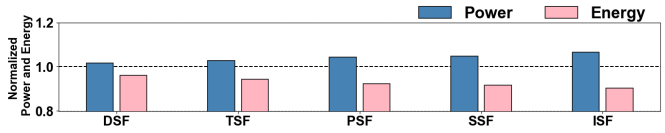

Fig. 10: Normalized power and energy consumption of different matching policies compared with partitioned baseline.

Power. We conduct a power consumption analysis using the AccelWattch platform [20]. The results are normalized and depicted in Figure 10. Compared to the partitioned baseline, all matching policies exhibit an increase in power consumption because they complete the same workload in a shorter period. However, higher power consumption does not necessarily lead to a rise in heat generation. The acceleration of program execution reduces circuit operating time, which in turn decreases static energy consumption and heat produced by control logic circuits. Notably, under the highly effective SSF strategy, while power consumption increases by 4.7%, energy consumption experiences a more significant reduction, decreasing by 8.3%.

VII. Related Work

Resource Sharing. Various internal GPU sharing strategies at different granularities have been proposed to enhance resource utilization and improve overall performance. [21], [22] focused on optimizing the memory subsystem by enabling the private L1D cache of one SM to be accessible by other SMs. This approach not only reduced data redundancy but also significantly increased memory access efficiency, addressing the bottlenecks commonly associated with memory-bound workloads. [23] introduced BigSM, which meets the computational demands of different kernel types by sharing all resources among adjacent SMs, demonstrating the potential of resource pooling in achieving greater flexibility and scalability in GPU. Tao Zhang et al. [25] shared the pipeline front-end across different SMs, effectively reducing power consumption. Other research [24] targeted sharing at the warp level within an SM by employing a combination of hardware and software techniques to enable register file sharing.

FU Utilization. In addition to sharing methods, previous research has explored different approaches to improve the FU utilization in GPUs. [30]–[34] concentrated on mitigating the impact of branch divergence. By increasing the number of active threads per warp, these approaches effectively reduced the number of idle compute units, ensuring a more balanced workload distribution and enhancing overall throughput in branch-heavy applications. [35]–[37] proposed modifications to warp scheduling strategies aimed at maximizing thread-level parallelism. By carefully prioritizing warps, their method ensured a steadier supply of instructions to the FUs. Meanwhile, [38]–[41] introduced out-of-order execution structures into the SM, utilizing instruction-level parallelism to further reduce pipeline stalls before the execution stage.

Compared to prior works, our approach is the first to explore sharing at the granularity of different SM sub-cores and to primarily focus on functional units as the central sharing objects. Additionally, our approach can complement previous sharing strategies, further improving overall utilization.

VIII. Conclusion

In partitioned SM architectures, the separation of sub-core resources can significantly impact execution efficiency. This paper quantifies the performance impact of resource integration, identifying functional units as critical in compute-intensive applications. To address this issue, we propose ACRS, an architecture enabling functional unit sharing between adjacent sub-cores when operand collectors are blocked. We also introduce several sub-core matching policies, with experimental results showing that the sequential policy yields the greatest performance gains.

***Abstract*—This paper introduces HoBBy, a compiler-based tool that hardens unbalanced branches at the instruction level, making parallel control flows indistinguishable to state-of-the-art attacks that bypass the source-code level balancing. To achieve this, we propose a single-step analysis method to identify unbalanced instructions in secret-dependent branches, and implement instruction shadowing, cogging, and spiraling techniques to protect them. We evaluate HoBBy by hardening secret-dependent branches in four real-world applications, validating its resilience against three state-of-the-art attacks targeting Intel SGX and AMD SEV. HoBBy achieves a runtime overhead of 2.8% for cryptographic libraries and a binary size overhead of 0.6%.**

I. INTRODUCTION

Modern CPUs incorporate Trusted Execution Environments (TEEs), such as Intel Software Guard Extensions (SGX) [16] and AMD Secure Encrypted Virtualization (SEV) [3], to safeguard the instructions and data of applications, preventing data leakage from malicious programs, including the operating system. However, TEE designers do not comprehensively address side-channel threats [27], which has led to various control flow attacks [5], [9], [26] that expose control flow information, such as the target of a secret-dependent branch, posing significant risks to applications like cryptographic libraries used for RSA [23], [39] and ECDSA [22] algorithms.

To defend against these attacks, researchers propose constant-time programming, which maintains constant execution time regardless of the specific data being processed. Two primary methods are available for implementing constant-time programming. The first approach is to avoid making control flow directly dependent on secrets [7], [15], thereby preventing control-flow attacks by eliminating associations between sensitive data and control flow. However, this technique is often limited to specific cryptographic algorithms [9] and may introduce significant performance overhead [7], [26]. The second method is branch balancing, also known as code obfuscation [1], [36], which ensures equal execution time across branch paths, making it difficult for attackers to distinguish between paths using CPU side channels. Branch balancing is algorithm-agnostic and preserves program semantics, enhancing its deployability.

However, existing branch balancing implementations still expose vulnerabilities and have been bypassed by recent attacks [5], [25], [26], primarily due to the following three reasons. First, current branch balancing techniques are designed mainly to counter traditional power, frequency and timing side-channel attacks [35], [41], ensuring only that the overall execution time of two branch paths remains consistent. They overlook that attackers with root privileges have access to advanced techniques, such as single-step execution [30], [31], [37], which enable detection of information at the instruction level. Second, current branch balancing is typically implemented at the source-code level [22], [23] and does not account for imbalances introduced during compilation, which may introduce new attack surfaces [25], [32]. Third, existing branch balancing does not fully consider the influence of the Program Counter (PC) [36]. For example, even if two branches contain identical instructions, differing PCs can still impact CPU behavior in ways exploitable by attackers [5], [26]. Currently, no approach has been proposed to harden secret-dependent branches at the instruction level.

In this paper, we propose HoBBy, an algorithm-agnostic, compile-based software defense that Hardens unBalanced Branches at the instruction level. By ensuring consistency in instructions (i.e., undistinguishable instruction types, counts, data flow, and PC targets) on both branch paths during compilation, HoBBy eliminates side-channel information exploitable by attackers, effectively defending against such threats. To achieve this, HoBBy first performs single-step analysis through instrumentation to evaluate the balance of secret-dependent branches within applications, identifying unbalanced instruction sequences that may be vulnerable to side-channel leakage. Next, HoBBy employs instruction and data shadowing, replicating instructions and registers without altering program semantics, to maintain balance in instruction type, count, and data flow across both branch paths. Finally, HoBBy adjusts the layout of original and shadow instructions within memory pages, merging store and load instructions to maintain the PC targets balance.

We implement HoBBy with LLVM [21] and apply it to harden the unbalanced branches in three cryptographic [22], [23], [39] and one non-cryptographic applications [19]. To assess HoBBy's attack resilience, we show that HoBBy can drop the accuracy of three state-of-the-art attacks, two on Intel SGX [5], [28] and one on AMD SEV [9], to the equivalent of random guessing (i.e., approximately 50%). Finally, we evaluate HoBBy's performance overhead, showing that HoBBy introduces an average runtime overhead of 2.8% for

* These authors contributed equally to this work.
¶ Corresponding author.

the cryptographic libraries, with a binary size overhead of 0.6%, which is much lower compared to other mitigations [7].

In summary, the contributions of this paper are as follows:

- We introduce HoBBy, a tool that hardens unbalanced branches at the instruction level in real-world applications, and defends against state-of-the-art control flow attacks on these applications.
- We propose a method to evaluate the security of secret-dependent branches, enabling automated analysis of unbalanced instructions along branch paths and identifying potential side-channel risks.
- We develop various methods to balancing branch in terms of instruction type, count, data address and PC target.
- We evaluate HoBBy's effectiveness and performance overhead in 4 real-world applications, demonstrating that HoBBy defends against state-of-the-art attacks on Intel SGX and AMD SEV with an average runtime overhead of approximately 2.8% for the cryptographic libraries, and a binary size overhead of approximately 0.6%.

II. BACKGROUND ON CONTROL FLOW ATTACKS

Control flow side-channel attacks infer which code of an application running in the TEE is executed by detecting changes in architecture-level or microarchitecture-level states, thereby leaking secrets related to control flow. Secret-dependent branches [5], [14] are one of the primary targets of such attacks, as the execution of these branches depends on a secret determining whether the branch is taken or not. Secret-dependent branches are commonly found in cryptographic applications, such as RSA and ECDSA [22], [23], [39], and are also present in non-cryptographic applications [18], [19].

Current control flow attacks targeting secret-dependent branches can be divided into two categories. The first category is branch-oriented attacks [14], [17], [42], [43], which exploit the effects of branch instructions on the branch predictor to leak sensitive data. The second category is non-branch-oriented attacks [5], [9], [25], [26], [28], [40], which infer the branch direction by exploiting side channels of other instructions along the branch paths.

For branch-oriented attacks, the leakage source is known, and defenses can be implemented by flushing the branch predictor during context switches [42], [43] or confounding the control flow through compiler [12], [17]. Therefore, such attacks are not considered in this paper. For non-branch-oriented attacks, imbalances between the two branch paths, such as differences in instruction count [25], instruction types [2], [9], data addresses [12], [28], or instruction addresses (PC) [5], [26], are exploited to infer branch paths, as shown in Table I. This type of attack leverages various complex microarchitectural side channels and diverse code patterns, posing significant challenges to effective defenses.

SQUIP [9]	Scheduler	Type & Count

III. OVERVIEW OF HOBBY

A. Motivation

Branch balancing prevents various side-channel attacks by ensuring identical CPU behavior on both sides of a branch. This approach does not modify program algorithms and has therefore already been adopted by some developers [22], [23], [39]. However, current branch balancing is primarily implemented at the source-code level, without addressing imbalances introduced during compilation [25] or leakage from instruction PCs due to specific CPU characteristics [5], [26]. As a result, branch balancing is not always effective against control flow attacks. In this work, we look at the fundamental root causes of branch balancing issues and propose new compiler-based techniques to eliminate branch-balancing issues. Specifically, we aim to strengthen balanced branches at the instruction level to defend against state-of-the-art non-branch-oriented attacks, such as those listed in Table I.

B. Assumptions and Threat Model

We assume an attacker with root privileges (e.g., a malicious OS) aims to leak the direction of a secret-dependent branch within the TEE application using control flow attacks. The attacker can manage page tables and handle exceptions to execute victim code in single-step mode (e.g., using SGX-Step [31] or SEV-Step [37]) and perform side-channel attacks. The victim is a user application running in the TEE, and seeks to harden its code against control flow attacks through compiler-based defenses. Both the victim and attacker can profile the binary file and identify secret-dependent branches. The victim can compile, modify, and execute the binary, while the attacker can only analyze the binary.

C. Workflow of HoBBy

The workflow of HoBBy is illustrated in Fig. 1. The input is the source code containing secret-dependent branches that require hardening. First, HoBBy automatically identifies these branches and their paths. Next, HoBBy instruments each instruction along the branch paths to analyze the context of each instruction. After the analysis, HoBBy balances the type, count, data flow, and PC of instructions along the branch paths to defend against control flow attacks. The output is a hardened application, preventing privileged attackers from using side channels to distinguish between different branch paths.

In Sections IV and V, we introduce the design of secret-dependent branch analysis (❶) and branch balancing (❷),

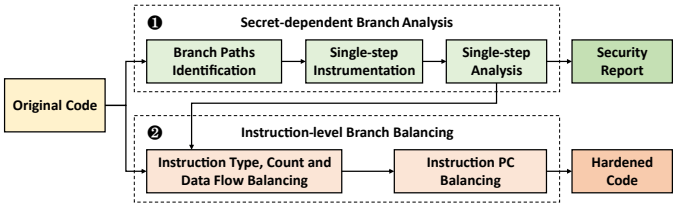

Fig. 1. Workflow of HoBBy. HoBBy first identify and evaluate the security of secret-dependent branches (❶), and then balancing the instruction type, count, data flow and PC target (❷).

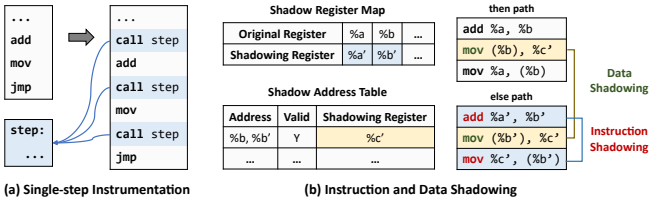

Fig. 2. Methods to perform single-step analysis at the instruction level (a), and to implement instruction and data shadowing (b) so that instruction types and memory accesses are undistinguishable on the two branch paths.

respectively. In Section VI, we present the effectiveness and performance evaluation of HoBBy.

IV. SECRET-DEPENDENT BRANCHES ANALYSIS

In this section, we introduce HoBBy's single-step analysis of secret-dependent branches. This step identifies unbalanced and potentially vulnerable instruction sequences, which will be hardened in subsequent steps.

A. Branch Paths Identification

Similar to previous research [8], we use DFSan [20] to perform taint analysis for identifying secret-dependent branches. Next, we analyze the program's Control Flow Graph (CFG) to determine the control flow in both directions of each branch. For most secret-dependent branches, only a small portion of the secret (e.g., a single bit) is processed per execution, causing these branches to be executed multiple times. Consequently, there is often a common successor across different paths for the majority of secret-dependent branches. Based on this observation, we first use Breadth-First Search (BFS) to identify the nearest common successor among different branch paths.

Subsequently, we use Depth-First Search (DFS) to trace all paths from the basic block containing the secret-dependent branch to the nearest common successor. During DFS, other branches may be encountered along these paths (e.g., branches for loops or exception handlers [23], [39]), adding complexity to the control flow. To handle loops, we perform a static analysis to partition the loop into the loop head and loop body, ensuring that each loop body is analyzed only once. For branches handling exceptions, we apply a heuristic approach: if the number of predecessors for the branch target exceeds a specified threshold, and the basic block's successor is unreachable from the nearest common successor on the branch path, we skip the analysis of that basic block and its successors.

B. Single-step Instrumentation

According to the threat model described in Section III-B, the attacker can interrupt the victim's code [45] at the instruction level [30] and perform side-channel attacks. To analyze the vulnerability of branches, we conduct a dynamic single-step analysis on the instructions along the branch paths after identifying them. To achieve this, we insert a `call` instruction targeting the function `step` between each instruction, as shown in Fig. 2(a). In each `step`, we save the current context by sequentially storing the values of the `EFLAGS` register and general-purpose registers, followed by values in the call stack. Additionally, for store and load instructions, we capture their virtual addresses for later offline analysis.

To ensure that `step` does not alter the program's context, we save the current stack frame register `RSP` before executing `step`, then adjust it to a new stack space to store the execution context. Furthermore, to retrieve information about the executing instruction, we additionally save the PC stored in `RIP`. Given that the length of the instrumented instructions is known, we can dynamically calculate the PC of each analyzed instruction and access the corresponding instruction page to retrieve its machine code. Finally, after `step` completes, we restore the context and adjust the stack base to ensure the program continues to execute in single-step mode.

C. Analysis on Unbalanced Instructions

After collecting the context of each instruction along the branch paths, we perform an offline analysis to determine whether the instructions are balanced and, if not, identify which instructions might be vulnerable to side-channel attacks. First, we disassemble the machine code to obtain the opcodes and then count the number of each opcode type on each path. If the instruction counts differ, or if there are different types of instructions, the branch may be vulnerable to port-based [2], [9] or interrupt-based attacks [25], [32]. Next, we analyze the presence of load and store instructions within the branch paths. If such instructions exist, the branch could be vulnerable to the attacks targeting the PC of these instructions [5], [26]. Finally, we analyze the operands of these instructions to determine whether the addresses for loads and stores are in different pages or cache lines, where hardening is required because distinct data flows may be vulnerable to side-channel attacks related to page [40], TLB [11], and cache [10], [28].

V. HARDENING UNBALANCED BRANCHES

In this section, we introduce HoBBy's methods for hardening unbalanced instruction types, instruction counts, data flow, and the PC targets. Even if an attacker can execute the victim code in single-step mode, identical instructions from the victim program are executed, and the same data addresses are accessed, which effectively prevents these control flow attacks.

A. Instruction Balancing with Instruction Shadowing

HoBBy first balances instruction types and counts through *instruction shadowing*. As shown in Fig. 2(b), we start by creating a shadow register mapping table that maps all register operands in unbalanced instructions to shadow registers.

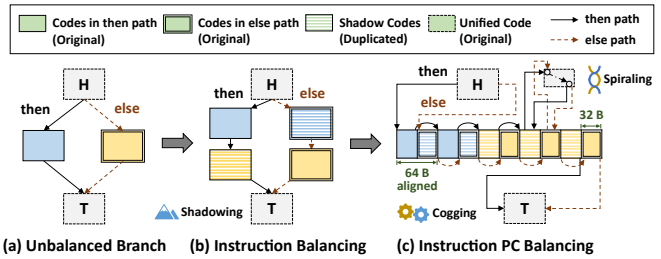

Fig. 3. Workflow of hardening the unbalanced branches. First, the instruction type, count and data flow are balanced through instruction and data shadowing (b). Next, the instruction PC target is balanced through instruction cogging and instruction spiraling (c).

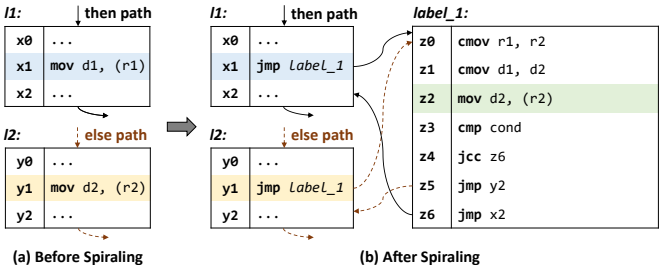

Fig. 4. Method to implement instruction spiraling. The load or store instructions on two branch paths can be merged to hide the side-channel effects caused by these instructions with different PCs.

Shadow registers are registers outside the program's original semantics and are not used as operands in the original instructions, and thus do not affect the program's behavior.

As shown in Fig. 3(b), if there are imbalances in instruction types or counts between the two branch paths, we replicate the basic blocks. We then insert new shadow instructions into the replicated basic blocks, adjusting the instruction opcodes to ensure that both branch paths contain the same number and types of specific instructions. When adding these instructions, we maintain the same relative position from the entry of each basic block so that, during the single-step execution, identical instruction types are executed on both branch paths. For shadow instructions, we ensure their target registers are always shadow registers, preventing the execution of these instructions from impacting the program's original context. For example, as shown in Fig. 2(b), if an `add` instruction exists on one branch path but not on the other, we replicate the basic block on the other path and add a shadow `add` instruction with operands drawn from the shadow register map.

B. Data Flow Balancing with Data Shadowing

Since store and load instructions trigger data accesses and impact CPU backend units such as the cache, we need to balance their memory addresses to avoid data flow imbalance through *data shadowing*. For load instructions, we access the same address in the shadow instructions. For store instructions, to prevent shadow instructions from modifying memory, we insert a shadow load before the shadow store to retrieve the original data from that address, as shown in Fig. 2(b). To balance the data flow, we also insert a load on the original path that accesses the same address but uses a shadow register as the destination, ensuring program correctness is maintained.

C. PC Target Balancing with Instruction Cogging

In modern CPUs, instructions are fetched from memory, so even if the types and counts of instructions are identical on both branch paths, instruction fetching can still affect the cache and TLB, potentially creating side-channel leakage risks [33]. Therefore, it is necessary to balance the instruction PC target to ensure that both original and shadow instructions reside on the same page and access the same instruction cache line.

To achieve this, we introduce the *instruction cogging* technique. As shown in Fig. 3(c), after completing instruction balancing, we divide the instructions on both branch paths into 32-byte blocks and alternately place these blocks within a 64-byte aligned address space, connecting the two paths with `jmp` instructions to maintain semantic correctness. This ensures that, even if an attacker executes instructions in single-step mode, balanced instructions from both paths appear simultaneously within the same instruction page and cache line, preventing related side-channel attacks.

D. PC Target Balancing with Instruction Spiraling

Recent attacks exploit the different effects of stores or loads with different PCs on CPU microarchitecture to infer which stores or loads are executed on different paths. For example, the Frontal Attack [26] leverages variations in single-step execution time for a store based on its distance from the conditional branch. AfterImage [5] takes advantage of loads with different 8 least significant bits (LSBs) in their PCs, which update distinct entries in the IP-stride prefetcher.

To defend against such attacks, only balancing the instruction and data flow is insufficient. Therefore, we propose the *instruction spiraling* technique, which merges the store and load instructions from both paths, as shown in Fig. 4. In the instruction balancing phase, we have ensured balanced store and load instructions and data flow on both branch paths using instruction and data shadowing. Now for each pair of balanced stores or loads, we create a new basic block in the CFG and replace the original stores or loads on both paths with `jmp` instructions targeting this new basic block.

In this new basic block, we insert a `cmov` instruction that, based on the branch condition, determines the source and destination registers for the stores or loads. This setup ensures that the same store or load with a fixed PC is executed on both paths each time, producing consistent effects on CPU microarchitecture. To maintain correct control flow, the program jumps back to one of the original paths based on the branch condition after executing the store or load in the new basic block, ensuring that execution proceeds as intended.

VI. EVALUATION ON HOBBY

We implement HoBBy in the LLVM backend [21] for the x86-64 instruction set. Specifically, we include single-step analysis, instruction shadowing, data shadowing, and instruction spiraling for stores and loads. Our implementation does not cover 32-bit instructions, extended instruction sets, or

TABLE II

SINGLE-STEP ANALYSIS ON THE UNBALANCED INSTRUCTIONS OF 8 SECRET-DEPENDENT BRANCHES IN 4 REAL-WORLD APPLICATIONS BEFORE HARDENING AND AFTER HARDENING. THE LAST 2 COLUMNS SHOW THE AVERAGE RUNTIME OVERHEAD OF THE HARDENING FOR THE FUNCTIONS THAT CONTAIN THE SECRET-DEPENDENT BRANCHES, AND THE WHOLE APPLICATIONS.

system instructions, as these are not present in the programs we analyzed. We leave these aspects for future work. In this section, we selected Libjpeg [19], WolfSSL [39], and MbedTLS [22], [23] for analysis, because recent research has identified secret-dependent branches in these applications as attack targets. We use single-step analysis before and after hardening to demonstrate HoBBy's effectiveness. We then show that HoBBy can defend against three state-of-the-art attacks targeting Intel SGX and AMD SEV. Finally, we present the performance overhead of HoBBy.

A. Effectiveness

In Table II, we select a few secret-dependent branches from each program and report the number of unbalanced instructions before and after hardening. The developers of WolfSSL and MbedTLS have considered side-channel attacks and implemented source-code level balancing (i.e., apart from function parameters, the code on both sides of the branches is identical). However, these branches still exhibit risks due to unbalanced instructions [5], [25], [26]. Through instruction balancing and PC target balancing, HoBBy eliminates the imbalance and mitigates potential side-channel risks.

As an example from a non-cryptographic library, Libjpeg does not consider branch balancing during development. Instead, Libjpeg's IDCT algorithm uses branching to skip complex computations when the image data is simple (e.g., a pixel block consists of a single color), and HoBBy efficienctly hardens these unbalanced instructions.

B. Case Studies

In this section, we select three state-of-the-art control-flow attacks to demonstrate the effectiveness of HoBBy. These attacks exploit imbalances in data flow, instruction count, and PC, respectively. For the victim, we use the secret-dependent branches in the modular inverse function of MbedTLS [23]. We do not implement a full end-to-end attack; instead, we achieve synchronization by actively switching between attacker and victim. This approach simplifies the attack process but is sufficient to demonstrate HoBBy's effectiveness.

Cache Attacks [4], [28] exploit the imbalance in the data flow. If the victim's load instructions on different branch paths access different data addresses, an attacker can use cache side channels to determine which load is executed. As shown in Fig. 5(a), if two loads access distinct cache sets, the attacker can distinguish which cache set the victim accessed after each branch execution using Prime+Probe [28], achieving a 99.75% success rate. HoBBy applies data shadowing to ensure that loads on both paths access the same cache sets, so the attacker always observes both cache sets as accessed, rendering the attack ineffective (i.e., equivalent to random guessing).

SQUIP [9] leverages the difference in the number of arithmetic instructions (e.g., multiplications) on different branch paths to create contention in the scheduler of AMD CPU execution units, thereby revealing which path the victim's code take. As shown in Fig. 5(b), the attacker's code exhibits different execution times for victim paths with varying numbers of multiplications, resulting in a 92.77% attack success rate. After hardening, the instruction counts on both paths are identical, and the execution time of the attacker's code becomes the same, reducing the attack success rate to around 50%.

AfterImage [5] exploits the differing effects of loads with distinct PCs on the prefetcher to infer which load is executed. For example, if a load on a particular path is executed, the prefetcher entry associated with that load's PC is updated; otherwise, the prefetcher entry remains unchanged. By repeatedly executing the victim code and using a cache side channel to detect the prefetcher update rate, the attacker can infer whether the load is executed. As shown in Fig.5(c), when the update rate is zero, the load is not executed, indicating that the branch does not follow that path, with a success rate of 98.89%. HoBBy effectively mitigates AfterImage by merging loads on both paths through instruction spiraling, so the attacker always observes a prefetcher update, making the attack ineffective.

C. Performance Overhead

We analyze the performance overhead of HoBBy on both the functions containing the secret-dependent branches and the

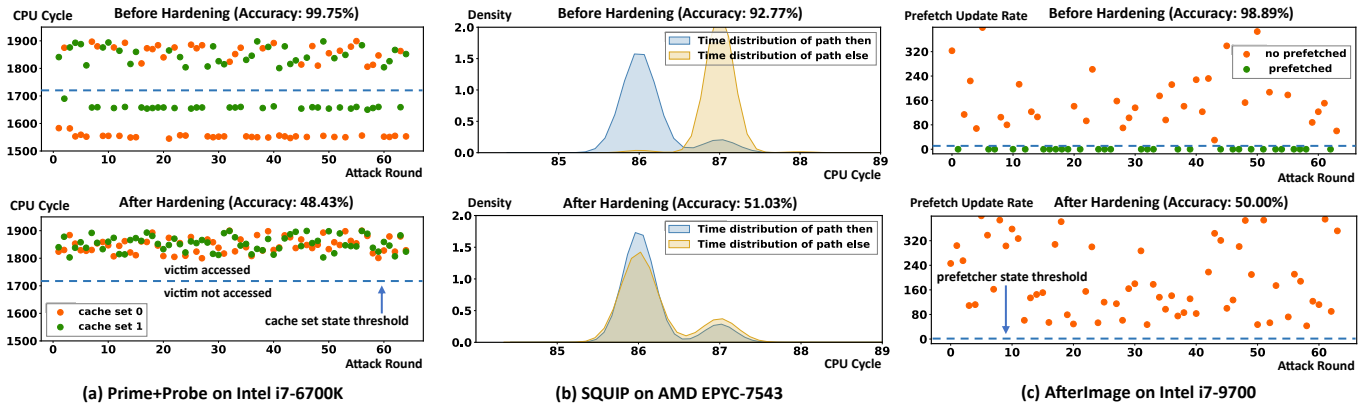

Fig. 5. Case studies on three state-of-the-art control flow attacks on Intel SGX and AMD SEV. HoBBy effectively defend these attacks by balancing the data flow [28], count of `imul` instructions [9] and load PC [5], making different paths of the secret-dependent branches not distinguishable.

overall program, as shown in the last two columns of Table II. For cryptographic libraries, we focus on the RSA algorithms as they are the most common attack targets in recent studies [5], [9], [28]. For Libjpeg, we focus on the IDCT function.

While hardening introduces runtime overhead, the overall performance impact remains acceptable given the security benefits. For instance, Libjpeg's IDCT function sees a significant 66.4% overhead due to disrupted optimizations, but the total overhead for Libjpeg is only 19.3%, which is acceptable in many cases. In cryptographic libraries, if the hardened function isn't on the critical execution path, the performance impact is minimal. For example, hardening the modular inverse function in MbedTLS results in just a 2.8% overall runtime overhead, indicating a negligible performance penalty.

We also evaluate the binary size overhead introduced by HoBBy. The additional instructions primarily stem from shadow instructions introduced by instruction and data shadowing and `jmp` instructions added by instruction spiraling. For branches that are not balanced at the source-code level (e.g., Libjpeg's IDCT), the number of added instructions is significantly higher than in other programs. However, in terms of overall binary size, these additional instructions do not have notable effects. For example, the size increase in WolfSSL and Libjpeg due to HoBBy does not exceed 0.6%.

VII. Related Work

Currently, various defenses have been proposed to mitigate control-flow attacks on Intel SGX and AMD SEV. First, as suggested by CPU vendors [15], preventing control flow from depending on secrets can fundamentally block all control-flow attacks [7]. However, this approach is difficult to extend to complex programs [9] and incurs significant overhead [7]. Second, code-oblivious techniques hide timing differences across different control flows. SGX-Shield [29] and Klotski [44] achieve branch control-flow balancing at the page level but cannot defend against finer-grained control-flow attacks. Compiler-Assisted Hardening [38] and Obfuscuro [1] offer finer-grained instruction balancing but do not address leaks due to PC imbalances. Obelix [36] is a state-of-the-art tool that protects both code and data within the TEE, defending against single-step control-flow attacks and ciphertext side channels [8] while also addressing PC imbalances [26]. However, Obelix primarily focuses on ensuring constant execution time for instructions during single-step execution and does not consider the persistent impact of specific instruction PCs on other CPU components, as highlighted in AfterImage [5].

In addition, some defenses are designed to mitigate specific attacks. First, by flushing the state of leakage sources during context switches, attacks with known sources can be mitigated, such as the BPU [42], [43] and Prefetcher [5] attacks. This approach is efficient and does not require modifications to the program, but is limited to specific attacks. Second, AEX-Notify [6] detects single-step attacks by monitoring the frequency of interrupts. However, it requires additional CPU support (e.g., microcode updates), which makes it unavailable for immediate deployment [36]. Besides, other TEEs (e.g., AMD SEV), currently lack support for similar techniques.

VIII. Conclusion

We present HoBBy, a tool that hardens unbalanced secret-dependent branches at the instruction level in applications running within a TEE. HoBBy balances instruction types, counts, data flow, and PC targets by employing single-step analysis, effectively defending against control-flow attacks on Intel SGX and AMD SEV. We demonstrate its effectiveness across four real-world applications, showcasing its ability to counter state-of-the-art control-flow attacks targeting these platforms. HoBBy incurs runtime and binary storage overheads of 2.8% and 0.6% for the RSA algorithm in cryptographic libraries, respectively. Overall, HoBBy provides strong security guarantees for secret-dependent branches within the TEE with acceptable overhead.

***Abstract*—Recently, machine learning-based techniques have been applied for layout hotspot detection. However, existing methods encounter challenges in capturing the decision boundary across the entire dataset and ignore the geometric properties and topology of the polygons. In this paper, we introduce CLI-HD, a novel contrastive learning framework on layout sequences and images for hotspot detection. Our framework improves the ability to distinguish between hotspots and non-hotspots by similarity computations instead of a single decision boundary. To effectively incorporate geometric information into the model training process, we propose Layout2Seq, which encodes polygon shapes as vectors within sequences that are subsequently fed into the CLI-HD. Furthermore, to better represent topology information, we develop an absolute position embedding, replacing the standard position encoders used in Transformer architectures. Extensive evaluations on various benchmarks demonstrate that CLI-HD outperforms current state-of-the-art methods, with an accuracy improvement ranging from 0.82% to 4.77% and a reduction in false alarm rates by 4.9% to 23.18%.**

I. Introduction

With the rapid development of semiconductor techniques, the shrinking of transistor feature sizes and the increasing size of dies present significant challenges to Design for Manufacturability (DFM). Hotspot detection is introduced as a critical procedure in DFM to identify potential defect patterns early. Lithography simulation techniques can accurately detect hotspot patterns, but they consume a large amount of time for simulation and are not applicable to chip fabrication. Other works were based on pattern-matching methods to identify hotspots with similar patterns by retrieval or clustering. Such methods cannot cover hotspots outside the pattern or layout libraries [1], [2].

Recently, machine learning-based methods have been applied in DFM [3], [4] and achieved impressive progress in hotspot detection [5], [6]. As shown in Fig. 1(a), existing methods convert the layout files into binary images and employ supervised learning to classify HotSpot (HS) and Non-HotSpot (NHS). However, these methods utilizing convolutional neural networks (CNNs) to distinguish hotspots are limited by the receptive field in acquiring the global topology information of the layout images. To represent the global topology, others utilize polygons to construct a layout graph and perform pattern graph classification with graph neural networks (GNNs) for hotspot detection [7], [8]. Nevertheless, they decompose the polygon into multiple rectangular nodes, which introduces additional complexity and results in the shape information loss of the polygon. Generally, existing CNN-based and GNN-based methods rely on supervised learning, which tends to suffer from a high false-alarm rate when trained to construct a single decision boundary across the entire dataset with very few hotspot samples [6].

Beyond image and graph-based approaches, alternative layout representations have been explored in other DFM applications. A sequence pattern representation [9] is proposed for layout pattern generation that attempts to learn the shape and spatial information of patterns by the Transformer. However, there is a representation gap when converting coordinates and edge values to language token embedding. In addition, it ignores the position of polygonal patterns. Other methods represent a layout clip by using a topological matrix and two vectors [3], [4]. This representation is not flexible for existing deep neural networks [9]. To the best of our knowledge, the

shape (e.g., height, width, orientation) of individual polygons, along with the topological relationships (e.g., edge2edge, side2side) among multiple polygons, are critical factors for identifying hotspots [4]. Thus, the aforementioned supervised learning methods and layout representation struggle to construct robust statistical models for hotspot detection.

Considering the existing issues, we design a novel contrastive learning framework on layout sequences and images for hotpot detection, CLI-HD, which effectively distinguishes between hotspots and non-hotspots through similarity computations while incorporating geometric representations and topological information. The main contributions of this paper are summarized as follows:

- We propose a novel contrastive learning framework for hotspot detection, that leverages similarity computations, thereby eliminating the need to establish a unified decision boundary across the entire dataset.
- We present Layout2Seq, a novel sequence representation for layouts that efficiently converts polygons into vector formats, facilitating the extraction of geometric features. This approach can also provide the possibility for other machine learning-based DFM applications.
- We develop the Absolute Position Embedding (APE) method for Transformer-based sequence models, specifically designed to efficiently encode the topology relationships of multiple polygons based on their position context within the layout.
- Experimental results demonstrate that CLI-HD significantly improves the discrimination of hotspots through contrastive methods, achieving an accuracy improvement of 0.82% to 4.77% and a reduction in false alarm rates ranging from 4.9% to 23.18%. Furthermore, CLI-HD can be effectively fine-tuned with a single linear layer, yielding remarkable performance in hotspot detection.

II. Preliminaries

The lithographic process utilizes a mask to transfer a precisely designed layout pattern onto the wafer. Sensitive patterns are particularly susceptible to yield reduction caused by variations in the manufacturing process. These patterns are defined as hotspots within the layout [5]. In our paper, hotspot detection is considered as a binary classification task for the layout clips. Different from [6], [8], [10], we are dealing with layout clips where the hotspot locations are random and may include multiple hotspots, rather than just a single centered marker. It will test the model's ability to learn non-fixed hotspot patterns making it more relevant to real-world applications relevant to real-world application scenarios. The following definitions and metrics are used to evaluate the performance of a hotspot detector.

Definition 1 (Accuracy). The ratio of correctly identified hotspots to the total number of ground truth hotspots.

Definition 2 (False Alarm). The ratio of non-hotspot clips that are detected as hotspots by the classifier.

To match the evaluation metrics above, we formulate the hotspot detection problem as follows.

Problem 1 (Hotspot Detection). Given a collection of layout clips containing hotspot and non-hotspot patterns, our goal is to learn a feature vector from building image representations and sequence representations. Based on this vector we can use contrastive learning to distinguish hotspots or fine-tune a classifier for detecting hotspots.

III. Methodology

A. Overview

As shown in Fig. 1(b), we initially obtain the image representation of the layout, consistent with previous work. To construct a geometric representation of polygons, Layout2Seq is proposed to transform the shape of each polygon into a vector and combine multiple polygon vectors into a sequence corresponding to a layout clip. Leveraging images and layout sequences, a contrastive learning framework is designed to generate a unified representation aligning visual features with the geometric properties of polygons. In the contrastive network, we discard the wrong position encoder in the Transformer and develop the APE for introducing the centroid location of polygons.

B. Contrastive learning framework in CLI-HD

As illustrated in Fig. 2, our proposed framework consists mainly of two key components, specifically image encoder $\mathcal{I}(\cdot)$ and sequence encoder $\mathcal{S}(\cdot)$. Motivated by the [11], our objective is to jointly train $\mathcal{I}(\cdot)$ and $\mathcal{S}(\cdot)$ using pairs of binary layout images and corresponding sequence representations, ensuring that the learned image embedding $\mathbf{F}^I = [f_1^I, f_2^I ..., f_N^I] \in \mathbb{R}^{N \times D}$ are effectively aligned with the sequence embedding $\mathbf{F}^S \in \mathbb{R}^{N \times D}$, where N denotes the batch size and D represents the embedding dimension. Basically, a ViT-based model [12] is utilized to encode binary layout images, generating their corresponding image latent representations. In our proposed, the sequence encoder $\mathcal{S}(\cdot)$ is implemented using a transformer architecture, which generates the sequence embedding $\mathbf{F}^S$ from the output of Layout2Seq. Specifically, for the given image-sequence pairs $(\mathbf{X}_i^I, \mathbf{X}_i^S)$, the embedding f_i^I and f_i^S can be computed as follows:

$$f_i^I, f_i^S = \mathrm{Proj}(\mathcal{I}(\mathbf{X}_i^I)), \mathrm{Proj}(\mathcal{S}(\mathbf{X}_i^S)) \tag{1}$$

where $\mathrm{Proj}(\cdot)$ denotes the projection layer. During training process, we compute the loss function of image-to-text $L_{I \to S}$ as:

$$L_{I \to S} = -\frac{1}{N} \sum_{i=1}^{N} \log \frac{\exp(\mathrm{sim}(f_i^I, f_i^S)/\tau)}{\sum_{j=1}^{N} \exp(\mathrm{sim}(f_i^I, f_j^S)/\tau)} \tag{2}$$

and the text-to-image contrastive loss $L_{S \to I}$:

$$L_{S \to I} = -\frac{1}{N} \sum_{i=1}^{N} \log \frac{\exp(\mathrm{sim}(f_i^S, f_i^I)/\tau)}{\sum_{j=1}^{N} \exp(\mathrm{sim}(f_i^S, f_j^I)/\tau)} \tag{3}$$

where the τ is the temperature parameter and $\mathrm{sim}(\cdot)$ denotes the similary function which is calculated as:

$$\mathrm{sim}(f_i^I, f_i^S) = \frac{f_i^I \cdot \left(f_i^S\right)^{\mathrm{T}}}{\left\|f_i^I\right\| \cdot \left\|f_i^S\right\|} \tag{4}$$

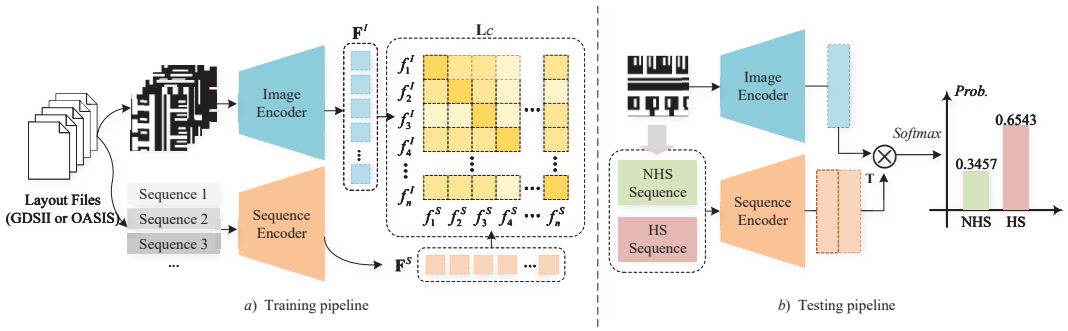

Fig. 2. The framework of contrastive learning. a) The training process of the constrastive learning for the hotspot detection. b) The simple testing process of our proposed framework.

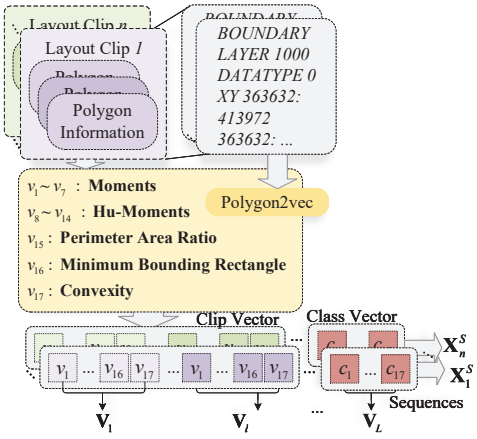

Fig. 3. Illustration of Layout2Seq.

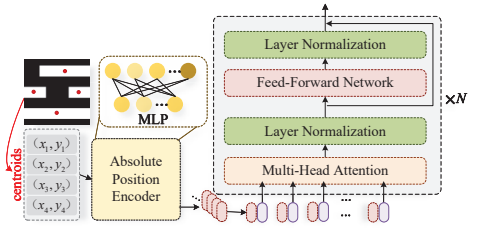

Fig. 4. Illustration of absolute position embedding in sequence encoder.

The total contrastive loss L_{con} in Fig 2(a) is calculated as:

$$L_c = \frac{L_{I \to S} + L_{S \to I}}{2} \tag{5}$$

This loss function is designed to optimize the model by increasing the similarity between matched pairs of representations, (f_i^I, f_i^S), while simultaneously decreasing the similarity between mismatched pairs, (f_i^I, f_j^S), for $i \neq j$.

As shown in Fig 2(b), given a layout image $\mathbf{X}^I$, the Layout2Seq is employed to extract both the hotspot sequence $\mathbf{X}_{hs}^S$ and the non-hotspot sequence $\mathbf{X}_{nhs}^S$ during the inference phase. These sequences, along with the image itself, are subsequently encoded via separate image and sequence encoders to generate their corresponding latent embedding, denoted as $(f^I, (f_{hs}^S, f_{nhs}^S))$. The similarity scores between the image embedding and each sequence embedding are then computed to facilitate category assignment.

Algorithm 1 Layout2Seq

Require: a set of polygons for the layout clip $\{P^k\}_{k=0}^{l}$, the polygon number of the layout clip l, the sequence context length L, the label of the layout $\hat{Y}$.
Ensure: the sequence for the i-th layout clip $\mathbf{X}_i^S$.

Initialize empty sequences $\mathbf{X}_i^S \leftarrow ()$.
for $k = 1$ to l **do**
  Initialize empty sequences $\mathbf{V}_i^k \leftarrow ()$;
  Rendering a binary image I^k by polygon P^k;
  Compute $\tilde{\mathbf{M}}_{pq}^k, \mathbf{Hu}_i^k$ by Equation(6)(7)(8)(9) and I^k;
  $\{v_1 \sim v_7\} = \{\tilde{\mathbf{M}}_{20}^k, \tilde{\mathbf{M}}_{11}^k, \tilde{\mathbf{M}}_{02}^k, \tilde{\mathbf{M}}_{30}^k, \tilde{\mathbf{M}}_{21}^k, \tilde{\mathbf{M}}_{12}^k, \tilde{\mathbf{M}}_{03}^k\}$;
  $\mathbf{V}_i^k \leftarrow \{v_1 \sim v_7\}$;
  $\{v_8 \sim v_{14}\} = \{\mathbf{Hu}_1, \mathbf{Hu}_2, \mathbf{Hu}_3, \mathbf{Hu}_4, \mathbf{Hu}_5, \mathbf{Hu}_6, \mathbf{Hu}_7\}$;
  $\mathbf{V}_i^k \leftarrow \{v_8 \sim v_{14}\}$;
  $a = \text{Area}(P^k), p = \text{Perimeter}(P^k)$;
  $w_{bbox}, h_{bbox} = \text{getBoundingRect}(P^k)$;
  $v_{15} = p/a, v_{16} = a/(w_{bbox} \times h_{bbox})$;
  $v_{17} = \text{isContourConvex}(P^k)$;
  $\mathbf{V}_i^k \leftarrow \{v_{15}, v_{16}, v_{17}\}$;
  $\mathbf{X}_i^S \leftarrow \mathbf{V}_i^k$;
end for
$l_{cur} = len(\mathbf{X}_i^S)$;
for $l = l_{cur}$ to L **do**
  if $\hat{Y} = HS$ **then**
    $\mathbf{X}_i^S \leftarrow \{1\}^{17}$;
  else if $\hat{Y} = NHS$ **then**
    $\mathbf{X}_i^S \leftarrow \{-1\}^{17}$;
  end if
end for
return $\mathbf{X}_i^S$.

C. Layout to Sequence

As shown in prior work [5], [6], converting layout files into their corresponding binary images is a straightforward task. However, to effectively capture geometric information from polygon, we propose a novel approach, called Layout2Seq.

This method transforms layout files into sequences, thereby enhancing the extraction and analysis of geometric features.

As shown in Fig. 3, we extract polygon coordinates from the original layout files and systematically parse each polygon using a vectorized polygon method. Image moments are extensively employed in computer vision and image processing to characterize object shapes [13]. Therefore, for each polygon P^k, where k is the index of the polygon, we generate a binary image I^k using the polygon's coordinates. Subsequently, the geometric moment $\mathbf{M}^k$ of the I^k is computed by:

$$\mathbf{M}_{pq}^k = \sum_{x=0}^{W} \sum_{y=0}^{H} x^p \cdot y^q \cdot I^k(x, y) \tag{6}$$

where W and H represent the width and height of I^k, p and q denote the order of the moment. We further compute the central moments $\mathbf{C^k}$ as:

$$\mathbf{C}_{pq}^k = \sum_{x=0}^{W} \sum_{y=0}^{H} (x - \frac{\mathbf{M}_{10}^k}{\mathbf{M}_{00}^k})^p \cdot (y - \frac{\mathbf{M}_{01}^k}{\mathbf{M}_{00}^k})^q \cdot I^k(x, y) \tag{7}$$

where $\mathbf{M}_{00}$, $\mathbf{M}_{10}$ and $\mathbf{M}_{01}$ can be used to compute the x-coordinate and y-coordinate of the centroid. For scale-invariant moments which are useful for comparing shapes regardless of their size, we compute the normalized moments $\tilde{\mathbf{M}}^k$ as follows:

$$\tilde{\mathbf{M}}_{pq}^k = \frac{\mathbf{C}_{pq}^k}{(\mathbf{M}_{00}^k)^{(p+q)/2+1}} \tag{8}$$

The $\{\tilde{\mathbf{M}}_{20}^k, \tilde{\mathbf{M}}_{11}^k, \tilde{\mathbf{M}}_{02}^k, \tilde{\mathbf{M}}_{30}^k, \tilde{\mathbf{M}}_{21}^k, \tilde{\mathbf{M}}_{12}^k, \tilde{\mathbf{M}}_{03}^k\}$ are incorporated into the polygon vector $\mathbf{V}^k$ as components $\{v_1 \sim v_7\}$.

It is well known that polygons in hotspot patterns exhibit geometric invariants, such as rotational invariance and other transformation properties. In our work with Layout2Seq, we utilize Hu's seven moments [13] to encapsulate the shape invariants of polygons, thereby enhancing robustness against geometric transformations. The Hu's moments can be calculated as:

$$\{\mathbf{Hu}_i\}_{i=1}^7 = \{\mathrm{f}_i(\tilde{\mathbf{M}}_{pq})\}_{i=1}^7 \tag{9}$$

where f_i is specific function or formula (non-linear combination) of the normalized moments $\tilde{\mathbf{M}}_{pq}^k$. The detailed calculations of the seven Hu moments can be found in [13]. Additionally, we have incorporated area-perimeter ratio v_{15}, minimum bounding rectangle v_{16}, and convexity v_{17} to more accurately characterize the geometric properties of polygons. Consequently, for each polygon, we derive a comprehensive vector of geometric information, denoted as $\mathbf{V}_i^k$, which includes a total of 17 values.

For the final sequence $\mathbf{X}^S \in \mathbb{R}^{L \times 17}$, where L denotes the length of the sequence, we insert an additional class vector to facilitate the similarity calculation in the contrastive learning. We assign a value of $+1$ to the category vectors for clips corresponding to the hotspot, while for all other cases, we assign a value of -1. Ultimately, l polygon vectors, along with their corresponding category vectors, collectively constitute the sequence $\mathbf{X}^S$. The complete Layout2Seq pipeline is detailed in Algorithm 1.

Algorithm 2 Training and testing for our proposed

Training process:

Require: Training pair set of layout representations $\{\mathbf{X}_i^I, \mathbf{X}_i^S\}_{i=0}^N$, where $\mathbf{X}_i^S$ is from Alogorithm 1.

Parameters: An image encoder $\mathcal{L}$, an sequence model $\mathcal{S}$.

Initialize $\mathcal{L}$, $\mathcal{S}$ randomly.
for $i = 1$ to N **do**
  $\mathbf{X}_i^{pos} \leftarrow$ Compute centroid by Equation (11);
  $\mathbf{X}_i^S = \mathbf{X}_i^{pos} + \mathbf{X}_i^S$, Absolute Position Embedding;
  Compute (f_i^I, f_i^S) by Equation (1);
  Optimize $\mathcal{L}, \mathcal{S}$ by Equation (5);
end for

Testing process:

Require: A layout clip image $\mathbf{X}^I$, $\mathcal{L}$ and $\mathcal{S}$, as returned by training process.

Ensure: the prediction result Y.

Assuming $\hat{Y} = HS$, compute the $\mathbf{X_{hs}^S}$ by Alogorithm 1;
Assuming $\hat{Y} = NHS$, compute the $\mathbf{X_{nhs}^S}$ by Alogorithm 1;
$f^I = \mathrm{Proj}(\mathcal{I}(\mathbf{X}^I))$;
$f_{hs}^S, f_{nhs}^S = \mathrm{Proj}(\mathcal{S}(\{\mathbf{X_{hs}^S}, \mathbf{X_{nhs}^S}\}))$;
$score_{hs}, score_{nhs} = \mathrm{Softmax}(\mathrm{sim}(f^I, (f_{hs}^S, f_{nhs}^S)))$;
$Y \leftarrow score_{hs}, score_{nhs}$;
return Y.

D. Absolute position embedding

The polygon-based topology is commonly associated with the definition of hotspots in design rules. We embedded the positions of the polygons into the learning process of the sequence model by the proposed APE. For a given polygon P^k, the centroid coordinates (x_k, y_k) are computed by central moments as follows:

$$x_k = \frac{\mathbf{C}_{10}^k}{\mathbf{C}_{00}^k}, y_k = \frac{\mathbf{C}_{01}^k}{\mathbf{C}_{00}^k} \tag{10}$$

As shown in Fig. 4, we exclude the position encoder typically employed in Transformer architectures, as the lack of continuous contextual relationships between polygons. Instead, we developed a straightforward multi-layer perceptron (MLP) to encode the coordinates for integration into the sequence model, yielding absolute position embedding $\mathbf{X}_i^{pos}$ as follows:

$$\mathbf{X}_i^{pos} = \{\sigma(\mathrm{FC}([\hat{x}_k, \hat{y}_k]))\}_{k=1}^l \tag{11}$$

Here, the coordinates need to be normalized as $\hat{x}_k = \frac{x_k}{W}$ and $\hat{y}_k = \frac{y_k}{H}$, W and H denotes the width and height of the input layout clip image, l denotes the number of polygon. Consistent with other approaches utilizing position embedding, we adopt summation to fuse position information into the sequence representation. Therefore, for the sequence model $\mathcal{S}(\cdot)$, the inputs are $\mathbf{X}_{i,input}^S = \mathbf{X}_i^{pos} + \mathbf{X}_i^S$.

The entire training and evaluation process for CLI-HD, which combines Layout2Seq and APE, is detailed in Alogorithm 2.

IV. EXPERIMENTAL RESULTS

Our experimental framework is implemented using PyTorch, with all models trained on 8 NVIDIA GeForce RTX A6000 GPUs (48 GB memory) for accelerated computation. We evaluate our approach on the ICCAD2012 [15], ICCAD2016 [16], and ICCAD2019 benchmarks [17]. Notably, our experiments on the ICCAD2016 dataset incorporate random cropping of image sizes, a novel augmentation technique that allows for the presence of multiple hotspots within a single image. This increases both the complexity and challenge of hotspot detection, distinguishing our methodology from prior works. Comprehensive dataset details are provided in TABLE I.

A. Comparison with State-of-the-Art Hotspot Detection Works on ICCAD2012

To demonstrate the efficacy of our proposed approach, we present the performance results on the ICCAD2012 dataset. As shown in TABLE II, a comparison is made between our method and the currently state-of-the-art techniques for hotspot detection. Our proposed method demonstrates superior accuracy compared to other state-of-the-art algorithms (98.25% of DAC'2021 [6], 98.90% of TODAES'2022 [14], 98.77% of TCAD'2022 [10], 98.42% of DATE'2022 [8] and 96.20% of DATE'2023 [5] v.s. 99.72% of ours). Moreover, the proposed method effectively addresses the problem of excessive false positives encountered by existing approaches. On the ICCAD2012 benchmark, our method reduces the false alarm rate to 1.2%. The computational efficiency of the proposed algorithm is a key consideration. Our method achieves competitive performance while maintaining an acceptable trade-off between the accuracy and speed.

Comparison with the state-of-the-art deep learning-based methods on ICCAD2016. a) Bars with solid red borders indicate optimal results. † denotes our results of supervised fine-tuning. #Miss denotes the number of false negatives. b) Comparison of model detection speed and accuracy on ICCAD2016.

TABLE III
RESULTS ON ICCAD2019-1 FOR OUR PROPOSED

Benchmark	Accuracy(%)	FA(%)
Benchmark1	76.60	29.66
Benchmark2	86.76	22.53
Benchmark3	88.63	19.45
Benchmark4	83.58	22.65
Benchmark5	93.00	20.43
Benchmark6	88.67	18.52
Benchmark7	85.75	21.36
Benchmark8	86.85	20.37
Benchmark9	93.40	9.71

B. Comparison with State-of-the-Art Deep Learning-based Classification Model on ICCAD2016

We evaluated four state-of-the-art backbone networks (ResNet50 (R-50) [18], MobileNetV2 (M-V2) [19], ViT-16 [12], and Swin-Transformer Tiny (Swin-T) [20]) using supervised learning on the ICCAD2016 datasets, and compared their performance against our proposed method. As shown in Fig. 5(a), our proposed method achieves an optimal accuracy of 96.16% with reducing the number of missed detections to only 50. Specifically, we evaluate the generalization of the proposed method by fine-tuning the learned representations under a supervised learning framework, denoted as Ours†. We attained comparable accuracy to a 50-layer ResNet (88.24% vs 88.16%) by fine-tuning contrastive learning representations with a single-layer neural network. Furthermore, as illustrated in Fig. 5(b), our fine-tuned model demonstrates significantly improved inference speed, achieving nearly 200 FPS, outperforming all comparative methods.

C. Comparison with State-of-the-Art on ICCAD2019

We perform comparative experiments using the ICCAD2019 benchmark, which consists of two subsets, ICCAD2019-1 and ICCAD2019-2, both sharing a common training set. It is considered a more accurate evaluation of the detector's capacity to detect never-before-seen hotspots. TABLE III provides detailed results for the ICCAD2019-1 dataset. TABLE IV reports the performance of our proposed method and four state-of-the-art hotspot detection algorithms, as presented in TCAD'2020 [21], TODAES'2022 [14], DATE'2023

TABLE IV
COMPARISON ON ICCAD-2019 BENCHMARK WITH THE STATE-OF-THE-ART METHODS.

Benchmark	TCAD'2020 [21]		TODAES'2022 [14]		DATE'2023 [5]		GLSVLSI'2024 [22]		Ours	
	ACC(%)	FA(%)	ACC(%)	FA(%)	ACC(%)	FA(%)	ACC(%)	FA(%)	ACC(%)	FA(%)
ICCAD2019-1	80.90	2.50	87.20	9.70	91.60	8.60	62.30	3.70	**96.10**	**1.00**

Average	85.30	43.20	88.75	46.90	91.05	46.25	73.30	33.95	**91.56**	**10.77**

[5], and GLSVLSI'2024 [22]. Firtly, our proposed framework achieves an average accuracy of 91.56%, outperforming TCAD'2020 [21], TODAES'2022 [14], DATE'2023 [5], and GLSVLSI'2024 [22], which report accuracies of 85.30%, 88.75%, 91.05% and 73.30%, respectively. Furthermore, the results indicate that the existing methods exhibit a significant false positive rate on the ICCAD2019-2 dataset. Our framework demonstrates a substantial advantage in effectively suppressing false alarms, achieving a rate of 20.53% on ICCAD2019-2 and an average of 10.77%.

V. CONCLUSION

In this work, we propose CLI-HD, a novel hotspot detection method that leverages the topological representation of layout patterns and a contrastive learning framework. We develop a contrastive learning framework that aligns feature representations across binary images and sequence representations. The Layout2Seq is proposed to integrates geometric information of polygons in the process of pattern representation. We introduce absolute position information to learn the topological structure. Our results show that CLI-HD surpasses previous methods, achieving a 0.82%-4.77% gain in accuracy while reducing false alarm rates by 4.9%-23.18%. Future work will explore the application of topological and contrastive learning techniques across diverse downstream tasks beyond hotspot detection.

***Abstract*—3D intelligence leverages rich 3D features and stands as a promising frontier in AI, with 3D rendering fundamental to many downstream applications. 3D Gaussian Splatting (3DGS), an emerging high-quality 3D rendering method, requires significant computation, making real-time execution on existing GPU-equipped edge devices infeasible. Previous efforts to accelerate 3DGS rely on dedicated accelerators that require substantial integration overhead and hardware costs. This work proposes an acceleration strategy that leverages the similarities between the 3DGS pipeline and the highly optimized conventional graphics pipeline in modern GPUs. Instead of developing a dedicated accelerator, we enhance existing GPU rasterizer hardware to efficiently support 3DGS operations. Our results demonstrate a 23× increase in processing speed and a 24× reduction in energy consumption, with improvements yielding 6× faster end-to-end runtime for the original 3DGS algorithm and 4× for the latest efficiency-improved pipeline, achieving 24 FPS and 46 FPS respectively. These enhancements incur only a minimal area overhead of 0.2% relative to the entire SoC chip area, underscoring the practicality and efficiency of our approach for enabling 3DGS rendering on resource-constrained platforms.**

***Index Terms*—Hardware Architecture, Graphics Processors, 3D Gaussian Splatting**

I. Introduction

3D intelligence is set to become the next major frontier in AI by leveraging rich 3D features to enhance understanding and interaction within complex environments. As Prof. Fei-Fei Li, co-founder of ImageNet, emphasized, *"...we need spatially intelligent AI that can model the world and reason about objects, places, and interactions in 3D space and time..."* [38]. This underscores the importance of 3D intelligent applications such as autonomous driving [39], robotics [32], and augmented/virtual reality (AR/VR) [4] shown in Fig. 1. A foundational task within 3D intelligence is 3D scene rendering, which provides essential features for downstream AI tasks that require spatial information.

Recently, 3D Gaussian Splatting (3DGS) [14] has emerged as the leading method for 3D scene rendering. As summarized in Table I, unlike previous techniques like triangle meshes [33] and neural radiance fields (NeRF) [20], 3DGS maps 3D scenes onto a set of Gaussian balls, offering superior rendering quality and automated scene reconstruction. Thanks to these advantages, 3DGS has been rapidly adopted in various 3D applications, including autonomous driving [13], [30], [42], robotics [1], [12], [19], and AR/VR [18], [31], [40].

Fig. 1. Representative examples of 3D intelligent applications, including autonomous driving, robotics, and augmented/virtual reality [11], [21], [27].

TABLE I
Comparison of Rendering Methodologies

	Triangle Mesh [33]	NeRF [20]	3D Gaussian [14]
Scene Reconstruction	Manual	Automatic	Automatic
Rendering Quality	Manually Decided	High	Very High
Rendering Speed on GPU [22]	Fast	Slow	Medium

Despite its robust performance on high-powered ($\geq$ 200 W) GPUs [25], achieving real-time rendering of $\geq$ 30 frames per second (FPS), 3D Gaussian Splatting cannot achieve high framerates on edge computing platforms with GPUs, such as those with power limitations ($\leq$ 10 W) like the NVIDIA Jetson Orin NX [22]. These platforms are increasingly crucial due to the growing demand for 3D processing in mobile and embedded systems [11], [27]. Specifically, 3DGS achieves only 2-5 FPS on these platforms [22] with commonly used real-world, large-scale datasets [3], falling short of the performance requirement for most practical applications. This performance gap poses challenges for deploying advanced 3D intelligence in resource-constrained environments, highlighting the need for hardware acceleration of 3DGS.

Existing efforts to accelerate 3D Gaussian Splatting [16] and similar rendering pipelines [10], [17] typically focus on developing dedicated hardware accelerators. While these specialized units can provide performance benefits, they require exclusive hardware resources and often lead to increased system complexity and cost. Moreover, the integration of dedicated accelerators may not be feasible for all edge platforms, especially those with stringent area and power constraints. However, modern GPUs are already equipped with optimized fixed-function graphic acceleration hardware for triangle meshes. As these fixed-function units also target graphics rendering, their inherent capabilities present an opportunity to leverage

Fig. 2. Visualization of a 3D Gaussian representation: (a) Rendered RGB image depicting the scene with realistic color and detail; and (b) the corresponding Gaussian ball representation of the same scene, showing the underlying 3D structure before rendering. Both images are rendered using the 'Bonsai' scene from the NeRF-360 [3] dataset.

existing resources to accelerate 3DGS rendering without introducing significant additional overhead.

To mitigate the challenges associated with designing dedicated memory systems and software stacks for specialized accelerators [6], we propose an alternative solution: enhancing the existing graphics units—specifically, the rasterizer for triangle meshes—within GPUs to accelerate 3DGS rendering. By leveraging the capabilities of current GPU hardware, we aim to enhance performance without the need for additional dedicated accelerators. We begin with an in-depth profiling of the 3DGS rendering pipeline to identify time-consuming operations and analyze its similarities with operators in the triangle mesh rendering pipeline, which are already supported by the GPU's native graphic hardware units. This analysis reveals opportunities to adapt and enhance these units to efficiently process 3D Gaussian operations.

Building on these insights, we propose and develop an enhanced rasterizer, GauRast, for GPUs that enables the efficient execution of the dominant operator in the 3DGS rendering pipeline while preserving the original capabilities for standard triangle mesh rendering. This design ensures compatibility with existing GPU architectures and minimizes disruptions to conventional workflows. By enhancing existing hardware rather than introducing entirely new components, our approach strikes a balance between performance improvements and resource utilization. Our contributions are as follows:

- We advocate an alternative direction for accelerating 3DGS, the leading algorithm in neural rendering, by enhancing existing GPU units originally dedicated to traditional workloads.
- We detail comprehensive profiling and analysis of the 3DGS rendering pipeline [14] to identify the critical operators requiring acceleration, and demonstrate that the bottleneck operator in the 3DGS rendering pipeline shares similarities with the triangle rendering pipeline, which is already well-accelerated by existing GPU's triangle rasterizer.
- We propose an enhanced rasterizer, named GauRast, to support the dominant operator in the 3DGS rendering pipeline while maintaining its functionality for standard triangle mesh rendering tasks.
- We present a GauRast hardware prototype that achieves a 23× speedup and a 24× improvement in energy efficiency on the target SoC for the dominant operator with the original 3DGS rendering pipeline. This leads to a 6× end-to-end speedup in the original 3DGS rendering pipeline [14] and a 4× end-to-end speedup in the latest efficiency-optimized 3DGS rendering pipeline [9], achieving 24 FPS and 46 FPS, respectively. Notably, GauRast incurs an area overhead of only 21% for the enhanced graphics units, corresponding to 0.2% of the total SoC area.

Taken together, our proposals demonstrate a promising approach to enabling real-time 3DGS rendering on future edge devices.

II. 3DGS and Its Rendering Bottleneck

A. 3D Gaussian Splatting Algorithm

3D Gaussian Scene Representation. The state-of-the-art (SOTA) method for 3D scene rendering employs a 3D Gaussian-based representation [14] as illustrated in Fig. 2. This approach strikes a balance between high rendering quality and efficient rendering speed, especially on standard desktop-level GPUs. In this representation, objects are modeled as collections of elliptical 3D Gaussian balls. Each Gaussian ball is characterized by a 3D Gaussian probability density function and an associated color vector. The rendering process distributes colors over the regions covered by the Gaussians' probability densities, collectively forming the complete scene.

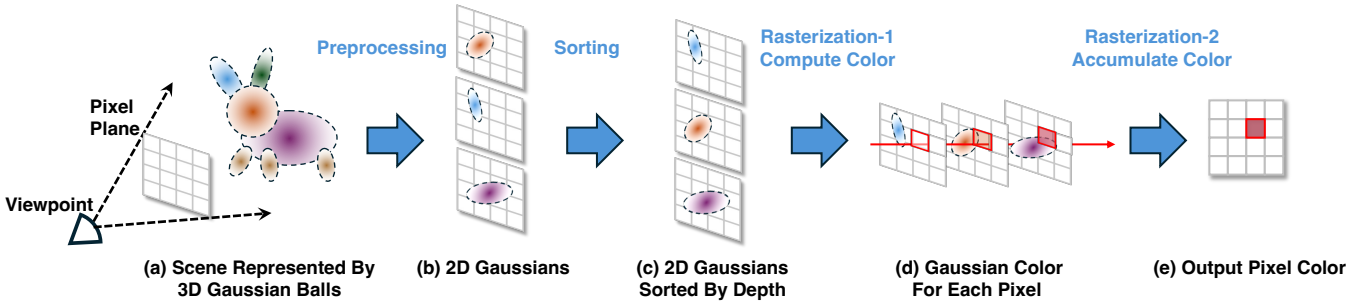

Fig. 3. Overview of the 3DGS pipeline [14]: (a) *Scene representation*: The scene is depicted as 3D Gaussian balls, viewed from a specific viewpoint and projected onto a 2D pixel plane. (b) *Preprocessing*: These 3D Gaussians are projected onto the 2D plane, resulting in 2D Gaussian representations. (c) *Sorting*: 2D Gaussians are ordered by depth to ensure the correct rendering sequence and handle occlusion properly. (d) *Initial rasterization*: Colors for each pixel are calculated based on the Gaussians covering that pixel. (e) *Color accumulation*: Colors are accumulated to produce the final pixel color output.

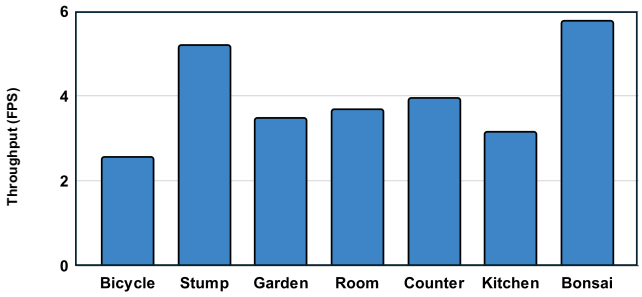

Fig. 4. Throughput achieved by the 3DGS rendering pipeline [14] across all seven scenes from the large-scale, real-world NeRF-360 dataset [3], as measured on the NVIDIA Jetson Orin NX [22] with a 10W power limit.

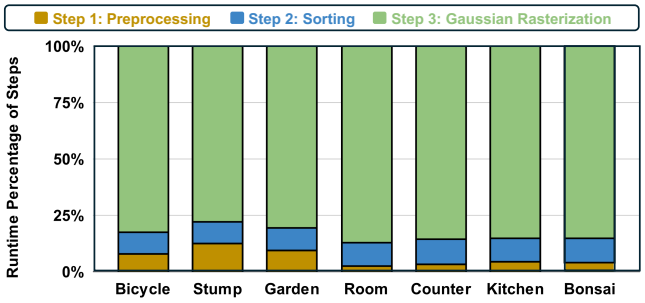

Fig. 5. Runtime breakdown of the 3DGS rendering pipeline [14] across all seven scenes from the large-scale, real-world NeRF-360 dataset [3] as measured on the NVIDIA Jetson Orin NX [22] with a power limit of 10W.

Rendering an image from a specific viewpoint using this representation (described in Fig. 3) involves three main steps:

Step 1: Preprocessing. The first stage of 3DGS rendering, depicted in Fig. 3(a), is preprocessing, which serves three purposes: projecting all 3D Gaussians onto a 2D plane according to the specified viewing position and angle, converting the color vector of each Gaussian to an RGB representation based on the viewing parameters, and computing the depth of each 3D Gaussian relative to the given viewpoint. This step transforms the 3D representation into a set of 2D Gaussians, each characterized by an opacity function o, an assigned RGB color c, a depth value d, a covariance matrix Σ representing the 2D Gaussian probability distribution, and a center point μ.

Step 2: Sorting. The second stage, as illustrated in Fig. 3(b), involves sorting the projected 2D Gaussians. Due to the potential overlap of Gaussians, each pixel may be influenced by multiple Gaussians. The rendering order impacts their visibility since Gaussians rendered earlier can obscure those rendered later. To maintain correct occlusion relationships and ensure visual consistency, the 2D Gaussians are sorted by their depth values. This depth-based sorting ensures that Gaussians nearer to the viewing position are rendered first, preserving proper occlusion handling.

Step 3: Gaussian Rasterization. The final step, Gaussian rasterization, applies the color of each Gaussian to the pixels it covers, based on opacity and Gaussian probability, and follows the depth order determined in Step 2. As shown in Fig. 3(c), for each Gaussian applied to a specific pixel, the density $\alpha_{P,i}$ is computed using the formula:

$$\alpha_{P,i} = o_i e^{-\frac{1}{2}(P-\mu_i)^T {\Sigma_i}^{-1}(P-\mu_i)}$$

where P represents the pixel coordinate, i is the index of the Gaussian, and o_i is the opacity of the Gaussian. This density reflects the contribution of the Gaussian to the pixel. Once the density $\alpha_{P,i}$ is calculated, the RGB color contribution for that pixel is accumulated as follows, as shown in Fig. 3(d):

$$\mathbb{C}_P = \sum_{i=1}^{n} T_{P,i}\alpha_{P,i}c_i$$

The term $T_{P,i} = \prod_{j=1}^{i-1}(1-\alpha_{P,j})$ represents the accumulated density of all previously applied Gaussians at the pixel, accounting for the occlusion effects from preceding Gaussians. This ensures that only visible portions of overlapping Gaussians contribute to the final rendered color in Fig. 3(e).

B. Locating the Bottleneck of 3DGS Rendering

To identify bottlenecks in rendering 3D Gaussians on edge SoCs, we conducted detailed profiling to analyze the runtime distribution across various rendering steps. Profiling was performed on the widely used 3D rendering dataset NeRF-360 [3], which includes seven real-world multi-object scenes. Kernel runtimes for the different rendering steps were measured using NVIDIA Nsight Systems [28] on the NVIDIA Jetson Orin NX [22] operating under a 10W power limit typical for edge devices [8], [41]. The average runtime for rendering all viewpoints in each scene is summarized in Fig. 4. The results indicate that the edge SoC achieves only 2-5 FPS, necessitating significant speedups before it can be used in real-world applications. The detailed runtime breakdown for each rendering step is shown in Fig. 5. Step 3, the Gaussian rasterization stage, dominates the overall runtime, accounting for over 80% of the total rendering time across all scenes, thereby representing the primary performance bottleneck.

III. Leveraging the GPU Rasterizer for 3DGS

A. Opportunities in GPU's Rasterizer

The computational demands of dominant Gaussian rasterization in the 3DGS rendering pipeline have motivated various acceleration efforts [16]. Current research primarily emphasizes the development of dedicated hardware accelerators for emerging 3D rendering pipelines such as 3DGS [16] and NeRF [10], [17]. Although these accelerators offer performance improvements, they can introduce significant trade-offs, including increased complexity in memory systems and software stacks [6] and the need for exclusive hardware resources. Unlike these dedicated approaches, our strategy focuses on enhancing existing GPU hardware to leverage the built-in capabilities of modern GPUs. This approach enhances 3DGS performance while preserving compatibility with conventional GPU operations and the original programming interface, minimizing disruptions to established workflows and fully utilizing the GPU's existing data path.

Modern GPUs have dedicated units optimized for triangle mesh rasterization [23]. This process involves iterating over

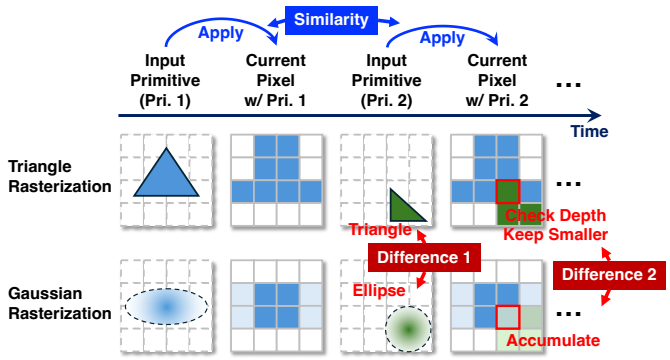

Fig. 6. Comparison of triangle and Gaussian rasterization. Both techniques sequentially apply primitives to pixels with key differences in primitive type (Difference 1) and reduction algorithm (Difference 2).

primitives (here referring to triangles) and mapping their parameters to display pixels. The pipeline is highly parallelized, relying on fixed-function accelerators for rapid computation [2], [5], [37]. Our approach begins with an investigation of the similarities and differences between Gaussian rasterization and triangle rasterization, the latter of which is efficiently supported by these optimized GPU hardware units.

B. Contrasting Gaussian and Triangle Rasterization Methods

3DGS rasterization shares key foundational elements with traditional triangle mesh rasterization. As illustrated in Fig. 6, both processes iterate over primitives—triangles in conventional rendering and Gaussians in 3DGS—and map their respective parameters onto pixels. This similarity in the basic dataflow and computation pattern provides an opportunity to adapt existing GPU rasterizers to support 3D Gaussian operations.

However, there are also differences between the two rasterization processes. First, in triangle rasterization, the algorithm involves determining if a pixel lies within a triangular boundary. In contrast, 3DGS requires calculating Gaussian probability distributions to assess the coverage. This distinction necessitates modifications to the detection function to accommodate elliptical shapes rather than triangles. Second, for triangle mesh rasterization, the reduction method relies on a minimum-depth selection to determine which primitive's parameters should be applied to each pixel, whereas 3D Gaussian Splatting aggregates color contributions from multiple overlapping Gaussians. This approach increases the complexity of the reduction function, as overlapping Gaussians contribute to pixel color based on their calculated densities and occlusion effects. Effectively addressing these differences is essential to adapting current rasterization hardware for 3DGS, ensuring compatibility and preserving performance.

C. Enhancing the Triangle Rasterizer for 3DGS

Building on our identified similarities and differences between Gaussian and triangle rasterization, we propose enhancing the existing triangle rasterizer to support 3DGS. A comparison of the resource requirements for triangle and Gaussian rasterization is summarized in Table II. As shown in the table, both rasterization processes have identical input

TABLE II
COMPUTATIONAL PRIMITIVES FOR RASTERIZATION

Subtask (Operator)	**Triangle Rasterization [33]**	**Gaussian Rasterization [14]**
Input	Vertices' Coordinates (9 FP Numbers)	Σ, o, μ, c (9 FP Numbers)
1	Coordinate Shift (ADD, MUL)	Coordinate Shift (ADD, MUL)
2	Intersection Detection (ADD, MUL, DIV)	Gaussian Probability Computation (ADD, MUL, EXP)
3	UV Weight Computation (ADD, MUL)	Color Weight Computation (ADD, MUL)
4	Min-Depth Color Hold (ADD, MUL)	Color Accumulation (ADD, MUL)
Output	UV Weight, Depth (3 FP Numbers)	Accumulated Color (3 FP Numbers)

and output parameter sizes and follow a similar procedure: initializing pixel storage and then applying primitives to each pixel. Owing to this shared I/O width and access pattern, the existing memory interface can be directly reused from the existing triangle rasterizer.

Regarding computational resources, as highlighted in Table II, both processes primarily require multipliers and adders for their core tasks. This similarity allows us to introduce a reconfigurable datapath capable of supporting both triangle and Gaussian primitives with the same hardware resources. However, each primitive type has specific resource requirements: triangle rasterization requires a divider, while Gaussian rasterization necessitates an exponentiation unit. To address these specialized needs, we propose adding dedicated hardware units for these distinct operations, enabling seamless support for both types of rasterization.

IV. PROPOSED GAURAST HARDWARE

A. Overview of the GPU architecture with GauRast

Building on the analysis in Section III-C, we present the hardware design of GauRast, an enhanced rasterizer that extends existing hardware capabilities to efficiently support 3DGS. Unlike previous approaches that rely on dedicated accelerators, GauRast utilizes the built-in GPU rasterization hardware, specifically the triangle rasterizer, to execute 3DGS rendering tasks. This approach ensures seamless integration with existing GPU workflows, maintaining compatibility with conventional rendering while introducing minimal overhead.

As shown on the left side of Fig. 7(a), the GauRast hardware builds upon the Graphics Processing Cluster (GPC) of modern GPU architectures [24], [26]. Each GPC contains multiple Streaming Multiprocessors (SMs) for general-purpose computations and specialized fixed-function units for graphics processing. Within this architecture, we implemented an enhanced rasterizer capable of handling both triangle and Gaussian rasterization, extending the functionality of the original rasterizer that only supports triangle rasterization. As shown in Fig. 7(a), our modifications are confined to the rasterizer within the GPC, leaving the SMs untouched and preserving the overall GPU structure. The enhanced rasterizer is optimized

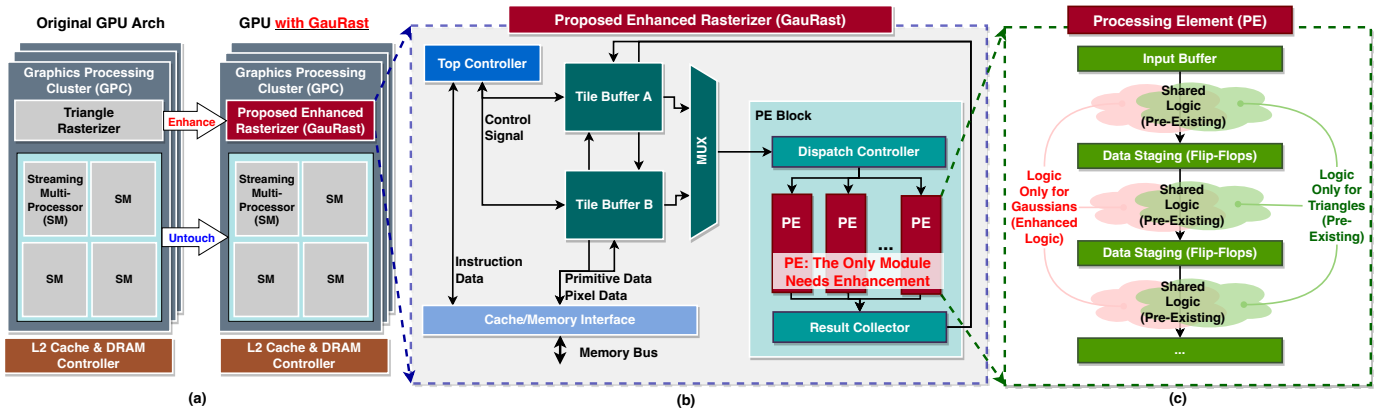

Fig. 7. Overview of the proposed hardware architecture: (a) Block diagram of the GPU's Graphics Processing Cluster (GPC) with proposed enhancements. (b) Detailed view of the enhanced rasterizer. (c) Internal structure of each PE, displaying dedicated and shared logic paths for Gaussian and triangle primitives.

to process Gaussian splatting, incorporating new logic paths alongside the existing hardware inside of each Processing Element (PE) as shown in Fig. 7(c), thus enabling seamless switching between traditional triangle rendering and Gaussian rasterization.

B. Proposed GauRast Hardware

The enhanced rasterizer consists of several key components, as shown in Fig. 7(b):

Tile Buffers (A and B). These ping-pong buffers store primitives (either Gaussians or triangles) and pixel data, enabling efficient data management during the rendering process. By alternating between Tile Buffer A and Tile Buffer B, GauRast minimizes memory latency and allows concurrent data access for both Gaussian and triangle primitives.

PE Block. The core computation of the rasterization process is handled by the PE Block, which contains multiple PEs. Each PE is tasked with computations required for either Gaussian or triangle primitives. The PE Block operates with a high degree of parallelism, leveraging the intrinsic parallel structure of the rendering task for acceleration.

Processing Element (PE). Each PE supports both Gaussian and triangle rasterization and is equipped with a combination of shared and dedicated logic units, as shown in Fig. 7(c). The shared logic handles common operations, while dedicated logic paths manage primitive-specific computations, such as evaluating Gaussian probability distributions for 3DGS rendering and performing depth division for triangle meshes. Importantly, the existing triangle rasterizer includes both shared and triangle-specific logic; thus, only Gaussian-specific logic is added. Compared to a standard triangle rasterizer, our design requires minimal additional hardware in each PE: two adders, one multiplier, and one exponentiation unit for Gaussian support, while reusing nine adders and nine multipliers from the triangle rasterizer. The PE is the only module requiring additional logic to facilitate 3DGS rendering.

The GauRast hardware optimizes performance and resource utilization by reusing existing memory interfaces, such as Tile Buffers and Controllers, and incorporates minimal additional logic for 3DGS tasks. This design ensures that the enhanced rasterizer remains compatible with the existing triangle rendering pipeline, thus minimizing hardware complexity.

C. CUDA-Collaborative Scheduling

In triangle mesh rasterization, CUDA cores and the hardware rasterizer collaborate to complete the rendering process. Specifically, non-dominant tasks such as 3D-to-2D projection and color querying are handled by the CUDA cores, while the rasterization is managed by the hardware rasterizer [23]. Similarly, we adopt a hybrid scheduling strategy to enhance efficiency, assigning non-dominant operations like preprocessing and sorting to the CUDA cores, while the enhanced rasterizer handles the dominant rasterization workload which is the primary bottleneck in 3DGS rendering.

V. Evaluation

A. Evaluation Setup

Dataset & Baselines. To evaluate the processing speedup and efficiency improvement achieved by our proposed GauRast, we conducted experiments using the widely adopted NeRF-360 dataset [3], a large-scale, real-world dataset using both the original 3DGS algorithm [14] and its latest efficiency-optimized variant [9]. For baselines, we consider both the NVIDIA Jetson Orin NX SoC [22], a representative edge GPU, and the only previously published accelerator proposal for 3DGS, GScore [16].

Hardware Implementation. We implemented a prototype of the enhanced rasterizer with 16 PEs using C++ and synthesized the design into RTL using Siemens Catapult [34]. This RTL was then synthesized, placed, and routed using Synopsys Fusion Compiler [36], targeting a 28 nm CMOS technology node (typical corner, 0.9 V, 1 GHz clock), following the methodology described in [15]. Fig. 8 shows the layout and area breakdown of the prototype. The typical power consumption of the prototype is 1.7 W as reported by Synopsys PrimePower [35] based on post-layout netlists and RTL simulation activities using randomly sampled test images from the target dataset. To ensure correct implementation, we validated the functional accuracy of both triangle and Gaussian rasterization against the software implementations, confirming that the RTL implementation's rendering output

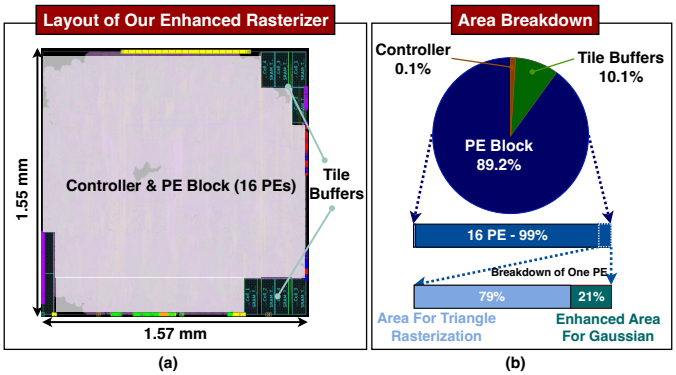

Fig. 8. Layout and area breakdown of the proposed enhanced rasterizer.

for both triangle rasterization [7] and 3DGS rendering [14] matches perfectly without any loss in rendering quality.

Simulator Setup. To match the effective area of the triangle rasterizer units in the baseline SoC [22], we scaled up our GauRast design to include 15 instances of the 16-PE rasterizer module, totaling 300 PEs. Consequently, the enhanced portion of the hardware occupies approximately 0.2% of the total area of the baseline Jetson Orin NX SoC [22]. We further developed a cycle-accurate simulator for fast evaluation of this scaled-up design. The simulator's runtime and power outputs were validated against the aforementioned RTL simulation results to ensure accuracy and reliability.

B. Comparison Against the Baseline SoC

Fig. 9 illustrates the speedup and efficiency improvements achieved by GauRast in Gaussian rasterization compared to CUDA implementations across all scenes in the benchmark dataset, for both the original algorithm [14] and its latest efficiency-optimized version [9]. The results show that our enhanced rasterizer achieves an average runtime reduction of 23× and an average energy efficiency improvement of 24× for the original algorithm. For the efficiency-optimized algorithm, it achieves a 20× runtime reduction and a 22× improvement in energy efficiency. Additionally, as shown in Fig. 10, replacing CUDA-based rasterization with our proposed enhanced rasterizer leads to substantial end-to-end performance improvements. GauRast achieves a 6× reduction in runtime for the original 3D Gaussian Splatting algorithm and a 4× reduction for the optimized algorithm, yielding average frame rates of 24 FPS and 46 FPS, respectively.

C. Comparison Against SOTA 3DGS Accelerator

SOTA work GSCore [16] on 3DGS rendering acceleration achieved a 20× speedup on an edge SoC [29] for Gaussian rasterization, utilizing a dedicated area of $3.95\,\mathrm{mm}^2$ with FP16 precision. If we re-implement GauRast to perform FP16 operations, our design achieves equivalent performance to GSCore but requires only $0.16\,\mathrm{mm}^2$ area, achieving a 24.7× improvement in area efficiency. This efficiency gain is attributed to the reuse of existing resources built in the triangle rasterizer. These results highlight the effectiveness of our enhancement approach in efficiently leveraging existing GPU components.

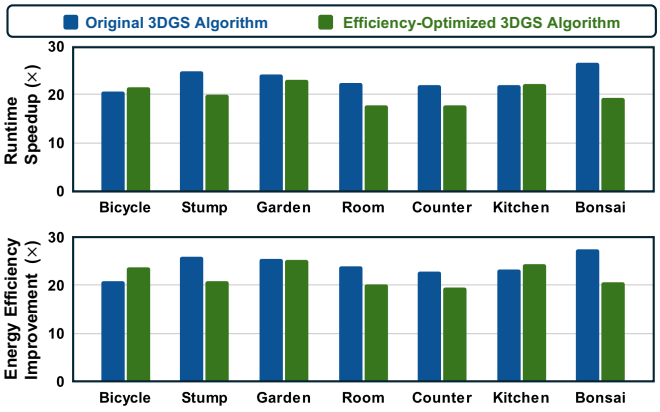

Fig. 9. Speedup and energy efficiency improvements achieved by GauRast in Gaussian rasterization, compared to CUDA implementations on the NVIDIA Jetson Orin NX [22]. Evaluations were conducted using both the original 3DGS algorithm [14] and its latest efficiency-optimized version [9], across all seven scenes of the large-scale, real-world NeRF-360 dataset [3].

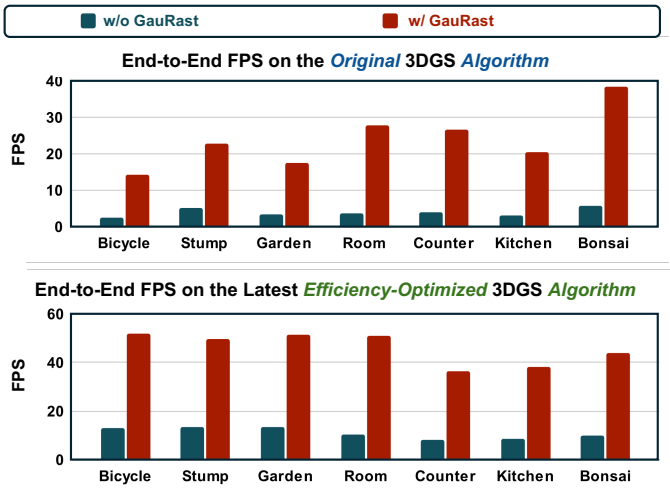

Fig. 10. End-to-end FPS comparison between the baseline SoC [22] and the baseline SoC enhanced with GauRast, using both the original 3DGS [14] and its latest efficiency-optimized version [9]. The evaluation was conducted across all seven scenes from the large-scale, real-world NeRF-360 dataset [3].

VI. Conclusion

This work presents GauRast, an enhancement for existing GPU rasterizers designed to accelerate 3DGS rendering. Experiment results show that our enhanced rasterizer achieves a 6× speedup in end-to-end runtime for the original 3DGS and a 4× speedup for the latest efficiency-optimized pipeline on the NVIDIA Jetson Orin NX, with an area overhead of only 0.2%, demonstrating a promising path forward to enable real-time 3DGS rendering on edge devices.

VII. Acknowledgment

The authors would like to thank the anonymous reviewers for their valuable questions and constructive feedback. This work is supported by an internship at NVIDIA Research, the National Science Foundation (NSF) Computing and Communication Foundations (CCF) program (Award ID: 2312758), and the Department of Health and Human Services Advanced Research Projects Agency for Health (ARPA-H) under Award Number AY1AX000003.

***Abstract*—Ensuring the confidentiality and integrity of DNN accelerators is paramount across various scenarios spanning autonomous driving, healthcare, and finance. However, current security approaches typically require extensive hardware resources, and incur significant off-chip memory access overheads. This paper introduces SeDA, which utilizes 1) a *bandwidth-aware encryption mechanism* to improve hardware resource efficiency, 2) *optimal block granularity* through intra-layer and inter-layer tiling patterns, and 3) a *multi-level integrity verification mechanism* that minimizes, or even eliminates, memory access overheads. Experimental results show that SeDA decreases performance overhead by over 12% for both server and edge neural processing units (NPUs), while ensuring robust scalability.** [1]

***Index Terms*—Memory protection, secure DNN accelerators, confidentiality and integrity, deep neural networks**

I. Introduction

Securing Deep Neural Networks (DNNs) on neural processing units (NPUs) is increasingly vital for mission-critical applications in areas such as autonomous driving [1], healthcare [2], and finance [3]. The Artificial Intelligence (AI) hardware market was valued at USD 54.10 billion in 2023 and is expected to surge to USD 474.10 billion by 2030, reflecting a remarkable CAGR of 38.73% [4]. Protecting DNN accelerators by ensuring confidentiality and integrity is crucial for several reasons: *Data Confidentiality*: The sanctity of training data is non-negotiable. Protecting training data is essential to prevent unauthorized access and exploitation of private or sensitive information. *Resource Costliness*: The substantial investment in training resources necessitates stringent security protocols. Safeguarding these resources not only ensures their optimal utilization but also protects against financial losses and inefficiencies. *Vulnerability to Malicious Attacks*: Malicious intent poses a significant threat to DNN models. Protecting these models from potential tampering and attacks is critical to maintaining their integrity and functionality, safeguarding against adverse outcomes and ensuring the reliability of AI systems.

To protect traditional DNN accelerators from model theft and malicious tampering, as illustrated in Fig. 1(a) and Fig. 1(b), broad approaches [5]–[11] have been proposed to secure these accelerators, with the primary aim of minimizing off-chip memory access overhead for security metadata. They typically use the counter-mode encryption of Advanced Encryption Standard (AES-CTR) for confidentiality and the message authentication code (MAC) for integrity verification, as shown in Fig. 1(c). The counter value in AES-CTR concatenates the physical address (PA) and a ⓐ version number (VN) of a data block, with the VN stored off-chip and incremented with each write. To ensure the integrity of off-chip memory data, each data block is accompanied by a ⓑ message authentication code (MAC). Additionally, a ⓒ Merkle Tree (MT) [12] and its variants are often utilized, with the root stored on-chip to prevent replay attacks.

[1]SeDA source code: https://github.com/wayne4s/seda.git

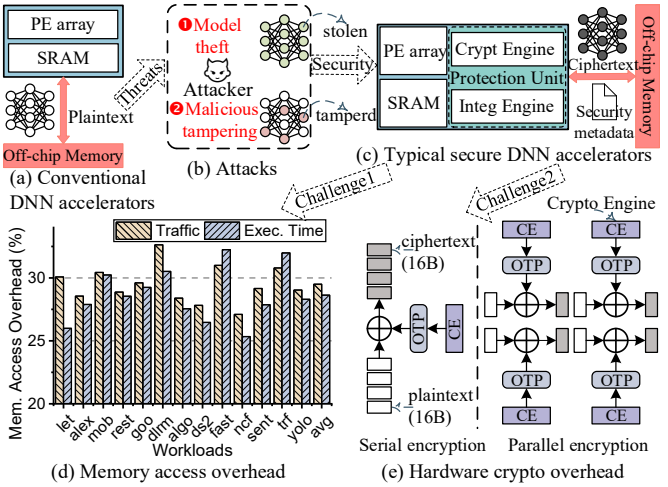

Fig. 1. Insight of typical secure accelerators. (a) Traditional DNN accelerators use untrusted off-chip memory and communication buses, risking model theft and malicious tampering, as shown in (b). (c) Secure DNN accelerators typically protect data confidentiality and integrity with memory protection schemes using AES encryption and Hash function. (d) Accessing security metadata in off-chip memory adds overhead. (e) Parallel hardware encryption incurs overhead to meet bandwidth needs of accelerators.

Motivation ❶ ▶ *Costly Off-Chip Memory Access Overhead for Integrity Verification*. Accessing security metadata (e.g., ⓐⓑⓒ) to ensure the confidentiality and integrity of untrusted off-chip memory significantly increases memory access overhead, as shown in Fig. 1(d). Existing approaches propose several optimizations: using Bonsai Merkle Tree (BMT) [13] instead of traditional MT for smaller version numbers (VNs); employing coarser-grained protection units, such as 512B data blocks instead of 64B cachelines; and dynamically updating VNs based on DNN model state information to eliminate off-chip memory access [8], [9]. Securator [11] uses a layer-level MAC to reduce off-chip memory access for integrity checks. However, it overlooks the overlap of intra-layer tiles and distinct tiling patterns across layers, potentially leading to redundant encryption/decryption and integrity verification overhead. Moreover, not considering inter-layer tiling pattern differences may result in false negatives.

Motivation ❷ ▶ *High Hardware Overhead for Confidentiality Protection*. Due to the AES Engine's limitation of en/decrypting

only a 128-bit data block at one time, typical solutions to meet the high bandwidth demands of DNN accelerators involve increasing the number of AES Engines. For example, Securator [11] uses four AES engines to en/decrypt a 64B data block, as shown in Fig. 2(c). However, this approach adds strain on resource-limited accelerators, requiring a careful balance between hardware resource allocation and security performance. As illustrated in Fig. 1(e), a single Crypto Engine can only perform serial encryption, failing to meet the high bandwidth demands of DNN accelerators, while multiple AES engines can satisfy these demands but result in significant hardware encryption overhead.

In this paper, we introduce SeDA, a novel secure and efficient DNN accelerator architecture with reduced hardware resource consumption and near-zero performance overhead for integrity verification, while maintaining the same level of security and practical applicability. This paper makes the following major contributions:

- **Insight.** Providing an in-depth insight of limitations of current memory protection strategies for DNN accelerators highlights two critical concerns: the substantial *hardware overhead for encryption* and the expensive *off-chip memory access for integrity verification*.
- **Solution.** Through hardware/software synergy, we present SeDA, a secure and efficient accelerator architecture. It incorporates a *bandwidth-aware encryption mechanism* that utilizes a single AES engine with adjustable encryption granularity, minimizing hardware resource overhead. Furthermore, its *multi-level integrity verification mechanism* significantly reduces or eliminates off-chip memory access overhead.
- **Evaluation.** Conducting extensive experiments using cycle-accurate simulators for DNN accelerators, memory protection schemes, and off-chip memory accesses. Experimental results of SeDA demonstrate a performance improvement, reducing overhead by 12.26% for server NPU and 12.29% for edge NPU, while also providing robust scalability with minimal hardware overhead to meet the bandwidth demands of accelerators.

This paper is structured as follows: Section II reviews related work on memory protection and the threat model for our study. In Section III, we provide a detailed introduction to the proposed SeDA architecture. We then conduct extensive experiments on various DNN models in Section IV. Finally, Section V concludes our work.

II. Related Work and Threat Model

Based on the corresponding threat model, secure DNN accelerators typically provides robust confidentiality and integrity guarantees in untrusted environments.

A. Confidentiality Protection

Confidentiality protection typically uses AES-CTR mode due to several advantages: 1) it utilizes the same AES engine for en/decryption, reducing hardware overhead (see Fig. 2(a)); 2) One time pad (OTP) generation can be parallelized with communication and DNN computation, minimizing time overhead; and 3) its block-based streaming mode does not require prior knowledge of data size and scale. The AES-CTR encryption requires a non-repeating and incrementing counter to produce a OTP for each encryption/decryption under the same key. The counter concatenates the physical address of a data block that will be encrypted and version number that is incremented on each write memory operation. Here, let $K_e, \mathcal{P}, \mathcal{C}$ be the AES encryption key, plaintext, ciphertext, respectively. The AES-CTR mode for encryption and decryption can be formulated as following Eq. 1 and Eq. 2, where $AES\text{-}CTR_{K_e}(PA||VN)$ produces

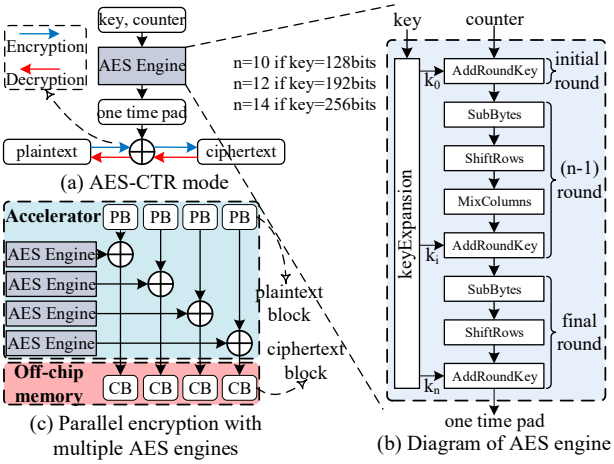

Fig. 2. Summary of AES-CTR mode. (a) Reusing AES engine for encryption and decryption in AES-CTR mode. (b) Diagram of the AES engine, featuring the AddRoundKey, SubBytes, ShiftRows, MixColumns, and keyExpansion modules. (c) Utilization of multiple AES engines for parallel encryption to boost high-bandwidth capabilities.

a OTP, $||$ and $\oplus$ represents a bit-wise concatenation and XOR operator, respectively.

$$\mathcal{C} = \mathcal{P} \oplus AES\text{-}CTR_{K_e}(PA \,||\, VN) \quad (1)$$

$$\mathcal{P} = \mathcal{C} \oplus AES\text{-}CTR_{K_e}(PA \,||\, VN) \quad (2)$$

When an accelerator reads a data block from off-chip memory, the protection module uses the VN to generate an OTP and decrypts the block by XORing it with the OTP (red path in Fig. 2(a), Eq. 2). Similarly, when writing a data block to off-chip memory, the module increments the VN to generate an OTP and encrypts the block by XORing it with the OTP (blue path in Fig. 2(a), Eq. 1). Fig. 2(b) illustrates the diagram of the AES engine along with its key functional modules.

B. Integrity Verification

To ensure data integrity against off-chip memory tampering, an integrity verification engine computes a message authentication code (MAC) by concatenating a data block with its physical address and version number. This MAC is generated during every write operation and verified during reads to ensure data authenticity. Relying solely on MAC for a data block fails to guarantee freshness and opens the door to replay attacks. To counter this threat, prior works utilize an Integrity Tree for hierarchical MAC verification, such as MT [12] and Bonsai Merkle Tree (BMT) [13], with the root stored on-chip to prevent malicious tampering. The overhead of integrity verification is non-trivial since it requires traversing both MACs and the nodes of the Integrity Tree stored in the off-chip memory to prevent the replay attack.

C. Secure DNN Accelerators

Intel SGX [5] creates a secure enclave using CPU hardware mechanisms, using AES-CTR mode and MT with its root in the Trusted Computing Base (TCB). SEAL [6] introduces a criticality-aware smart encryption scheme that selectively bypasses the encryption engine for partial data and colocates data with corresponding counters. GuardNN [7] proposes a secure accelerator architecture by using small TCB and low overhead for privacy-preserving deep learning. MGX [8] introduces a secure DNN accelerator with application-specific version number management, utilizing on-chip status for version number

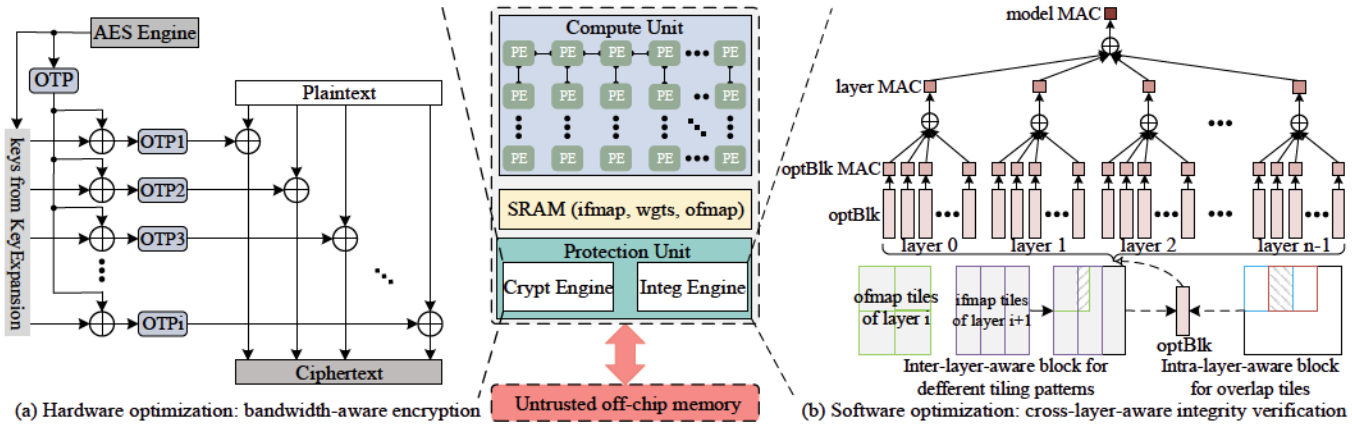

Fig. 3. Overview of SeDA architecture. (a) The Crypt Engine optimizes hardware by XORing keys from the AES Engine's KeyExpansion module with OPT, creating bandwidth-sensitive encryption granularity and reducing hardware overhead compared to using multiple AES Engines. (b) The Integ Engine optimizes software by analyzing overlapping tiles within a layer and patterns across layers to determine the optimal block size, optBlk, for integrity verification. This leads to a multi-level integrity verification mechanism with optBlk MAC, layer MAC, and model MAC.

generation and coarse-grained integrity verification to reduce off-chip memory overhead. In a similar vein, TNPU [9] generates all version numbers within an on-chip cache. Securator [11] introduces a layer-level integrity checks by XORing all message authentication codes (MACs) within a layer.

D. Threat Model

Similar to the threat model proposed in literature [8], [9], we assume that the accelerator itself is secure, meaning that its internal state cannot be directly observed or tampered with. Any external device connected to the accelerator is considered untrusted, such as off-chip memory and communication buses, meaning that attackers could potentially access or manipulate any information stored in these devices through physical or software attacks. Notably, we do not consider other physical side-channel attacks to infer DNN model architectures [14], such as power channel attacks and electromagnetic attacks. Additionally, adversarial attacks [15] against machine learning algorithms are also not within scope to ensure that decryption is restricted to authorized users possessing the key.

III. SeDA Architecture

This section initially provides an overview of SeDA. We then subsequently explores the scalability challenges of cryptographic hardware and the expensive off-chip memory access overhead in integrity verification, providing corresponding solutions for each.

A. Overview

SeDA provides a secure and efficient environment for DNN accelerators by hardware/software co-optimization. The overview architecture of the framework is presented in Fig. 3. The AES Engine's limitation to encrypting only a 128-bit data block at one time poses a challenge in meeting the high bandwidth demands of DNN accelerators. SeDA addresses these issues by utilizing bandwidth-aware encryption mechanism to optimize hardware resources impacted by security concerns, as illustrated in Fig. 3(a). Additionally, the inclusion of security metadata by secure DNN accelerators results in storage and access overheads in off-chip memory. For example, using an 8B MAC to represent a 64B data block alone leads to a 12.5% increase in memory traffic. To mitigate this, SeDA introduces a multi-level integrity verification software optimization mechanism, showcased in Fig. 3(b). Furthermore, securely housing these limited MACs directly in on-chip SRAM can eliminate off-chip memory access overheads entirely.

Algorithm 1: Attack and defense of SECA

```
Attack of SECA
Input  : OTP: one time pad for a data block (blk);
         most_value_p: most used plaintext in blk.
Output : value_p: all plaintext of blk
most_value_c ← CalcFreqValue(blk)
OTP ← most_value_p ⊕ most_value_c
for each encrypted element value_c of blk do
    value_p ← value_c ⊕ OTP

Defense of SECA
Input  : PA, VN: physical address and version number of blk.
Output : OTP_i: generate multiple OTPs for blk
OTP ← AES-CTR_{K_e}(PA ‖ VN)
for each 128-bit key_i in keyExpansion of AES-CTR do
    OTP_i ← (OTP ⊕ key_i)
```

B. Bandwidth-aware encryption mechanism

To meet the high bandwidth demands of accelerators, increasing the number of AES engines incurs significant overhead, while using the same OTP for all data in a block introduces security risks.This dilemma often leads to a suboptimal trade-off between security and computational efficiency.

Challenge 1: High Hardware Resources for Confidentiality Protection. While maintaining an equivalent level of security, numerous approaches have bolstered encryption parallelism by stacking multiple AES engines. For example, Securator [11] uses four AES-128 engines to concurrently encrypt a 64B data block, as shown in Fig. 2(c). Nevertheless, the drawback of sacrificing hardware resources to achieve performance improvements in encryption and decryption is apparent, particularly for edge DNN accelerators constrained by limited hardware capabilities. This situation emphasizes the crucial equilibrium needed to optimize security and operational efficiency in these systems.

Challenge 2: Security Threat for Shared OTP. A straightforward approach is to use each engine once per data block, with each 128-bit

segment within this data block sharing the same OTP. Nevertheless, assigning a OTP to a individual data block poses security risks and could be vulnerable to a Single-Element Collision Attack (**SECA**). The principle of a SECA attack when a data block shares the same OTP is outlined in lines 1-4 of Algorithm 1. By employing the CALCFREQVALUE function, we can identify the most frequently encrypted data within the block, denoted as $most_value_c$. Through comprehensive data analysis, we can infer the most common plaintext data within the block, denoted as $most_value_p$ (e.g., 0). Referring to the AES-CTR encryption formula Eq. 1, we can calculate the OTP for that block as $most_value_c \oplus most_value_p$, as shown in line 2 of Algorithm 1. Since the block shares this OTP, once obtained, we can derive all plaintext values within the encrypted block, as shown in lines 3-4 of Algorithm 1. Extending this principle further, we can extract the data values from every DNN layer and even the entire model.

Solution. We introduce a novel bandwidth-aware encryption mechanism to meet the high bandwidth requirements of accelerators without compromising the security of encryption. This method leverages the inherent features of AES-CTR encryption mode, using just a single AES engine and a minimal number of XOR logic gates, as illustrated in Fig. 3(a). To defend against SECA attacks, we first employ a standard AES-CTR encryption engine to create a shared OTP for a data block, as shown in line 5 of Algorithm 1. Subsequently, utilizing the keys array produced by the keyExpansion module within the AES-CTR encryption engine, we can generate multiple distinct OTPs by XORing the OTP with keys, as shown in lines 6-7 of Algorithm 1. This ensures that each 128-bit data segment within the data block corresponds to a unique OTP, thereby thwarting SECA attacks to safeguard security. Moreover, this mechanism significantly conserves hardware resources by utilizing a small number of XOR logic gates instead of an equivalent number of AES engines, commonly used by traditional methods.

When it comes to securing the entire DNN model, using a single key in the AES-CTR keyExpansion process is typically sufficient to ensure security. We proceed with the assumption that multiple keys are generated through the keyExpansion module using just one key. The keys produced by key expansion are inherently secure. These keys can be stored on-chip or generated in real-time. By XORing the shared OTP from a data block with these different keys, new secure OTPs can be generated. When generating OTPs from multiple keys derived from a single key input for keyExpansion doesn't meet the accelerator's bandwidth requirements, expanding the key expansion input to $key \oplus$ (PA ‖ VN) can solve the issue. This approach produces enough OTPs for a data block, meeting both security and bandwidth needs simultaneously.

C. Multi-level integrity verification mechanism

The granularity of integrity verification, whether too large or too small, can be problematic. Small granularity increases security metadata and off-chip memory overhead, affecting performance. Larger granularity reduces metadata overhead but can lead to redundant processing due to tiling overlaps. SeDA addresses this with a multi-level integrity verification mechanism that combines the flexibility of fine granularity, which avoids redundant security computations, with near-zero overhead of coarse granularity, significantly reducing or eliminating off-chip memory access overhead.

Challenge 1: Expensive Off-Chip Memory Access for Integrity Checks. While recent research efforts [8], [9] have successfully eliminated the off-chip memory access overhead of VNs and Merkle Trees, the overhead introduced by MACs still remains to be adequately addressed. Securator [11] proposed a layer-level freshness and integrity check method to reduce the MACs overhead by XORing MACs of all blocks within a layer, with a block size granularity of 32 bytes. The approach didn't consider tile overlaps within a layer, causing redundant computations like repeated integrity checks, which adds costs. Securator also ignored different tiling patterns between layers. Fig. 3(b) shows that $ofmap$ in layer i and $ifmap$ in layer i+1 use different strategies, which can vary in size and direction. Not addressing inter-layer tiling properly can lead to extra costs or disrupt the model due to inaccurate integrity checks.

Challenge 2: Security Threat for XOR-MAC Scheme. The XOR-MAC scheme offers parallelizability, incrementality, and provable security, with its security being on par with that of chaining MAC [16]. However, XORing all MACs generated by directly hashing the ciphertext within a layer to produce a unique layer MAC could lead to a Re-Permutation Attack (RePA), as illustrated in lines 1-6 of Algorithm 2. SHUFFLEORDER rearranges the order of data blocks in the current layer and computes SUM_MAC_shuffle for that layer using XOR operations. Because XOR is commutative, meaning the order of operands doesn't affect the result, an attacker can successfully pass the VERIFYINTEG(SUM_MAC, SUM_MAC_shuffle) verification. This rearrangement of data blocks within a layer can hinder correct decryption of ciphertext, posing a security risk due to RePA vulnerability.

Solution. To reduce off-chip memory access overhead from integrity verification, we propose a secure multi-level mechanism. It combines block-level and layer-level checks to minimize memory access by leveraging deterministic memory access patterns of DNNs, while ensuring security. We use the scheduling search strategy proposed in the SecureLoop [10] to obtain the optimal authentication block

Algorithm 2: Attack and defense of RePA

```
Attack of RePA
Input  : MAC_i: the MAC of a data block in one layer.
Output : plaintext_e: error plaintext.
1 SUM_MAC ← ⊕_{i=1}^{n} MAC_i
2 SHUFFLEORDER(MACs)
3 SUM_MAC_shuffle ← ⊕_{i=1}^{n} MAC_i'
4 if True = VERIFYINTEG(SUM_MAC, SUM_MAC_suffle) then
5     for each encrypted data block blk of one layer do
6         plaintext_e ← DECRYPT(blk)

Defense of RePA
Input  : layer_id, fmap_idx, blk_idx: layer number, feature
         map index and block index of layer_id.
Output : Secure layer MAC.
7 for each encrypted data block blk of layer_id do
8     MAC_i ← HASH_{K_h}(blk ‖ PA ‖ VN ‖ layer_id ‖ fmap_idx
        ‖ blk_idx)
```

TABLE I
COMPARISON OF MULTI-LEVEL INTEGRITY VERIFICATION GRANULARITY.

Granularity	Flexibility	Off-chip Access Overhead	Storage
optBlk	●	◔	Off-chip
layer	●	◔	Off/On-chip
model	●	○	On-chip

*Note: Color depth shows intensity, while coverage area indicates ratio.

TABLE II
DNN SIMULATION CONFIGURATIONS [20], [21].

Metrics	Server (Google TPU v1)	Edge (Samsung Exynos 990)
PE	256 x 256 in systolic array	32 x 32 in systolic array
Bandwidth	20 GB/s with 4 channels	10 GB/s with 4 channels
Frequency	1 GHz	2.75 GHz
SRAM	24 MB	480 KB
Presision	1-B for per element	1-B for per element

(optBlk), which synergizes with our work orthogonally. We propose a novel multi-level integrity verification mechanism involving three granularities of MAC types: optBlk MAC, layer MAC, and model MAC, as shown in Fig. 3(b). Table I compares their features in detail. The optBlk MAC offers flexibility by accounting for intra-layer tiling overlap and diverse inter-layer tiling patterns, avoiding redundant computations from repeated integrity checks. By XORing all optBlk MACs within a layer to create the layer MAC, we achieve a significant reduction in the number of MACs needed for DNN model integrity verification, despite a slight delay due to layer-specific checks. This allows layer MACs to be stored in on-chip SRAM, eliminating off-chip memory access costs. The Model MAC uses a single MAC to represent the entire model weights on-chip, further reducing off-chip memory costs and conserving on-chip SRAM, with verification results available only at the end of model inference. To prevent RePA attacks, we associate each encrypted optBlk data block with specific location details like PA, VN, $layer_{id}$, $fmap_{idx}$, and blk_{idx}. We then compute the corresponding MAC using hashing, as detailed in lines 7-8 of Algorithm 2. In summary, our multi-level integrity verification mechanism can remove off-chip memory overhead from security metadata, ensuring security while maintaining integrity guarantee.

IV. EVALUATION

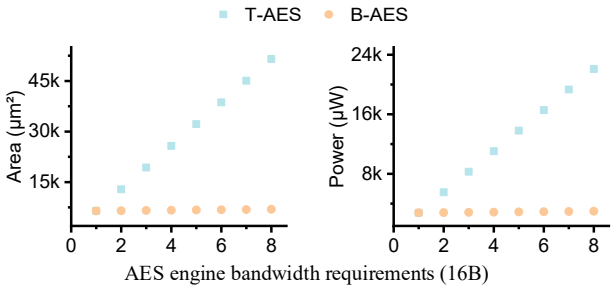
A. Experimental Setup

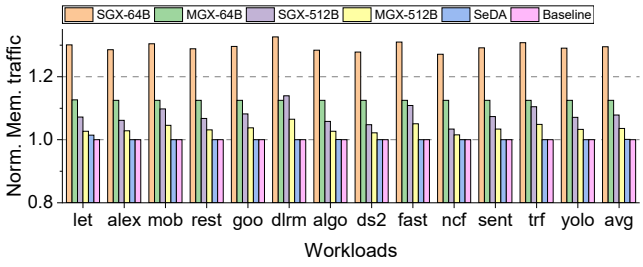
Accelerators. In order evaluate DNN inference behaviours, we use an open-source cycle-level DNN simulator SCALE-Sim2 [17], [18] developed by ARM Research to 1) study the inference execution for various DNN models; 2) analyse the performance overhead of different memory protection schemes. The DNN accelerator can generate detailed computation information of systolic array, and DRAM access traces. After obtaining the DRAM traces, we use various memory protection mechanisms to calculate execution time and bandwidth usage, producing the total DRAM traces after running the security simulator. Finally, we use the DRAM simulator Ramulator2 [19] to simulate the total DRAM access traces.

Configurations. Table II presents the DNN simulation configurations, featuring a server NPU (Google TPU v1) and an edge NPU (Samsung Exynos 990). To balance DNN computation and memory bandwidth, we simulate four 64-bit DDR channels for both the server and edge NPUs.

Benchmarks. For DNN accelerators, we evaluate SeDA across various DNN models, including Lenet (let), Alexnet (alex), Mobilenet (mob), ResNet18 (rest), GoogleNet (goo), DLRM (dlrm), AlphaGoZero (algo), DeepSpeech2 (ds2), FasterRCNN (fast), NCF_recommendation (ncf), Sentimental_seqCNN (sent), Transformer_fwd (trf), Yolo_tiny (yolo). These models are selected from diverse machine learning domains, such as computer vision, speech recognition, natural language processing, gaming, and personalized recommendation.

Memory Protection Simulation. We implemented accelerators based on Intel SGX, MGX, and SeDA security mechanisms, using an unprotected accelerator as a benchmark, and set the size of protected memory to 16GB. SGX uses a multi-level Integrity Tree with 56-bit VNs and 64-bit MACs, along with a 16KB VN cache and 8KB MAC cache, both using an LRU replacement policy for write-back and write-allocate strategies. We use two different protection granularities: 64B and 512B. To ensure fairness, SeDA stores layer MACs off-chip.





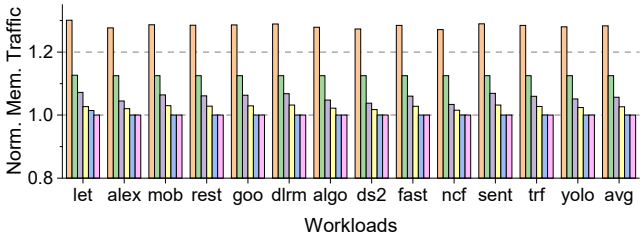


Fig. 4. The area and power with increasing AES engine bandwidth requirements.

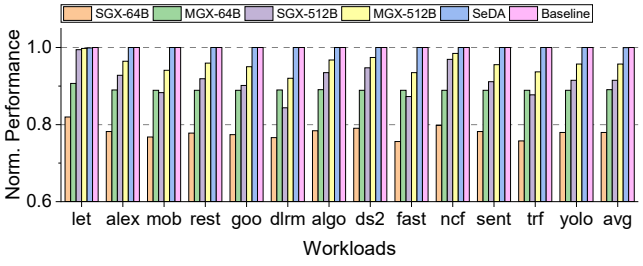
(a) Server NPU

(b) Edge NPU

Fig. 5. The normalized memory traffic of memory protection schemes for various workloads

B. Experimental Results

We compare the memory traffic, which refers to the data exchanged between off-chip memory and accelerators, and performance across a unprotected baseline and five protection schemes: SGX-64B, SGX-512B, MGX-64B, MGX-512B, and our proposed SeDA, as shown in Table III. All results are normalized to the baseline without protection.



Area and Power. We developed a simulator based on 28nm technology to evaluate area and power, utilizing the AES engine implementations detailed in [22]. We refer to the bandwidth-aware encryption mechanism as B-AES, and other traditional methods using multiple AES engines as T-AES. Through simulation, we assessed the changes in area and power. The x-axis represents the bandwidth required by the encryption engine to match the accelerator's bandwidth needs, expressed as multiples of the bandwidth provided by a single AES engine. As shown in Fig. 4, our proposed B-AES demonstrates strong scalability, with minimal increases in area and power consumption as the accelerator bandwidth increases.

Memory traffic. Fig. 5 compares the memory traffic overhead using the DNN simulation configurations listed in Table II. On average,

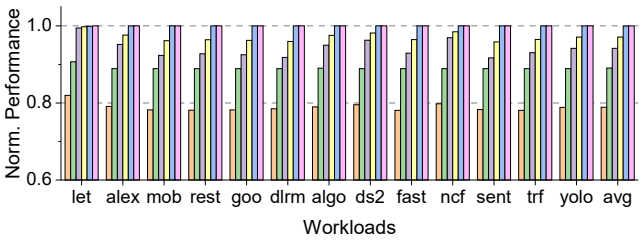


TABLE III
COMPARISON OF MEMORY PROTECTION SCHEMES.

Protection Scheme	Encryption Granularity	Integrity Granularity	Off-chip Memory Access	DNN Tiling Pattern	Encryption Scalability
SGX-64B	16B	64B	MAC,VN,IT	✗	✗
SGX-512B	16B	512B	MAC,VN,IT	✗	✗
MGX-64B	16B	64B	MAC	✗	✗
MGX-512B	16B	512B	MAC	✗	✗
SeDA	bandwidth-aware	multi-level	minimal to no cost	✓	✓

*Note: "IT" signifies integrity tree.

(a) Server NPU

(b) Edge NPU

Fig. 6. The normalized performance of memory protection schemes for various workloads

SGX-64B increases memory traffic by 30% for Server NPU and 28.29% for Edge NPU. In contrast, MGX-64B, without the overhead from additional VNs and MT, increases traffic by only 12.51% and 12.63%, respectively. Increasing the protection granularity from 64B to 512B significantly reduces memory traffic. SGX-512B cuts traffic by 7.83% on Server NPU and 5.13% on Edge NPU. MGX-512B achieves reductions of 3.59% and 2.39% on these devices, respectively. Expanding the protection granularity to 512 bytes reduces memory traffic by minimizing security metadata. However, using larger data blocks can lead to inefficiencies due to misalignment with intra-layer tiling overlaps and varying inter-layer tiling patterns. This mismatch can hinder memory access and resource utilization, emphasizing the need for a balanced approach in selecting granularity to improve system performance and efficiency. Our proposed SeDA uses a multi-level integrity verification mechanism by XORing all optBlk MACs into a layer MAC. Fig. 5 shows that SeDA introduces near-zero memory traffic, with an overhead of only 0.12% for Server NPU and 0.03% for Edge NPU, highlighting the superiority of our proposed protection mechanism.

Performance. Fig. 6(a) presents a performance comparison analysis among the baseline and five memory protection mechanisms on Server NPU. SGX-64B is 22.04% slower, MGX-64B is 10.93% slower, SGX-512B is 8.49% slower, and MGX-512B is 4.28% slower than the unprotected baseline. In contrast, our proposed SeDA impacts performance by less than 1%, making it nearly negligible. This is primarily attributed to proposed multi-level integrity verification mechanism, which can reduce or even completely eliminate the performance overhead of off-chip memory accesses caused by integrity verification. By minimizing the storage and retrieval of MACs in off-chip memory, SeDA effectively manages the security metadata overhead from integrity verification. Additionally, by storing these small layer or model MACs directly in on-chip SRAM, we can remove the performance overhead associated with off-chip access for integrity verification. For Edge NPU, Fig. 6(b) presents similar findings. Compared to the baseline, SGX-64B, MGX-64B, SGX-512B, and MGX-512B slow down by 21.10%, 10.95%, 5.84%, and 2.90%, respectively. Remarkably, our proposed SeDA results in an almost imperceptible performance drop.

V. CONCLUSION

In this work, we introduce SeDA, a secure and efficient DNN accelerator architecture designed to ensure confidentiality and integrity in untrusted environments. Using bandwidth-aware encryption and multi-level integrity verification mechanisms, SeDA provides excellent scalability with minimal overhead to match computational bandwidth of accelerators, and significantly reduces or even eliminates off-chip memory access overhead. Experimental results show that proposed SeDA meets bandwidth requirements with near-zero hardware overhead, and significantly reduces the performance overhead compared to the state-of-the-art approaches.

***Abstract*—Compute eXpress Link (CXL) offers an effective interface for connecting CPUs with external computing and memory devices. CXL Memory eXpander Controller (CXL-MXC) is gaining attention for its ability to boost memory capacity and bandwidth more efficiently than traditional DDR DIMMs. Despite extensive research on MXC performance and adaptation, DRAM reliability in CXL architecture remains underexplored. Traditional fault tolerance mechanisms like replica or RAID-based systems would significantly increase bandwidth overhead in the CXL fabric, adversely affecting system performance. To address this, we propose the on-CXL-Memory-Expander-Controller ECC (CXL-ECC), by using Locally Recoverable Codes (LRC) as the Inter-Channel-ECC (IC-ECC) and offloading its process to the expander, we eliminate extra memory access requests in the CXL fabric. Consequently, we conduct several experiments to demonstrate that our approach enhances DRAM reliability by more than 10^9, compared to state-of-the-art ECC methods. Relative to RAID-enabled CXL switch, it reduces additional bandwidth overhead from 63.5% to 3.4% and improves system performance by 12%.**

***Index Terms*—DRAM Reliability, ECC, Compute eXpress Link**

I. Introduction

Memory failures are the primary factor affecting server reliability, with over 37% of hardware faults caused by memory errors [1]. To mitigate memory errors, Error Correcting Code (ECC) [2–4] is commonly implemented in the traditional DDR memory devices. Specifically, Rank-Level ECC (R-ECC) and On-Die ECC (OD-ECC) [5] encodes data and stores error correction bits in parity DRAM chips and redundancy on DRAM chips. However, merely increasing redundancy within a DRAM device to improve reliability is insufficient. Therefore, researchers have proposed various solutions, such as Memory Mirror [6], RAIM-3 [7], and RAIM-5 [8], which implement Channel-Level Fault Tolerance (Channelkill) by using replicas or RAID [9] across memory channels. Given that these methods are integrated within memory controllers of computing devices, we categorize them as Compute Managed Type (C-Type).

In recent years, Compute eXpress Link (CXL) [10] has been proposed as an emerging open industry standard interconnect technology, inherits high-bandwidth characteristics of the PCIe protocol and provides additional cache and memory semantics, significantly reducing interface latency. This makes CXL an ideal choice for connecting CPUs and heterogeneous computing and memory devices, and it is applied in the latest storage devices, including CXL Dynamic Random Access Memory (DRAM), Solid State Drive (SSD) or Hybrid [11], and CXL Persistent Memory (PM) [12]. Extensive research has addressed CXL memory prototype devices performance, focusing on operating system adaptation and memory-intensive application optimization [13–15].

TABLE I: Comparison of Channelkill technology applied in CXL architectures

	RAIM-5	Switch-RAID	CXL-ECC
HW Modification	LLC and IMC	CXL Switch	CXL MXC
Bandwidth overhead	Medium	High	None ☺
Compatibility	Low	High	High ☺
System Overhead	Low	High	Low ☺
IC-ECC Code	XOR	XOR	LRC ☺
DRAM Reliability	Low	Low	High ☺

CXL may bring new opportunities for memory reliability improvement. To facilitate Channelkill implementation within the emerging interconnect, some researchers have suggested Switch Managed Type (S-Type) mechanism, where the switch maintains RAID management [16]. However, when applied to the CXL architecture, both C-Type and S-Type still have two major drawbacks: ❶ Parity update introduces a substantial addition of memory requests across the CXL fabric, resulting in significant degradation of system performance. ❷ XOR-based Inter-Channel-ECC (IC-ECC) exhibits poor capability of error correction in addressing multiple random faults.

To enhance high memory reliability and optimal system performance simultaneously, we propose an efficient on-CXL-Memory-eXpander-Controller ECC (CXL-ECC) approach in this paper. ❶ This method confines the parity update related memory requests within the MXC, thus reducing external memory bandwidth usage and improving system efficiency. ❷ It innovatively implements Locally Recoverable Codes (LRC) [17] as the IC-ECC within the CXL MXC for fault tolerance in extensive fine-grained faults while maintaining Channelkill. Table I compares RAIM-5 (SOTA Type-C), Switch-RAID (SOTA Type-S) and CXL-ECC across the compatibility, system performance and reliability. We also employ the Multi-Logic Device (MLD) mechanism from CXL 2.0 [10], enabling the Fabric Manager to allocate protected regions in a granularity of Logic Device for selective protection.

We have the following contributions in this paper,

- We propose an IC-ECC-enabled CXL Memory eXpander Controller with selective protection. It eliminates the bandwidth consumption of parity updates in the CXL fabric by offloading IC-ECC processing logic to CXL MXC.
- We propose a LRC-based IC-ECC, which enhances the fault tolerance of Channelkill while ensuring the tolerance of numerous random faults. Furthermore, our study conducts the first comprehensive reliability analysis of LRC in the

context of DRAM ECC.

- We evaluated our design using the Champsim [18] and Ramulator2 [19] simulators across various workloads. Our proposed CXL-ECC outperforms state-of-the-art methods, achieving a 60% reduction in bandwidth consumption on average and enhancing DRAM reliability by more than 10^9, with negligible system performance cost.

II. Background and Motivation

A. CXL Memory eXpander Controller

Compute Express Link (CXL) [10] is a cutting-edge interconnect protocol designed to optimize communication between processors and various devices, such as accelerators and memory expander. Leveraging the physical layer of PCIe 5.0/6.0, CXL facilitates high bandwidth while enabling low-latency, coherent memory access. CXL Memory eXpander Controller (MXC), classified as Type-3 devices, implements `CXL.io` and `CXL.mem` protocols to deliver high-performance memory expansion and enable hardware memory pooling. Leading memory manufacturers including Samsung, SK Hynix, and Micron have released CXL MXC products. Marvell also supplies MXC chips [20]. Additionally, internet companies are actively testing MXC performance and modifying systems [13, 21], to support this emerging technology.

B. DIMM Organization and DRAM Faults

1) ***Dual-Inline-Memory-Module (DIMM) Organization****:* DRAM chips have multiple data pins (DQs) that transmit data in parallel, and a chip with N DQs is generally referred to as an xN chip. The DDR5 JEDEC [5] DIMM is equipped with two independent 32-bit sub-channels. In x4 ECC-DIMM, as shown in Fig. 1, each sub-channel is equipped with 10 x4 DRAM chips, where 2 parity chips are used to store the check data of Rank-Level ECC (R-ECC). The internal structure of DRAM chip follows a hierarchical organization, where each consists of multiple independent banks, and each bank can be further divided into rows and columns. DDR5 implements On-Die ECC (OD-ECC), utilizing a (136,128) SEC code for data protection within bank.

2) ***DRAM Faults****:* Currently, there are two major types of faults in DRAM devices: **(i) Operational Faults** are caused by manufacturing defects and wear-out during usage, and can manifest as cell, row, column, or bank-level faults at a coarser granularity [22]. **(ii) Scaling Faults** appear in the form of random cell faults. As DRAM manufacturing technology scales down, the scaling fault rate increases, reaching as high as 10^{-4} when the process is scaled down to sub-20nm [23]. Each fault introduces random errors, varying from a single bit to 2 symbols in an ECC codeword, and poses significant challenges to the design of high-reliability memory architectures.

C. Error Correcting Code in DRAM

Error Correcting Code (ECC) detects and corrects errors through the addition of redundant information, known as parity, which is algorithmically generated from the protected data. The combination of data and parity forms an ECC codeword.

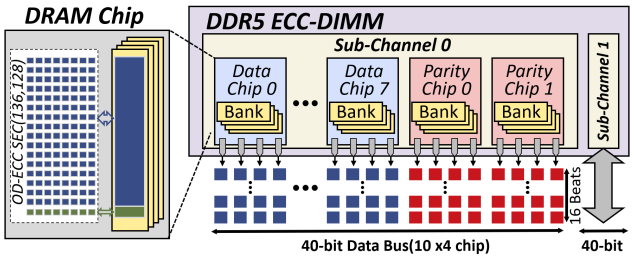

Fig. 1: Organization of x4 DDR5 ECC-DIMM

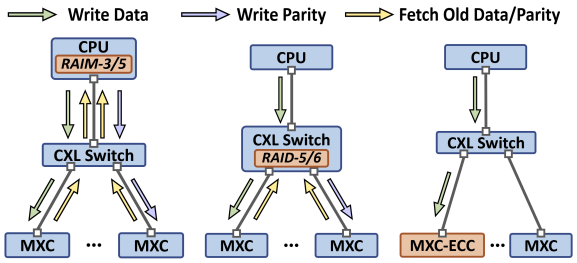
1) ***Distinctions among various ECCs****:* Single Error Correction (SEC), Single Error Correction-Double Error Detection (SEC-DED), and Double Error Correction (DEC) are a class of commonly used codes in Rank-Level ECC, which can detect and correct single or multiple bit errors. Another category of codes is represented by Reed-Solomon (RS) codes [2], specifically RS(n, k) codes, which are a type of Maximum Distance Separable (MDS) code. In RS(n, k) codes, n and k represent the total number of symbols and data symbols in the codeword, respectively. When multiple parity chips are available, RS codes can be used to implement Chipkill [4], a fault-tolerant technique that can correct errors even when a single chip completely fails.



2) ***Recent Advances in R-ECC*** *:* Researchers have made great efforts on the collaborative design of R-ECC and OD-ECC. XED [24] uses SEC-DED as OD-ECC and replaces the original R-ECC with XOR, enhancing the error detection capability of OD-ECC to improve the error correction capability of R-ECC. DUO [25] encodes the data and R-ECC and OD-ECC parity of a single cache line into a long RS code, achieving Chipkill capability while correcting additional random faults. Unity ECC [26] abandons OD-ECC and selects a coding matrix that satisfies both RS$(10, 8)$ and BCH$(80, 64)$ [27], simultaneously achieving Chipkill and DEC fault tolerance.

However, these techniques have three common issues. (i) The simultaneous modification of both DIMM device and memory controller, and potentially even requiring modifications to the DRAM chip's OD-ECC encoding [24, 25, 28], poses notable compatibility challenges to JEDEC DDR standards [5]. (ii) They require pre-setting the redundancy in the DIMM, which cannot adapt to diverse memory reliability requirements. (iii) To achieve Chipkill, two parity chips are essential, requiring the exclusive use of x4 DRAM chips and affecting DIMM specification design.

D. Challenges with Current Channelkill Technology

To address these aforementioned common issues and further enhance the memory reliability beyond Chipkill, the Cross Channel-Level Fault Tolerance Mechanism (Channelkill) has been proposed and extensively studied, including C-Type and S-Type (defined in § I).

1) ***Compute Managed Type (C-Type)****:* Memory Mirror [6] and IBM-RAIM3 [7] achieve Channelkill fault tolerance by constructing channels as RAID-1/3. RAIM-5 [8] encodes 64B cache lines as RAID-5 stripes, introducing gang-writeback

(a) C-Type (b) S-Type (c) CXL ECC

Fig. 2: IO traffic of writeback in three types of Channelkill architecture

and selective protection that enables low-overhead and high-flexibility Channelkill. However, this type of Compute Managed Type (C-Type) Channelkill poses significant challenges to compatibility, because it's nearly impossible for two independent hardware manufacturers to implement a fully compatible complex fault tolerance mechanism.

*2) **Switch Managed Type (S-Type)**:* This type of approaches address the challenge of memory expander failures within the CXL fabric. SMC [16] proposed integrating replication and RAID-5/6 functionality within the CXL switch, referred to as Switch-RAID. It enables the CXL switch to intercept memory requests from upstream devices and manage parity updates and data recovery, effectively resolving compatibility issues with computing devices.

However, existing Channelkill are still remaining challenges: ❶ **Significant overhead incurred by parity update:** The implementation of C/S-Type fault tolerance in CXL fabric, as illustrated in Figures 2(a) and 2(b), introduces a two-step writeback process: reading the original data and parity from cache lines, and writing back their updated versions. These additional operations consume a substantial amount of CXL fabric bandwidth, severely impacting system performance. ❷ **XOR-based IC-ECC suffers from poor reliability:** Current IC-ECC widely employs XOR Code for correcting single cache line errors, which fails to correct errors when multiple channels encounter moderate faults, such as multiple symbol errors in RS codes. The root cause is that XOR does not account for the correlation between error distribution in cache lines and DRAM device failure patterns, a detailed explanation will be presented in § III-A.

*3) **MXCs serve as an optimal position for IC-ECC logic**:* The latest CXL MXCs are equipped with 16 CXL lanes and 4 DDR5 6400MHz channels [20]. Although the total read/write bandwidth of the CXL fabric is limited to 80GB/s, the device's internal bandwidth exceeds 200GB/s. Combining this with the analysis of the above challenges, this motivates us to integrate the IC-ECC processing logic into the memory expander, so that the additional memory requests generated by IC-ECC parity updates can be limited within the expander, effectively alleviating the bandwidth pressure on the CXL fabric. Therefore, we propose the CXL-Memory-Expander Controller ECC (CXL-ECC).

*4) **LRC exhibits potential as IC-ECC**:* Locally Recoverable Code (LRC) [17] is a variant of RS codes, denoted as LRC(n, k, r, p), where n denotes total code length, k denotes data length, r denotes global parity length, and p denotes local parity length. The data is divided into $\frac{k}{p}$ local parity groups, each forming an RS$(\frac{k}{p}+p, \frac{k}{p})$ code with local parity. The r global parity blocks are computed from the total k data blocks. LRC exhibits excellent ① **Local Recovery**, ② **Incremental Parity Update** and ③ **High Global Reliability** properties that satisfy the requirements of IC-ECC. LRC is widely used as an erasure code in cloud storage systems [29], but its application in memory systems for ECC has not been explored yet to the best of our acknowledgment.

III. Design of Proposed CXL-ECC

CXL-ECC consists of two main components: (i) LRC-based Inter-Channel ECC (IC-ECC) algorithm design. (ii) IC-ECC-enabled CXL-MXC controller design.

A. Design of LRC-based IC-ECC Algorithm

Drawing upon the analysis presented in § II-C, we propose LRC-based IC-ECC as a solution to address the challenges outlined in § II-D. LRC maintains Single-Symbol-Correction (SSC) capability within each data channel, eliminating the need to read all cache lines that constitute IC-ECC during error detection and correction. By incorporating local parity into the global decoding process, the system achieves robust correction capabilities for numerous random symbol faults.

*1) **Code Construction**:* Optimal LRC codes [30] conventionally enforce strict constraints on codeword parameters, thereby restricting the number of global parities to not exceed the data symbols within a local group. Therefore, we adopt Pyramid Code [31] for IC-ECC implementation, as it provides equivalent data symbol fault tolerance. Leveraging RS codes constructed with a Vandermonde matrix over GF(256), we implement the code through the following steps:

Step I: We set the number of data channels to be c, then the corresponding Vandermonde matrix for $RS(8\times c+12, 8\times c)$ is calculated as shown in Equation 1:

$$G_V = \begin{bmatrix} (2^0)^0 & (2^0)^1 & \dots & (2^0)^{8\times c-1} \\ (2^1)^0 & (2^1)^1 & \dots & (2^1)^{8\times c-1} \\ \vdots & \vdots & \ddots & \vdots \\ (2^{11})^0 & (2^{11})^1 & \dots & (2^{11})^{8\times c-1} \end{bmatrix} \tag{1}$$

Step II: Let $i = 0, 1, \dots, c-1$. We align and partition the first two rows of G_V into segments of 8 columns each to obtain the encoding matrix A_i within the local parity group. As demonstrated in Equation 2, forms a generator matrix for a local parity group constructing an RS(10,8) codeword, thus satisfying the local recovery requirements of LRC.

$$A_i = \begin{bmatrix} 1^{8i} & 1^{8i+1} & \dots & 1^{8i+7} \\ 2^{8i} & 2^{8i+1} & \dots & 2^{8i+7} \end{bmatrix} \tag{2}$$

Step III: We define the global coefficients of the LRC generator matrix shown in Equation 3:

$$G_G = \begin{bmatrix} (2^2)^0 & (2^2)^1 & \dots & (2^2)^{8\times c-1} \\ (2^3)^0 & (2^3)^1 & \dots & (2^3)^{8\times c-1} \\ \vdots & \vdots & \ddots & \vdots \\ (2^{11})^0 & (2^{11})^1 & \dots & (2^{11})^{8\times c-1} \end{bmatrix} \tag{3}$$

Step IV: We define the generator matrix of the LRC as Equation 4, the construction of our proposed LRC-based IC-ECC is completed:

$$G_{LRC} = \begin{bmatrix} & & I & \\ A_0 & & & \\ & A_1 & & \\ & & \cdots & \\ & & & A_{c-1} \\ & & G_G & \end{bmatrix} \tag{4}$$

*2) **Data Encoding and Organization**:* Identical to the § III-A1, we assume a total of c data cache lines, encoded into $c+1$ cache lines using LRC. Fig. 3 illustrates the data layout of cache lines in the IC-ECC structure: the 80 bits received from two consecutive Beats are first aligned, then divided into 10 symbols according to the 4-DQ width to form an IC-ECC coding unit. Let C_{ij} denote the data transmitted in the j-th coding unit within the i-th cache line, where $i \in \{0, 1, \ldots, c\}$ and $j \in \{0, 1, \ldots, 7\}$. These units are encoded into an LRC$(10 \times (c+1), 8 \times c, 10, 2)$ code, with C_{cj} containing the global parities and each remaining C_{ij} constituting a local parity group. Cache lines are arranged in a RAID5 left-asymmetric layout [9] to minimize the I/O bottleneck caused by parity update operations.

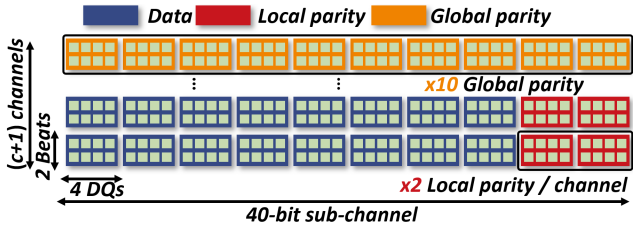


Fig. 3: an example of IC-ECC data layout

*3) **Decoding Process and Correction Capability**:* IC-ECC employs a two-level error correction scheme: **(a) Intra-channel local decoding:** R-ECC possesses SSC capability, which can achieves Chipkill on x4 DIMMs and Half-Chipkill on x8 DIMMs respectively. When R-ECC correction fails, an Uncorrectable Error (UE) is reported, triggering global decoding. **(b) Inter-channel global decoding:** All data and parity bits across channels are combined into a global $RS(c \times 8 + 12, c \times 8)$. This allows for either the recovery of a single faulty channel through erasure decoding or the correction of up to 6 random symbol errors using the RS Decoder.

TABLE II: Configurations and error correction capabilities of IC-ECCs

		w/o	XOR	RS	LRC
IC-ECC		-	$XOR(5,4)$	$RS(40,32)$	$RS(44,32)$
Global Parities		-	$64B \times 1$	$1B \times 8$	$1B \times 12$
Correctable symbol errors	min	1	3	4	6
	max	$c+1$	$c+10$	$c+10$	$c+10$
Chipkill w/ x4 DIMM		1	3	4	6
Chipkill w/ x8 DIMM		0	1	2	3

*4) **Compare performance of IC-ECCs within Channelkill**:* XOR-based IC-ECC generates parity by XORing data chips within each channel across 64B cache lines. RS-based IC-ECC, similar to LRC-based IC-ECC, uses data chips in the parity channel to store parity symbols that protect data chips in other channels. Table II presents the configurations and error correction capabilities of the three IC-ECCs with 4 data channels ($c = 4$). Due to its coarse encoding granularity, XOR-based IC-ECC exhibits limited tolerance for fine-grained errors, failing to correct dual-symbol errors occurring simultaneously in two channels. While RS-based IC-ECC offers superior fine-grained error correction compared to XOR, its local parity does not contribute to global decoding, limiting its correction capability to 4 arbitrary symbol errors. By contrast, LRC-based IC-ECC integrates local and global redundancy to form 12 parity symbols.

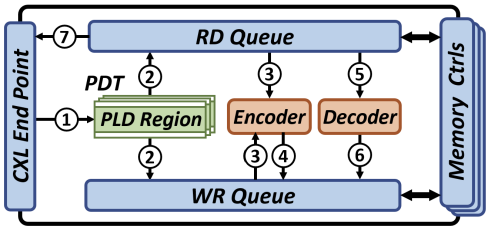

Fig. 4: Architecture of the CXL-ECC controller

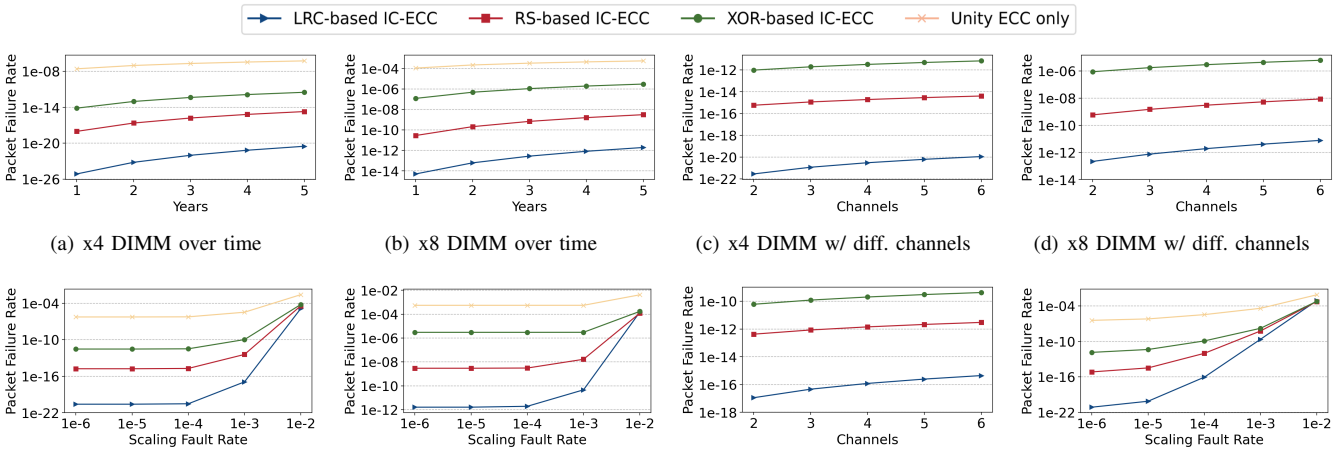

B. Design of CXL-ECC Controller System Architecture

The system architecture of CXL-ECC implements selective protection management, parity update procedures, and data recovery mechanisms.

*1) **Selective protection with Protected LD Table (PDT)**:* Multiple Logic Device (MLD) characteristic enables each Type-3 device to be logically partitioned into Logic Devices (LDs) and independently assigned to computing devices. Memory space is protected by IC-ECC at the LD granularity, with all protected LDs being recorded in the Protected LD Table (PDT). During high-reliability memory allocation by the Fabric Manager (FM), a sequential process is executed wherein: (1) the FM initiates an allocation request to the MXC, (2) the MXC performs physical space allocation within its internal DDR channels and registers the allocation in the PDT, and (3) the resultant protected LD is subsequently exported and assigned through the FM.

*2) **Parity update and data recovery via En-/De-coder**:* The processes for parity updates and data recovery of IC-ECC are executed by the En-/De-coder modules. **(i) Request Serve** begins with ① a filtering in the PDT. If an operation falls within the PDT, ② then while the request is placed in the RQ/WQ, the protected flag needs to be set in the corresponding entry. Read requests for previously written data and parity required for the incremental update are inserted into the RQ. ③ Upon completion of all read requests for a writeback operation, both new and previous data, along with the old parity, are passed to the Encoder. ④ A write request is issued for the encoded result. **(ii) Data Recovery** is triggered upon the detection of a R-ECC UE [1] in an entry with protected flag set. Subsequently, read requests associated with data recovery are enqueued in the RQ. ⑤ When all data required for the recovery operation has been retrieved, the Decoder fetches the data and performs

[1]To enable the IC-ECC En-/De-coder to access data from the parity chips, we relocate the R-ECC encoding and decoding operations from the memory controller to the MXC.

(e) x4 DIMM w/ diff. error rates (f) x8 DIMM w/ diff. error rates (g) w/ diff. channels & w/o OD-ECC (h) w/ diff. error rates & w/o OD-ECC

Fig. 5: The packet failure rate of different IC-ECC schemes over time , with different channels and scaling fault rates.

the decoding. ⑥ Following this, write requests for the decoded results are queued in the WQ. If the R-ECC UE is not in the PDT or the Decoder fails to decode, an UE is reported to the CXL End Point.

*3) **Scheduler optimization and conflicts management**:* The First-Ready First-Come-First-Serve (FR-FCFS) scheduling policy is modified to assign higher priority to CPU load requests when multiple read requests have equivalent priority levels. This optimization minimizes the impact on load latency caused by the data reads required for IC-ECC parity updates. To maintain data consistency during simultaneous parity updates and data recovery operations on the same IC-ECC codeword, operations are serialized, prioritizing data recovery to avoid deadlocks.

TABLE III: Operational fault rates[22]

Mode	Transient	Permanent
Single bit	14.2	18.6
Single word	1.4	0.3
Single column	1.4	5.6
Single row	0.2	8.2
Single bank	0.8	10.0

IV. Evaluation Method

A. Reliability Simulation Setup

To evaluate the reliability of LRC-based IC-ECC, we compare it with schemes using only Unity ECC (SOTA Rank-level ECC) as R-ECC, Xor-based IC-ECC (incorporated by both RAIM-5 and Switch-RAID) and RS-based IC-ECC with Unity ECC. The experiments employ 2-6 data channels plus one parity channel to construct IC-ECC with DDR5 x8 and x4 ECC-DIMM [2]. During fault injection process, random cell faults are inserted with a probability between 10^{-6} and 10^{-2} to simulate Scaling Faults, then Operational Faults are injected using the failure rates shown in Table. III [22] to simulate wear-out after 1-5 years of device operation. As the probability of UE occurring in LRC-based IC-ECC is extremely low (in some cases less than 10^{-20}), making it difficult to simulate the failure rate using Monte Carlo methods. We theoretically calculate the packet failure rate corresponding to 5×80 bits data constituting an IC-ECC.

[2]In the default configuration, the system employs 4 data channels, maintains a scaling fault rate of 10^{-4}, operates over a 5-year period, and implements OD-ECC protection for DRAM chips.

B. Performance Simulation Setup

TABLE IV: The system simulation configuration

Processor	
Cores	16 cores 4GHz, 4-wide OoO
L1I	32KB, 64B line, 8 way, 4 cycles, 8 MSHRs
L1D	48KB, 64B line, 12 way, 5 cycles, 16 MSHRs
L2C	512KB, 64B line, 8 way, 10 cycles, 32 MSHRs
LLC	32MB, 64B line, 16 way, 20 cycles, 1024 MSHRs
CXL Fabic [13]	
Latency	CPU Port: 25ns, Switch: 130ns, Memory Port: 40ns
Bandwidth	x8 CXL (PCIe5.0) lanes, 32 GB/s (bi-dierctional)
Memory eXpander Controller	
Queue Depth	MXC: 1024, DDR controller: 32
DDR Spec.	1 rank , DDR5 [5] 6400MHz, 32Gb ×8 chip, 8 bank groups, 4 banks per bank group
Channels	5 channel (4-data + 1-parity)

To evaluate the system-level performance of the CXL-ECC architecture, we integrate the Champsim [18] CPU simulator with the Ramulator2 [3] [19] Memory simulator, implementing the CXL protocol in Ramulator2. We also implement RAIM-5, RAID5-enabled Switch (Switch-RAID), and CXL-ECC. We evaluate 145 traces sampled from 41 workloads from SPEC CPU2006 [32], SPEC CPU2017 [33], PARSEC 2.1 [34], and Ligra [35]. During simulation execution, we run the same trace on all CPUs, measuring the execution time and CXL fabric traffic for around 100M instructions (after 10M warmup). Table IV summarizes all configurations used in the system simulation.

V. Evaluation Results

A. Impact on Reliability

(a) CXL-ECC substantially enhances DRAM reliability. Fig. 5(a) and Fig. 5(b) show the packet error rate over time

[3]Ramulator2 only support single sub-channel per DDR5 channel, we halve the CXL fabric bandwidth to simulate realistic DDR5 performance.

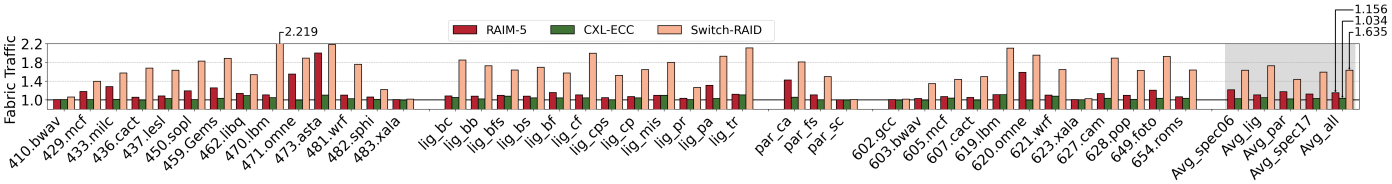

Fig. 6: Normalized fabric traffic of RAIM-5, Switch-RAID and CXL-ECC on each benchmark suite and the overall average

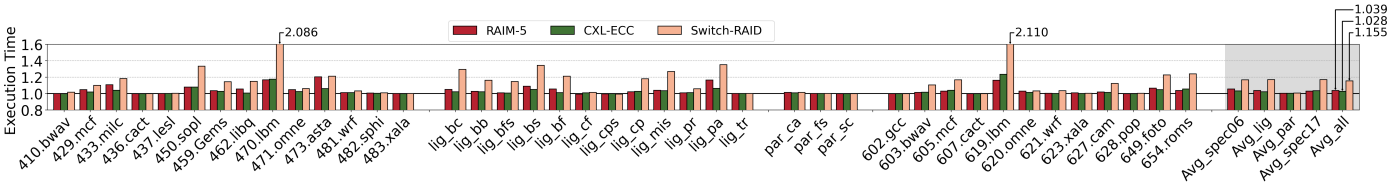

Fig. 7: Normalized execution time of RAIM-5, Switch-RAID and CXL-ECC on each benchmark suite and the overall average

for x4 and x8 DDR5 ECC-DIMM using different IC-ECC mechanisms. Equipped with x4 DIMM, CXL-ECC can achieve a packet failure rate below 3.1×10^{-21} while providing tolerance for complete failures of individual DIMMs, enabling highly reliable memory expansion for computing devices in CXL fabric. In comparison to the XOR-based ECC employed in existing Channelkill mechanisms, LRC-based IC-ECC yields reliability improvements of 6.3×10^5 and 10^9 in x8 and x4 DIMMs, respectively. Furthermore, LRC exhibits superior global error correction capabilities compared to refined RS codes, resulting in reliability improvements of 1.6×10^3 and 1.5×10^6 in x8 and x4 DIMMs, respectively.

Although x8 DIMMs inherently lack Chipkill capabilities, the use of LRC-based IC-ECC enables them to tolerate up to 3 random chip failures, thereby demonstrating robust resilience against both scaling and operational faults. Furthermore, the packet failure rate of x8 DIMMs employing LRC-based IC-ECC remains below 2×10^{-12}, which is lower than the 3×10^{-12} rate of x4 DIMMs protected by XOR-based IC-ECC.

(b) CXL-ECC demonstrates robust reliability across numerous channels and high failure rates. Fig. 5(c), 5(d), 5(e), and 5(f) illustrate the reliabilities of various IC-ECC mechanisms under different channel configurations and scaling error rates. Experimental results demonstrate that LRC-based IC-ECC-protected x4 DIMMs maintain an exceptionally low failure rate of 1.2×10^{-17} even when the scaling fault rate reaches 10^{-3}. Even with up to 6 data channels in x8 DIMMs, a minimal error rate of 7.8×10^{-12} can be maintained.

(c) CXL-ECC sustains exceptional reliability even in the absence of OD-ECC. Fig. 5(g) and 5(h) show the relationship between failure rates and varying parameters (channel count and error rate) for x4 DDR5 DIMMs without OD-ECC. Compared to OD-ECC-enabled configurations, all IC-ECC schemes show diminished error correction capabilities. Among these, LRC-based IC-ECC exhibits the most severe reliability degradation under increased scaling errors. This phenomenon can be attributed to the SSC-only mechanism of R-ECC within data channels, exhibiting inferior random error tolerance compared to the DEC-enabled Unity ECC deployed in other IC-ECCs. At an error rate of 10^{-3}, LRC maintains superior reliability despite these limitations, showing 29x and 98x improvements over RS-based and XOR-based implementations, respectively.

B. Impact on Performance

(a) CXL-ECC significantly reduces fabric bandwidth overhead. As shown in Fig. 6, the average additional bandwidth consumed by CXL-ECC across all workloads is 3.4%, which is significantly lower than the 15.6% and 63.5% of RAIM-5 and Switch-RAID, respectively. This is because all extra memory requests related to parity updates are confined within the MXC. For write-intensive applications such as `GemsFDTD`, `lbm`, and `BFS`, CXL-ECC can reduce the additional CXL fabric bandwidth overhead by up to 114% compared to S-type Switch-RAID technology.

It is worth noting that some applications, such as `omnetpp`, have a large additional bandwidth overhead but do not affect system performance. This is because they are not memory-intensive applications, and the additional memory requests do not put pressure on the CXL fabric.

(b) CXL-ECC has negligible impact on overall system performance. Fig. 7 shows the normalized execution time of CXL-ECC, Switch-RAID, and RAIM compared to the baseline system without IC-ECC. The S-Type Switch-RAID mechanism causes an execution time increase of over 13.4%, significantly impacting system performance. This is because a large amount of fabric bandwidth is used for parity updates. The workloads with severe performance degradation in Fig. 7 generally generate high fabric traffic in Fig. 6.

CXL-ECC and RAIM-5 exhibit marginal performance degradation of 2.8% and 3.9% respectively, significantly outperforming Switch-RAID with its substantial 15.5% overhead. Furthermore, our approach surpasses traditional C-type solutions like RAIM-5 while eliminating the need for extensive CPU modifications. Experimental results indicate that CXL-ECC delivers superior reliability and system-level performance while maintaining architectural compatibility.

VI. Conclusion

This paper presents on-CXL-Memory-Expander ECC (CXL-ECC) which integrates LRC-based IC-ECC in the CXL

memory controller. This approach effectively leverages the robust global error correction capabilities of LRC and mitigates the bandwidth demands imposed by parity updates on the fabric, thereby enabling the realization of highly reliable memory, which enhances a UE rate of lower than 3.1×10^{-21}, with minimal system performance overhead of 2.8%.

***Abstract*—Activation outliers in Large Language Models (LLMs), which exhibit large magnitudes but small quantities, significantly affect model performance and pose challenges for the acceleration of LLMs. To address this bottleneck, researchers have proposed several co-design frameworks with outlier-aware algorithms and dedicated hardware. However, they face challenges balancing model accuracy with hardware efficiency when accelerating LLMs in a low bit-width manner. To this end, we propose OutlierCIM, the first algorithm and hardware co-design framework for the compute-in-memory (CIM) accelerator with outlier-aware quantization algorithm. The key contributions of OutlierCIM are 1) an outlier-clustered tiling strategy that regulates memory access and reduces inefficient workloads which are both introduced by outliers, 2) a hybrid-strategy quantization and a reconfigurable double-bit CIM macro array that overcome the low storage utilization and high latency of outlier-based LLM quantization, and 3) a quantization factor post-processing strategy and a dedicated quantizer that efficiently unify the multiplication and accumulation of outlier-caused FP-INT workloads. Implemented in a 28nm CMOS technology, OutlierCIM occupies an area of 2.25 mm². When evaluated at comprehensive benchmarks, OutlierCIM achieves up to 4.54× energy efficiency improvement and 3.91× speedup compared to the state-of-the-art outlier-aware accelerators.**

***Index Terms*—large language model, compute-in-memory, neural network accelerator, activation outlier, quantization.**

I. Introduction

Large Language Models (LLMs), which are scaled from pre-trained language models [1], [2], have demonstrated exceptional performance across various natural language processing tasks, including machine translation [3], text summarization [4], and question answering [5]. Despite these advancements, LLMs' increasing size and complexity pose significant challenges to their application and deployment. For instance, the LLaMA-65B model, containing 65 billion parameters, necessitates 260 GB (twelve RTX 3090Ti GPUs) of VRAM for inference.

Quantization reduces LLM size by converting parameters to low bit-width, thereby improving model inference efficiency and memory utilization [6]–[9]. For example, the weight parameters of the LLaMA-65B model can be compressed to 4-bit integer precision, reducing the model size to 32.5 GB [11]. However, the activations of LLMs are challenging to quantize to low bit-width due to outliers which exhibit small quantities but large magnitudes. These outliers introduce large data distribution, resulting in limited quantization bit-width.

Considering the bottleneck caused by activation outliers, several algorithms have been proposed to smooth the distribution of activations [6]–[9]. However, these algorithm-only methods introduce additional mathematical space transformations that can not be fully leveraged by general computing platforms, creating a mismatch between hardware and algorithm. As a result, hardware and algorithm co-design frameworks have been developed to enhance the benefits of quantization [12]–[15]. These frameworks quantize activation outliers with high data precision and design dedicated hardware accelerators. However, the balance of hardware and algorithm is still not optimally achieved. GOBO [12] and OLAccel [13] treat outliers as sparse matrices which require additional complex control logic. OliVe [14] eliminates neighboring values of outliers to enable localized outlier storage, resulting in significant model accuracy loss at low bit-width quantization. Oltron [15] increases data precision of normal values in outlier channels and permutes channels to maintain regular bit-width for each input tiling block. However, it undergoes low efficiency at nonlinear workloads. Furthermore, the hardware implementations of these approaches face a memory wall challenge due to the memory-bound characteristic of LLMs [11], creating an additional bottleneck.

In this paper, we propose OutlierCIM to address the above challenges. The contributions are listed as follows:

- **Outlier-clustered tiling strategy** that regulates memory access and reduces inefficient workloads. This method overcomes element bit-width variation by clustering all outliers in a single input tiling block, ultimately enhancing data movement and computation efficiency.
- **Hybrid-strategy quantization and reconfigurable double-bit CIM macro array** are designed to address low CIM storage utilization and high latency caused by outlier-based LLM quantization.
- **Quantization factor post-processing strategy and dedicated quantizer** are designed to efficiently perform the multiplication and accumulation of outlier-caused FP-INT workloads with low data bit-width.
- **OutlierCIM** is evaluated at comprehensive benchmarks and achieves up to 4.54× energy efficiency improvement

and 3.91× speedup compared to baselines. To our best knowledge, **OutlierCIM is the first work to address LLMs acceleration with CIM-based accelerator and outlier-aware quantization algorithm co-design**.

II. Background and Motivation

A. Related Works

Numerous quantization algorithms have been proposed to reduce the memory and computational costs of LLMs by addressing activation outliers [6]–[10]. These methods observe that outliers cluster in specific channels and transfer their extreme magnitudes to weights. However, achieving low bit-width quantization requires complex matrix scaling and transformations [8], [9], which results in low efficiency on general computing platforms. To address this issue, co-design frameworks for digital accelerators and mixed-precision quantization algorithms have been proposed [12]–[15]. These frameworks encode or quantize outliers using large bit-width, enabling near 4-bit LLM inference with dedicated accelerators. However, the balance between hardware and algorithm remains suboptimal. For example, GOBO [12] and OLAccel [13] process outlier-based activation matrices sparsely, leading to complex control logic and irregular memory access. OliVe [14] solves this issue by eliminating neighboring normal values of outliers, but this approach sacrifices model accuracy and introduces element bit-width variation within a single input tiling block. In contrast, Oltron [15] enhances the precision of normal values in outlier channels and regulates memory access through channel-wise permuting. Nevertheless, it encounters inefficiency at post-nonlinear workloads, as only a portion of its processing element (PE) array is capable of FP processing. Moreover, the memory-bound nature of LLMs further restricts the acceleration efficiency of these approaches. Compute-in-memory (CIM) has emerged as a promising solution for memory-bound applications [18]–[20]. However, existing CIM-based accelerators are not optimal for mixed-precision workloads in LLMs, leading to low hardware efficiency.

B. Challenges and Motivation

OutlierCIM seeks to enhance hardware efficiency through a CIM-based accelerator and balance model accuracy with specialized algorithmic strategies. However, several challenges remain to be addressed, as depicted in Fig. 1.

Firstly, large bit-width outliers result in irregular memory access and reduced CIM utilization. On one hand, a significant memory bandwidth is required to maintain a consistent input size. On the other hand, the computation of normal elements must wait additional cycles for outliers due to the bit-serial input nature of the CIM macro. In the case of LLaMA-7B [26] on the WikiText2 [29] dataset, the CIM utilization drops to 58%, and memory energy consumption increases by 23.1%.

Secondly, the outlier-based quantization strategies of current advanced algorithms lead to a conflict between model accuracy and hardware efficiency when processing normal value workloads [7]–[9]. A given 4-bit asymmetric quantized element should be aligned with zero point (ZP) before the multiplication and accumulation (MAC). This operation leads to high input latency and wastes up to 50% storage density due to the expanded bit-width. Although symmetric quantization introduces lower overheads, it fails to maintain model accuracy at low-bit quantization [15].

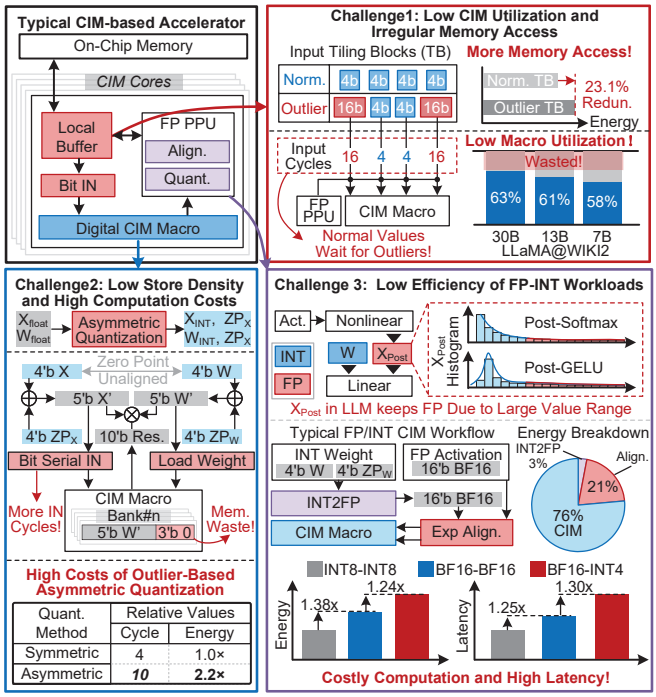

Fig. 1. Typical CIM-based FP/INT accelerator and challenges caused by activation outliers in LLMs

Thirdly, outlier-caused FP-INT workloads incur hardware under-efficiency. Given the expanded activation distribution range caused by outliers, the nonlinear layers in LLMs further aggravate this problem. To maintain model accuracy, the activations of post-nonlinear layers should be kept in FP format [22]. Since the missed support of FP-INT computation in current CIM-based accelerators, the INT weights should be converted to FP format and subsequently perform exponent alignment. In the case of LLaMA-7B@WIKI2, this workflow leads to 1.24× energy cost and 1.30× latency.

III. OutlierCIM Co-design Framework

The overview of the proposed OutlierCIM, a comprehensive CIM-based accelerator and algorithm co-design framework, is presented in Fig. 2. The structure of this paper is organized as follows. Sec. III-A introduces the outlier-clustered tiling strategy, which regulates memory access and reduces outlier workloads. Sec. III-B introduces the hybrid-strategy quantization and reconfigurable double-bit CIM macro array, which are designed to overcome low storage utilization and high latency. Sec. III-C introduces the quantization factor post-processing strategy and dedicated quantizer, which are designed to boost the calculation efficiency of FP-INT workloads.

A. Outlier-Clustered Tiling Strategy

Given the large dimensions of LLMs, input activations must be loaded and computed in a tiling manner. However, high-

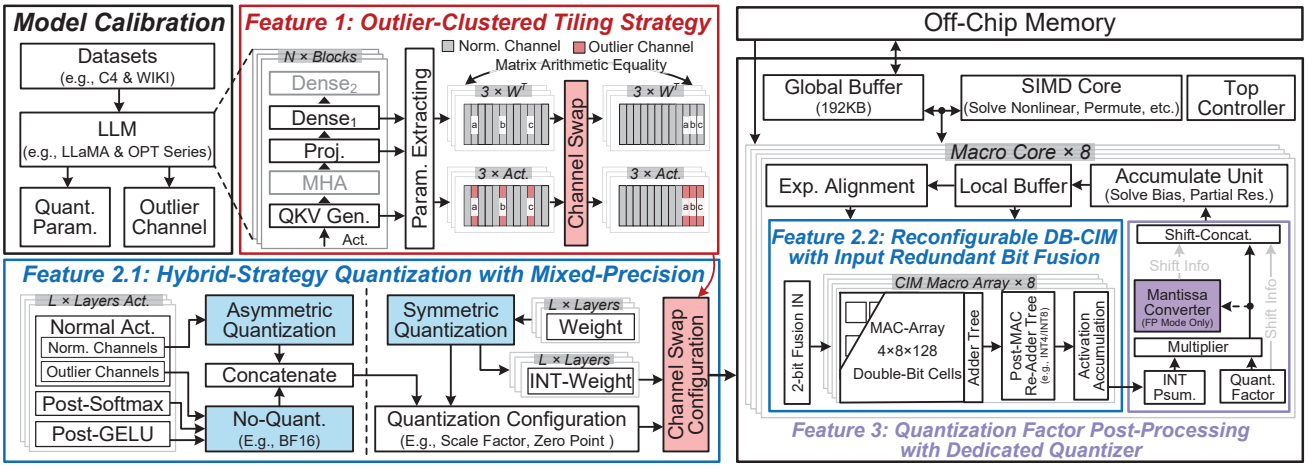

Fig. 2. The overview of proposed algorithm and hardware co-design framework for LLM acceleration

precision outliers significantly increase memory access costs when using the original tiling strategy, illustrated in Fig. 3. OliVe [14] mitigates this issue by nullifying normal values and encoding outliers with large bit-width. However, this tiling strategy is not well-suited for CIM-based architectures. For instance, if a single outlier is quantized using BF16 within a 128-element input vector, the remaining 127 normal values computed in 4 cycles must wait for additional cycles to complete the processing of the current vector.

To address this problem, the Outlier-Clustered Tiling Strategy (OCTS) is proposed, as illustrated in Fig. 3. First, OCTS increases the data precision of normal values within outlier channels. Second, OCTS clusters all outlier channels into the last tiling block of a given activation matrix by swapping outlier channels with the last normal channels. The overall workflow of the proposed OCTS is detailed in Fig. 2 (Feature 1). Outlier channel positions are generated through the model calibration process with the empirical 3σ rule [14]. The activations of the second layer of the Multi-Layer Perceptron (MLP) and the Multi-Head Attention (MHA) layer are not calibrated due to the FP format of post-nonlinear activations [10]. Each tiling block consists of 128 channels, which is sufficiently large to accommodate all outlier channels. As the number of outlier channels may not equal 128, we increase all other normal channels' precision within the last tiling blocks to maintain regular memory access and CIM utilization. Although this strategy introduces additional costs, the small proportion of these last tiling blocks does not significantly affect overall performance (e.g., 128/4096@LLaMA-7B). Finally, the weight dimensions are permuted to ensure the correctness of the general matrix multiplication (GEMM).

The primary advantages of OCTS stem from two key aspects. First, memory access becomes regular compared to the original pattern. Second, low-utilization workloads are eliminated and replaced with uniform data-type tiling blocks. Fig. 4 presents the evaluation of OCTS. The baseline here is a rebuilt bit-serial CIM macro with the original input strategy. OliVe and OCTS tiling strategies are then deployed on the baseline hardware. For OliVe, it fails to reduce latency due

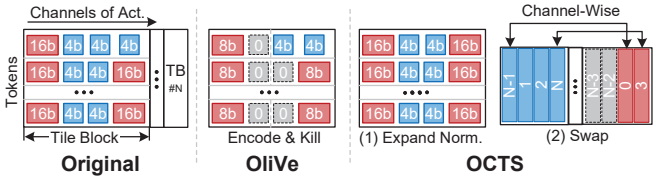

Fig. 3. Comparison of proposed OCTS and other strategies

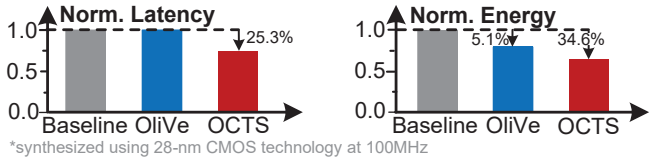

Fig. 4. Performance comparison of outlier-clustered tiling strategy and previous works. The model and dataset here are LLaMA-7B and WikiText2

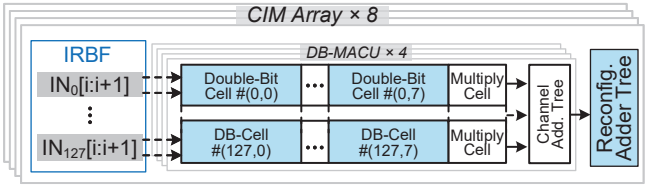
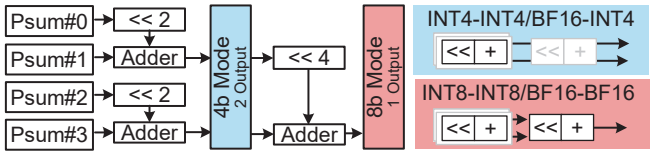


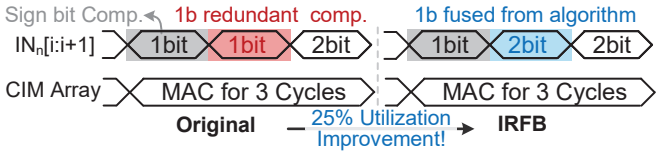
to low CIM utilization caused by variable element bit-width. However, it achieves energy savings from its regular memory access. In contrast, the proposed OCTS reduces latency by 25.3% and achieves up to 34.6% energy savings compared to the baseline. Nevertheless, these improvements are not ideal due to the inefficient INT-INT and FP-INT workloads, which are further addressed in the following sections.

B. Hybrid-Strategy Quantization and Reconfigurable Double-Bit CIM macro array



To address the CIM-unfriendly quantization in LLMs, OutlierCIM introduces a Hybrid-Strategy Quantization (HSQ) depicted in Fig. 2 (Feature 2.1). At the weight aspect, we deploy symmetric quantization, which does not require zero point alignment. The quantization and requantization functions are defined as g_w and g_w^{-1} in Eq. 1, where W is the original FP weight matrix, Q_W is the quantized weight, and Δ_W is the scale factor.

$$\begin{aligned} Q_W &= g_w(W) = \text{round}(\frac{W}{\Delta_W}) \\ W &= g_w^{-1}(Q_W) = \Delta_W \times Q_W, \end{aligned} \tag{1}$$



The CIM storage density is therefore improved at 2×. Additionally, the performance loss of symmetric quantization is

(a) Proposed double-bit CIM array architecture

(b) Post-MAC reconfigurable adder tree

(c) Comparation of IRFB and original input strategy

Fig. 5. Detailed double-bit CIM array architecture with reconfigurable adder tree (Re-DBCIM) and input redundant bit fusion strategy (IRBF)

compensated by group-wise weight quantization technology co-design, which is then introduced in Sec. III-C. At the activation aspect, asymmetric quantization is still used to maintain the model performance. The quantization and re-quantization functions are defined as f_x and f_x^{-1}, following:

$$\begin{aligned} Q_X &= f_x(X) = \text{round}(\frac{X}{\Delta_X}) + Z_X \\ X &= f_x^{-1}(Q_X) = \Delta_X \times (Q_X - Z_X), \end{aligned} \tag{2}$$

where X is the original FP activation matrix, Q_X is the quantized activation matrix, Δ_X is the scale factor, and Z_X is the zero point. Notably, the activations of post-nonlinear layers and outlier channels are kept in BF16 format due to their large data distribution range. The quantization scale factors and zero points are generated following the methodology described in OmniQuant [6]. Finally, the quantization configuration is combined with the OCTS strategy to enable regular memory access and high CIM utilization.

Since the expanded bit-width input still introduces high latency, a Double-Bit Reconfigurable CIM macro (Re-DBCIM) array is designed to solve this problem from the hardware aspect. The architecture of Re-DBCIM is shown in Fig. 5 (a), which consists of 4 Double-Bit Cell MAC Units (DB-MACUs). For one DB-MACU, there are 128×8 DB-Cells, which store 2-bit of 128×8 weight matrix. For instance, DB-MACU#0 stores the two most significant bits of a given 128×8 INT4 weight matrix, and DB-MACU#1 stores the remaining two least significant bits. The input 2-bit is then broadcasted to these 2 DB-MACUs, and the MAC operation of each DB-MACU is serially processed by 2-bit multiply-cells and channel-wise adder trees. Subsequently, the MAC results of 2-bit activations and 4-bit weights are generated by weight-wise shift-add. The remaining input bits are then processed similarly and accumulated to operate GEMMs in a tiling manner.

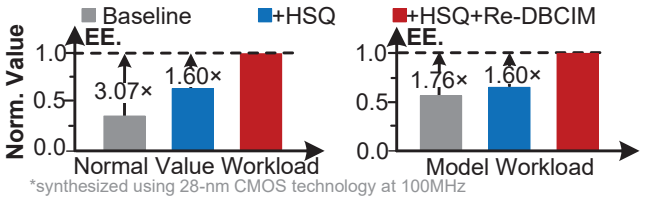


Fig. 6. Energy Efficiency (EE) improvement of gradually deploying proposed algorithm and hardware strategies

To enhance hardware flexibility and expand application scenarios, a reconfigurable adder tree is designed to handle INT8-INT8 or BF16-BF16 workloads, as shown in Fig. 5 (b). At the INT4/BF16-INT4 mode, the first-level shift-add is activated to generate two MAC results as two 128×8 4-bit matrices are stored in the CIM macro array. At the INT8/BF16 mode, all four DB-MACUs store a 128×8 matrix in INT8 or 8b two's complement mantissa format. Subsequently, the second-level shift-add is activated to complete the 8-bit MAC operation, producing one result from the four DB-MACUs.

An Input Redundant Bit Fusion strategy (IRBF) is proposed to address bit-redundancy in the conventional DB-CIM macro [23], as illustrated in Fig. 5 (c). The original DB-CIM macro workflow requires an additional cycle to process the sign bit, resulting in a 25% utilization loss [23]. The IRBF is designed to merge the low-utilization cycle with another bit derived from our proposed hybrid-strategy quantization, where the input is a cardinal bit-width after zero point alignment. Consequently, the utilization of our Re-DBCIM is improved by 25% compared to the conventional DB-CIM.

Fig. 6 illustrates the improvement achieved by gradually deploying the proposed algorithm and hardware strategies. The baseline and model configuration are consistent with Sec. III-A, and OCTS is then deployed for a comprehensive comparison. Compared to the baseline, the HSQ achieves limited energy efficiency improvement due to the high latency caused by expanded input bit-width. The Re-DBCIM is subsequently deployed to address this issue, resulting in a 3.07× energy efficiency improvement at normal value workloads. However, overall model energy efficiency remains constrained by FP-INT workloads, leading to suboptimal results, which is further addressed in Sec. III-C.

C. Quantization Factor Post-Processing Strategy with Dedicated Quantizer

The benefits of quantization strategies are derived from mapping the FP parameters to integers. However, the process of FP-INT workload requires data from these two numerical spaces, resulting in limited efficiency at general computing platforms and conventional FP/INT CIM-based accelerators [20], [21]. The detailed computation process is depicted in Eq. 3, where g_w^{-1} is the requantization function.

$$X_{FP} \times W_{FP} = X_{FP} \times g_w^{-1}(Q_W), \tag{3}$$

The only benefit of the FP-INT process here is low bit-width weight movement. The computation of GEMMs is then operated in the costly FP format.

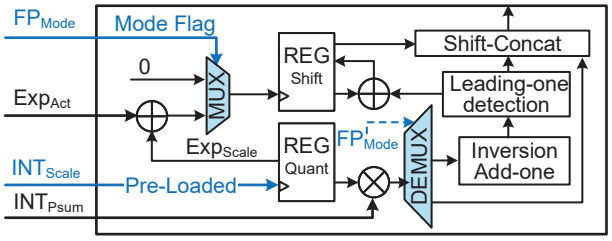

Fig. 7. Proposed quantizer for quantization factor post-processing

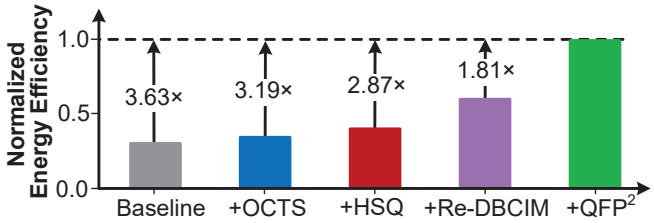

Fig. 8. Improvement breakdown analysis of OutlierCIM

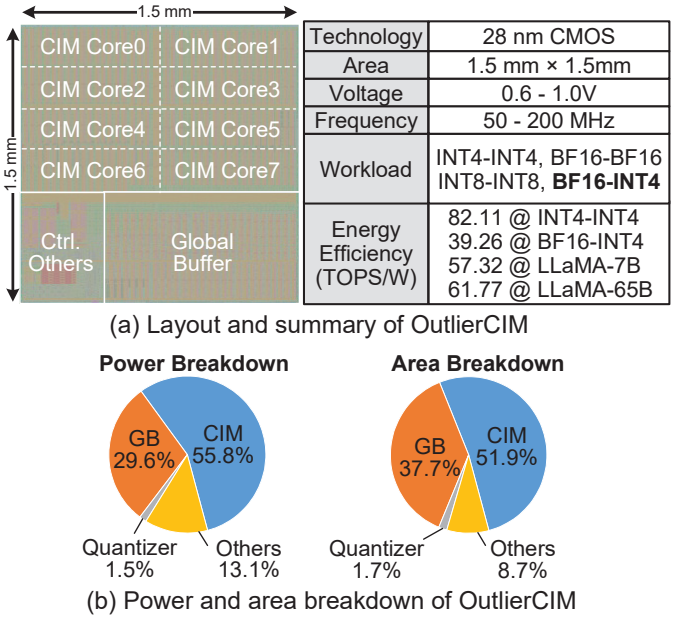

Fig. 9. Layout and breakdown analysis of OutlierCIM accelerator

To this end, the Quantization Factor Post-processing (QFP^2) strategy is proposed to leverage the benefits of integer data movement and computation. We define that the quantized weights are within the integer numerical space $\mathbb{Z}$, while the original weights exist within the floating-point numerical space $\mathbb{R}$. It is evident that the mathematical spaces $\mathbb{Z}$ and $\mathbb{R}$ are linear homomorphism spaces. Given that the mapping function g_w^{-1} defined in Eq. 1 is a linear function, the linear mapping operation $g_w^{-1} \in Hom(\mathbb{Z}, \mathbb{R})$ satisfies both the associative and commutative properties [17]. Consequently, the computation of FP-INT workloads is optimized to Eq. 4:

$$X_{FP} \times W_{FP} = g_w^{-1}(X_{FP} \times Q_W), \tag{4}$$

For the MAC operation of FP and INT, the block float point (BFP) computation method is introduced, and the aligned exponent of INT values is set to 0 to match the BFP [20], [23]. For the map function of g_w^{-1}, QFP^2 follows Eq. 5:

$$\begin{aligned} g_w^{-1}(X_{FP} \times Q_W) = \Delta_W(X_{FP} \times Q_W) &= \frac{A}{2^B}(X_{FP} \times Q_W) \\ &= \frac{A}{2^B}\frac{1}{2^{E_X}}(M_X \times Q_W), \end{aligned} \tag{5}$$

where the phase $\frac{A}{2^B}$ serves as the integer approximation of the scale factor Δ_W, which can be implemented using multiplication and shift operations [24]. Based on the BFP method, E_X, and M_X represent the aligned exponent and two's complement mantissa values of the input X, respectively. Group-wise weight quantization is supported by adjusting Δ_W according to the group size of the weights. Therefore, the MAC operations for FP-INT workloads are efficiently unified and processed in a low bit-width manner.

As shown in Fig. 7, a dedicated quantizer is designed to enhance the efficiency of QFP^2. INT_{Psum} represents the MAC results of two's complement mantissas M_X and quantized weights Q_W from the CIM macro array. The scale factor Δ_W is decomposed to Exp_{Scale} and INT_{Scale} following Eq. 5. Since the proposed CIM array has an accumulation length of 128, group-wise quantization for 128 elements is inherently supported in an efficient hardware configuration. For the FP mode, the MAC results of $M_X \times Q_W$ are multiplied by the scale factor parameter and subsequently perform leading-one detection for shift configuration. Finally, the aligned input exponent, scale factor parameter, and leading-one information are fused to get the standard IEEE 754 float-point format by configuring the shift-concat module. For the INT mode, only scale factor parameters are used to execute the QFP^2 and group-wise quantization strategies.

The main benefits of QFP^2 and quantizer arise from three aspects: 1) the computation of FP-INT workloads is optimized by fully leveraging low bit-width precision; 2) memory access costs are significantly reduced by moving quantized INT4 weights; and 3) model accuracy is maintained by the co-designed group-wise quantization. Fig. 8 demonstrates the improvement breakdown of unified OutlierCIM. The baseline here remains consistent with Sec. III-A. The proposed OutlierCIM achieves an overall 3.63× energy efficiency increase compared to the baseline.

IV. Evaluation

A. Experimental Setup

Algorithm. The algorithm part of OutlierCIM is evaluated on LLaMA series (7B-65B) [26] and OPT series (6.7B-66B) [27]. The perplexity values of language generation tasks are evaluated on WikiText2 [29] and C4 [28]. For hybrid-strategy quantization and group-wise weight quantization, we reconfigure the OmniQuant [6] to our proposed methods.

Hardware. The OutlierCIM accelerator is implemented using commercial 28nm CMOS technology, occupying an area of 2.25 mm^2. A cycle-accurate simulator is developed to simulate the performance of the OutlierCIM accelerator, with energy costs derived from the post-layout simulation.

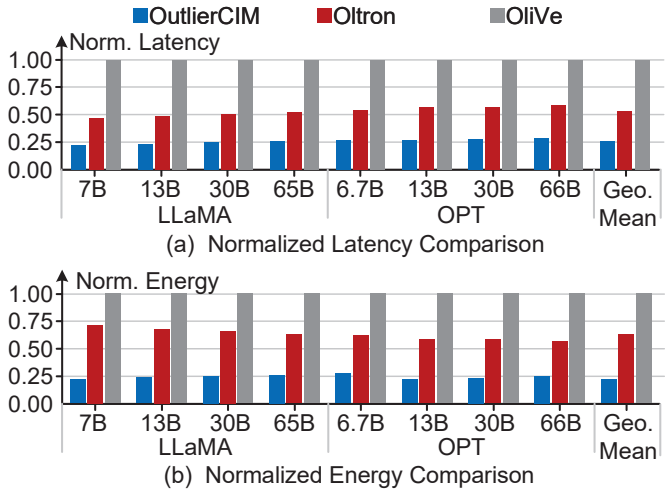

Fig. 10. Comparison of baseline accelerators and OutlierCIM on WikiText2.

Fig. 9 (a) displays the layout and summary of the OutlierCIM accelerator. Notably, the counterpart of the CIM macro array is derived from post-simulation in Virtuoso.

B. Algorithm Result

The comparison between OutlierCIM algorithm and other methods is shown in Table I. The activation bit-width of OutlierCIM is 4.1-bit, as partial activations are stored in BF16 format, following the same definition as Oltron [15]. The perplexity of OutlierCIM without group-wise weight quantization is slightly higher than that of Oltron due to the loss introduced by symmetric weight quantization. However, the co-design framework of OutlierCIM with group-wise weight quantization surpasses the baselines across all benchmarks.

C. Hardware Result

Detailed Configuration. The detailed configuration of OutlierCIM is shown in Fig. 9 (a). The area and power breakdown are presented in Fig. 9 (b).

Performance. For a fair comparison of different architectures, the throughput values of the baseline accelerators are scaled to the same level, following the methodology described in [30]. Fig. 10 (a) highlights the superior performance of OutlierCIM, which achieves an average speedup of 2.06× and 3.91× compared to Oltron and OliVe, respectively.

Energy. Fig. 10 (b) displays the energy comparison between OutlierCIM and the baseline accelerators. OutlierCIM achieves lower energy consumption than OliVe and Oltron while delivering higher performance. Specifically, OutlierCIM achieves an average energy efficiency improvement of 4.54× and 2.83× compared to OliVe and Oltron, respectively.

Comparison with State-of-the-Art Works. Table II provides a detailed comparison with state-of-the-art works. ReDCIM [20] is a unified FP/INT CIM-based accelerator, while OliVe [14] and Oltron [15] are digital outlier-aware accelerators. Compared to the baseline CIM-based accelerator, OutlierCIM supports additional computation paradigms and achieves superior energy efficiency for LLM workloads. Moreover, OutlierCIM demonstrates top-tier energy efficiency compared to the baseline outlier-aware accelerators.

V. CONCLUSION

This paper proposes OutlierCIM, the first framework to address LLMs acceleration with a CIM-based accelerator and outlier-aware quantization algorithm co-design. The key insights of OutlierCIM are: 1) At the hardware aspect, a reconfigurable double-bit CIM array is designed to overcome the low efficiency of previous accelerators. 2) At the algorithm aspect, a hybrid-strategy quantization algorithm and a map strategy are proposed to boost the efficiency of the CIM array at workloads caused by outliers. Combining these two parts, the proposed OutlierCIM achieves up to 4.54× energy efficiency and 3.91× speedup compared to baseline accelerators at comprehensive benchmarks.

***Abstract*—A significant number of users depend on Large Language Models (LLMs) for downstream tasks, but training LLMs from scratch remains prohibitively expensive. Sparse fine-tuning (SFT) has emerged as an effective strategy to reduce both the time and memory requirements of fine-tuning LLMs, achieving accuracy on par with fully fine-tuned models. Although SFT has the potential to achieve superior performance by minimizing computational requirements, SFT on GPUs often underperforms compared to dense algorithms like LoRA due to sparse data accesses that modern GPUs cannot efficiently handle. To address these issues, we propose Structured Sparse Fine-Tuning (SSFT). It comprises a novel algorithm, SSFT-Alg, which introduces predictable sparsity patterns to reduce memory access overhead and enhance regularity in the SFT process. To support SSFT-Alg, an accelerator, SSFT-Hw, is proposed to optimize SSFT-Alg through an innovative sparsity-aware design, avoiding the overhead of sparsity operations on GPUs and optimizing latency and energy efficiency. Experiments with relevant models and benchmarks demonstrate that SSFT achieves comparable accuracy to state-of-the-art models on BERT, LLaMA 2 7B, and LLaMA 2 13B. Moreover, SSFT-Hw outperforms both GPUs and the state-of-the-art sparsity-aware transformer accelerators in throughput by $51.0\times$ and $1.32\times$, respectively, while improving energy efficiency by $19.0\times$ and $1.48\times$.**

I. Introduction

The scale of Large Language Models (LLMs), such as BERT [8], GPT-4 [1], and LLaMA [22], is fundamental to their cutting-edge performance. Adopting these models on downstream tasks is a universal demand, but the training cost makes it inaccessible for most users. Fine-tuning is the most practical approach for general users and companies to improve the accuracy of LLMs for these downstream tasks. However, fully fine-tuning these large models is hindered by their extensive memory and time requirements. Recent advancements in fine-tuning methods, particularly those employing Sparse Fine-Tuning (SFT) strategies, have demonstrated significant promise in reducing the memory requirements and latency while retaining accuracy [3], [4], [21]. These methods improve the balance between a minimal number of parameters and superior fine-tuning accuracy without introducing additional parameters into the LLM architectures like LoRA [11]. This approach effectively eliminates extra memory and computation overhead in practical applications.

Although SFT algorithms exhibit significant promise to minimize the number of parameter updates compared with dense fine-tuning techniques [12], their unique sparsity characteristics pose compatibility issues with contemporary processors, such as GPUs and Transformer accelerators, due to the irregularity in gradient calculation, the most time- and energy-intensive aspect of LLM fine-tuning. Specifically, as shown in Fig. 1, SFT algorithms either dynamically or statically calculate masks from the information derived from previous training steps. These masks are then applied to the gradients to update the current parameters. According to the principle of SFT algorithms, the bulk of gradients do not contribute to weight updates, leading to a large number of unnecessary memory accesses and MAC operations, given that a substantial majority of parameters ($> 95\%$) are frozen. Therefore, efficiently managing the masked gradients is key to improving the performance of SFT. However, neither the GPUs nor the state-of-the-art sparsity-aware transformer accelerators can efficiently manage the irregularity and high sparsity of masked gradients. As depicted in Fig. 1, computing the gradients matrix $\frac{\partial L}{\partial W}$ for parameter matrix W requires 16 memory accesses and 64 MAC operations but 12 accesses and 48 MAC operations are unnecessary for this algorithm, resulting in inefficiencies in both latency and energy consumption.

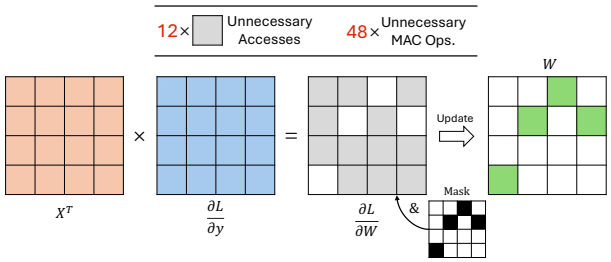

Fig. 1. An example of weight gradient generation and weight update stages with the previous sparse fine-tuning algorithm. While all weight gradients are calculated, only 4 are utilized to update weights, leading to 12 unnecessary accesses and 48 unnecessary MAC operations. SSFT can eliminate unnecessary accesses and operations.

The design of current accelerators, particularly those for Transformers (the foundational architecture of LLMs), fails to efficiently support sparsity throughout fine-tuning [20], [23], [24], [28]. The state-of-the-art sparsity-aware transformer accelerator, TransCODE [24], demonstrates limitations in handling LLM fine-tuning with high sparsity because of the

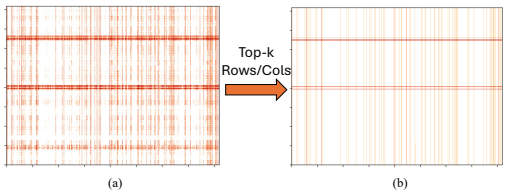

Fig. 2. (a) The distribution of top-k gradients in the parameters of Attention-Q in the first layer of LLaMA 2 7B. Similar structures are observed in crucial parameter matrices across Transformer-based LLMs like BERT and LLaMA. (b) SSFT selects the top-k rows and columns of crucial parameters to generate the structured mask of Attention-Q.

high energy cost and latency of processing irregular sparse data and the requirement to load all weights into the on-chip buffer for computation. Even though the design has proven its effectiveness for mid-size language models such as $\text{BERT}_{\text{TINY}}$ [25](∼4M params) and $\text{BERT}_{\text{BASE}}$ [8](∼110M params), it still struggles with larger size models such as $\text{BERT}_{\text{LARGE}}$ [8] (∼340M params) or LLaMA 2 [22] ($>$ 7B params) due to the high memory requirements. Other designs, such as accelerators for SpM*SpM [19], fail to accelerate Transformer-based models adequately due to their inability to perform specific Transformer operations like Softmax and layer normalization [20].

A key insight is that *previous work has not been able to take advantage of structured information in SFT,* given that structured sparsity is recognized for its hardware compatibility in AI workloads [5], [6], [10]. To bridge the gap between SFT algorithms and hardware, we present Structured Sparse Fine-Tuning (SSFT), a collaborative approach at the algorithm (SSFT-Alg) and hardware levels (SSFT-Hw). Fig. 2(a) illustrates the distribution of original top-k parameters based on gradients, revealing row and column patterns that previous work has overlooked. Building on this observation, SSFT-Alg structurally selects rows and columns containing a top-k number of values, shown in Fig. 2(b), while maintaining comparable accuracy. This is because structured sparsity retains most of the essential information from the original crucial parameters. Meanwhile, given that structured sparsity is recognized for its hardware compatibility in AI workloads [5], [6], [10], attributable to uniform memory access patterns and computation, it gives SSFT-Alg the opportunity to surpass the performance and energy efficiency of unstructured algorithms.

To leverage the potential of SSFT-Alg and address the inefficiencies of existing hardware in handling high sparsity, we propose SSFT-Hw, an accelerator designed with highly parallel dataflow and sparsity-aware modules that bypass unnecessary gradient computations and flexibly handle various stages of the fine-tuning process. In addition, SSFT-Hw can process Softmax and layer normalization operations, which are not supported by general SpM*SpM accelerators. This hardware is the first accelerator that can support sparse fine-tuning on LLMs, providing higher efficiency than GPUs and existing accelerators in handling high-sparsity fine-tuning. The main contributions of our work follow.

- We introduce a novel structured sparse fine-tuning algorithm called SSFT-Alg. Based on the inherent structural characteristics in parameter matrices, SSFT-Alg selects the top-k important rows or columns in the parameter matrix based on the gradient during the sampling process, establishing a pattern that allows for uniform access and processing of gradients while maintaining accuracy.
- We propose the SSFT-Hw accelerator, which leverages the sparse masks resulting from SSFT-Alg with a dataflow providing high parallelism and sparsity-aware modules. This design enables SSFT-Hw to achieve high performance and a low memory footprint with the regularity provided by SSFT-Alg.
- SSFT-Alg is verified on both BERT and LLaMA 2, demonstrating accuracy comparable to that of current algorithms. SSFT-Hw achieves $1.32\times$ higher throughput and $1.48\times$ greater energy efficiency compared to the SOTA while maintaining comparable accuracy.

TABLE I
DETAILED PROCESSES FOR LLM FINE-TUNING. VARIABLES INCLUDE L (LOSS), X (INPUT ACTIVATIONS), Y (OUTPUT ACTIVATIONS), W (WEIGHTS), γ (LEARNING RATE), AND W^* (UPDATED WEIGHTS).

Forward	$X \times W = Y$
Backward	$\frac{\partial L}{\partial Y} \times W^T = \frac{\partial L}{\partial X}$
Weight Gradient	$X^T \times \frac{\partial L}{\partial Y} = \frac{\partial L}{\partial W}$
Weight Update	$W - \gamma * \frac{\partial L}{\partial W} = W^*$

II. BACKGROUND AND MOTIVATION

A. Fine-tuning process of LLMs

Taking stochastic gradient descent, one of the standard fine-tuning algorithms for LLMs, as the example, it comprises four stages, illustrated in Table I:

- The forward stage runs the inference algorithm to determine the model's predictions for training inputs and calculate the loss L (i.e., the training error). This consists of convolving the input tensor X with a set of weights W to obtain the output tensor Y.
- The backward stage propagates the loss gradient across the model's layers. This is done by convolving the loss gradient with respect to the output gradients $\frac{\partial L}{\partial Y}$ with transposed weights W^T.
- The weight gradient generation stage calculates the gradients that are utilized in updating weights. This consists of convolving the backpropagated loss gradients with respect to the gradient $\frac{\partial L}{\partial Y}$ with the transposed input X^T.
- The weight update stage determines how much weight should be decreased by computing the multiplication of learning rate γ and gradients $\frac{\partial L}{\partial W}$.

B. Motivation

To further illustrate the suboptimal performance of the SFT algorithm on GPUs, we compare SFT with LoRA (set to rank 64 to achieve the same sparsity as SFT) in terms of the number of operations, latency, and efficiency (ops/cycle). As shown in Fig. 3, despite original SFT processes 41.6% fewer number of operations than LoRA, which has the potential to outperform LoRA on GPUs, its latency and efficiency

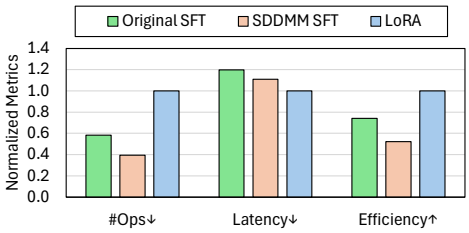

Fig. 3. Comparison of original SFT, SDDMM SFT, and LoRA in terms of number of operations, latency, and efficiency (ops/cycle). All metrics are normalized to LoRA. ↑ indicates that taller bars are better, while ↓ indicates the opposite. While the SDDMM version of SFT reduces 32.6% #Ops, it reduces latency by only 7.2% and decreases efficiency by 25.7%.

is 20.0% and 25.9% lower, respectively. Then we optimize the core operation, gradient generation, in SFT with a more efficient implementation called Sampled Dense-Dense Matrix Multiplication (SDDMM) [16], which is supported by the NVIDIA cuSPARSE library. Enhanced with SDDMM, GPUs calculate only the necessary weight gradients instead of the entire weight gradient matrix. Despite SDDMM reducing 32.6% operations, as shown in Fig. 3, total latency decreases less than only 7.2% over the original SFT, and the efficiency even becomes worse. This decline is due to low-computation-density operations such as gather_scatter and topk in SFT prevent optimal performance. Specifically, gather_scatter and topk account for 32.2% of cycles but only 0.8% of operations, which significantly harms efficiency. Therefore, based on current GPUs and optimization libraries like cuSPARSE, the potential of SFT cannot be fully realized. Both an efficient algorithm and a customized accelerator capable of efficiently processing SFT are critically required.

III. Structured Sparse Fine-Tuning

One of the main contributions of this paper is a method for pre-computing a structured sparse subset of a model's parameters to update over many subsequent training iterations. To construct such a subset, we calculate the average of gradients as a signal of how important the parameter is for a given task during sampling. We then select the top-k rows and columns from the gradient matrix to create a subset of it. We refer to the resulting subset (i.e., a list indicating which parameters are included in the subset) as a $mask$. In this section, we detail the steps necessary for computing a structured sparsity mask. This process is diagrammed in Fig. 4 and listed in Algorithm 1.

A. Crucial Parameter Detection

Unlike previous works that utilize complex and time-consuming methodologies such as Fisher information [21], lottery-ticket [2], and delta vectors [3], SSFT-Alg adopts a static top-k gradient selection method to reduce running overhead while maintaining accuracy. The first step of SSFT-Alg is to select the subset of parameters that are crucial to update. One way to generate this subset is to consider how much each of the parameters will be impacted by the training data. In the general training process of neural networks, gradients are utilized to update the parameters with different

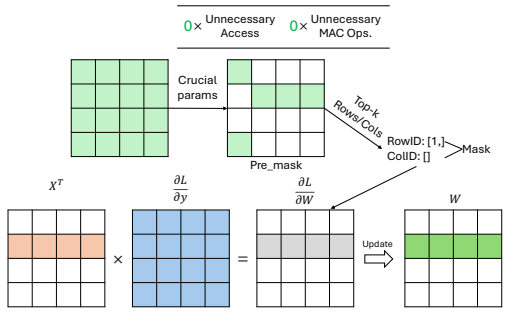

Fig. 4. An example of SSFT-Alg involves calculating trainable parameters of 4×4 weight matrix. SSFT-Alg selects the crucial parameters based on gradients after sampling. It selects rows or columns with the highest number of crucial parameters, incorporating them into a list of trainable elements. This list, comprising all trainable rows and columns, is employed during gradient computation to minimize unnecessary access and processing.

types of optimizers. As lines 4-9 show, SSFT-Alg takes the $sampling_steps$ as a parameter to decide the number of steps required by sampling. The parameters are updated in the same way as done in the general training process. The gradients of each of the parameters are then accumulated. After collecting all gradients, weights are reset to the original weights to avoid the impact of the sampling step. After completing the sampling process, the gradient matrices of each layer are scanned. The top-k gradients are selected from the matrices based on the

sparsity requirement from the input. These generated masks are named *pre-masks*. Despite current SFT algorithms that can generate or detect crucial parameters, they leave irregularity and dynamic detection overhead that harm both performance and memory access. In the next section, we describe how SSFT-Alg takes this data to introduce structured sparsity.

B. Mask Generation

Recall that our goal is to get subsets of trainable parameters in each layer with structured sparsity to update over many iterations of training while keeping the remainder of the parameters fixed. SSFT-Alg scans all pre-masks of each layer horizontally and vertically. During the scan process, SSFT-Alg counts non-zero values of each row and column (lines 17-25). After scanning all pre-masks, SSFT-Alg selects rows or columns with the top-k number of non-zero values as the final masks. Fig. 2 shows an example of this step. Intuitively, the pre-mask with irregular distribution is converted to a structured distribution with more regularity. Taking Fig. 4 as an example, there are 5 parameters selected as the crucial parameters. Two of these values are in the first column and three of these values are in the second column. If k is set to 1, which means 1 row or column with the maximal number of values is selected, the second row is selected as the *mask*. The mask generation stage of SSFT-Alg can be utilized not only with our crucial parameter detection method but also can cooperate with any of the mask selection methodologies as a plug-in, like Fish [21], Delta [3], etc.

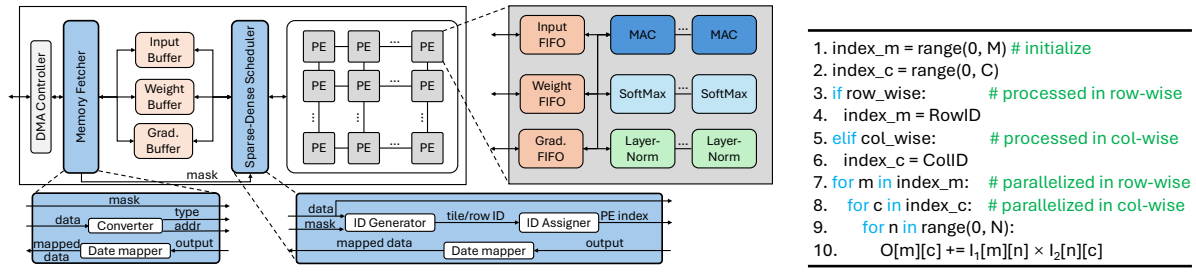
C. Weight Update

After generating the structured sparse masks, these masks are utilized in the weight-updating stage. As shown at the bottom of Fig. 4, the gradients are computed based on the generated masks. Specifically, only rows and columns recorded in the list are required to be computed in the weight-updating stage. Therefore, SSFT-Alg only needs to access specific rows or columns of input matrices, which are X^T and $\frac{\partial L}{\partial Y}$, to generate necessary gradients ($\frac{\partial L}{\partial W}$). Furthermore, to update the weight matrix with the gradients of each weight, only specific rows and columns are updated.

IV. Microarchitecture

Fig. 5(a) shows an overview of SSFT-Hw. Two critical sparsity-aware modules, Memory Fetcher and Sparse-Dense Scheduler, are highlighted for clearer visualization of their details. Data is brought to the on-chip buffers from DRAM by the direct memory access (DMA) controller. Memory Fetcher fetches distinct types of data according to the stages and transfers data to the on-chip buffer. It also sends information about mask and sparse-dense mode to the Sparse-Dense Scheduler. The buffers store the activations, gradients, and weights, respectively. Sparse-Dense Scheduler passes data from on-chip buffers to the PE array. The PE array uses the compressed data and compression information in the $mask$ to perform the main compute operations in the LLM fine-tuning.

A. Sparsity-aware Design



Due to irregularity and limited sparsity support, existing hardware platforms struggle with sparse fine-tuning. To efficiently support the structured sparse fine-tuning algorithms, two sparsity-aware modules, Memory Fetcher (Fetcher) and Sparse-Dense Scheduler (Scheduler), are introduced into the SSFT-Hw. Combined with a novel structured sparse dataflow shown in Fig. 5(b), Fetcher and Scheduler enable SSFT-Hw to process SSFT-Alg with high efficiency. There are four steps in fine-tuning LLMs: forward, backward, weight gradient generation, and weight update. SSFT-Hw processes weight gradient generation and weight update with sparse mode and forward and backward with dense mode.

In the sparse mode, to address the irregularity and sparsity issues shown in Fig. 1, Fetcher first takes the $mask$ generated by Algorithm 1 as the additional input, along with transposed input X and gradient $\frac{\partial L}{\partial Y}$ from previous layer in the weight gradient generation stage. In $mask$, gradients to be updated are represented in a structured way, which stores only row and column indices to avoid the overhead of unstructured data storage in a general compressed format. Fetcher parses data from DRAM based on the information in $mask$. Parsed values are stored separately in on-chip buffers. $Mask$ is then passed to the Scheduler for further processing. Scheduler reads data stored in on-chip buffers according to the information in $mask$, assigning data to different PEs based on row/column IDs for parallel processing, as shown at the bottom of Fig. 5(a). SSFT-Hw generates output matrix row by row or column by column following the information in $mask$. This also means that only several rows or columns of the input matrix (matrices X^T and $\frac{\partial L}{\partial Y}$) are required during the computation. After completing the computation of gradients, Fetcher fetches the relevant weights and updates weights with the structurally masked gradients without any unnecessary computation and memory access. In dense mode, SSFT-Hw performs dense-dense matrix multiplication during forward and backward stages in a tiled approach, a technique widely used in current accelerators [24].

The main modules present inside a PE are shown on the right of Fig. 5(a), which is the basic compute block in our accelerator. The PE design is based on an open-source design [24]. The data are stored in local registers of the PE by the input first-in-first-out (FIFO), weight FIFO, and gradient FIFO registers. PE takes the structured data and data information from DRAM. The PE then forwards data and information to the MAC lanes (for matrix multiplication), SoftMax modules (for SoftMax operation), or the Layer-Norm module (for layer normalization operation). MAC lanes and SoftMax modules can be utilized simultaneously with the schedule of the Scheduler to achieve high utilization. Finally, PE will write the results into input FIFO and then write the results back to the DRAM.

B. Dataflow

As shown in Fig. 5(b), a novel dataflow is proposed to enable high parallelism in SSFT-Alg. An $M \times N$ matrix

(a) Hardware architecture

```
1. index_m = range(0, M) # initialize
2. index_c = range(0, C)
3. if row_wise:          # processed in row-wise
4.   index_m = RowID
5. elif col_wise:        # processed in col-wise
6.   index_c = ColID
7. for m in index_m:     # parallelized in row-wise
8.   for c in index_c:   # parallelized in col-wise
9.     for n in range(0, N):
10.      O[m][c] += I1[m][n] × I2[n][c]
```

(b) Dataflow

Fig. 5. (a) The hardware architecture of SSFT-Hw consists of the DMA controller, Memory Fetcher, on-chip buffers, Sparse-Dense Scheduler, and PE array. Each PE contains three types of FIFOs to store inputs, weights, and gradients. These FIFOs are connected with three types of computing units: MAC units, SoftMax units, and layer normalization units. (b) The dataflow used in SSFT-Hw to process the sparse weight gradient generation. Row or column are processed by a single PE in parallel.

TABLE II
SPECIFICATION OF SSFT-HW.

Module	Configuration	Module	Configuration
DRAM Bandwidth	256GB/s	LayerNorm Units	1/PE
PEs	512	Act. Buffer	16MB
MAC Units	32/PE	Weight Buffer	64MB
SoftMax Units	32/PE	Grad. Buffer	16MB

(I_1) is multiplied by an $N \times C$ matrix (I_2) to generate an $M \times C$ matrix (O). Rows or columns to be processed are specified by array RowID or ColID (line 3 to line 6), which store mask information as shown in Fig. 4. Each row or column is processed by a dedicated PE in parallel, maximizing parallelism (lines 7 and 8). Consequently, each PE outputs a complete row or column (lines 9 and 10). This dataflow maximizes resource utilization, achieving high efficiency by eliminating zero values and irregularity.

V. EVALUATION

A. Experiment Setup

1) Algorithm: We demonstrate that our approach matches the performance of standard gradient-based training on the GLUE benchmark [26] while updating only 5% of the model's parameters per task. All experiments for GLUE are run with the $\text{BERT}_{\text{LARGE}}$ variant of BERT [8]. Sampling_step is 5.

To demonstrate the effectiveness of SSFT-Alg on larger models, we instruction-tune LLaMA 2 7B and 13B on Flan v2 [14] and GPT4-Alpaca [17] with 2.3% density mask. We evaluate instruction-tuned LLMs on the following benchmarks to capture a range of abilities: MMLU [10], TyDiQA [6], and HumanEval [5]. Furthermore, we compare SSFT-Alg with LoRA [11], as it offers the best performance–efficiency trade-off and is arguably the most widespread pre-existing PEFT method [7], as well as IA^3 [13]. We use the LoRA and IA^3 implementations in the PEFT library [15]. Experiments of BERT and LLaMA 2 7B are run on an NVIDIA A100-40GB and LLaMA 2 13B is run on an NVIDIA H100-96GB.

2) Hardware: To have a fair comparison with the state-of-the-art work, TransCODE, we set our hardware configuration the same. Table II shows the associated design choices. The RTL model is synthesized using Synopsys Design Compiler version P-2019.03, targeting the 14-nm FinFET technology library [9], which provides power and area information in the synthesis report. We fixed the clock rate to 700 MHz based on the delay of all modules in the proposed architecture. We set the number of multipliers to 16 in each PE. We run the simulation to get the latency based on the open-source simulator proposed by TransCODE [24] along with our hardware modules. We compare the performance of SSFT-Hw with many previously proposed accelerators.

TABLE III
GLUE TEST SERVER EVALUATION RESULTS WITH $\text{BERT}_{\text{LARGE}}$. TRAINING WITH THE SSFT-ALG GAINS COMPETITIVE ACCURACY WHILE UPDATING ONLY 5% OF MODEL PARAMETERS.

Method	FullFT	Bit Fit	Diff Pruning	Monarch	Fish Mask	SSFT-Alg
QNLI	93.4	90.4	91.9	87.0	93.3	**93.1**
SST-2	94.0	94.5	93.8	92.4	93.6	**93.1**
MNLImm	87.0	84.8	85.5	82.3	85.6	**86.0**
CoLA	66.0	60.3	61.0	59.6	64.8	**64.1**
MRPC	88.8	86.3	86.2	90.1	89.6	**89.9**

QQP	91.2	78.5	80.1	87.7	89.1	**88.6**
AVG	85.6	81.2	81.5	82.8	85.2	**85.0**

B. Accuracy of SSFT-Alg

1) BERT: Our results on SSFT-Alg can be seen in Table III. SSFT-Alg training results in effectively the competitive accuracy (85.0%) with SOTA SFT [21] (85.2%) and standard "dense" fine-tuning (85.6%), despite updating just 5% of $\text{BERT}_{\text{LARGE}}$ parameters. Specifically, SSFT-Alg reduces maximally 0.7% accuracy in each task and achieves only 0.2% accuracy reduction compared with Fish Mask. SSFT-Alg training is competitive with all other parameter-efficient transfer learning approaches.

2) LLaMA 2: We present the main results of our experiments in Table IV. For LLaMA 2 7B, we find that SSFT-Alg outperforms LoRA and IA^3 consistently across evaluation benchmarks and instruction tuning datasets, including Flan v2 and GPT4-Alpaca. SSFT-Alg achieves better accuracy than LoRA on 5 out of 6 tasks. We also find that 4-bit quantization

TABLE IV
ACCURACY OF PEFT AND QUANTIZED PEFT ALGORITHMS ON A RANGE OF EVALUATION TASKS FOR VARIOUS INSTRUCTION TUNING DATASETS.

Method	Flan v2 MMLU				Flan v2 TyDiQA				GPT4-Alpaca HumanEval			
	LLaMA 2 7B		LLaMA 2 13B		LLaMA 2 7B		LLaMA 2 13B		LLaMA 2 7B		LLaMA 2 13B	
	Original	Quant	Original	Quant	Original	Quant	Original	Quant	Original	Quant	Original	Quant

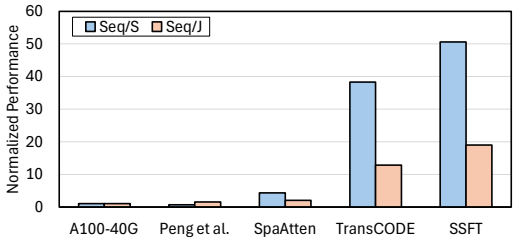

Fig. 6. Performance and energy efficiency comparisons. Seq/S represents sequences per second, and Seq/J represents sequences per joule. Implementation on A100-40GB is based on original $\text{BERT}_{\text{base}}$ [8].

TABLE V
LATENCY AND ENERGY EFFICIENCY OF RUNNING LARGER MODELS ON DIFFERENT PLATFORMS. TRANSCODE CANNOT SUPPORT LLAMA 2 7B DUE TO THE OUT-OF-MEMORY (OOM) ISSUE.

Model	Design	Seq/S	Seq/J
$\text{BERT}_{\text{LARGE}}$	A100	31.90	0.13
	TransCODE	357.90	2.06
	SSFT-Hw	476.61	3.13
LLaMA 2 7B	A100	2.21	0.01
	H100	6.40	0.02
	TransCODE	OOM	OOM
	SSFT-Hw	8.70	0.04

results in only a modest reduction in performance across PEFT methods, and their relative performance remains similar. These results demonstrate that SSFT-Alg is a competitive PEFT method even in extremely resource-constrained scenarios. Meanwhile, SSFT-Alg can also achieve competitive accuracy with the SOTA SFT, SpIEL [3], with less than a 0.2% accuracy drop for all but one task. On LLaMA 2 13B, SSFT-Alg archives less than 0.2% accuracy drop. On some of the tasks, such as MMLU, SSFT-Alg even achieves better accuracy than SpIEL. Overall, SSFT-Alg is competitive in all 6 combinations of scales and instruction tuning datasets on LLaMA 2 with less than a 1% accuracy drop. Hence, SSFT-Alg appears to be a strong method that provides competitive accuracy with a hardware-friendly algorithm.

C. Performance and Energy Efficiency of SSFT

Fig. 6 shows performance comparisons of SSFT with various platforms. These platforms include NVIDIA A100, which is widely used in LLM fine-tuning. We also add co-design methods implemented on ASIC-based accelerators [24], [27] and FPGAs [18]. The throughput and energy values are normalized with respect to the A100 GPU. Since some of the baselines do not support training, we report the performance values based on the inference performance scaling with the percentage of computation in the inference stage proposed in [24]. SSFT achieves $51.0\times$ higher throughput and $19.0\times$ lower energy consumption when compared to the off-the-shelf A100 GPU. SSFT also outperforms the state-of-the-art sparsity-aware Transformer training accelerator TransCODE $1.32\times$ on throughput and $1.48\times$ on energy consumption, respectively. Furthermore, to demonstrate the scalability of our methodology, we present the latency and energy consumption on $\text{BERT}_{\text{LARGE}}$ and LLaMA 2 7B in Table V. On $\text{BERT}_{\text{LARGE}}$, SSFT-Hw outperforms A100 and TransCODE $14.94\times$ and $1.33\times$, respectively, in terms of latency (Seq/S). And it outperforms TransCODE $1.52\times$ on energy efficiency (Seq/J). On LLaMA 2 7B, TransCODE fails to support fine-tuning due to memory limitations. Consequently, SSFT-Hw is $3.9\times$ and $1.4\times$ faster than A100 and H100, respectively, while saving $4.0\times$ and $2.0\times$ energy compared to the A100 and H100. These performance gains can be attributed to the support of structured gradient generation.

VI. CONCLUSION

This work introduces Structured Sparse Fine-Tuning (SSFT), a significant advancement in fine-tuning LLMs that bridges the gap between algorithmic efficiency and hardware capability. SSFT-Alg shows that integrating structured sparsity into the fine-tuning process is possible. Complemented by the SSFT-Hw accelerator which is designed to efficiently utilize sparse gradients with sparsity-aware modules and a novel dataflow, our approach not only enhances computational efficiency and reduces memory usage but also demonstrates superior performance and energy efficiency compared to existing methods. Validated on prominent models like BERT, LLaMA 2 7B and 13B, SSFT outperforms GPUs and the state-of-the-art sparsity-aware transformer accelerators by $51.0\times$ and $1.32\times$ in throughput and $19.0\times$ and $1.48\times$ in energy efficiency, respectively, with less than 1% accuracy reduction.

***Abstract*—3D Gaussian Splatting (3DGS) has gained popularity for its efficiency and sparse Gaussian-based representation. However, 3DGS struggles to meet the real-time requirement of 90 frames per second (FPS) on resource-constrained mobile devices, achieving only 2 to 9 FPS. Existing accelerators focus on compute efficiency but overlook memory efficiency, leading to redundant DRAM traffic. We introduce STREAMINGGS, a fully streaming 3DGS algorithm-architecture co-design that achieves fine-grained pipelining and reduces DRAM traffic by transforming from a tile-centric rendering to a memory-centric rendering. Results show that our design achieves up to 45.7× speedup and 62.9× energy savings over mobile Ampere GPUs.**

***Index Terms*—3D gaussian splatting, rendering, accelerator**

I. INTRODUCTION

In virtual and augmented reality (VR/AR), photo-realistic and real-time rendering is essential for delivering immersive user experiences. Among various rendering techniques [1]–[6], 3D Gaussian Splatting (3DGS) [7]–[12] has quickly gained its popularity for its efficient rendering process and sparse Gaussian representation (also called Gaussian ellipsoids) of scene geometries.

Nevertheless, 3DGS still falls short of the real-time requirement in the VR/AR domain, namely 90 frames per second (FPS) [13]–[15], on mobile devices like VR headsets. Our experiments show that 3DGS merely achieves 2 to 9 FPS on the Nvidia Orin NX [16] [1]. Although several studies have proposed dedicated accelerators for 3DGS [18], their designs primarily optimize compute efficiency and often overlook off-chip memory traffic during rendering, making them hard to satisfy the real-time requirement in real-world scenarios.

Algorithmically, existing methods [7], [18] focus on a tile-centric rendering paradigm which requires excessive intermediate data communication between stages, leading to frequent off-chip traffic in Fig. 1a. Our characterization shows that, under a 90 FPS real-time requirement, the DRAM traffic of the current rendering paradigm would exceed the bandwidth limits of today's mobile devices on real-world scenes (Sec. II-B).

[1]The performance of the Ampere GPU (3.7 TFLOPS, released in February 2023) is comparable to that of the GPU (3.5 TFLOPS) in the latest Snapdragon XR2 [17], released in September 2023 for VR.

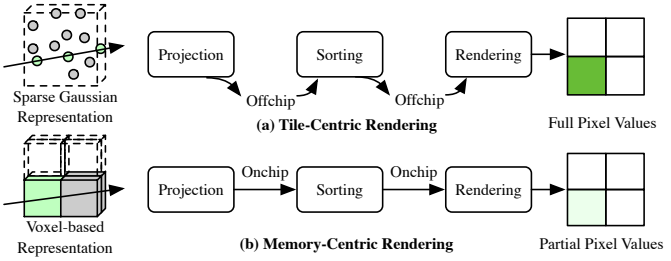

Fig. 1. Tile-centric rendering (a) vs. memory-centric rendering (b). The computation pattern is highlighted in green. Tile-centric rendering computes the complete pixel values tile-by-tile. Memory-centric rendering computes the partial pixel values voxel-by-voxel and regularizes the memory accesses.

The high data communication in the conventional tile-centric rendering comes from sequential processing ray-Gaussian intersections for each individual pixel, leading to redundant off-chip traffic and memory irregularity [18]–[21]. To address the bandwidth limitation, we argue to shift the rendering paradigm from a *tile-centric* to a *memory-centric* approach. Here, we introduce a fully streaming algorithm for 3DGS to address memory access irregularity (Sec. III). Our key idea is to regularize sparse Gaussian representations by partitioning the scene into voxels and performing on a voxel basis as shown in Fig. 1b. With all the points within a voxel stored contiguously in DRAM, we allow all points within a voxel to be streamed onto the on-chip buffer and only write the final pixel values off-chip, completely eliminating the intermediate off-chip traffic between stages.

While our memory-centric approach eliminates the intermediate off-chip traffic, our approach potentially introduces unnecessary off-chip traffic at the voxel streaming, as all points within a voxel are loaded on-chip as a whole. To reduce the unnecessary off-chip traffic, we propose hierarchical filtering to progressively exclude irrelevant Gaussians (Sec. III-B).

Specifically, we split each Gaussian feature into two halves and intentionally keep the first half lightweight. We then perform coarse yet lightweight computation to filter out irrelevant points based on the first half (i.e., the position and radius). Next, we perform precise filtering to further remove the irrelevant Gaussians by loading the second half. To further

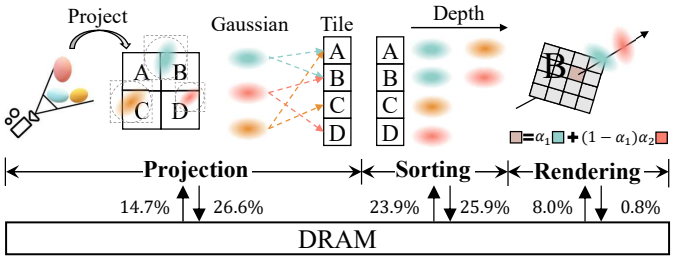

Fig. 2. The overall rendering pipeline of 3DGS. The percentage numbers represent the DRAM traffic proportion across stages.

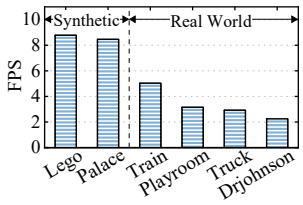

Fig. 3. FPS of different scenes on a mobile SoC, Orin NX. 3DGS cannot achieve real-time on both synthetic and real-world scenes.

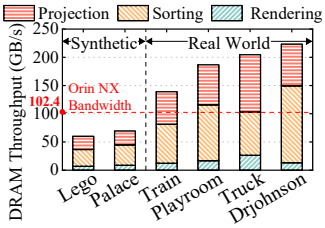

Fig. 4. The DRAM bandwidth requirement for 90 FPS under different scenes. The red dashed line highlights the bandwidth limit of Orin NX.

reduce the overhead of feature loading, we compress the second half using vector quantization. By storing a compact codebook on-chip, we just need to fetch their lightweight indices from DRAM. In this way, we drastically reduce the DRAM traffic at the voxel streaming.

To unleash the full potential of our fully streaming algorithm, we co-design an efficient accelerator (Sec. IV), including a voxel sorting unit to accelerate the determination of voxel rendering order and a dedicated hierarchical filtering unit to support Gaussian filtering at the voxel streaming. Coupled with our algorithmic optimizations, our design achieves a 45.7× speedup and 62.9× energy savings compared to a Nvidia mobile Ampere GPU [16]. Even compared against the state-of-the-art accelerator, GSCore [18], we can achieve a 2.1× speedup and 2.3× energy savings.

In summary, our contributions are as follows:

- We introduce a *memory-centric* rendering paradigm that can achieve fully streaming 3DGS rendering, completely avoiding intermediate off-chip traffic.
- We propose a hierarchical filtering scheme to further reduce the data traffic of the voxel streaming.
- With our architectural supports, our optimizations achieve an order of magnitude speedup and energy savings compared to a mobile Ampere GPU. We also achieve a 2.1× speedup and 2.3× energy savings against GSCore.

II. Background and Characterization

A. Background

Overall, 3DGS uses Gaussian ellipsoids to render a scene in a tile-by-tile fashion. Fig. 2 shows that this process can be classified into three stages:

- **Projection.** This stage projects each Gaussian ellipsoid onto the 2D screen and determines its intersected tiles as shown on the left side of Fig. 2. Each Gaussian might intersect with multiple tiles, as the colored dashed arrow lines show. Meanwhile, this stage calculates Gaussian properties, such as color and depth, for the later stages.
- **Sorting.** Each tile then sorts its intersected Gaussians based on Gaussian depths to ensure the correct rendering order from the closest to the farthest.
- **Rendering.** Every pixel within a tile traverses the same sorted Gaussian list and accumulates Gaussian colors to itself via alpha blending. For instance, we show tile B needs to blend two Gaussians, a blue one and a red one.

B. Characterization

Performance. We first show that 3DGS algorithms cannot achieve real-time performance on mobile devices. Fig. 3 characterizes the FPS of 3DGS [7] across various scenes on NVIDIA's Jetson Orin NX [16]. As the rendering scenes become more complex, shifting from synthetic to real-world scenes, performance drops from 8.5 to 4.9 FPS.

DRAM Traffic. We then show that DRAM traffic has a strong correlation with performance. Fig. 4 illustrates the DRAM throughput required to achieve the real-time requirement (90 FPS) for AR/VR applications [13], [14] across different rendering scenes. For real-world scenes, the DRAM bandwidth demand exceeds the bandwidth limit of a recently released mobile device, Nvidia Orin NX [16], as highlighted in the red dashed line. This means that the data communication requirement alone has made it impossible to achieve real-time.

We further dissect the DRAM traffic contributions across different scenes. As shown in Fig. 4, *projection* and *sorting* dominate the overall off-chip data communication, together accounting for 90% of the total DRAM traffic. The reasons that *projection* and *sorting* become the major contributors are:

- In projection, each Gaussian requires loading 59 parameters into the on-chip buffer and writing the processed features and intersection metadata back to DRAM, accounting for 41% of DRAM traffic.
- In sorting, repetitive read and write operations for progressive Gaussian sorting lead to repetitive DRAM access, taking up over 49% of DRAM traffic.

Overall, the intermediate data communication accounts for 85% of the total off-chip traffic in Fig. 2. This result motivates us to propose a fully-streaming algorithm that minimizes the off-chip traffic. Sec. III presents our algorithm design and Sec. IV explains the architectural support for our algorithm.

III. Algorithm Design

Sec. III-A first gives an algorithm overview and challenges that we need to address. Then, Sec. III-B and Sec. III-C explain the key components in our algorithm and the data layout that supports our algorithm, respectively.

A. Overview

The main downside of the original 3DGS pipeline is that it renders a frame tile-by-tile and each tile executes three stages sequentially. The reason is that the intermediate data of each

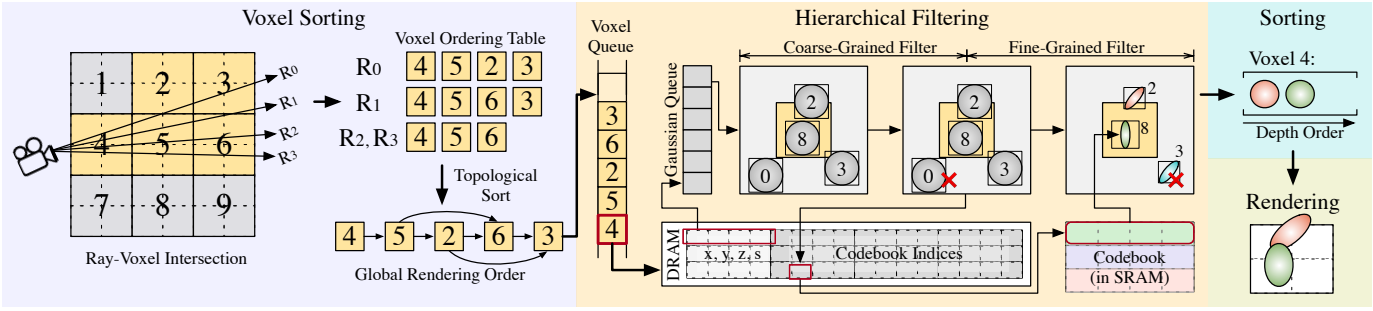

Fig. 5. The overview of our fully-streaming algorithm. Our algorithm initially partitions the entire 3D scene into small voxels. For each image tile, we first establish a rendering order of the intersected voxels via topological sort, then, process these voxels sequentially. During each voxel processing, we apply hierarchical filtering to further reduce the Gaussian loading within a voxel before the remaining sorting and rendering stages. The final pixel values are obtained by accumulating all the partial results across voxels.

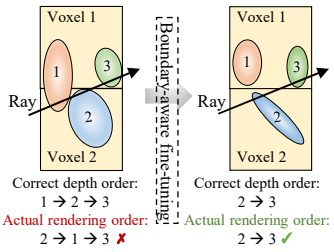

Fig. 6. An example of incorrect rendering order among Gaussians and the effect of boundary-aware fine-tuning.

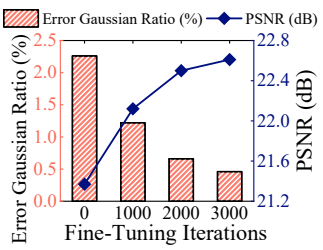

Fig. 7. Changes in the ratio of Gaussians with incorrect depth order and PSNR during the boundary-aware fine-tuning process.

stage is too large to be accommodated on-chip, inevitably, introducing frequent off-chip traffic during the execution.

Idea. To eliminate frequent off-chip communications at intermediate stages, our idea is to partition an entire 3D scene into small voxels and incrementally render the entire scene voxel-by-voxel. By processing one voxel at a time, our algorithm guarantees the intermediate data between stages can be completely held on-chip, thus, no off-chip traffic occurs.

Fig. 5 gives an overview of our algorithm. Our algorithm renders a group of pixels together, e.g., R_0 to R_3 are in the same group. For each group, we first identify which voxels intersect with these pixel rays and store the results in the voxel rendering table. Once each pixel's intersected voxels are determined, we establish their global rendering order. Then, each voxel goes through hierarchical filtering, sorting, and rendering in order, and obtain the partial pixel values of this tile. The final pixel values are obtained by accumulating all the partial results across voxels. By rendering one voxel at a time, each stage requires minimal data communication, thus, no off-chip traffic is required throughout the execution.

Challenges. However, there are three challenges when applying our algorithm:

- *Inter-Voxel Order.* Pixels within a single group often intersect with multiple voxels, as shown in Fig. 5. The rendering order for each pixel should be from the closest voxel to the farthest. The first challenge is to ensure the correct global order for all intersected voxels.
- *Cross-Voxel Gaussian Order.* Recall, each pixel is required to render Gaussians from the closest to the farthest in 3DGS, but the correct voxel-level ordering does not always guarantee the rendering order correctness at Gaussian-level granularity. For instance, on the left side of Fig. 6, Gaussian 2 in voxel 2 renders before Gaussian 1 in voxel 1, whereas the correct order should be reversed.
- *Redundant Gaussians in Voxels.* Lastly, each voxel includes Gaussians within close proximity; however, loading an entire voxel might unintentionally bring unrelated Gaussians on-chip. Leaving these redundant Gaussian without care would introduce excessive DRAM traffic.

B. Fully Streaming Algorithm

In this section, we explain how we address these challenges.

Inter-Voxel Order. To establish the correct voxel order across pixels in each tile, we first collect the rendering order of individual pixels in a voxel ordering table in Fig. 5. Based on individual rendering orders, we construct a direct acyclic graph (DAG), where each voxel is represented as a node, and edges represent the rendering dependencies. We then apply a topological sort [22] on the DAG to guarantee that no cycles in this graph and all the render dependencies are satisfied. The sorted order is then used in the remaining process.

Cross-Voxel Gaussian Order. To ensure correct rendering order among Gaussians, we observe that the incorrect order occurs only when a Gaussian spans across multiple voxels. In Fig. 6, Gaussians should be rendered from Gaussian 1 (the closest) to Gaussian 3 (the farthest). However, with voxel-by-voxel rendering, Gaussian 2 is incorrectly rendered before Gaussian 1. Fig. 7 shows that incorrect ordering can lead to a degradation in rendering quality.

To alleviate this issue, we introduce a *boundary-aware fine-tuning* to adjust cross-voxel Gaussians. Specifically, we keep each Gaussian position fixed to retain the scene geometry while fine-tuning its remaining trainable parameters, such as scale, orientation, etc. The fine-tuning reduces the size and modifies the orientation of Gaussians, minimizing their likelihood of spanning across other voxels.

In our fine-tuning, we propose a new loss function to punish the cross-boundary Gaussians,

$$\mathcal{L} = \mathcal{L}_{origin} + \beta \mathcal{L}_{CBP}, \tag{1}$$

where $\mathcal{L}_{origin}$ is the original loss in 3DGS and $\mathcal{L}_{CBP}$ is the cross-boundary penalty loss which penalizes Gaussians that span across voxel boundaries. β is a hyper-parameter to balance the influence of $\mathcal{L}_{CBP}$.

$\mathcal{L}_{CBP}$ minimizes the scale of the Gaussians that cross voxel boundaries and is expressed as,

$$\mathcal{L}_{CBP} = \frac{1}{N}\sum_{i=0}^{N-1} S_i T_i, \tag{2}$$

$$\text{where } T_i = \begin{cases} 1, & \text{if depth}_i < \max_{j\in[0,i)}\{\text{depth}_j\}, \\ 0, & \text{otherwise}, \end{cases}$$

where N is the total number of Gaussians, S_i is the maximum scale of Gaussian i. T_i is an indicator that checks if current Gaussian i has the largest depth compared to all previously rendered Gaussians. If this condition is not satisfied, we penalize it by setting T_i to be 1.

Fig. 7 illustrates the effectness of our boundary-aware fine-tuning. After 3,000 iterations, the percentage of cross-boundary Gaussians decreases from 2.3% to 0.4%, while the rendering quality regains from 21.37 dB to 22.61 dB.

Redundant Gaussians in Voxels. Recall that during projection, each Gaussian requires 59 parameters. To avoid irrelevant Gaussians, we propose a two-phase *hierarchical filtering* to progressively fetch Gaussian parameters in Fig. 5.

The first phase serves as a lightweight but coarse-grained filter that approximates whether Gaussians are intersected with the image tile. In this phase, each Gaussian only requests 4 parameters (3D coordinates and maximum scale) from off-chip memory to compute the projected center and the maximum projected radius with respect to the image tile. If a Gaussian does not pass the coarse-grained filter, we skip its remaining computations and avoid loading its remaining 55 parameters. For example, Gaussian 0 in Fig. 5 does not intersect with the image tile in yellow, we can safely remove it from the subsequent computation.

In the second fine-grained filtering, we identify the actual Gaussians that are intersected with the image tile by computing precise projection. For example, after getting shapes and orientations, we can know that Gaussian 3 in Fig. 5 does not intersect with the image tile actually and hence can skip its subsequent sorting and rendering. To further reduce the off-chip traffic, we propose a novel data compression scheme to encode the remaining parameters into a compact codebook. This way, we only need to load codebook indices from DRAM instead of the original parameters. We explain our data compression scheme in Sec. III-C. Combining coarse- and fine-grained filtering, our hierarchical filtering reduces the number of Gaussians processed in each voxel by 76.3%.

C. Customized Data Layout

To reduce data communication in hierarchical filtering, we propose a customized data layout in Fig. 8. Overall, we divide all Gaussian features into two halves, which are stored separately in DRAM and used at different filtering phases. The first half, containing 4 parameters (the 3D coordinates and maximum scale), is used for the coarse-grained filter. The second half, used in the fine-grained filter, includes the remaining parameters, such as rotation matrices.

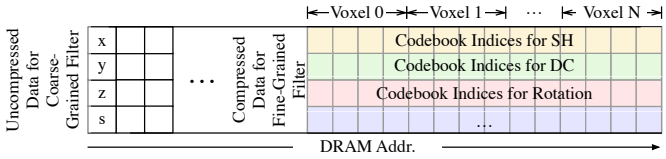

Fig. 8. The DRAM Data layout. We separate the Gaussian features into two halves for two filtering phases and compress the data for the second phase using vector quantization to reduce the off-chip communication.

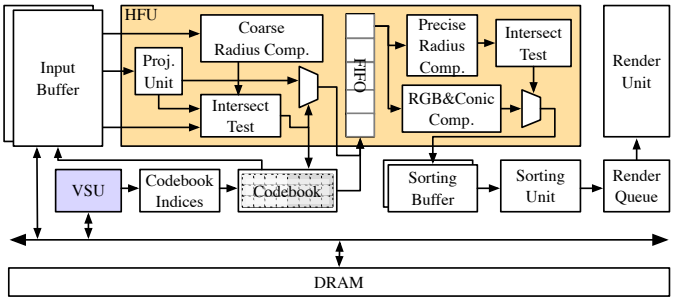

Fig. 9. Overview of StreamingGS accelerator, consisting of four components: a voxel sorting unit (VSU), a hierarchical filtering unit (HFU), a sorting unit, and a rendering unit. Our contributions are highlighted in colors: HFU is in yellow and VSU is in purple. The detailed design of VSU is in Fig. 10.

To alleviate DRAM traffic, we apply the vector quantization to compress the second half, so that we store only codebook indices off-chip while keeping the codebook itself on-chip for decoding. In addition, we encode different parameters into separate codebooks to preserve quantization precision and adopt the quantization-aware fine-tuning [9] to update the Gaussian parameters, allowing the indices to capture feature variations without loss of detail. Our result shows that, during the voxel streaming, only the codebook indices are fetched from DRAM and reduce 92.3% DRAM traffic. Note that, we only compress the second half, because we empirically find that compressing the first half leads to accuracy loss.

IV. Architectural Support

A. Overview

To support our fully-streaming algorithm, we propose our co-designed accelerator in Fig. 9. Our architecture consists of four components: a voxel sorting unit (VSU), a hierarchical filtering unit (HFU), a sorting unit, and a rendering unit.

Given a set of ray directions, VSU first identifies and sorts the intersected voxels. Then, for each intersected voxel, HFU applies a hierarchical filter to identify intersected Gaussians. Both designs will be explained in Sec. IV-B and Sec. IV-C, respectively. Once HFU obtains the filtered Gaussians, sorting and rendering units execute the sorting and rendering stage from their individual buffer, respectively. Both sorting and rendering designs are adopted from GSCore [18]. However, we simplify the sorting unit by just adopting the bitonic sorting unit from GSCore, as our voxel-based rendering only requires establishing the rendering order for Gaussians within a voxel.

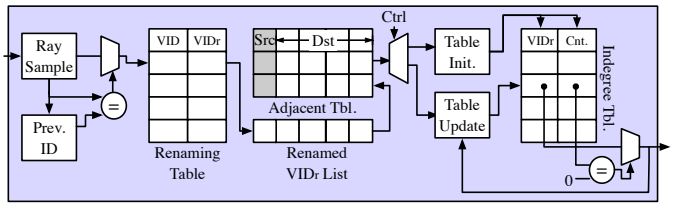

Fig. 10. The design of voxel sorting unit (VSU). It first identifies the intersected voxels for every pixel within a tile and then establishes the global rendering order of these voxels for sorting and rendering.

B. Voxel Sorting Unit (VSU)

The architecture of VSU is illustrated in Fig. 10. For pixels within a group, VSU samples along each pixel ray to identify the intersected voxels and performs a topological sort to establish the global rendering order of these voxels. Since we partition the entire scene into voxels offline, the voxel ID (VID) can be directly computed by the coordinate of a ray sample. To reduce the VID range, we further filter out those empty voxels with no Gaussians by augmenting a renaming table in VSU to reassign each VID with a new VID_r.

Each time we obtain a renamed VID_r list for one pixel, we use this list to construct an adjacent table. This adjacent table functions like a cache to help the dependency lookup among voxels. Each table entry has a tag and a value, representing a source voxel and all its corresponding destination voxels, respectively. The adjacent table is constructed once VSU finishes iterating all pixel rays in a group.

VSU then uses the adjacent table to initialize an in-degree table. Each entry in the in-degree table is directly indexed by a VID_r value and stores its in-degree count, which records the number of source voxels this VID_r has. If an in-degree of a VID_r becomes zero, this VID_r has no source dependency and can be written to the later stage. Each time VSU outputs a VID_r, VSU also updates the in-degree table accordingly. The topological sort finishes when the in-degree table is empty.

C. Hierarchical Filtering Unit (HFU)

Once VSU generates the rendering order of intersected voxels, HFU starts to load one voxel at a time and process the Gaussians within this voxel. Overall, HFU, highlighted in yellow in Fig. 9, consists of a frontend and a backend, responsible for coarse-grained and fine-grained filtering, respectively.

Coarse-Grained Filter. HFU only reads each Gaussian coordinate and maximum scale in the coarse-grained filter, computing its projected position and coarse radius. These results are sent to the intersection test unit to determine if the Gaussian intersects with the current image tile. If the condition is met, HFU signals the codebook to decode the remaining parameters from the codebook buffer, as shown in Fig. 9. The decoded parameters, along with the uncompressed parameters, are then fed into a FIFO for fine-grained filtering.

Fine-Grained Filter. This step computes the exact radius computation and performs the intersection test. Meanwhile, the fine-grained filter unit also computes the RGB values and conic matrix from decoded parameters, such as scales and rotation. Based on the intersection result, HFU conditionally outputs a Gaussian RGB and conic results to the sorting buffer if this Gaussian passes the intersection test.

In our design, the coarse-grained filter largely reduces the computation (from 427 MACs to 55), compared to fine-grained filters. In addition, the coarse-grained filter avoids decoding and reading unnecessary Gaussians to FIFO in HFU.

TABLE I
CONFIGURATION AND AREA

Unit	Configuration	Area [mm^2]
Voxel Sorting Unit	1 Unit	0.06
Hierarchical Filtering Unit	4 Units	0.79
Sorting Unit	2 Units	0.04
Rendering Unit	64 Units	2.53
SRAM (Input Buffer, Codebook, others)	355KB	1.95
Total		5.37

V. EVALUATION

A. Experimental Setup

Hardware Setup. Our accelerator consists of 1 VSU, 4 HFUs, 2 sorting units, and $4 \times 4 \times 4$ rendering units at 1GHz clock frequency. Each HFU has 4 coarse-grained filter units (CFUs) and 1 fine-grained filter unit (FFU). The sorting unit and the rendering unit are identical to the bitonic sorting unit and the volume rendering unit in GSCore, respectively [18]. The overall on-chip buffer consists of a double-buffered input buffer with a size of 16 KB, a 250 KB codebook buffer, and the remaining 89 KB to store intermediate data between stages.

Our architectural design is developed using an EDA process and synthesized with Synopsys and Cadence tools on TSMC's 32 nm FinFET technology. SRAM components are estimated by CACTI 7.0 [23] at 32 nm technology. The DRAM model in our simulations is based on Micron's 16 Gb LPDDR3 with 4 channels according to its datasheet [24], with energy consumption data sourced from Micron System Power Calculators [25].

Software Setup. We configure a codebook with 4096 entries for scale, rotation, and DC, and a codebook with 512 entries for SH coefficients in Sec. III-C. The voxel size is set to 2 for real world scenes and 0.4 for synthetic scenes. The hyper-parameter, β, in Sec. III-B is set to 0.05.

Area. STREAMINGGS design has a total of 5.37 mm^2 in Tbl. I. The major area contributors are 4 HFUs (0.79 mm^2), 64 rendering units (2.53 mm^2), and on-chip buffers (1.95 mm^2). Overall, our design has a similar area compared to GSCore (5.53 mm^2) which is scaled to 32 nm by DeepScaleTool [26].

Workloads. We evaluate both synthetic and real-world datasets: Synthetic-NSVF [27], Synthetic-NeRF [3], Tanks&Temples [28] and Deep Blending [29]. Each scene is initially trained with a default 3×10^4 iterations, followed by 3×10^3 iterations of boundary-aware fine-tuning (Sec. III-B) and 5×10^3 iterations of quantization-aware fine-tuning (Sec. III-C). We evaluated our method on three widely-adopted 3DGS algorithms, including original 3DGS [7], Mini-Splatting [8], and LightGaussian [10].

Baselines. We compare against two hardware baselines: Nvidia GPU Orin NX [16] and a dedicated accelerator, GSCore [18]. GPU performance and power consumption are

TABLE II
QUANTITATIVE COMPARISON OF RENDERING QUALITY (PSNR ↑) ACROSS DIFFERENT DATASETS AND ALGORITHMS.

Algorithm \ Dataset	Train	Truck	Playroom	Drjohnson	Lego	Palace
3DGS	22.54	26.65	30.18	29.21	36.11	38.56
Ours	22.52	26.61	30.27	29.07	36.02	38.52
Mini-Splatting	21.49	25.19	30.32	29.23	36.20	39.00
Ours	21.44	25.11	30.37	29.34	36.18	38.98
LightGaussian	22.29	26.02	28.58	25.87	35.18	37.76
Ours	22.32	25.89	28.47	25.79	35.15	37.68

obtained using built-in hardware measurements. We implement GSCore based on its published specifications and validate our results against reported data.

Variants. We evaluate three variants:

- w/o VQ+CGF performs our fully-streaming algorithm without vector quantization and coarse-grained filtering.
- w/o CGF performs our fully-streaming algorithm without coarse-grained filtering.
- STREAMINGGS is our full-fledged version including all optimization techniques.

B. Rendering Quality

Tbl. II shows a quantitative comparison of rendering quality between the original pipeline and our fully streaming pipeline across three 3DGS algorithms. Overall, our fully streaming pipeline shows no accuracy degradation in visual quality. On average, our pipeline drops the rendering quality by 0.04 dB. Our results sometimes achieve higher PSNR than the original approach. Our rendering results are also presented here: link.

C. Performance and Energy Efficiency

Fig. 11 illustrates the performance and energy savings of our design against three hardware baselines. All values are normalized against the corresponding Orin NX. Both speedup and energy numbers are averaged across four datasets.

On average, STREAMINGGS achieves 45.7× speedup against Orin NX. In comparison, GSCore can barely achieve 21.6× speedup. Our result also shows that coarse-grained filtering affects the performance of STREAMINGGS significantly. Without coarse-grained filtering, the speedup drops from 45.7× to 22.2×, while VQ has a minimal impact on the performance. This is because VQ only affects the voxel streaming which is overlapped by the subsequent stages.

On energy saving, STREAMINGGS achieves 62.9× energy reduction over Orin NX and 2.3× energy reduction over GSCore. The primary energy savings are from DRAM traffic reduction and efficient early-stage irrelevant Gaussian filtering. In addition, coarse-grained filtering and VQ contribute to 35.6× and 5.8× energy savings, respectively.

D. Sensitivity Study

Fig. 12 shows the sensitivity of rendering quality and energy savings to voxel size on one real-world scene, *train*. All variants are retrained according to our training procedure in Sec. V-A. Generally, smaller voxel sizes result in more cross-boundary Gaussians, leading to incorrect depth ordering. Our result shows that the rendering quality drops from 22.3 dB to 21.5 dB when the voxel size decreases from 2 to 0.5. However, further increasing voxel size shows minimal impacts on rendering quality. Meanwhile, larger voxels might potentially include more irrelevant Gaussians in every voxel, increasing the filtering workload and lowering energy efficiency. We empirically find a voxel size of 2 has a good balance between performance and rendering quality.

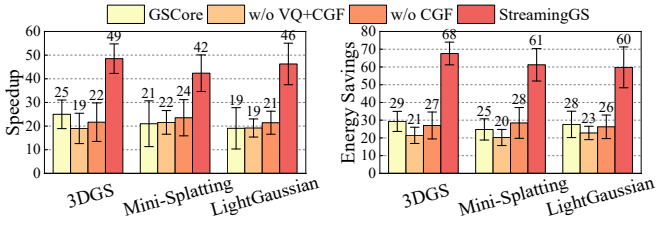

Fig. 11. End-to-end speedup and energy savings of our variants over the GPU baseline. The numbers are averaged over four datasets and normalized to the GPU baseline.

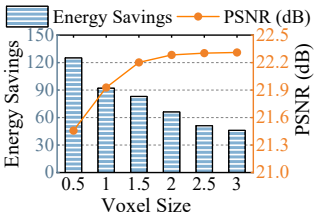

Fig. 12. The sensitivity of energy efficiency and rendering quality on the original 3DGS to voxel size. We only evaluate on *train* scene.

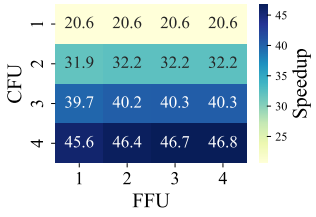

Fig. 13. The sensitivity of speedup on the original 3DGS to the numbers of CFUs and FFUs. Only *train* scene is evaluated.

Fig. 13 illustrates the sensitivity of performance to the numbers of coarse-grained filter units (CFUs) and fine-grained filter units (FFUs) in HFU (Sec. IV-C). We choose the same *train* scene and normalize all performance numbers to the GPU baseline. The results show that adding FFUs beyond the number of CFUs does not yield any speedup. In contrast, increasing the number of CFUs consistently boosts speedup, underscoring their importance in accelerating the filtering process. However, an excessive number of CFUs would lead to increased area overhead. Thus, we choose 4 CFUs with 1 FFU as our default configuration.

VI. CONCLUSION

This paper introduces STREAMINGGS that rethinks the 3DGS pipeline and proposes a new computing paradigm to process Gaussian points. Our fully streaming pipeline eliminates intermediate off-chip memory traffic and regularizes the off-chip accesses, all with a minimal but principle architecture augmentation. Overall, our algorithm-architecture co-design demonstrates 45.7× and 2.1× speedup compared to mobile GPUs and the state-of-the-art 3DGS accelerator, respectively.

***Abstract*—Large language models (LLMs) are increasingly utilized for complex tasks requiring longer context lengths, with some models supporting up to 128K or 1M tokens. This trend, however, presents significant challenges in inference speed and memory management. The primary bottleneck in long-context LLM inference is the quadratic computational complexity of attention mechanisms, causing substantial slowdowns as sequence length increases. KV cache mechanism alleviates this issue by storing pre-computed data, but introduces memory requirements that scale linearly with context length, hindering efficient LLM deployment. Quantization emerges as a promising approach to address the widening gap between LLM size and memory capacity. However, traditional quantization schemes often yield suboptimal compression results for KV caches due to two key factors: i) On-the-fly quantization and de-quantization, causing significant performance overhead; ii) Prevalence of outliers in KV values, challenging low-bitwidth uniform quantization. To this end, we propose MILLION, a novel quantization framework achieving low-bitwidth KV cache through product quantization. First, we conduct a thorough analysis of KV cache distribution, revealing the limitations of existing quantization schemes. Second, we introduce a non-uniform quantization algorithm based on product quantization, which efficiently compresses data while preserving accuracy. Third, we develop a high-performance GPU inference framework with efficient attention kernel and pipeline design for MILLION that leverages sparse computation and asynchronous quantization, significantly enhancing inference speed. Comprehensive evaluation results demonstrate that MILLION can achieve 4 bits quantization with trivial perplexity and accuracy loss, and achieve 2.09x end-to-end performance gains at 32K context length. Code is released at https://github.com/ZongwuWang/MILLION.**

I. Introduction

Large language models (LLMs) have demonstrated remarkable capabilities across various tasks, with recent efforts focusing on expanding their context lengths to further enhance performance. Longer context lengths enable new applications such as long document summarization, retrieval-based question answering for extensive documents, extended multi-turn interactions, and code analysiscite [1]. This demand has driven significant advancements in long-context models in both industry [2], [3] and academiacite [1]. While increased contextual capability enhances model intelligence, it also introduces substantial computational demands, scaling quadratically ($O(n^2)$) with context length. To address this challenge, modern LLM frameworks have adopted the key-value (KV) cache, which reduces the computational complexity to $O(n)$ at the cost of increased memory usage. However, the practice of batch processing requests, while improving tensor processing efficiency, further exacerbates storage overhead as KV caches cannot be shared between multiple requests [4], [5].

KV cache storage scales linearly with context length, often surpassing device memory limits. For example, in the 540B PaLM model, a batch size of 512 and context length of 2048 can result in a 3TB KV cache—three times the model's parameter size. Additionally, each token generation in the decoding phase requires full KV cache access, creating a major memory bottleneck in long-context scenarios. Recent research has focused on addressing these memory-related challenges in LLMs through three primary approaches: **1) Optimized attention mechanisms:** Techniques such as MQA [6], GQA [7], MLA [8], YOCO [9], and CHAI [10] have been proposed to reduce computational and storage overheads by sharing KVs among attention heads. However, these optimizations often come at the cost of reduced accuracy, with only GQA currently seeing widespread adoption in state-of-the-art LLMs. **2) Sparse attention mechanisms:** These approaches aim to reduce the complexity of attention computations. For example, given the importance of local context, sliding window attention maintains a fixed-size sliding window of recent token states to limit the number of tokens involved in computations [11]. Streaming-LLM further improves on this by introducing the "attention sink" tokens [12], demonstrating that retaining initial token KVs can recover much of the lost performance. More advanced KV sparsity techniques [13]–[18] attempt to identify and remove less important token KVs based on historical attention patterns. However, recent studies [19], [20] suggest that these approaches may suffer from accuracy degradation, as past attention distributions may not reliably predict future attention needs in long-context generation. **3) Key-value quantization:** Quantization, successful in model weight compression [21]–[24], has emerged as a promising technique for KV cache optimization. However, applying weight quantization methods directly to KV caches presents unique challenges: First, the presence of outliers in the KV states of LLMs expands the quantization range, making low-bit quantization

† These authors contributed equally. This work was supported by the National Key Research and Development Program of China (2024YFE0204300), National Natural Science Foundation of China (Grant No.62402311), and Natural Science Foundation of Shanghai (Grant No.24ZR1433700).

difficult. Second, since KVs are dynamically generated during inference, quantization or de-quantization delays can negatively impact real-time performance. According to [25], 4 bit integer dequantization contributes 20% to 90% of the inference latency. Additionally, linear attention mechanisms like Manba [26], RWKV [27] and InfiniTransformer [28] have been developed to further reduce the complexity of attention computations. However, these approaches also tend to trade off some degree of model accuracy for efficiency gains.

Recent works have attempted to address these challenges: QServer [25] proposed SmoothAttention, which implements 4-bit KV cache quantization with the SmoothAttention scale Λ into previous layers' weights to reduce de-quantization overhead, however the accuracy is limited by the hard constraint introduced by the rotary positional embedding. KIVI employs group-wise quantization, adapting to outlier distribution through channel-wise and token-wise quantization of keys and values. KVQuant further refines this approach with outlier isolation and non-uniform quantization, improving low-bitwidth accuracy at the cost of inference performance. Unfortunately, these techniques often degrade inference speed due to the overhead introduced by outlier isolation and non-uniform quantization. The ideal solution would balance these factors without significantly compromising any single aspect.

This work introduces MILLION, a novel quantization scheme for efficient dynamic KV compression in LLMs. MILLION utilizes non-uniform quantization and eliminates de-quantization overhead, integrating seamlessly with a high-performance system optimized for GPU-based inference. First, we thoroughly analyze the distribution patterns of KVs in LLMs, uncovering the limitations of existing quantization methods. Based on these distribution characteristics, we propose a non-uniform quantization scheme using Product Quantization (PQ). By clustering vectors, PQ distributes quantization power unevenly across channels, which helps handle outliers in the KV states. PQ also naturally supports mixed-precision quantization, offering flexibility in balancing performance and accuracy. Finally, we design an efficient GPU inference framework for MILLION, which accelerates inference by leveraging sparse computation and asynchronous quantization, boosting processing speed while reducing memory overhead.

In summary, we make the following contributions:

- **KV distribution analysis**: We perform an in-depth analysis of the distribution characteristics of key-value pairs in LLMs, identifying the limitations of existing quantization methods and highlighting the unique challenges posed by outliers and dynamic KV generation.
- **PQ-based non-uniform quantization**: Building on the insights from the KV distribution analysis, we propose a novel non-uniform quantization scheme based on PQ. This approach leverages clustering to distribute quantization power unevenly across channels, enabling efficient compression while maintaining high accuracy.
- **Efficient GPU inference system**: We design and implement a high-performance GPU-based inference framework optimized for MILLION. This system accelerates inference through sparse computation and asynchronous quantization, effectively eliminating de-quantization overhead while ensuring fast, scalable, and memory-efficient processing of long-context inputs.

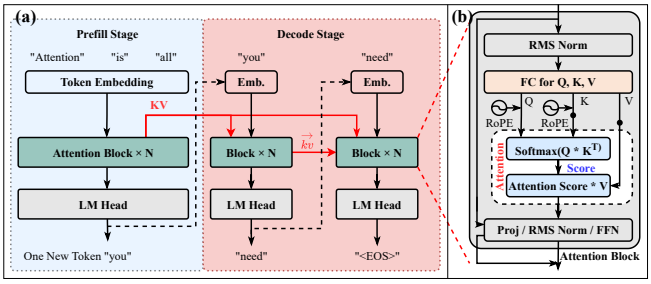

Fig. 1. Overview of transformer model structure. (a) Transformer model consists of two stage, the prefill stage processes the prompt prefilling of all tokens in batches, and the decode stage generates tokens one by one; (2) Details of the attention block.

II. PRELIMINARY

A. Attention-based LLM model.

The Transformer model architecture consists of two main stages: the Prefill stage and the Decode stage, as depicted in Fig. 1(a). In the Prefill stage, the model processes the entire input sequence in batches, and generate the key and value vectors for each prompt tokens simultaneously. The Decode stage operates auto-regressively, generating the output sequence token by token. The auto-regressively interaction is handled by the attention blocks, which is the most important modules in the transformer models. The detailed algorithm of the attention block is depicted in Fig. 1(b). The unique attention mechanism, highlighted with a white background, enables token interactions within the context. This process is formalized as follows:

$$A_n = \text{Softmax}(\frac{Q \times K^T}{\sqrt{d_k}}) \times V \tag{1}$$

Where $Q \in \mathbb{R}^{n_q \times d_k}$, K and $V \in \mathbb{R}^{n_k \times d_k}$ represent the query, key, and value vectors corresponding to each token, d_k denotes the head dimension, n_q and n_k denote the token number of query and key/value for the attention computation, respectively. Due to the causality of the language model, the query vector of each token needs to be feature fusion with all previous key/value vectors. Then the attention scores are utilized to calculate the weighted sum of the value vectors for each token, resulting in the current context state vector. This is followed by feature extraction using additional FFN layers.

B. Integer Quantization

Existing integer quantization maps high-precision numbers to discrete levels, the process can be formulated as:

$$\begin{cases} \boldsymbol{Q_X} = \lceil \frac{\boldsymbol{X}}{s} + z \rfloor \\ s = \frac{\boldsymbol{X}_{max} - \boldsymbol{X}_{min}}{q_{max} - q_{min}} \\ z = \lceil q_{min} - \frac{\boldsymbol{X}_{min}}{s} \rfloor \end{cases} \tag{2}$$

where $\boldsymbol{X}$ is the floating point tensor, $\boldsymbol{Q_X}$ is its n-bit quantized counterpart, s is the scaling factor and z is the zero point. Thus, the dequantized tensor can be represented as,

$$\hat{\boldsymbol{X}} = Q(\boldsymbol{X}) = (\boldsymbol{Q_X} - z) \cdot s \tag{3}$$

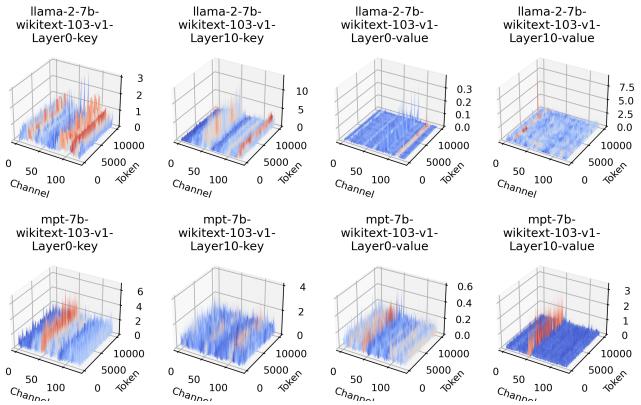

Fig. 2. Magnitude distribution of key and value cache for Llama-2-13B and Falcon-7B.

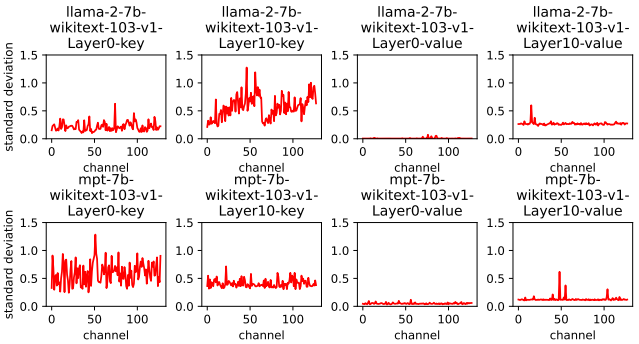

Fig. 3. channel-wise standard deviation distribution of key and value cache for Llama-2-13B and Falcon-7B.

This is known as asymmetric quantization, where $\boldsymbol{X}max = max(\boldsymbol{X})$, $\boldsymbol{X}min = min(\boldsymbol{X})$, and $q_{max} - q_{min} = 2^n - 1$ for n-bit integer quantization. Fig. 2 can be further simplified to symmetric quantization, where the zero point z is set to 0, and the range is centered around zero with $\boldsymbol{X}max = -\boldsymbol{X}min = max|\boldsymbol{X}|$. In this case, $q_{max} - q_{min} = 2^n - 2$, as one bit is reserved for the sign.

The de-quantization process of integer quantization needs to be implemented using general-purpose CUDA cores, which are less efficient for this type of operation. This implementation introduces a significant performance bottleneck, resulting in 20% to 90% overhead [25].

C. Product Quantization

Product Quantization (PQ) is an innovative algorithm that revolutionizes high-dimensional vector retrieval. It offers an efficient and scalable solution for large-scale approximate nearest neighbor searches (ANNS) in high-dimensional spaces [29]. The key concept of PQ is the partitioning of high-dimensional vectors into several lower-dimensional subspaces, each independently quantized. This approach significantly reduces the complexity and storage cost of high-dimensional vector similarity operations. According to [30], PQ can achieve 90% memory compression without significant accuracy loss.

The PQ process begins with a training phase, where a codebook is created for each subspace using k-means clustering. Each vector is partitioned and assigned to the nearest centroid in its subspace, with the centroid index stored as a compact code, effectively compressing the data and reducing storage. During the retrieval phase, query vectors are similarly partitioned and quantized. The algorithm approximates the distance by summing precomputed distances between the query subvectors and the centroids of each corresponding subspace in the database. This asymmetric distance computation enables fast ANNS without decoding, achieving both storage efficiency and quick retrieval.

D. Motivation

In this section, we analyze the distribution of KV cache to reveal the limitations of existing low-precision quantization methods. This insight informs our proposed product quantization-based scheme for efficient KV cache compression.

1) Outliers hinder low-precision quantization. To explore the root cause of poor performance in existing KV quantization algorithms, we analyzed the KV distributions across different models, as shown in Fig. 2. Our findings reveal that in various models, outliers in the key cache are concentrated in several channels, while the value cache vectors also contain outlier points but without obvious anisotropy in their distribution. As shown in Fig. 2, quantization accuracy depends on the distribution range of the tensor for a given bit width. Concentrated tensor distributions yield higher quantization accuracy. However, outliers significantly expand the numerical distribution range, complicating low-precision quantization. While group-wise and mixed-precision quantization can mitigate outliers, they introduce additional overheads for quantization/de-quantization.

2) Exploring Opportunities for Non-uniform Quantization. We further explore the standard deviation distribution of KV across different channels in Fig. 3. Key standard deviations are notably prominent in certain channels, which we term as standard deviation outliers. In contrast, value standard deviations remain relatively small across channels. The channel-wise standard deviation indicates the range of numerical distribution across channels, corresponding to $\boldsymbol{X}max - \boldsymbol{X}min$ in Fig. 2. This suggests that integer quantization of keys is more challenging than values, necessitating distinct quantization precisions for different channels.

Given the presence of amplitude and standard deviation outliers in KV cache, we propose using PQ for KV cache compression. PQ splits vectors into multiple subspaces and clusters multiple channels within each subspace for quantization. Channels in the same subspace are uniformly quantized to 2^{nbits} states, where $nbits$ denotes the quantization bits of each subspace vector. Following PQ centroid training principles, channels with higher quantization difficulty will occupy more states in the PQ centroid, inherently supporting mixed precision quantization between channels.

III. Efficient KV Cache Compression via PQ

A. MILLION Framework Overview

This section illustrates the algorithm framework of the proposed MILLION, which enhances dynamic KV compression using the PQ algorithm. As shown in Figure 4, MILLION consists of three main phases: (1) offline PQ codebook training, (2) online prefill with KV cache quantization, and (3) online decode with KV cache quantization.

Offline PQ Codebook Training. The process begins with offline PQ codebook training of the KV cache, similar to obtaining activation distribution in activation quantization scenarios. During baseline inference, KV cache is sampled, and then

sampled keys and values are used for PQ training to determine the codebooks. Figure 4 a) illustrates this process: sampled key/value vectors are first partitioned into multiple sub-vectors ①, then the k-means algorithm is applied to find centroids for each sub-space ②. After that, the trained centroids are stored in GPU memory as codebooks for future quantization.

Online Prefill with KV Cache Quantization. During the prefill phase, the generated full-precision keys and values are used for attention computation ③, and quantized with the trained codebooks ④. The compressed KV (centroid indices) are then saved into the KV cache. The quantization and de-quantization process can be expressed as Eq. (4) and Eq. (5), respectively.

$$\begin{cases} \Delta_K = \|_{n=1}^{M} argmin(\|(K^i \times C_K^i)\|) \\ \Delta_V = \|_{n=1}^{M} argmin(\|(V^i \times C_V^i)\|) \end{cases} \tag{4}$$

$$\begin{cases} \hat{K} = \|_{n=1}^{M} \Delta_K^i \otimes C_K^i \\ \hat{V} = \|_{n=1}^{M} \Delta_V^i \otimes C_V^i \end{cases} \tag{5}$$

where M indicates the subspace number of PQ, $\|$ denotes concatenation of M sub-vectors, C_K^i and $C_V^i \in \mathbb{R}^{2^{nbits} \times d_k}$ are the i-th PQ codebooks of K and V. Δ_K^i and $\Delta_V^i \in \mathbb{R}^{n_k}$ are the quantized K and V of the i-th subspace, and $nbits$ denotes the the quantization bits for each subspace of PQ, so the 2^{nbits} is the codebook size of each subspace, and the symbol $\otimes$ means column-wise sampling C^i according to the indices of Δ_i. $\hat{K}$ and $\hat{V}$ represent the de-quantized K and V.

Online Decode with KV Cache Quantization. In the decode phase, the current token generates pairwise query, key, and value vectors. Based on the auto-regressive mechanism, the current token needs to compute attention not only with itself but also with all historical tokens ⑥. This phase requires traversing all codes in the KV cache and restoring them to float vectors by looking up the codebooks. The attention computation can be represented as:

$$A_n = \text{Softmax}(\frac{q_n \times [\hat{K}_{n-1}^T, k_n^T]}{\sqrt{d_k}}) \times [\hat{V}_{n-1}, v_n] \tag{6}$$

Where A_n denotes the attention output of the n-th token. We obtain $\hat{K}$ and $\hat{V}$ by Eq. (5). Lastly, the current key and value are quantized using codebooks and appended to the KV cache⑦.

B. Efficient Quantization Transformation

While PQ compression reduces KV cache memory demands, quantization and de-quantization overheads (as shown in Eqs. (4) to (6)) still persist during the decoding phase. This section introduces an efficient design to address these inefficiencies.

Attention Computation Transformation. We begin by transforming the attention computation as follows:

$$\begin{aligned} A_n =& \text{OlSoftmax}(\frac{q_n \times \|_{i=1}^{M} {C_K^i}^T \otimes {\Delta_K^i}^T}{\sqrt{d_k}}) \times \Big\|_{i=1}^{M} \Delta_V^i \otimes C_V^i \\ &+ \text{OlSoftmax}(\frac{q_n \times k_n}{\sqrt{d_k}}) \times v_n \end{aligned} \tag{7}$$

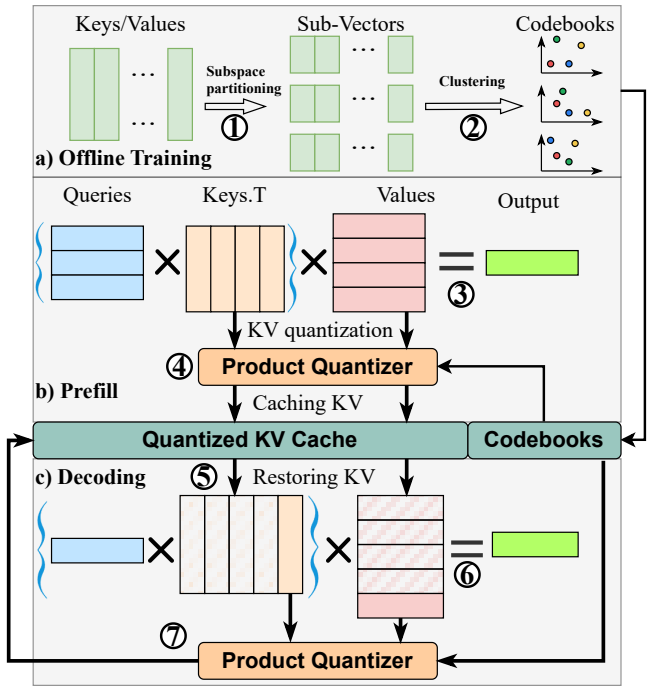

Fig. 4. An overview of MILLION algorithm framework. MILLION's algorithm framework consists of three parts: 1) offline PQ centroid training; 2) Prefill stage with KV quantization; 3) Decode stage with KV quantization.

Here, *OlSoftmax(·)* denotes an online softmax operation that splits the attention computation into two parts:

1) The current token's attention output to past tokens (first term $\text{OlSoftmax}(\frac{q_n \times \|_{i=1}^{M} {C_K^i}^T \otimes {\Delta_K^i}^T}{\sqrt{d_k}}) \times \|_{i=1}^{M} \Delta_V^i \otimes C_V^i$)
2) The current token's self-attention output (second term $\text{OlSoftmax}(\frac{q_n \times k_n}{\sqrt{d_k}}) \times v_n$)

The second part of the Eq. (7), dealing with the current token's self-attention, thus uses the full-precision key and value. It has $\mathcal{O}(1)$ computational complexity and requires no quantization or de-quantization for subsequent token generation. The first part, on the other hand, addressing attention to past tokens, is computed through two steps: 1) Calculate $q_n \times \|_{i=1}^{M} {C_K^i}^T$ with $\mathcal{O}(1)$ complexity; 2) Sampling the resulting vector with Δ_K, having $\mathcal{O}(n)$ complexity.

Efficient Attention Implementation. Given that Δ_K matrix columns are index vectors, we developed an efficient CUDA kernel. This kernel loads $q_n \times \|_{i=1}^{M} {C_K^i}^T$ as a look-up table into GPU L1 cache for fast random accessing during sampling and obtains the final result through sampling, thus the quantized Δ_K can be computed directly without de-quantization. Besides, the Δ_K matrix is prefetched with float4 data format, which further enhances the efficiency of continuous memory access. For instance, with 8-bit subspace product quantization ($nbits$ = 8), each thread in the CUDA kernel can simultaneously load 16 indexes into registers in float4 format, and then use these to perform 16 shared memory address lookups in int8 format. Furthermore, the kernel effectively paralleliz table lookup of Δ_K and de-quantization of Δ_v over CUDA thread blocks inspired by flash decoding.

Asynchronous Quantization Strategy. As of this point

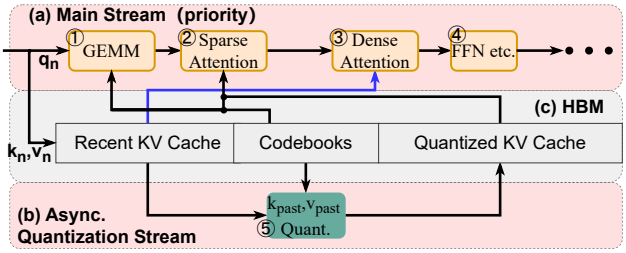

Fig. 5. Efficient Attention Implementation of MILLION with Asynchronous Quantization.

of introducing, quantization of k_n and v_n is still performed sequentially before the attention mechanism. However, cached codes are not needed until next token generation, indicating the computational independence of these two steps. Given the fact that decoding phase is memory-bounded, we assign quantization to a lower-priority CUDA stream to enable asynchronous execution of quantization and the subsequent processing, aiming at maximizing GPU utilization.

C. MILLION Dataflow

The dataflow of MILLION for LLM decoding is illustrated in Fig. 5. To minimize the impact of (de-)quantization on inference performance, MILLION employs two CUDA streams: 1) A high-priority main (CUDA) stream for attention computation; 2) A low-priority auxiliary (CUDA) stream is responsible for key and value quantization.

The process begins with the hidden state undergoing linear transformation to generate the query, key, and value for the current token, which serve as inputs to the attention layer. As analyzed in the previous section, the query performs a GEMM operation with the codebooks to calculate distances from each query to all centroids in the codebooks ①. The resulting distance vector is then used for sparse attention calculation with the quantized keys and values ②. Concurrently, the query undergoes dense attention computation with the recent KV cache (full precision) ③. Sparse and dense attention outputs are combined through online softmax and fed into subsequent operators for further inference ④. To avoid blocking the the main stream, keys, and values generated during decoding are temporarily stored in the recent KV cache. When GPU utilization of the main stream's CUDA kernel is low, the asynchronous quantization stream initiates the quantization kernel. It retrieves full-precision KV from the static recent KV cache for batch quantization ⑤. This design efficiently balances the computational demands of attention processing and quantization, optimizing overall inference performance.

IV. EXPERIMENTS

A. Experimental Setup

Models. Given the critical role of positional embeddings in the query and key components of LLMs, we conduct extensive experiments across various models employing different positional encoding techniques. Detailed specifications of these models are presented in Table I.

Tasks. We evaluate the quantization performance of MILLION across two distinct task categories: First, to assess model accuracy, we employ Perplexity (PPL), widely regarded as the most stringent metric, to compare the accuracy of various quantization schemes during the prefill stage. We conduct the PPL experiments on both Wikitext-2 and PTB datasets. Second, we conduct generation tasks using LongBench [31] for long context scenarios. This comprehensive assessment covered a range of linguistic challenges across various context lengths.

Baselines. We use the LLM model in float16 format as the baseline. We also compare our method with two state-of-the-art KV cache quantization works: KIVI [32] and KVQuant [33]. For these comparisons, we use the quantization bit widths recommended in their original papers. KIVI employs 2-bit and 4-bit quantization, while KVQuant adopts 3-bit and 4-bit quantization.[1]

B. Accuracy Results

PPL Evaluation. Table II compares the perplexity between KVQuant and MILLION. We reproduce KVQuant's evaluation on the Llama-2 model and extended the comparison to various models and datasets. KVQuant uses non-uniform quantization for all configurations in Table II. The results show that KVQuant, despite combining key/value quantization in different dimensions with non-uniform quantization, still incurs significant PPL loss. In contrast, full-precision sparse storage of 1% outliers achieves near-lossless performance at 3 bits. This demonstrates the impact of outliers on low-bit-width quantization. While isolating outliers for mixed-precision quantization effectively reduces KV cache quantization bit-width, it has drawbacks. This approach leads to unaligned memory access and introduces performance bottlenecks due to online sparse encoding, decoding, and computation. MILLION, employing uniform quantization, outperforms KVQuant in both 4-bit and 3-bit quantization[2]. Its accuracy is slightly lower than KVQuant's 1% outlier mixed-precision scheme. This indicates

[1]We conclude that the PPL of KIVI is huge and therefore omit it from the PPL experiment.

[2]We scanned different combinations of M and $nbits$ of PQ, and in this paper, the experiments adopted the best accuracy conditions of 3b and 4b, which were (64, 8) and (32, 12), respectively.

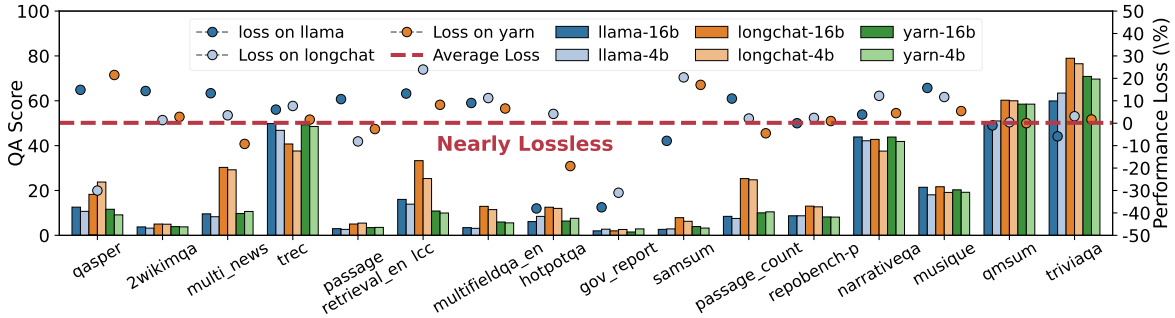

Fig. 6. Performance evaluation of MILLION on various models across a range of benchmarks in LongBench. While 16b denotes the baseline performance with fp16 KV cache, and the 4b depicts the MILLION performance of 4 bits KV quantization.

TABLE III
THE INFLUENCE OF 1% OUTLIERS ON PPL ON KVQUANT AND MILLION

	kv-3b	kv-3b -1%	sensitivity -3b	kv-4b	kv-4b -1%	sensitivity -4b
KVQuant	11.21	5.22	**53.4%**	6.99	5.14	**26.5%**
MILLION	5.2	5.22	**-0.38%**	5.21	5.18	**0.58%**

TABLE IV
TPOT (MS) COMPARISON OF KV QUANTIZATION METHODS.

Prefill Length	1K	2K	4K	8K	16K	32K
Baseline(fp16)	32.53	35.64	42.04	54.83	80.49	132.97
KIVI(4b)	46.69	46.88	46.92	47.86	OOM	OOM
KVQuant(4b)	75.73	73.92	75.34	74.90	78.17	90.16
MILLION(4b)	30.36	31.57	34.05	38.34	46.53	63.41

that MILLION effectively handles low-bit-width quantization with outliers while maintaining scheme efficiency.

LongBench Evaluation. Figure 6 shows MILLION performance on various models across LongBench benchmarks, the residual block size is set to 0 for stress evaluation. While 4-bit quantization shows some performance degradation compared to full-precision 16-bit models, it maintains sufficient accuracy for many applications. Specifically, MILLION with 4-bit KV cache quantization resulted in a score drop of 0.95 for llama-2-7b and 0.93 for longchat-7b. Notably, MILLION improved the score of yarn-llama-2-7b (with a $128K$ context) by 0.45, demonstrating its effectiveness for models with the longest contexts.

Outlier-immune Study. To verify MILLION's sensitivity[3] to outliers, we conduct additional experiments, as shown in Table III. We identified the top 1% of outliers in the KV cache based on data distribution and stored them in a sparse full-precision format. After applying MILLION to the filtered KV cache on LLMs, the PPL improved by only -0.38% and 0.58% in the 3-bit and 4-bit quantization scenarios, respectively. This marginal improvement suggests that MILLION is naturally robust to outliers, and incorporating sparse outlier handling offers little benefit, *while significantly degrading end-to-end system performance.*

C. System Performance

Generation Speed: We compare the performance of different KV quantization schemes by running Llama2-7b inference tasks on an A40 GPU. We assessment the average time per output token (TPOT) across different prefill lengths with 100 tokens generation. All schemes use 4-bit KV quantization,

[3]Sensitivity represents the proportion of PPL reduction caused by considering 1% sparse outliers.

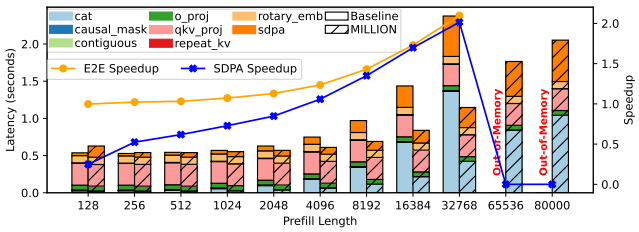

Fig. 7. Latency breakdown analysis. MILLION significantly outperforms the baseline on two KV access operators, the performance margins increasing with the severity of the memory bottleneck.

with results shown in Table IV. KIVI, which uses a simpler quantization scheme, outperforms the baseline at 8K context lengths. In contrast, KVQuant's non-uniform quantization significantly slows inference, and the outlier sparsity scheme further reduces performance. MILLION reduces computational complexity while maintaining high compression, delivering superior performance even at 1K context length.

Latency Breakdown: Fig. 7 shows the latency breakdown of each operator to highlight the performance gains in the MILLION system. Compared to the baseline, MILLION achieves significant performance improvements in two operators: Scaled Dot Product Attention (SDPA), which performs the attention operation, and Concatenate (cat), which manages the KV cache. This demonstrates that MILLION suppresses the access bottleneck in the generation phase by compressing the KV bitwidth, while reducing the computational complexity of attention further enhances performance. In contrast, other compression schemes incur higher computational overhead due to de-quantization. Besides, Fig. 7 shows the SDPA and end-to-end performance gains at different context lengths. The speedup of MILLION increases with context length, reaching 2.01x and 2.09x in attention and end-to-end acceleration ratios, respectively, at 32K context length.

V. CONCLUSION

We present MILLION, a novel and efficient PQ-based quantization framework for LLM inference. MILLION efficiently compresses data while preserving accuracy. It incorporates asynchronous quantization, enhancing inference speed and reducing additional operations caused by hardware-inefficient quantization/dequantization for KV cache compression. Experiments demonstrate that MILLION achieves better model performance while maintaining low latency.

***Abstract*—With the surge in data computation, Remote Direct Memory Access (RDMA) becomes crucial to offering low-latency and high-throughput communication for data centers, but it faces new security threats. This paper presents RAGNAR, a comprehensive suite of hardware-contention-based volatile-channel attacks leveraging the under-explored security vulnerabilities in RDMA hardware. Through comprehensive microbenchmark reverse engineering, we analyze RDMA NICs at multiple granularity levels and then construct covert-channel attacks, achieving 3.2x the bandwidth of state-of-the-art RDMA-targeted attacks on CX-5. We apply side-channel attacks on real-world distributed databases and disaggregated memory, where we successfully fingerprint operations and recover sensitive address data with 95.6% accuracy.**

I. INTRODUCTION

With the boom of data computation, the data center has prevailingly used Remote Direct Memory Access (RDMA) [31] for low latency and high throughput [41]. RDMA allows kernel bypass and zero-copy, crucial for large-scale and real-time data processing [8], [20].

However, recent studies have shown that RDMA also opens up new attack vectors [13], [17], [34], [37]. These security threats can significantly compromise the data security of RDMA-related systems.

Given the extensive attack surface, we ❶ *provide a systematic abstraction and analysis of RDMA security*, categorizing them from the perspectives of HW/SW, RDMA-targeted/related, granularity, and attack types. While several studies [17], [18], [22], [33], [34], [37] cover various aspects of RDMA security, significant gaps remain. We propose RAGNAR[1], which addresses these uncharted security concerns by exploring the potential of RDMA-targeted contention-based volatile-channel[2] covert-channel and side-channel attacks.

To better understand RDMA hardware, we ❷ *comprehensively reverse engineer RDMA NICs (RNICs) with four different levels of traffic granularity*. We analyze hardware resource contention between flows across traffic classes, memory regions (MRs), and address offsets within the same MR, and spot new hardware vulnerabilities.

We then ❸ *build covert-channel attacks given the reverse-engineered results, achieving 3.2× bandwidth compared with state-of-the-art RDMA covert channels on the same setup*. Our attacks achieve a data rate of 84.3 Kbps on CX-6 and 63.6 Kbps on CX-5, outperforming PYTHIA's covert channel (20 Kbps on CX-5) [37] and not being mitigated by state-of-the-art RDMA isolation defenses [22].

Furthermore, we ❹ *perform side-channel attacks on distributed database [23] and disaggregated memory [39]* to demonstrate the real scenario impact of RAGNAR. We fingerprint different shuffle/join application patterns and target a key-value store application, obtaining information about the victim's access address with 95.6% accuracy.

§Shuwen Deng is the corresponding author.

[1]Ragnar Lodbrok is a legendary Norse hero known for his multiple conflicts and raids, symbolizing intense warfare and struggle. His many battles represent significant interference and opposition, mirroring the volatile contention that happened in RDMA attacks.

[2]Volatile channels refer to the cases that the sender and receiver share the resources on the fly, which maps to the hardware contention scenario previous RDMA attacks do not explore and we will introduce more in Section II.

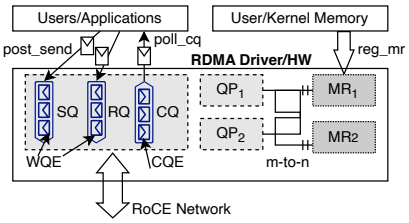

Fig. 1: Data Structures and Architecture of RDMA

Our main contributions are as follows:

- Propose granularity levels and analyze the stealthiness of RDMA-targeted HW attacks and mitigation with such metrics.
- Comprehensively reverse-engineer RDMA hardware from four different traffic granularity, especially reconstructing information on traffic priority and address offset.
- Construct 3 different granularity-level covert-channel attacks achieving 3.2× bandwidth compared with state-of-the-art attack.
- Build 2 side-channel attacks on real-world applications including distributed database and disaggregated memory, achieving up to accuracy of 95.6% on recovering victim address.

The code used in this paper will be released under an open-source license at https://github.com/THU-HAS/Ragnar.

II. BACKGROUND, RELATED WORK AND ATTACK ANALYSIS

A. Remote Direct Memory Access (RDMA)

RDMA is a network technology enabling direct memory access between physical servers, bypassing the OS [4], [7], [14], [30], [31], [35]. For a connection, each side generates queue pairs (QPs) for request queuing, registers memory region (MR) for access control, and exchanges MR addresses, as shown in Figure 1. Once connected, both sides post work queue entries (WQEs) and poll completion queue entries (CQEs) for message exchange.

B. Side-Channel and Covert-Channel Attacks

Side-channel attacks leverage indirect information of the architecture and hardware leakage to extract secrets [15], [16], [28]. *Covert-channel attacks* are where the sender and receiver establish covert communications through indirect information channels.

These channels can be categorized into *persistent channels* and *volatile channels* [42]. Persistent channels utilize state changes, e.g., the cache state attacks [1], [3], [5], [11], [28]; volatile channels utilize resource sharing on the fly, e.g., exploiting port contention in the execution engine [2], or contend network-on-chip (NoC) [9], [27].

C. Security Issues on RDMA

RDMA introduces variant security issues. We categorize these issues from two perspectives: SW/HW, RDMA-targeted/related.

- **RDMA-targeted/related SW issues.** Software implementation issues by REDMARK [33], and one-sided non-auditability [32].

TABLE I: Comparisons with prior works on RDMA-targeted HW attacks. Attack Types and Granularity Levels are discussed in II-D.

	Type	Grain	Defended	Channel	Steal.
Zhang [43]	P	II	[22]	-	Medium
Kong [18]	P	II	[22]	-	Medium
HUSKY [17]	P	II	[22]	-	Medium
Kim [13]	S	I	-	Volatile	Low
PYTHIA [37]	C+S	IV	[3]	Persistent	High
RAGNAR	C+S	I/II/III/IV	-	Volatile	High

- **RDMA-targeted HW issues.** Hardware vulnerabilities of RNICs on performance isolation [43], [18], [17], and persistent covert-channel issues with onboard cache by PYTHIA [37].
- **RDMA-related HW issues.** RNIC exacerbates vulnerabilities together with other components in RDMA-enabled systems, e.g., DRAM, DDIO, by THROWHAMMER [36] and NETCAT [19].

When we focus on RDMA-targeted vulnerabilities, we find limitations of the existing works on the hardware side, where we propose new hardware vulnerabilities and build new volatile-channel attacks.

D. Analysis and Comparison on RDMA-Targeted HW Vulnerabilities

We sort out works on RDMA-targeted HW security issues and compare them with our work, RAGNAR, in TABLE I.

Attack Types. RDMA-Targeted HW Vulnerabilities are categorized into 3 types: 1) *Performance (P)* performs availability attacks on bandwidth or PFC; 2) *Covert (C)* performs covert-channel attacks; and 3) *Side (S)* performs side-channel attacks.

Granularity Levels. For attacks, the levels refer to the granularity of resources or parameters the attacker manipulates; for defenses, they refer to counters or metrics the defender monitors. We divide the granularity into the coarsest Grain-I to the finest Grain-IV.

- **Grain-I**. Traffic pressure. Attackers can manipulate traffic pressure to exert influence on bandwidth. For defenses, modern RNIC provides native Grain-I per-traffic-class counters and flow control to detect and defend Grain-I attacks easily.
- **Grain-II**. Main traffic patterns, e.g., traffic classes, opcodes, and message sizes. Several studies [17], [18], [43] manipulate Grain-II parameters to apply availability attacks. For defenses, HARMONIC [22] provides Grain-II counters on RDMA opcodes for performance isolation to mitigate these Grain-II attacks.
- **Grain-III**. RDMA-specific resources engaged, e.g., PDs, QPs, MRs. For attacks, variant RDMA resources can be utilized to exert influence. For defenses, HARMONIC also provides RDMA-specific resource utilization counters to detect Grain-III attacks.
- **Grain-IV**. Addresses and other detailed parameters of traffic patterns. If an attacker keeps accessing different addresses with such parameters, as done by PYTHIA [37], typical Grain-I-to-III defenses cannot detect the existence of such an attacker.

As discussed above, Modern RNIC provides native Grain-I counters for resource isolation and detection to mitigate Grain-I attacks. Several studies [17], [18], [43] exploits Grain-II performance issues that bypass native Grain-I PFC mitigation but are defended by the consequent work HARMONIC [22] providing Grain-II/III counters.

Kim [13] implements side-channel attack [13] utilizing PCIe contention, but is not fine-grained enough[4]. PYTHIA [37] utilizes Grain-IV address manipulation to build side-channel attacks with onboard caches. Due to fine granularity, PYTHIA can bypass Grain-I-to-III counters and mitigations provided by RNIC and HARMONIC. However, PYTHIA is a cache-based attack, so general cache-attack detection and mitigation [38] can be applied to mitigate PYTHIA. Also, the PYTHIA PTE attack can be mitigated by widely-used huge pages [37].

[3]Defenses are discussed in Tsai's work [37]. Using huge pages or physical addresses can mitigate PTE-based attacks, and sniffers can easily detect evicting operations.

[4]It can only steal coarse information if the GPU is running rather than reveal detailed data.

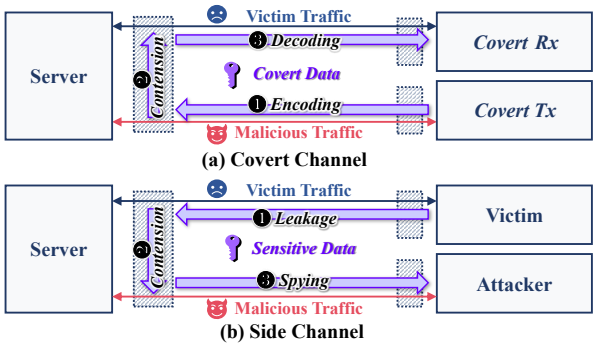

Fig. 2: Threat models of (a) covert channel and (b) side channel. Light blue boxes are hosts, and dotted boxes are RNICs. Blue and red arrows show the victim and malicious traffic, respectively. Purple arrows show the covert/sensitive data flow in contention channels.

TABLE II: Specifications of Test Environment

Host	Processor	RNIC	OS	RAM
H1	AMD EPYC 9554	CX6	Ubuntu 20.04	755GB
H2	Intel Xeon S4314	CX4,5	Ubuntu 18.04	256GB
H3	Intel Xeon P8480+	CX4-6	Ubuntu 22.04	1TB

TABLE III: Parameter Sheet of CX-4 to CX-6 Network Adapters

Feature	ConnectX-4	ConnectX-5	ConnectX-6
Speed	25Gbps	100Gbps	200Gbps
PCIe Interface	PCIe 3.0 x8	PCIe 3.0 x8	PCIe 4.0 x16

Comparison with related work. Compared with prior works, RAGNAR utilizes up to Gran-IV to achieve high stealthiness and bypass state-of-the-art defense HARMONIC. Compared with PYTHIA, RAGNAR is based on the processing path in RNICs. It does not rely on cache mechanism. Volatile channel brings our attack higher stealthiness and more general applicability.

III. THREAT MODEL AND EXPERIMENTAL SETUP

A. Threat Model

In our attack scenario, three parties are involved, as illustrated in Figure 2. The server hosts data, such as an in-memory database or key-value store. One client keeps regular traffic to access the server's in-memory data via RDMA, while the other client controls malicious traffic to perform the attack.

For (a) covert channels, the covert *Tx* ❶ sets up malicious traffic to encode covert data, and ❷ transfers the encoded data to observable effects in the victim traffic, which ❸ is decoded by covert *Rx*.

For (b) side channels, the victim ❶ leaks sensitive data in its traffic and ❷ influences the malicious traffic through the contention channel. ❸ The attacker sets up and observe variant malicious traffic at the same time to recover sensitive data and the access patterns of the victim.

B. Experimental Setup

We run all the tests and attacks across different hosts and environments, including various processors from Intel and AMD listed in TABLE II, as well as various network cards such as CX-4, CX-5, and CX-6 listed in TABLE III.

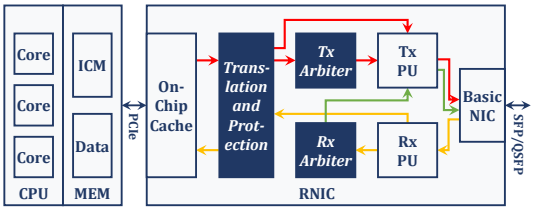

Fig. 3: Framework of RDMA System. Red arrows are the Tx flow, yellow arrows are the Rx flow, and green arrows are the replying flow. Lightboxes are microarchitectures whose existence and basic processing logic are known. Dark boxes are exponents that are black boxes to us, where we find new features by reverse engineering. [6]

IV. Reverse-Engineer RDMA NICs

The deployment of RDMA networks is contingent upon the support of RNICs. To develop RDMA-specific covert-channel and side-channel attacks, we provide some reverse-engineering results for a better understanding of RNICs in this section.

A. Architectural and Microarchitectural Analysis

Due to the black-box nature of detailed structure, we provide an architectural and microarchitectural picture of the RNIC, which are recovered from ETHTOOL [25] bps and pps counters and description of existing literature[5] and Nvidia manual [24], [26], as shown in Figure 3.

The RNIC is usually connected to the network with a Fiber Optic Interface and to the CPU/MEM with PCIe. MRs are pinned to physical memory to avoid page faults in the data path. The RNIC typically has the same functional parts as general network cards (Basic NIC) with typical L1 to L3 layer operations. Main RDMA-specific microarchitectures on the RNIC are shown in Figure 3.

In Figure 3, the red arrow indicates the Tx flow of outbound traffic. The RNIC reads the SQE from the host and arbitrates among all the SQEs. Requests are sent to the processing part according to RDMA opcodes and then handed over to the basic NIC for non-RDMA-specific procedures.

The yellow arrow indicates the Rx flow of inbound traffic. The basic NIC hands over the received and parsed message to the Rx processing pipeline.

RDMA Reads, as well as reliable service, need ACK packets, forming a reverse flow (green arrows). The reverse flowis arbitrated and processed as the outbound flow.

B. Grain-I/II Contention on Different-Priority Traffics

We identify *arbiters* that arbitrate packets of different flows within the RDMA hardware pathway. This arbitration impacts RDMA traffics in very different priorities in contention scenarios depending on parameters like opcodes, QP count, and message size.

Setup and Priority Indication. We systematically test the priority behavior of traffic during contention to evaluate the impact of different RDMA operations on competing flows. Using the `mlnx_qos` tool [26], we configure two traffic flows in ETS mode, each allocated 50% of the bandwidth. *However, we observe unbalanced bandwidth affected by priority mechanisms and hardware arbiters.* We configure traffic with varying QP numbers and message sizes and monitor changes in bits per second (bps) and packets per second (pps).

Comprehensive study on priority effects between traffics. We run a comprehensive benchmark of over 6000 parameter combinations to describe traffic performance in competitive scenarios. Analysis of the results yields a conceptual diagram (Figure 4) illustrating competition patterns under typical parameters. From Figure 4, we have the following key observations:

- The competition between RDMA Read and Write operations is complex and non-monotonic. As shown in the blue-outlined section ❶ of Figure 4, when message sizes are small, RDMA Write traffic loses over 50% of its bandwidth due to competition. However, once the write message size reaches around 512 Bytes, its bandwidth increases significantly, causing RDMA Read traffic bandwidth to drop by 30% to 80%.
- The RDMA Atomic operation exhibits a similar trend when competing with RDMA Read/Write operations, as illustrated in the orange-outlined section ❷ of Figure 4.
- In some cases, competition increases both traffic flows, resulting in total traffic exceeding 200% of the original single flow, as demonstrated in the green-outlined section ❸ of Figure 4.
- RDMA Write and reverse RDMA Read traffic with identical parameters show different competition dynamics when competing with RDMA Write traffic, highlighted in the yellow-outlined section ❹ of Figure 4.

From the analysis of the above observations, we can derive the following findings:

> **Key Finding 1: Non-monotonic bandwidth contention.** When the competing write flow is small, only the medium read flow experiences a significant drop, while the bandwidth of both the small and large read flows remains unaffected. However, as the competing write flow increases, the situation is reversed.
> **Key Finding 2: Abnormal bandwidth increment.** Contention of small RDMA Writes traffic can lead to abnormal BW increment in both traffic, which can be related to NoC activation.
> **Key Finding 3: Arbiter priority.** The logical Tx arbiter has a higher priority than the logical Rx arbiter.

C. Grain-III/IV Contention within Memory Region

We then post the fixed pattern of requests in a single-threaded manner and involve a new metric to explore finer-grained features.

Unit latency increase. The latency Lat_{total} from completing the `ibv_post_send` to polling a completion with `ibv_poll_cq` is a more precise and stable per-message observable than throughput statistics. Since Lat_{total} includes the queuing delay in the WQ before actual transmission, we assume that Lat_{total} should have a linear relationship with the queue length as $Lat_{total} = k \cdot (len_{sq} + 1) + C$. len_{sq} is the number of WQEs in front of the measured WQE. k stands for the latency increase caused by each queuing request, namely the *Unit Latency Increase (ULI)*. C is some len_{sq}-independent constant term caused by other overhead. Both theoretical analysis [7] and experiments [8] support the linearity and $C \approx 0$. So we use $ULI \approx Lat_{total}/(len_{sq} + 1)$ to characterize the contention.

[5]Only a few studies provide their original description. PYTHIA [37] proved the existence of multiple on-chip caches and reverse-engineered their parameters, Kalia et al. [12] illuminates the software-hardware interface data flows of various RDMA operations.

[6]The TxPU/RxPU and TxArbiter/RxArbiter in the figure are logically separated, but this does not mean that they are deterministically separated parts in hardware. For the convenience of discussion, we will still consider them separately later.

[7]If we consider an SQ reaching the maximum send queue size $len_{sq,max}$ in the stable traffic case, all these $len_{sq,max}$ work requests on the fly should be uniformly distributed in a Lat_{total} round trip time, where ULI should be $k = Lat_{total}/len_{sq,max} = Lat_{total}/(len_{sq} + 1)$.

[8]The linear relationship fits well with Pearson correlation coefficient = 0.9998, and C can be neglected.

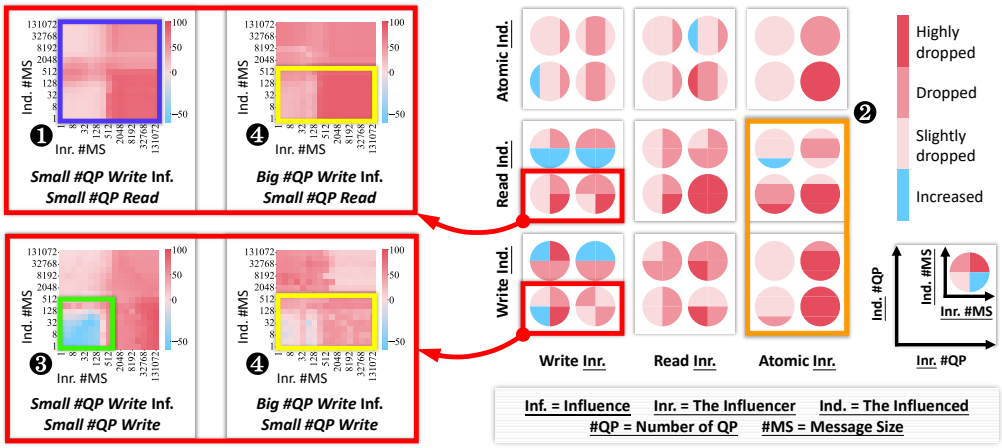

Fig. 4: Conceptual traffic priority diagram. This figure illustrates the competition-caused reduction in one party's traffic when competing with another under various conditions. For instance, the subplot of Write Inr. and Read Ind. shows a decrease in Read traffic when competing with Write traffic. The axes of each subplot represent qp number (qp_num), and the pie chart sections show results for different message sizes, as depicted in the legend. Dark red indicates no significant decrease, medium red a 50% decrease, light red a slight decrease, and blue an abnormal increase. These pie charts summarize measured data, with details expanded on the left side and key phenomena highlighted.

TABLE IV: Parameters of Grain-III/IV microbenchmark. *a*@MR#*b* means the address with offset *a* to the base address of the *b*th MR.

Operation	Msg Size	Remote Address 1	Remote Address 2
RDMA Read	1 - 1MB	0 @ MR#0	0 - 4KB @ MR#0
RDMA Read	1 - 1MB	0 @ MR#0	0 @ MR#1
RDMA Read	1 - 1MB	0 - 4KB @ MR#0	same as RA1

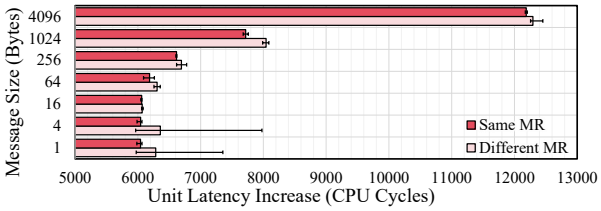

Fig. 5: ULI vs. same/different remote MRs vs. message size. Alternately accessing two addresses in the same/different remote MRs on CX-4 with RDMA Reads. Average and 10/90-percentile are shown.

Setup. We establish MRs on 2 MB huge pages, use 2 QPs, and set all resources within the same PD. We disable DDIO and bind the benchmark process to the same CPU core in the same NUMA node with the RNICs to eliminate the differences in address translation and context switching. Detailed configurations are shown in TABLE IV. [9] We perform the tests on CX-4, CX-5, and CX-6 RNICs.

With the Grain-II parameters unchanged, we focus on a more covert parameter, *remote address*. We find that the remote address of RDMA Reads can have a significant impact on the datapath contention. This impact can be reflected in ULI as the following:

- Latency distinction does not only occur when accessing different/same MR for RDMA Reads (Figure 5), but also when accessing variant addresses, with huge pages enabled, DDIO disabled, and affects of NUMA and cache excluded (Figure 6).
- The latency pattern caused by accessing different remote address offsets varies with message sizes but shows similar 2's power periodicity. As shown in Figure 6, 7 and 8, stable latency drops occur at addresses aligned with 8 Bytes under RDMA Reads. More significant drops appear at addresses multiples of 64 Bytes. An apparent periodicity at 2048 Byte intervals occurs as well.
- The absolute address offset (to the base address of the MR) and the relative address offset (between consequent RDMA Reads) have different impacts on latency, shown in Figure 6 and 8. The relative address offset effect indicates the mutual interaction among different packets due to complex mechanisms in the Translation and Protection module in Figure 3.

[9]Besides, we have tried RDMA Write, different MR sizes, and different local addresses. Yet, these variations do not bring up stable and observable effects.

Key Finding 4: Offset effect. Remote address offsets affect ULI in variant 2's power periodic manners for RDMA Reads.

V. Covert-Channel Ragnar Attacks

A. Covert-Channel Attack Setup

In this section, we present three covert-channel attacks. In our threat model (Figure 2(a)), the covert Tx/Rx cannot communicate mutually but share RDMA-based service with the same server. In V-B, the clients do not need to share a common address space, while in V-C and V-D, the clients are only permitted to perform certain RDMA Reads. In both cases, they cannot communicate directly.

The approach for these covert channel attacks is illustrated as follows: The sender modifies the mode of resource X based on the covert bits, which influences the receiver's observed metric of resource Y, allowing the receiver to infer the transmitted information.

B. Inter-Traffic-Class Priority-Based Channel

In this attack, the covert Rx maintains a flow with a small bandwidth, continuously monitoring its bandwidth (resource Y). Meanwhile, the covert Tx encodes bits 1/0 using the bandwidth of another flow (resource X). Covert Rx can infer the transmitted bits by observing Y.

Figure 9 shows our results on three RNICs, using the covert channel to transmit the bitstream `1101111101010010`. The TX performs RDMA Writes with 128 Bytes (bit `1`) and 2048 Bytes bit `0`). The results clearly show distinct bandwidth for bits `1` and `0`. This attack has a meager error rate because priority-based covert channel attacks rely on traffic bandwidth.

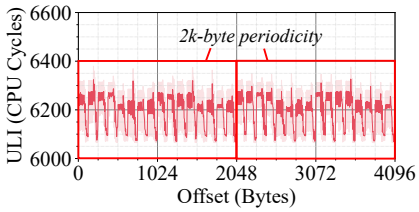

Fig. 6: ULI vs. *absolute* address offset. Alternately accessing two addresses with *64 B* RDMA Reads with the same remote MR on CX-4. Red lines and zone show the average and 10/90-percentile.

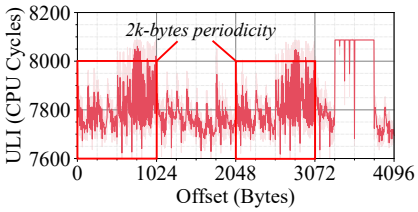

Fig. 7: ULI vs. *absolute* address offset. Alternately accessing two addresses with *1024 B* RDMA Reads with the same remote MR on CX-4. Red lines and zone show the average and 10/90-percentile.

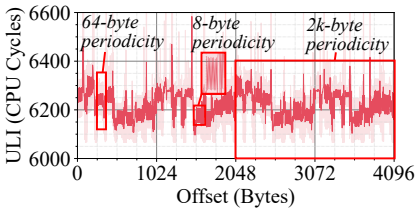

Fig. 8: ULI vs. *relative* address offset. Alternately accessing two addresses with *64 B* RDMA Reads with the same remote MR on CX-4.Red lines and zone show the average and 10/90-percentile.

TABLE V: Design features and evaluations of different granularity level covert-channels attacks on CX-4, CX-5, and CX-6.

Covert Channel	**Inter Traffic-Class**			**Intra Traffic-Class**					
				Inter MR			**Intra MR**		
Granularity Level	I+II			III			IV		
Base	Priority			RDMA resources			Offset effect		
RNIC (ConnectX)	CX-4	CX-5	CX-6	CX-4	CX-5	CX-6	CX-4	CX-5	CX-6
Bandwidth	1.0 bps	1.1 bps	1.1 bps	31.8 Kbps	63.6 Kbps	84.3 Kbps	32.2 Kbps	31.5 Kbps	81.3 Kbps
Error Rate	0.00%	0.00%	0.00%	5.92 %	3.98 %	7.59 %	6.95%	4.84%	4.08%
Effective Bandwidth	1.0 bps	1.1 bps	1.1 bps	21.5 Kbps	48.3 Kbps	51.6 Kbps	20.5 Kbps	22.7 Kbps	61.3 Kbps

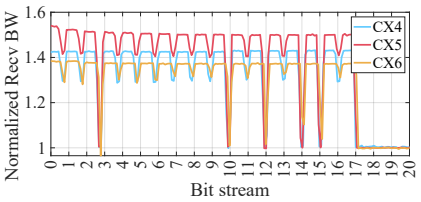

Fig. 9: Priority-based covert-channel attacks on CX-4/5/6. The significant drop means bit 0, and the slight drop means bit 1.

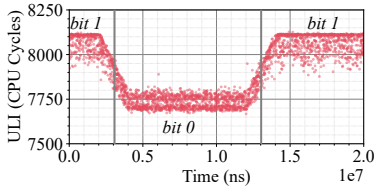

Fig. 10: Covert bits decoded from different unit latency increase, 1024 B RDMA Read, Max Send Queue Length = 256, on CX-4.

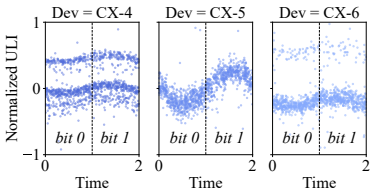

Fig. 11: Inter-MR resources-based channel on CX-4/5/6. X-axes indicate a folded period of two covert bits; Y-axes are normalized ULI.

C. Inter-MR Resource-Based Channel

We further employ Grain-III parameters, accessing the same or the different MRs (resource X) to encode the covert bits and measure the ULI (resource Y) of the background traffic.

Figure 10 demonstrates the folding ULI pattern with periodically switching covert bitstream. This ULI distinction remains stable over tens of seconds. More tests are done on CX-4, CX-5, and CX-6, utilizing 2 MB MR and 2 QPs. Under the best parameter combinations[10], the results are shown in Figure 11. As shown in TABLE V, RAGNAR's covert-channel attack on CX-6 reaches 84.3 Kbps bandwidth with 51.6 Kbps effective bandwidth.

D. Intra-MR Address-Based Channel

For better stealthiness, we manipulate Grain-IV parameters to construct an intra-MR channel. We switch address offsets (resource X) and observe ULI (resource Y) with 512 B RDMA Reads.

Under the best parameter combinations[11], the attack achieves 78.0 Kbps bandwidth on CX-6 with an error rate of 4.08 %, shown in TABLE V. Compared to the inter-MR channel, it offers higher stealthiness. This is because that encoding the covert bits brings nothing more than normal variation of access address offsets.

[10]Operations are 512 B Read, 64 B Read, 512 B Read respectively; max send queue sizes are 10, 6, 6 respectively.

[11]Max send queue size is set to 8. Covert bits are encoded to 0 B/255 B address offsets for CX-4 and CX-5, and 0 B/257 B address offsets for CX-6.

VI. SIDE-CHANNEL RAGNAR ATTACKS

In this section, we establish side-channel RAGNAR attacks on real-world applications.

We illustrate the threat model in Figure 2(b), where both the attacker and the victim are clients sharing an RDMA-based real-world service with the same server. We focus on privacy leakage of the access pattern rather than the data. In VI-A, we snoop database operation workloads in a distributed database. In VI-B, we reconstruct which data the victim accesses. In this model, the attacker and victim can read from a shared memory, like an open library or key-value store. Workload identification and access pattern leakage cause privacy breaches. An attacker can infer individual usage habits and expose system access hotspots in key-value stores. This leakage exacerbates the system's vulnerability. For instance, NVLEAK [40] compromise the privacy of a SQL database or key-value storage by maliciously spying on the victim's queries. Researches on Oblivious RAM indicate that curious attackers can concentrate resources on decrypting only hotspot data, analyze inter-query relations, and eventually break data confidentiality through access pattern snooping [29].

A. Fingerprint Distributed Database with Grain-II Attack

We exploit our reverse-engineering findings to fingerprint and extract operation workloads from the victim.

Specifically, we target an RDMA-based database shuffle/join application [23]. The shuffle/join method is a network-intensive operation and is widely used in distributed databases, especially suitable for

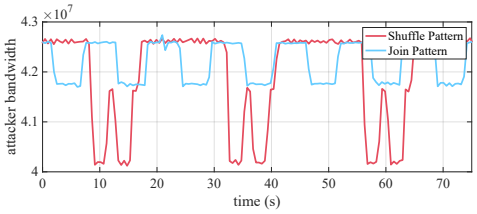

Fig. 12: Fingerprint patterns of shuffle/join.

Algorithm 1 Side-channel attack on SHUFFLE-JOIN

Input: $P_{Shuf/Join}$. Pattern of the Shuffle/Join operation
Output: Detected pattern P

$BW_{History} \leftarrow [\,]$
Establish RDMA connection and initialize monitoring traffic
while RDMA connection is active **do**
  Current time $t \leftarrow GetCurrentTime()$
  Current traffic bandwidth $BW \leftarrow GetTrafficBW()$
  Append (t, BW) to $BW_{History}$
  Maintain Time Window:
  for each entry $(time, _)$ in $BW_{History}$ **do**
    if $time < t - T_{window}$ **then**
      Remove $(time, _)$ from $BW_{History}$
    end if
  end for
  Traffic Pattern Detection:
  P = CorrelationDetect ($BW_{History}$, P_{Shuf}, P_{Join})
  Pattern P detected **if** P != P_{Null}
  Wait for the next monitoring cycle
end while
return P

large datasets. We establish a side channel based on priority-based contention, and perform fingerprinting on each shuffle/join operation.

In this experiment, we monitor the behavior of a small flow maintained by the attacker (as shown in Algorithm 1). As illustrated in Figure 12, the attacker's bandwidth decreases plateau-like during the shuffle and tooth-like during the join. The observed pattern slightly deviates from the baseline under different round times and configurations, demonstrating that this side-channel attack can extract clear information about shuffle/join operations.

B. Snoop on Disaggregated Memory with Grain-IV Attack

Disaggregated memory decouples CPU and memory into independent and network-attached components, computing, and memory servers (CS/MS) [6], [10], [21]. We choose SHERMAN [39], a disaggregated memory setup with write-optimized distributed B$^+$ Tree index, to perform our side-channel attack. SHERMAN is currently implemented as a 64 B KV store. We regard it as a file index in the MS cluster. We set the shared file to be 1 KB in the remote memory, assuming the ratio of numbers of file index access to file access to be 0.01 and the file access size to be 64 B.

In this setting, the attacker and the victim are procedures on CSs to read data from shared memory in an MS. Typically, one client cannot know which address the other client accesses, while the attacker aims to do so by posting certain RDMA Reads to trigger offset effect.

Figure 13 illustrates the attack's three steps. The victim repeatedly accesses an address from the *Candidate Set* (17 candidates, 0 B to 1024 B address offset) using 64 B RDMA Reads. During ❶, the attacker performs 64 B RDMA Reads on each address in the *Observation Set* (257 samples, 0 B to 1024 B address offset) N times

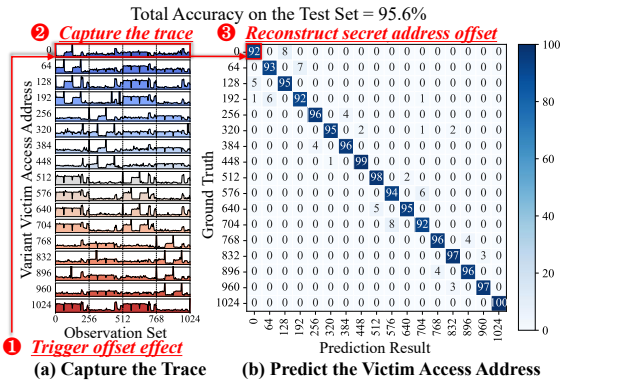

Fig. 13: Evaluation on the RAGNAR side-channel attack. (a) Differentiated traces were captured by the attacker under 17 variant victim access addresses. (b) ResNet18-based 17-Classifier achieves an overall 95.6% accuracy on recovering the address from a trace.

to measure ULI. In ❷, the average ULIs form a trace revealing the victim's access. For instance, if the victim accesses 0 B address offset, the trace will match the pattern in the red box shown in Figure 13(a).

Furthermore, ❸ we involve a ResNet18 classifier to recover the victim's access address from the captured trace. We train the classifier with 6720x 257-dimensional traces. It performs 17-classification on the traces and achieves an overall 95.6% accuracy on the test set, shown in Figure 13 (b). It shows that RAGNAR can easily steal the address accessed by the victim with high accuracy.

VII. DISCUSSION ON POTENTIAL MITIGATION

In this section, we discuss potential defenses.

Existing defenses. As discussed in II-D, the state-of-the-art performance isolation implementation HARMONIC [22] is not sufficient to mitigate RAGNAR's attack, since it does not take Grain-IV metrics into account and cannot eliminate the bandwidth differences completely. To the best of our knowledge, there is no direct existing mitigation to our attacks.

Hardware partitioning or adding noise. Direct mitigation involves fixing hardware features like eliminating priority races and mitigating offset effects by partitioning traffic workloads fairly according to counters from Grain-I-to-IV, which is costly and degrades performance. On the other hand, introducing sub-microsecond noise into packet latency can obscure ULI but may still leave detectable traces. Adding full noise for complete masking results in significant performance degradation.

VIII. CONCLUSION

This paper introduces RAGNAR, a comprehensive suite of RDMA-targeted volatile-channel attacks leveraging RNIC contention-based vulnerabilities at different granularity levels. Covert-channel RAGNAR attacks offer higher bandwidth and stealthiness than existing RDMA-targeted hardware attacks. Side-channel RAGNAR attacks can successfully reconstruct operations and achieve up to 95.6% accuracy in stealing secrets on real-world applications.

***Abstract*—In large-scale DNN inference accelerators, the many-core architecture has emerged as a predominant design, with layer-pipeline (LP) mapping being a mainstream mapping approach. However, our experimental findings and theoretical justifications uncover a hardware-independent and prevalent flaw in employing layer-pipeline mapping on many-core accelerators: a significant underutilization of buffer space across numerous cores, indicating substantial potential for optimization. Building on this discovery, we develop a universal and efficient buffer allocation strategy, BufferProspector, which includes a Buffer Requirement Calculator and Buffer Allocator, to capitalize on these unused buffers, addressing the timing mismatch challenge inherent in LP mapping. Compared to the state-of-the-art (SOTA) open-source LP mapping framework Tangram, BufferProspector averages a simultaneous increase in energy efficiency and performance by 1.44× and 2.26×, respectively. Moreover, we conduct some case studies on architecture and mapping. *BufferProspector will be open-sourced*.**

***Index Terms*—DNN Accelerators, Many-core, Buffer Management, Scheduling**

I. Introduction

Deep neural networks (DNNs) are widely deployed to solve real-world problems, such as image recognition [1], [2], [3] and natural language processing [4]. To achieve higher accuracy and robustness in complex scenarios, the size and complexity of DNN are becoming larger and larger, which results in increasing compute and storage demands. Therefore, many large-scale accelerators have been proposed to meet these demands [5], [6], [7], [8]. Among them, many-core architecture stands out as a predominant type [5], [6], [7], [8]. Within such accelerators, each core can independently handle a specific computational task. Moreover, the cores are interconnected via a Network-on-chip (NoC), ensuring mutual access.

Despite the rich on-chip computing and storage resources of large-scale many-core accelerators, harnessing their full potential to boost computing performance and energy efficiency remains challenging [9], [10], [11]. This has led to the introduction of LP mapping [8], [10], [11], [12]. In LP mapping, distinct layers are assigned to specific core groups, and their computed output feature maps (ofmaps) can be directly relayed to the consuming layer via the NoC, avoiding the expensive DRAM access costs. Compared to the traditional layer-sequential (LS) mapping [13], [14], where all computing cores are employed to compute layers one by one, LP mapping notably elevates both performance and utilization [11], [8]. For example, simply implementing LP mapping in Simba resulted in a 2.3× throughput increase over LS [8]. Due to its effectiveness, LP mapping is now widely embraced by most contemporary many-core accelerators [5], [6], [7], [8], [12].

Nonetheless, the prevailing LP mapping strategy exhibits a fundamental shortcoming: numerous cores suffer from extremely low buffer utilization rates. For example, when mapping ResNet-50 [1] on the default hardware setting (See Sec. V-A1) by existing SOTA LP mapping strategies [11], the buffer utilization of a half of the cores will be less than 25.64%. We conduct extensive theoretical analyses combined with empirical experiments to discern the direct proportional relationship between the Data-Compute Ratio (DCR) of each layer under LP mapping and the buffer utilization of the core processing it. DCR is defined as the ratio of a layer's data amount to its computation amount. Consequently, the substantial variability in DCR across different layers in modern DNNs contributes to the low utilization of numerous cores.

Upon unearthing this deficiency, we identified a significant amount of unused buffer. The next question to answer is: how to fully utilize such unused buffer resources and improve the performance and energy efficiency of the accelerator? We focus on the **timing mismatch challenge** in LP: Contemporary DNN architectures typically manifest as complex Directed Acyclic Graphs (DAGs) [1], [2], [4], and when two paths from a source layer to a destination layer have different lengths (e.g., in a residue block [1]), the shorter one will produce its ofmaps much earlier than the other. If we sent these early-produced fmaps directly to the consuming layer, there will be severe pipeline stalls. Thus, SOTA scheduling frameworks like Tangram [11] simply forbid such reuse and send it directly to DRAM for future usage, missing significant reuse opportunities. However, with the observation above, we can store such early-produced fmaps into the untapped buffers, which previous frameworks are unaware of, until the latest ones are ready.

Realizing the objectives above in a universal and efficient manner poses significant challenges. Specifically, with an arbitrary complex DNN DAG structure, how do we ascertain the buffer needs for each edge? Furthermore, how do we optimally distribute buffer space to accommodate these requirements? To address these issues, we introduce a comprehensive and efficient buffer allocation strategy, BufferProspector, which encompasses a universal buffer requirement calculator capable of pinpointing all edges that lead to timing discrepancies in any DNN DAG and determining the buffer needs for each edge. Thus, based on these requirements and the remaining capacity of each on-chip buffer, our efficient buffer allocator judiciously allocates unused on-chip buffer space to each demanding edge in a NoC-friendly manner.

In conclusion, we make the following contributions:

(1) We observe a fundamental deficiency in the widely-used LP mapping: a low buffer utilization rate in many cores, and analyze its cause qualitatively and quantitatively.

(2) To fully leverage the discovered unused buffer, we propose a universal and efficient buffer allocation strategy, BufferProspector, to address the time mismatch challenge within LP mapping. BufferProspector is open-sourced at this link [15].

(3) We conduct experiments spanning diverse DNN architectures, accelerator scales, and batch sizes. These experiments conclusively show that BufferProspector enhances both performance and energy efficiency over Tangram [11].

(4) We conduct case studies to explore the impact of buffer size,

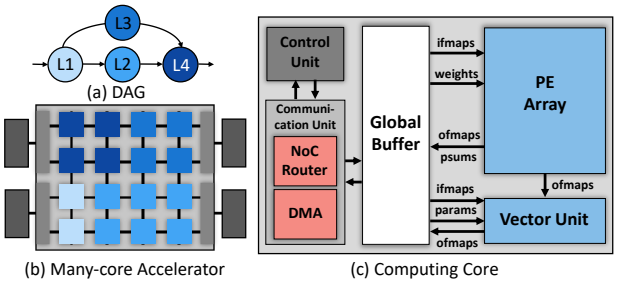

Fig. 1: Mapping Four Layers on A Many-core Accelerator.

a critical architectural factor, as well as the effect of pipeline depth, a key mapping factor, on performance and energy efficiency.

II. Background and Motivation

A. Many-core DNN Inference Accelerators

In recent years, many-core DNN inference accelerators have gained significant popularity in DNN acceleration. To facilitate a deeper investigation into their mapping strategies, we develop a universal and configurable hardware template (see Fig. 1) by extracting and synthesizing common features from a range of existing many-core inference accelerators [11], [5], [8], [10].

Overall, many-core accelerators comprise computing cores responsible for executing specific computing tasks, IO interfaces such as DRAM PHY & controllers (depicted as the light grey blocks on the edge of the chip in Fig. 1(b)), and a NoC, which manages data exchange between cores as well as between cores and DRAM.

The computing core (see Fig. 1(c)) is responsible for executing computing tasks. The following are its critical components. The communication unit, comprised of DMA and a router, enables seamless data exchange with other cores and DRAM. The control unit orchestrates computing tasks, drawing upon statically-compiled instructions and ongoing task progress data, and it also manages the inward and outward flow of data or messages from external cores or DRAMs. Each core is equipped with a Global Buffer (GLB), accessible throughout the accelerator, allowing for data reads and writes to and from the GLBs of other cores, given that the data is valid or the address is writable. The PE array and vector unit compute General Matrix Multiply (GEMM)/Convolution (Conv) operations and handle vector/scalar operations, respectively.

B. Layer-pipeline Mapping

In this section, we delve into the basis of LP Mapping and explore the challenges associated with timing mismatch that it faces.

1) Layer-pipeline Mapping: LP mapping is extensively employed in current large-scale many-core DNN accelerators [5], [8], [7], [6]. Under this mapping paradigm, each DNN graph is initially divided into various subgraphs, and each layer within a subgraph is assigned to a group of cores for computation. For instance, as illustrated in Fig. 1, L1-L4 are allocated 2, 6, 4, and 4 computing cores, respectively. Subsequently, a batch of data is divided into subbatches (SB), and each subbatch is processed in a pipelined manner by the core groups assigned to each layer. For example, once the first subbatch of data computed by L1 is sent to L2, L2 begins processing the first subbatch while L1 starts computing the second subbatch (see Fig. 2). This method can reduce the overhead of filling and draining while saving expensive DRAM access.

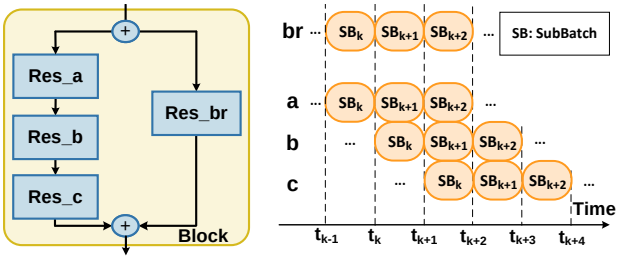

Fig. 2: An Example of Timimg Mismatch in LP Mapping.

2) Timimg Mismatch Challenge: With the development of Deep Learning, the DAG structures of DNN are becoming more and more complex [1], [16], [2], [4]. To balance each pipeline stage and reduce bubbles, the computing time of different Conv layers is kept roughly equal in LP mapping. This is achieved by controlling the number of cores allocated to each layer roughly proportional to the OP-num of that layer. However, when trying to pipeline map multiple branches with different lengths in a segment on the system, we will encounter timing mismatches. For example, as shown in Fig.2, both the shorter and longer branch receive the same input feature maps (ifmaps) at t_{k-1}, but the shorter one outputs data (at t_k) earlier than the longer branch output corresponding data (at t_{k+2}). However, the following element-wise add layer needs to get these ofmaps at the same time to calculate. This mismatch will lead to severe stalls in the pipeline, lowering the utilization of the system. Thus, existing works [11], [17], [18] give up mapping even one whole block containing multiple different branches, which limits the potential of LP mapping and increases expensive DRAM access costs.

III. Key Observation: Low Buffer Utilization with LP Mapping

As introduced in Sec. II-B, LP Mapping is widely employed by most many-core DNN accelerators due to its effectiveness in reducing expensive DRAM access and huge improvement on both performance and energy efficiency. However, in practice, we notice a key deficiency of current LP mapping on many-core accelerators: The buffer utilization of numerous cores is very low. For example, when mapping ResNet-50 [1] on the default hardware setting (See Sec. V-A1) by SOTA LP mapping framework [11], the buffer utilization of a half of the cores is less than 25.64%. Since buffers provide precious on-chip reuse opportunities, low buffer utilization implies that such opportunities are greatly wasted and the potential DRAM access reduction brought by on-chip data reuse in LP mapping is not fully explored.

Next, we aim to establish that this phenomenon is universally prevalent, solely related to the layers' DCR attribute, and independent of the hardware architecture. This proof also signifies the discovery of a substantial amount of underutilized buffer space, presenting numerous opportunities for optimization.

The Data-Compute-Ratio (DCR) of layer i is define as

$$DCR_i = \frac{data_i}{op_i} \tag{1}$$

where $data_i$ is the total data size of layer i, including ifmaps, weights, and ofmaps, and op_i is the OP-num of layer i. DCR depicts the ratio between the data size and computation of a layer. Typically, different layers in the same DNN will have different DCR values, and the variance of these values are relatively high. For example, the largest DCR among all convolution (Conv) layers in ResNet-50 [1] and DenseNet [2] are 11.25× and 6.14× larger than the smallest ones, respectively.

Then we conduct some theoretical analysis with some ideal assumptions to show the mathematical relation between DCR and buffer utilization of each layer. Let BU_i denote the buffer utilization of layer i, num_i denote the number of cores computing layer i, B denote the buffer capacity of each core, then we have

$$BU_i = \frac{data_i}{num_i \cdot B} \tag{2}$$

Furthermore, let C be the computing power of each core (the OP-num a core can compute in one time unit), t_i be the compute time of layer i, then by definition of C we have

$$t_i = \frac{op_i}{num_i \cdot C} \tag{3}$$

Combine equation 1, 2 and 3, we have

$$DCR_i = \frac{data_i}{op_i} = \frac{BU_i \cdot (num_i \cdot B)}{t_i \cdot (num_i \cdot C)} = \frac{B}{C} \cdot \frac{BU_i}{t_i} \tag{4}$$

which is a universal relation between DCR_i and BU_i: The DCR of a layer is proportional to the ratio between buffer utilization and compute time of that layer.

However, there is a fundamental property in LP mapping: To avoid bubbles and maintain high compute utilization, the compute time of each layer in the DNN must be roughly the same in LP mapping [8], [5], [10], [11]. In other words, there exists a constant T such that $t_i \approx T$ for different layers in the pipeline, then equation 4 becomes

$$DCR_i = \frac{B}{C} \cdot \frac{BU_i}{t_i} \approx \frac{B}{C \cdot T} \cdot BU_i = Const \cdot BU_i \tag{5}$$

This shows that the DCR of a layer is roughly proportional to its buffer utilization in LP mapping. Thus a high variance in DCR implies a high variance in the buffer utilization among different layers. Since the largest buffer utilization cannot exceed 100%, layers with low DCR will suffer from much lower buffer utilization.

Figure 3 demonstrates the DCR of four layers within a residual block from ResNet-50 and their corresponding buffer utilization in a practical LP mapping scenario. Among these layers, a relative proportionality is observed between their DCR and buffer utilization: Layer_a (L_a) has the highest DCR, which correlates with the largest buffer utilization among all layers. In contrast, layer L_b's DCR is only $0.089\times$ that of L_a, leading to a significantly lower buffer utilization of just 12.9%.

In summary, the analysis reveals a linear relationship between the DCR, a layer feature, and its buffer utilization. This, coupled with the fundamental requirement in existing layer-pipeline mapping strategies [11], [18], [17] for computational timing to be as identical as possible across different layers, leads to low buffer utilization under current mapping strategies. Thus, this deficiency is independent of hardware architecture and exhibits a universal presence.

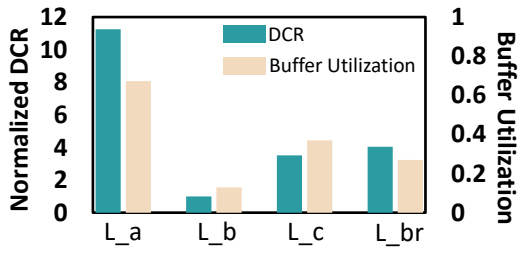

Fig. 3: DCR and Buffer Utilization of Mapping Four Layers in A Residual Block [1]. DCRs of all layers are normalized to the L_b layer with the lowest DCR.

IV. BufferPropector Strategy

After realizing the existence of such unused buffer on-chip, the next question to answer is: How can we turn such precious unused buffer resources into actual performance and energy efficiency gain? We focus on solving the timing mismatch challenge in LP mapping introduced in Sec. II-B2.

The high-level idea to solve the above challenge is straightforward: With the observation in Sec. III, we can store such early-produced fmaps (introduced in Sec. II-B2) into under-utilized buffers, which existing strategies are unaware of, and send buffered fmaps to the destination layer when required. As in the example in Sec. II-B2, the former ofmaps can be stored in unused buffers between t_k and t_{k+2}, and sent to the next layer at t_{k+2}. In this way, the ofmaps can be transmitted to the destination without storing into DRAM, which reduces a large amount of expensive DRAM accesses compared with existing works [11], [17], [18].

However, implementing this high-level concept universally and efficiently encounters two major challenges:

1. In an arbitrary DNN model with complex dependencies, how do we ascertain the buffer requirements for each timing mismatch?
2. With current buffer usage information, how do we efficiently allocate unused buffer space to accommodate these requirements?

Thus, we develop a universal and efficient buffer allocation strategy, BufferProspector, to solve these challenges. BufferProspector consists of a universal Buffer Requirement Calculator and an efficient Buffer Allocator. The Buffer Requirement Calculator detects all edges that lead to timing mismatch in the DNN dependency graph and calculates the buffer needed for each edge, solving the challenge 1. Then this calculated buffer requirement, along with the remaining capacity of each buffer, is sent to the Buffer Allocator, where the Buffer Allocator allocates unused on-chip buffer space to each edge in a NoC-friendly manner, which solves the challenge 2.

A. Buffer Requirement Calculator

Before calculating the buffer requirement of each edge in the DAG, we need to define the depth of each layer in the graph. For an arbitrary DNN with N layers denoted as $L_1, L_2, \ldots, L_N$, let $L_j \to L_i$ denote that there is an edge from L_j to L_i in the DAG. Then denote $P_i = \{L_j \mid L_j \to L_i\}$ be the preceding layers of L_i. Now the depth d_i of a layer L_i is defined as

$$d_i = \begin{cases} 0 & , P_i = \emptyset \\ \max_{L_j \in P_i} [d_j] + 1 & , P_i \neq \emptyset \end{cases} \tag{6}$$

where d_i can be calculated iteratively under a topological order of the DAG.

A layer has depth d means that there is a chain of d layers before that layer in the graph, and there does not exist any chain longer than d. Since when there is a dependency $L_j \to L_i$ in the graph, L_i must be processed at least one subbatch later than L_j (e.g. see Res_a $\to$ Res_b in Fig. 2), a layer of depth d will be processed d subbatches later than the first layer.

Then, for a dependency $L_j \to L_i$, the finishing of a subbatch at layer L_j is $d_i - (d_j + 1)$ subbatches before the starting of a subbatch at layer L_i. Thus if $d_i = d_j + 1$, then there is no need to buffer; if $d_i > (d_j + 1)$, a subbatch should be buffered during the processing of $d_i - (d_j + 1)$ subbatches, thus at most $d_i - (d_j + 1)$ subbatches will be buffered at the same time. However, to hide the latency of NoC transmission, each subbatch should be produced in a stream-processing manner and as long as some ofmaps are produced, NoC can start transmitting them. Similar to double buffering, such overlapping of NoC and processing requires the buffer capacity of

one additional subbatch, yielding a capacity of $d_i - d_j$ subbatches in total. Furthermore, notice that when the total number of subbatches NSB is smaller than $d_i - d_j$, then there is only NSB subbatches to be buffered in total. So if we denote c_j as the size of ofmaps of one subbatch in L_j, the capacity needed for $L_j \to L_i$ is

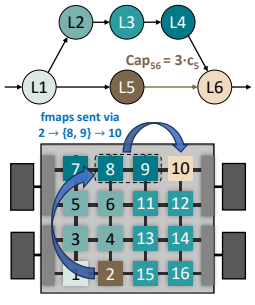
$$Cap_{j,i} = \min\left[d_i - d_j, NSB\right] \cdot c_j \tag{7}$$

Finally, when there are multiple edges starting from L_j that are needed to buffer, we only need to buffer the edge with the longest time interval. Since all buffering starts at the same time, the buffer needed for the ofmaps of L_j is:

$$Cap_j = \max_{\substack{L_j \to L_i \\ d_i > d_j + 1}} [Cap_{j,i}] = \min\left[\max_{\substack{L_j \to L_i \\ d_i > d_j + 1}} [d_i] - d_j, NSB\right] \cdot c_j \tag{8}$$

and if there are no such $L_j \to L_i$ with $d_i > d_j + 1$, let $Cap_j = 0$ and there is no need to buffer.

Taking Fig. 2 as an example: If the depth of the top Add layer is 0, then the depth of the bottom Add layer and Res_br is $d_{add} = 4$ and $d_{br} = 1$, respectively. Since SB_k is produced by Res_br before t_k and produced by the bottom add layer after t_{k+2}, it needed to be buffered between t_k and t_{k+2}. Then considering the transmission of NoC, we also need to allocate its buffer between t_{k-1} and t_k to receive the partial result from Res_br. Similarly, SB_{k+i} needs an allocation of buffer between t_{k-1+i} and t_{k+2+i}. In this way, the buffer needs to buffer SB_k, SB_{k+1}, SB_{k+2} at once, resulting with a capacity of 3 subbatches, which matches with $d_{add} - d_{br}$.



In summary, the Buffer Requirement Calculator firstly finds a topological order of the layers in the DNN, then calculate $d_1, d_2, \ldots, d_n$ using equation 6, at last outputs the buffer requirement of each layer by equation 8.

B. Buffer Allocator

After the buffer requirement of each edge is obtained, we need to allocate unused on-chip buffer space to satisfy these requirements. During the allocation, there are three factors to consider:

Number of Cores: Since the buffer requirement size usually contains multiple subbatches, we need to select multiple cores to buffer early-produced fmaps in many cases. However, allocating too many cores for a single requirement can lead to considerable concurrent synchronization overheads when the subsequent layer needs to fetch these fmaps.

Total NoC Distance: The NoC transmission of these fmaps will not only produce additional energy costs, but also occupy limited on-chip NoC bandwidth. Both factors are proportional to the total NoC distance from the producer and consumer layers to the buffer, so reducing the total NoC distance can improve performance and energy efficiency.

Buffer Allocation Example (3·c_5 =300 KB, L = 50 KB)

Core	Remaining Capa.	Distance	Selected
1	200 KB	7	
2	40 KB	5	
3, 5	10 KB	7	
4, 6	10 KB	5	
7	150 KB	7	
8, 9	150 KB	5	√
10	0 KB	5	
11~16	30 KB	5	

Fig. 4: An Example of Mapping Six Layers on A 16-core Accelerator. In the table "Capa." stands for Capacity and "Distance" represents the Total NoC Distance. Cores are labeled from 1 to 16, in which core 8 and 9 are selected to buffer the 300KB requirement of $L5 \to L6$. L is set to 50KB.

Algorithm 1: Buffer Allocator

Input: List of Requirements req_list, Remain Space of Each Buffer $rems$, Size Limit of Each Allocation L
Output: Buffer Allocated to Each Requirement $alloc$

```
// Iteratively allocate each requirement req
for each req in req_list do
    // Filter all buffers with at least L remaining capacity
    avail_bufs = [x for x in rems if rems[x] ≥ L]
    // Then sort with total NoC distance and allocate in this order
    sort_key = lambda i: dist(req.src, i) + dist(i, req.dst)
    avail_bufs.sort(key = sort_key)
    remain_req = req.size
    for each buf in avail_bufs do
        // Allocate all remaining capacity of buf to req
        alloc_size = min(remain_req, rems[buf])
        remain_req -= alloc_size
        rems[buf] -= alloc_size
        alloc[req][buf] = alloc_size
        if remain_req == 0 then
            break
        end
    end
    if remain_req > 0 then
        // All avail_bufs has used up, must use DDR
        alloc[req][DDR] = remain_req
    end
end
return alloc
```

Allocated Size of Each Buffer: If the allocated size on a buffer is too small (e.g., less than 1KB), the buffer will suffer fragmentation issues, and transmitting such a small amount of data is not NoC-friendly either.

Considering all three factors above, the Buffer Allocator is implemented with a greedy algorithm (Alg. 1): For each buffer requirement, we set a limit L, which is a configurable parameter, for the smallest allocated size on each buffer, and sort all cores with enough remaining buffer capacity by their total NoC distance to the producer and consumer layers. Then we allocate from the nearest core to the furthest, allocating all remaining capacity of its buffer, until the requirement is satisfied. If all such buffers cannot satisfy the requirement, DRAM is used to buffer the unsatisfied part. In our experiments, L is set to one-sixth of the total required size based on our experiment observations. In this way, the number of cores to buffer will not exceed 6, and the allocated size of each buffer will not be too small; on top of that, the Buffer Allocator minimizes total NoC distance, taking great care of all three factors.

Fig. 4 shows an example of buffer allocation: The edge $L_5 \to L_6$ has a buffer requirement of 3 subbatches, which is 300KB. L is set to 50KB, and core 1,3,4,5,6 have limited unused buffer capacity that does not exceed L. Among all the cores that has enough capacity, core 8 and 9 has minimal total NoC distance, thus is prioritized to satisfy the requirement. Although all cores of L_3 have minimal total NoC distance, their remaining capacity is too small (30KB) and we do not utilize such core in consideration of fragmentation.

C. BufferProspector Implementation

We have developed an end-to-end compiler framework based on BufferProspector for our test chip. Except for BufferProspector Scheduling Part, the compiler includes a model parser that processes models from mainstream frameworks like PyTorch or TensorFlow

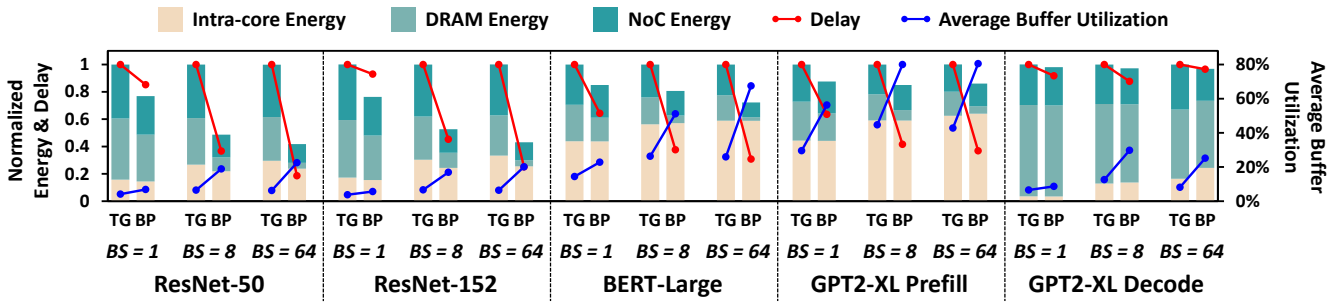


Fig. 5: Overall Comparisons Between Tangram (TG) and BufferProspector (BP). $BS = N$ is short for "batch size is N". Energy and Delay are normalized to Tangram in each pair of columns, while Average Buffer Utilization are shown in absolute values.

into the format required by our system. It also features an Intermediate Representation (IR) generator that organizes the information from the explored mapping scheme to create an IR conducive to instruction generation. Finally, an instruction generator transforms the IR into deployable hardware instructions.

V. Evaluation

A. Experiment Setup

1) Hardware Configuration: The default hardware architecture consists of 12×10 cores (this scale of core count is referenced from the well-known Tenstorrent Grayskull [5]), with each core equipped with a 1MB GBUF and 1024 MACs. The total DRAM bandwidth is set at 0.5GB/s per TOPs (120GB/s for the 120-core default accelerator). We also conduct sensitivity tests on accelerators with different scales. To systematically quantify the energy consumption for distinct operations required by the Tangram energy evaluators, such as MAC and buffer accesses, we employ a diverse array of tools and data. This includes directly obtaining data from commercial IP datasheets, or simulate RTL codes through a simulation flow developed during the chip design.

2) Workloads: In the overall comparison, we select ResNet-50 [1], ResNet-152 [1], BERT-Large [19], and GPT2-XL [20] as workloads due to their popularity in image and language applications and diverse structures; batch size is scaled among 1, 8 and 64, targeting both throughput-driven and latency-driven scenarios and demonstrating the efficiency of BufferProspector across different batches.

For the Design Space Exploration (DSE) experiments, we select BERT-Large as the default workloads regarding to its wide application; to include both cloud-based, throughput-driven scenarios and edge-based, latency-driven scenarios, batch size of 1 and 64 are selected; we also scale buffer size and DRAM bandwidth to study their impact on the effect of BufferProspector.

3) Baseline: We choose the open-sourced SOTA Tangram scheduling framework [11] as our baseline, since it employs optimized pipeline searching algorithms and mainstream intra-core tiling methods. The hardware configurations of Tangram and BufferProspector are kept the same throughout all experiments. Energy-delay Product (EDP) is selected as the optimization goal in all experiments, which matches the original Tangram paper [11].

B. Overall Comparison

As shown in Fig. 5, compared to Tangram, BufferProspector has demonstrated its value by achieving an improvement of 2.26× performance and 1.44× energy efficiency, on average across the five networks. A notable average reduction of 47.3% in DRAM energy consumption is observed, serving as the primary driver behind the observed enhancements in both performance and energy efficiency. This reduction can be primarily attributed to an increased buffer utilization, averaging 2.26 times, facilitating greater on-chip data reuse. The augmentation in buffer utilization can be attributed to two main advantages brought about by the BufferProspector strategy: (1) It relaxes the constraints on pipeline length present in Tangram (as introduced in Sec. II-B2, Tangram forfeits the mapping of layers that span more than one block due to timing mismatch challenges), allowing more layers to be computed on-chip concurrently, and enabling more feature maps to be directly generated and consumed on-chip without the need for DRAM access. (2) Feature maps that cannot be immediately consumed are temporarily stored on-chip, which avoids the need to write to DRAM and prevents stalling the overall pipeline.

1) Comparison among Networks: BufferProspector exhibits a significant performance improvement in all 6 workloads, which demonstrates the universal improvement of BufferProspector under different network topologies. The only exception here is the decode of GPT2-XL: GPT2-XL Decode has low compute density [21], and the dependency data for on-chip reuse is significantly smaller compared to the weight and KV cache data, leaving limited potential for BufferProspector to optimize.

2) Comparison among Batch Sizes: BufferProspector consistently achieves improvements over Tangram across various batch sizes. Even in latency-sensitive scenarios, where batch sizes can be as small as one, BufferProspector improves 1.29× performance and 1.19× energy efficiency compared to Tangram. The benefits of BufferProspector become increasingly pronounced with larger batch sizes, yielding 3.27× performance improvement and 1.66× energy efficiency improvement at batch size 64. This enhancement primarily attributes to the mitigation of filling and draining overheads in larger batch sizes. Since overheads brought by filling and draining is only relatively proportional to pipeline depth and remains the same in different batch sizes, lengthy pipelines will suffer less from such overheads in larger batch sizes. As a result, longer pipelines can be more efficiently mapped onto the accelerator, maximizing the advantages of BufferProspector and concurrently highlighting the constraints Tangram imposes on pipeline depth. As evidence, we observe that with the increase in batch size, BufferProspector reduces more DRAM access and enhances better buffer utilization. This indicates the ability of BufferProspector to buffer early-produced fmaps and utilize longer pipeline, thereby reducing DRAM access.

C. Design Space Exploration

To further investigate the architecture and layer-pipeline mapping of many-core accelerators, we conduct a DSE, providing in-depth analysis and discussion on the two critical factors of mapping and architecture: pipeline depth and buffer size.

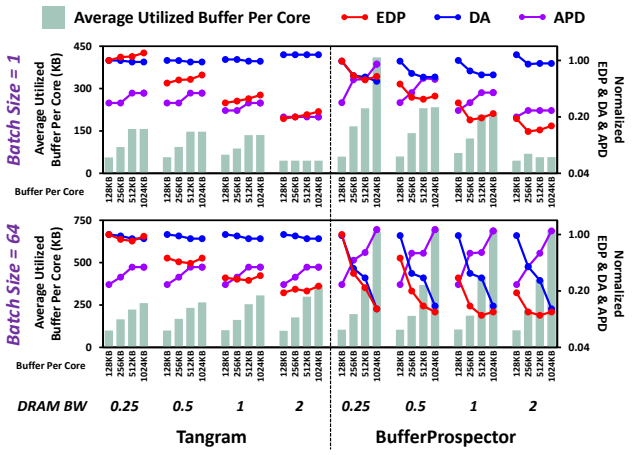

Fig. 6: DSE Experiments. The workload is Bert_Large. **DRAM BW** stands for DRAM bandwidth and 0.25 means "a DRAM bandwidth of 0.25GB/s per core", **DA** stands for DRAM Access, and **APD** stands for Average Pipeline Depth. EDP and DA in each plot is normalized to the first data point of Tangram, i.e. (128KB, 0.25GB/s), and APD is divided by 10 to match the scale. Normalized EDP, DA and APD is drawn in log-scale for better comparison.

1) Will A Deeper Pipeline Be Better? To analyze the influence of pipeline depth on overall performance, it is essential to evaluate the trade-offs associated with a deeper pipeline. On one hand, a deeper pipeline reduces the number of fmaps that need to be saved to DRAM, thereby lowering DRAM access and saving both energy and latency. On the other hand, it increases filling and draining overhead due to dependencies, as well as bubble costs caused by computational imbalances among different layers, which decreases computational utilization and negatively impacts performance. Therefore, determining whether a deeper pipeline is advantageous hinges on assessing whether the benefits outweigh the drawbacks, a trade-off that varies depending on the specific scenario.

When batch size is large, filling & draining overheads are relatively small, and its disadvantage is covered by the benefits of DRAM access reduction. Thus extending the pipeline is beneficial in most times, and both Tangram and BufferProspector will try their best to extend the pipeline depth, hoping for more DRAM access reductions. However, in a deeper pipeline, more layers are mapped onto the cores at the same time, posing a much larger buffer requirement. Thus, for BufferProspector, it will try to make full use of the buffer to pursue a deeper pipeline. This can be evidenced by the huge increase in APD and utilized buffer in Fig. 6 batch size 64, where the reduction of DRAM Access matches the increase of APD. Although Tangram will also try to extend its pipeline, it suffers from timing mismatch issues (introduced in Sec. II-B2) and has a much smaller APD limit, so APD will remain the same after hitting this limit, even with larger buffer, which greatly restricts its performance improvements. This can be seen clearly in Fig. 6 batch size 64.

When batch size is small, the pipeline will experience a much larger filling & draining overheads, thus compared with large batch sizes, extending the pipeline becomes less beneficial and its downside becomes comparable with the improvement of DRAM access reductions. As a result, pipeline tends to be longer when DRAM bandwidth is less sufficient (see Fig. 6 batch 1). Under a smaller DRAM bandwidth, the whole computation becomes more bounded by DRAM accesses, which highlights the contribution of DRAM access reductions to the reduction of overall latency, making longer pipelines more beneficial, and encouraging both Tangram and BufferProspector to extend to a larger pipeline, as shown in Fig. 6 batch 1.

In summary, in large-batch-size scenarios, BufferProspector will try its best to extend its pipeline, and pipeline depth is mostly constrained by the buffer size; while in small-batch-size scenarios, DRAM bandwidth will also be a decisive factor, and a smaller DRAM bandwidth prefers a longer pipeline. **Thus for BufferProspector, one should focus on designing larger buffers in throughput-driven scenarios and focus**

2) Will A Larger Buffer Be Better? When buffer size per core increases from 128KB to 1024KB, BufferProspector on average can reduce EDP by 47.4%. Such huge improvement mainly stems from the possibility of buffering more fmaps on-chip and reducing more DRAM access, as evidenced by a 5.21x average increment of utilized buffer and a 60.5% average reduction of DRAM access.

However, we can observe that such reduction of EDP becomes smaller when buffer size is larger, and for the 1GB/s and 2GB/s settings, the EDP forms a U-shaped curve, even increasing when buffer per core increases from 512KB to 1024KB. There are two main reasons that lead to the smaller reduction, or even increase, of EDP. Firstly, the pipeline cannot extend infinity, and fmaps that needs to be buffered is also limited, thus when the buffer is larger, fmaps that needs to be optimized to on-chip buffer is also fewer, which means expanding it brings less benefit on the EDP. In addition, accessing a larger buffer needs a larger energy cost. For example, it is shown that when the size of a buffer doubles, its access energy cost becomes 1.5 times larger [22]. Thus, an increased buffer size results in a larger energy cost, leading to an increased EDP.

In conclusion, on the one hand, larger buffer usually means better performance; but on the other hand, when buffer becomes larger, the reduction of DRAM access becomes less prominent, while the increase of energy cost becomes more dominant, giving out less performance optimizations, and when the extra energy cost outruns the reduced access, we will even get worse performance. **Thus to pursue the best performance of BufferProspector, one should not aggressively increase the buffer size, but find and follow the appropriate buffer size in accelerator designs.**

Notice that Tangram can barely reduce DRAM access with a larger buffer, thus suffering from an average increase of 14.5% in EDP when buffer size per core increases from 128KB to 1024KB.

VI. Conclusion

This paper begins by highlighting a deficiency commonly observed in existing LP mapping strategies: severe under-utilization of many cores' buffers. We then conduct qualitative and quantitative analyses of this phenomenon, deducing that under current LP mapping strategies, a linear relationship exists between a layer's DCR attribute and buffer utilization. This establishes the phenomenon's hardware independence and widespread prevalence at a theoretical level. Following this, we develop the BufferProspector strategy, which includes a Buffer Requirement Calculator applicable to any DAG and an efficient Buffer Allocator. These tools aim to leverage the substantial amounts of underused on-chip buffer resources discovered by us to address the timing mismatch challenges in layer-pipeline mapping. Finally, our empirical experiments demonstrate that BufferProspector offers significant performance and energy efficiency improvements over the SOTA open-source LP mapping framework, Tangram.

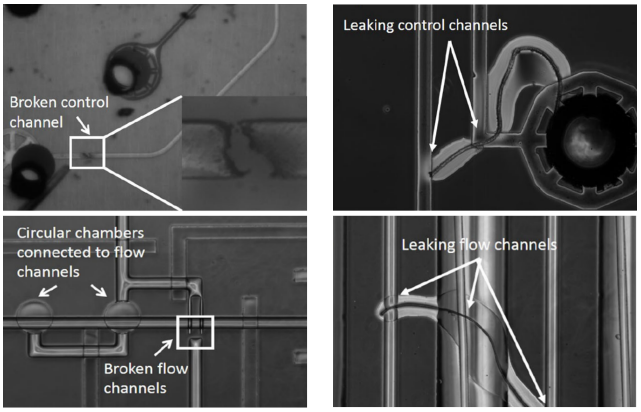
***Abstract*—As an emerging platform for biochemical experiments, flow-based microfluidic biochips are currently suffering from malfunctions caused by manufacturing defects, thereby having low yield. While many related studies have been conducted and reliability quantification models have been published, layout optimization methods are yet lacking. In this paper, we propose AutoRE, the first tool to automatically enhance reliability by optimizing layouts. AutoRE varies the layout within a certain range without changing its topology, and adopts Bayesian optimization (BO) to identify the most reliable variant. Experimental results demonstrate that AutoRE can efficiently and effectively improve the reliability across all testcases by around 40% on average.**

I. Introduction

Recently, flow-based microfluidic biochips have emerged as an increasingly attractive platform for biochemical experiments [1]–[3]. Such coin-sized chips incorporate many miniaturized devices to carry out complex experiments. Compared to traditional cumbersome laboratory instruments, these chips enjoy many advantages including low reagents consumption, high automation degree, and high-sensitivity [3]. Such a chip consists of two layers: a flow layer containing flow channels and a control layer containing control channels. Reagents are transported in the flow channels, and the pressure in the control channels controls the transportation [4].

Due to the limitations of material and manufacturing processes, manufacturing defects can happen to these chips and cause malfunctions, resulting in low yield [5]. As the demand for more complex experiments increases, the integration level of these chips becomes higher, introducing significantly denser and longer channels. Consequently, this increases the risk of manufacturing defects, making the reliability of these chips an even more severe concern [6]–[8].

To improve the reliability of these chips, many related works have been conducted. Apart from some works aiming to achieve breakthroughs in material reliability and manufacturing processes, most previous works focus on enhancing the layouts of these chips. Zhu et al. proposed to construct a logic forest, enabling certain valves and channel segments to share the same functionalities, realizing fault tolerance [9]. Huang et al. proposed to construct backup channels in original layouts, providing each device-device connection with multiple possible paths [10]. Moradi et al. proposed to expand the routing fabric, guaranteeing the existence of multiple paths through different transposers [11]. Liang et al. proposed a more efficient coding strategy, and proposed to merge certain channel segments to reduce the density and length of channels in multiplexers [12].



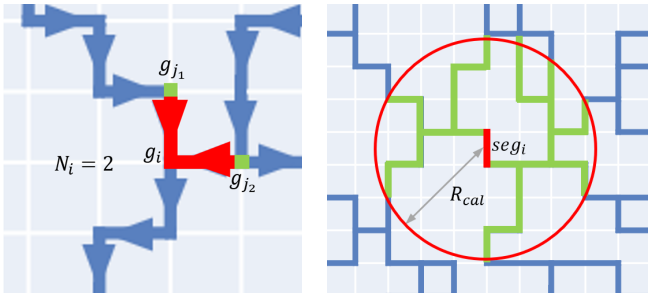


Fig. 1: Photos of common manufacturing defects [5]. (a) Blockage. (b) Leakage.

These studies mainly focus on modifying the layouts to improve the reliability. Unfortunately, all of them lack evaluation methods of the reliability, making it impossible to quantify the degree of the reliability improvement. To tackle this problem, Liang et al. proposed reliability quantification models of two main types of manufacturing defects [13]. However, there is still a lack of layout optimization methods that utilize quantification models to optimize layouts for higher reliability.

In this paper, we propose AutoRE, the first automatic reliability enhancement tool for flow-based microfluidic biochips. Specifically, we first segment the original layout, and alter the segments within a certain range while maintaining the same topology. This way, we identify a feasible domain, in which we can explore among all feasible layout variants for higher reliability. We adopt Bayesian optimization (BO) to improve the efficiency of the exploration, and utilize reliability quantification models proposed in [13] to evaluate the reliability during the process. According to experimental results, AutoRE is an efficient tool that can effectively improve the reliability across all testcases by around 40% on average.

The rest of the paper is organized as follows: Section II introduces the background knowledge. Section III presents the overall flow of the proposed method. Section IV illustrates the identification of the feasible domain. Section V demonstrates the Bayesian-optimization-based reliability enhancement. Sec-

tion VI shows the experimental results, and Section VII draws the conclusion.

II. Background

A. Reliability Quantification Models

There are two main types of manufacturing defects: blockage and leakage [5]. The corresponding quantification models of their probabilities were proposed in [13].

1) Anti-Blockage Reliability

Blockage refers to the accidentally broken channel segments. Examples of broken control and flow channels are shown in Fig. 1(a). For control channels, blockage prevents pressure transportation, leading to losing control of valves; for flow channels, blockage prevents reagents from reaching reactors. Blockage is usually caused by environmental particles and imperfect silicon wafer molds.

According to previous studies [5], [6], blockage occurs in different parts of the layout almost randomly. Based on this, the blockage probability model proposed in [13] assumes every unit channel segment in the grid-based layout to have the same probability of being blocked. When a segment fails, the probability that its backup segments can take over the fluid transportation is the most important factor in determining the anti-blockage reliability. Hence, this model uses a propagation-based strategy to calculate $P_{blockage}$, the probability of layout failure due to blockage.

As shown in Fig. 2(a), the model first derives the directions of fluid transportation using the equivalent circuit model [14]. Following the derived directions, the model progressively calculates the probability of successful fluid transportation to different parts of the layout until it reaches all the ending points. For each grid point g_i, there are N_i adjacent upstream grid points g_j, providing N_i possible paths for fluid transportation. The probability of successful fluid transportation to g_i is determined by considering the likelihood that at least one of the N_i paths successfully transports fluid from g_j to g_i. The layout is considered well-functioning only if the fluid successfully reaches all the ending points. Therefore, $P_{blockage}$ is ultimately derived from the probability of fluid failing to reach all the ending points, and the anti-blockage reliability is then determined by $1 - P_{blockage}$.

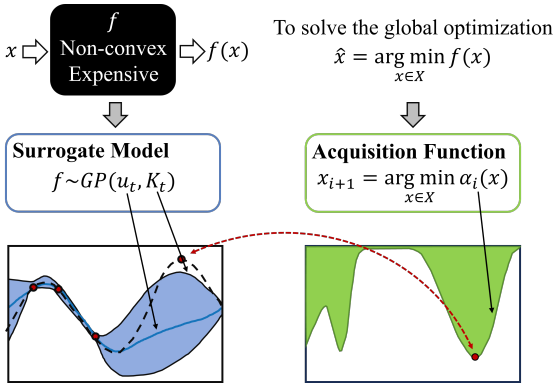

Fig. 3: Schematic of Bayesian optimization.

2) Anti-Leakage Reliability

Leakage refers to the unexpected connections between channels. Examples of leaking control and flow channels are shown in Fig. 1(b). For flow channels, leakage can make reagents unexpectedly infiltrate into other channels, resulting in catastrophic cross-contamination; for control channels, leakage transports pressure from one channel to the other, leading to unanticipated closure of valves. Leakage is usually caused by fiber pollutant and cracks in the layer.

According to previous studies [5], [6], the probability of leakage increases as the length of parallel channels increases or the distance between neighboring channels decreases. Based on this, the leakage probability model proposed in [13] assumes that each unit channel segment in the grid-based layout has the same probability to leak to another unit channel segment at a unit distance. Additionally, it assumes that leakage forms incrementally, unit distance by unit distance. In other words, the probability of leakage occurring between two unit channel segments decreases exponentially as the distance between them increases. This model combines leaking probabilities of each unit channel segment to derive $P_{leakage}$, the probability of layout failure due to leakage.

As shown in Fig. 2(b), for each unit channel segment seg_i, the model scans its nearby region within the range R_{cal}, and identifies all the nearby unit channel segments. The leaking probability of seg_i can then be calculated based on the probability of it leaking to any nearby unit channel segments. Since leakage may grow when high pressure is injected into the channels [5], the layout is considered well-functioning only if there is no leakage at all. Therefore, $P_{leakage}$ is ultimately derived from the probability of leakage occurring anywhere in the layout, and the anti-leakage reliability is then determined by $1 - P_{leakage}$.

B. Bayesian Optimization

As an efficient technique for black-box optimization method, Bayesian optimization (BO) seeks to quickly identify an input $\hat{x}$ that minimizes a function $f(x)$ within a domain $\boldsymbol{X}$, which is defined by finite lower and upper bounds for each variable.

$$\hat{x} = \underset{x \in \boldsymbol{X}}{\operatorname{argmin}} f(x) \tag{1}$$

The objective function $f(x)$ often lacks an analytical expression or derivative, limiting its evaluation to sampling at specific points x and obtaining potentially noisy responses. The feasible domain $\boldsymbol{X}$ is typically either a hyper-rectangle $\left\{x_i \in \mathbb{R}^d : a_i \leq x_i \leq b_i\right\}$ or a d-dimensional simplex $\left\{x_i \in \mathbb{R}^d : \sum_i x_i = 1\right\}$.

As shown in Fig. 3, BO relies on two critical components: (i) the surrogate model, which approximates the objective function; (ii) the acquisition function, which directs sampling to areas where an improvement over the current best observation f' is promising. The surrogate model is typically a Gaussian process (GP) [15], and many alternatives have also been been proposed for better performance, such as random forest (RF), Bayesian additive regression trees (BART), and Bayesian multivariate adaptive regression splines (BMARS) [16]–[18]. A popular acquisition function is expected improvement (EI) [19], defined as the expected value of the utility function $u(x) = \max(0, f' - f(x))$ under the GP predictive distribution for f. Other acquisition functions like log expected improvement (logEI), probability of improvement (PI), and lower confidence bound (LCB) are also widely used in different works [19]–[21]. BO iterates between fitting a model and gathering additional data. Initially, the surrogate model $p(y|x, \mathcal{D}_t)$ is trained on a small set D_t of t samples from the domain $\boldsymbol{X}$. Subsequently, new points $\{x_{t+1}, x_{t+2}, ..., x_T\}$ within the domain $\boldsymbol{X}$ are sequentially selected by optimizing an acquisition function S, which uses the current model $p(y|x, D_i)$ as a cost-effective surrogate for the expensive objective f. This guided point selection, driven by the acquisition function, enables BO to consistently identify superior points, significantly enhancing efficiency compared to random selection. Each observed point x_{i+1} is evaluated by the function f, producing an observed result $f(x_{i+1})$. The result $(x_{i+1}, f(x_{i+1}))$ is added to the historical set D_i, forming the new set D_{i+1}, which updates the surrogate model $p(y|x, D_{i+1})$ for the next observation point. Ultimately, the point $\hat{x}$ can be selected from D_T, ensuring that the objective function f approaches or reaches the global optimum at $\hat{x}$.

III. Overall Flow of the Proposed Method

The overall flow of AutoRE is shown in Fig. 4. The flow consists of two main stages: feasible domain identification, and BO-based reliability enhancement. We vary the given layout within the feasible domain to explore more reliable layout variants. In each round, we will vary the layout in only one of the x-axis and y-axis directions. The optimized layout from each round will serve as the initial solution for the next round, with the direction of variation being switched. This way, the relative locations of different parts will keep unchanged in each round, so that we can maintain the topology of the layout, preserving the functionality of the layout. Additionally, this approach simplifies the problem by reducing it from exploring a 2-D space to exploring multiple 1-D spaces, making the process more manageable and efficient.

Specifically, for a given layout, we first segment it into horizontal and vertical channel segments. In each round, only

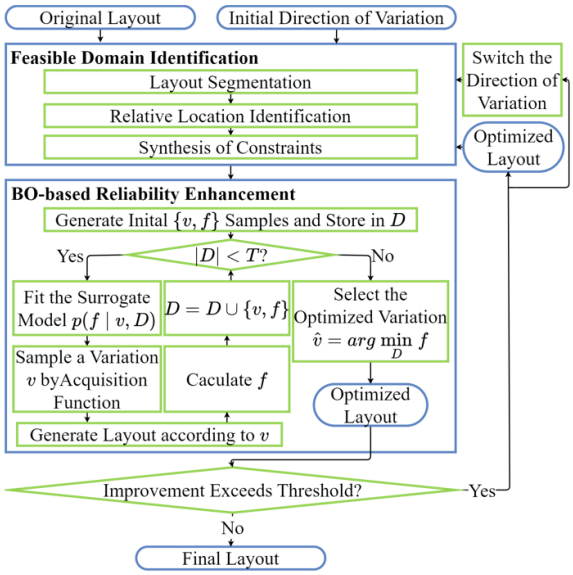

Fig. 4: The proposed overall flow of AutoRE.

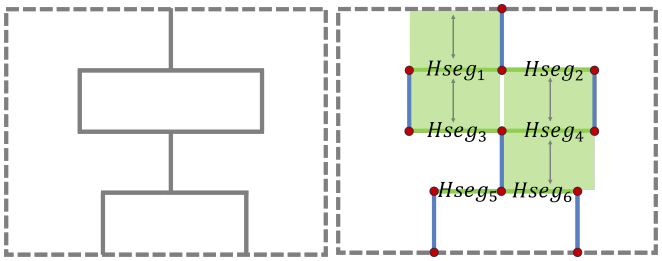
the locations of the segments perpendicular to the current variation direction will be actively altered to shift along this direction, while the other segments will be extended or shortened to maintain the topology based on their connection relationships. Next, we develop an algorithm to identify the relative locations of the segments perpendicular to the current variation direction, and synthesize constraints accordingly, forming the feasible domain for the next stage. For example, when the variation direction is along the y-axis, only the y-axis locations of the horizontal channel segments will be actively altered during this round. For each horizontal channel segment, we will identify its nearest upper and lower neighbors, and only allow its y-axis location to be altered between these neighbors. This ensures that the relative locations of segments remain consistent during the variation.



Within the feasible domain, there can be thousands of possible layout variants, making it impractical to traverse all of them. Hence, we utilize BO to efficiently explore more reliable layout variants with only a limited number of attempts. During the exploration, we repeatedly sample layout variants and derive their corresponding costs. The distribution of the cost function will be predicted based on the obtained samples, and layout variants that are predicted to have lower costs will be more likely to be sampled in the future. This way, we can use much fewer attempts to find the more reliable layout variant, significantly improving the efficiency of exploration.

IV. Feasible Domain Identification

Given a layout, we need to first identify the feasible domain, in which we can vary the layout and explore the more reliable layout variant. For example, in Fig. 5(b), the green regions represent the feasible domains of horizontal channel segments $Hseg_1$ and $Hseg_4$, respectively.

A. Layout Segmentation

To make the variation efficient, we choose to segment the layout into horizontal and vertical channel segments, and alter these segments to derive the layout variants.

(a) (b)

Fig. 5: Schematic of feasible domain identification. (a) The original layout. (b) Schematic of the identified feasible domains of two example horizontal channel segments.

Initially, we need to identify the terminals of segments. There are four types of points that can be terminals of segments: (i) starting points, where fluid is input into the design; (ii) ending points, where fluid is output from the design; (iii) branching points, which refer to points having more than two connections; (iv) corners, which refer to points with two connections forming a 90-degree angle. As shown in Fig. 5(b), the red dots represent the identified key points in the example layout shown in Fig. 5(a).

We then traverse all the terminals, identifying the horizontal and vertical connections among them as horizontal and vertical channel segments, respectively. As shown in Fig. 5(b), the green and blue segments between the red dots represent the identified horizontal and vertical channel segments, respectively. The connection relationships among these segments will also be recorded. Once segments in a certain direction are actively altered, segments in the other direction will be updated according to the connection relationships.

B. Relative Location Identification

During each round of variation, only the locations of segments perpendicular to the variation direction will be actively altered. To maintain the topology of the layout, we need to identify the relative locations of these segments, and only allow each segment to vary between its neighbors.

For example, when the variation direction is along the y-axis, for each horizontal channel segment $Hseg_i$, we will first search for all the horizontal channel segments overlapping with it in x-axis locations, and store them in $Overlap_i$. Whether or not two horizontal channel segments overlap in x-axis locations is determined by:

$$\mathbb{1}(\text{if overlap}) = \mathbb{1}(x_{i_{min}} \leq x_{j_{max}})\mathbb{1}(x_{i_{max}} \geq x_{j_{min}}) \quad (2)$$

where $\mathbb{1}(\cdot)$ is the indicator function, $x_{i_{min}}$, $x_{i_{max}}$, $x_{j_{min}}$, and $x_{j_{max}}$ represent the x-axis locations of the left and right terminals of $Hseg_i$ and $Hseg_j$, respectively.

For each $Hseg_j$ in $Overlap_i$, we then calculate d_{ij}, the y-axis distance from $Hseg_i$ to $Hseg_j$:

$$d_{ij} = y_j - y_i \quad (3)$$

where y_i and y_j represent the y-axis locations of $Hseg_i$ and $Hseg_j$, respectively. $Hseg_j$ that correspond to the smallest positive d_{ij} and the largest negative d_{ij} are identified as $Hseg_i$'s nearest upper and lower neighbors, respectively. As shown in Fig. 5(b), the upper and lower neighbors of $Hseg_4$ are $Hseg_2$ and $Hseg_6$, respectively. If there are no positive or negative d_{ij}, the upper or lower boundary of the layout will be regarded as the corresponding neighbor of $Hseg_i$. For example, in Fig. 5(b), the upper neighbor of $Hseg_1$ is the upper boundary. Besides, some $Hseg_j$ may be connected to the terminals of $Hseg_i$, making the corresponding $d_{ij} = 0$. Such a $Hseg_j$ is required to always keep the same y-axis location as $Hseg_i$, and it will be recorded in $Equal_i$ for later usage. Naturally, there can be at most two elements in $Equal_i$.

C. Synthesis of Constraints

We finally synthesize the constraints to identify the feasible domain for variation.

There are two types of constraints: (i) the upper and lower bounds of each segment; (ii) some segments need to have the same location in the variation direction. Taking the variation direction being along the y-axis as an example, we first synthesize type (i) constraints simply based on the neighbors of each $Hseg_i$. For type (ii) constraints, we refer to $Equal_i$. $Equal_i$ only contains $Hseg_j$ connected to $Hseg_i$, but the segments $Hseg_k$ connected to $Hseg_j$ are also required to have the same location as $Hseg_i$. Such relationship exists like a tree: $Hseg_i$ is the root, $Hseg_j$ in $Equal_i$ are the son nodes of $Hseg_i$, and $Hseg_k$ in $Equal_j$ are son nodes of $Hseg_j$. In this case, we recursively traverse nodes $Hseg_x$ and their corresponding $Equal_x$, until no new son nodes can be found. We then include all the upper and lower neighbors of segments in this tree into two sets UPs and $LOWs$, respectively. The type (i) constraint for $Hseg_i$ will be modified: the lowest segment in UPs and the upmost segment in $LOWs$ will become the new upper bound and lower bound, respectively. Type (i) constraints of other segments in this tree will be updated to let these segments have the same y-axis location as $Hseg_i$. These constraints build up the feasible domain for the variation, ensuring that layout variants within this domain maintain the same topology.

V. Bayesian-Optimization-based Reliability Enhancement

Since there can be thousands of possible layout variants within the previously identified feasible domain, it is impractical to traverse all of them. Hence, we utilize Bayesian optimization (BO) to efficiently explore more reliable layout variants.

As shown in Fig. 4, a set D is utilized to record all variations v and their corresponding costs f explored during the exploration. For a given feasible domain, we first randomly generate a few v and their corresponding layouts. These v and f will be recorded in D as the initial samples. When the size of D is smaller than the manually-set limit T, we will fit the surrogate model, sample a new v, derive the cost according to the corresponding layout, and update D. Once the size of D exceeds T, we will find the optimized v and its corresponding layout with the smallest cost. If this cost exceeds the improvement threshold, we will switch the direction of variation, pass the optimized layout to the

next round, and restart from the feasible domain identification stage. Otherwise, this optimized layout will be output as the final layout.

A. Problem Model

In a variation $v : \{v[1], v[2], \cdots, v[n]\}$, each element $v[i]$ relates to the location of a to-be-actively-altered segment, and n represents the number of such segments. Here, we take the variation direction being along the y-axis as an example without loss of generality. As the identified feasible domain only contains the relative locations of segments, the range of the possible location of each segment is related to other segments, thereby being unfixed in value. This makes it impractical to directly use the exact location of each segment in the variation v. To tackle this problem, for each to-be-actively-altered segment $Hseg_i$, we use a ratio between its upper and lower bounds as its corresponding $v[i]$. This way, each $v[i] \in [0, 1]$, enabling the exploration.

With a sampled v, we construct linear equations to solve the specific locations $y : \{y[1], y[2], \cdots, y[n]\}$, thereby deriving the corresponding layout variant. As a minimum distance d_{min} should be kept among channels, if both the upper and lower bounds are other segments $Hseg_{i_{up}}$ and $Hseg_{i_{low}}$, the real upper bound and lower bound of $y[i]$ should be $Realup_i = (y[i_{up}] - d_{min})$ and $Reallow_i = (y[i_{low}] + d_{min})$, respectively. For each linear equation, there are four possible scenarios, here we use b_{max} to represent the maximum boundary of the design in the current variation direction: (i) if both the upper and lower bounds are other segments:

$$y[i] - Reallow_i = v[i](Realup_i - Reallow_i) \tag{4}$$

(ii) if only the upper bound is another segment:

$$y[i] = v[i]Realup_i \tag{5}$$

(iii) if only the lower bound is another segment:

$$y[i] - Reallow_i = v[i](b_{max} - Reallow_i) \tag{6}$$

(iv) if neither of the bounds is another segment:

$$y[i] = v[i]b_{max} \tag{7}$$

We use the reliability evaluated by the quantification models proposed in [13] of the corresponding layout as the objective function f for v, which is defined as:

$$f(v) = (1 - w)P_{blockage} + wP_{leakage} \tag{8}$$

where $w \in [0, 1]$ is a user-defined parameter used to combine the anti-blockage and anti-leakage reliabilities. Our goal is to efficiently find the optimized variation $\hat{v}$ within only a limited number of attempts:

$$\hat{v} = \underset{v_i \in D}{\operatorname{argmin}} f(v_i), \ |D| <= T \tag{9}$$

Specifically, we employ a BO method named SMAC3 to address the problem [22].

B. Surrogate Model

Unlike traditional BO methods [7], [23], we use random forest (RF) [16] as the surrogate model instead of Gaussian processes (GP). RF consists of collections of regression trees, which are similar to decision trees but have real values at their leaves rather than class labels [24]. As a non-parametric approach, RF performs better on highly non-linear objective functions and is easy to parallelize [25], [26].

We construct an RF as a set of B regression trees, each built on m data points $\{v, f(v)\}$ sampled with replacement from the entire feasible domain. At each split point of each tree, a random subset of $[d \cdot p]$ of the d algorithm parameters is considered for splitting, where p is a parameter set as $p = \frac{5}{6}$. Another parameter is m_{min}, the minimum number of data points required in a node for it to be split further, which we set as $m_{min} = 10$. Finally, the number of trees is set as $B = 10$ to keep computational overhead low [27]. The RF's predictive mean μ_v and variance ${\sigma_v}^2$ for a new configuration v are computed as the empirical mean and variance of the individual trees' predictions for v.

C. Acquisition Function and Optimizer

Traditional expected improvement (EI) can suffer from vanishing gradients in high-dimensional spaces, making it difficult to optimize [20]. Therefore, we choose log expected improvement (logEI) as the acquisition function, which is defined as [20]:

$$\text{logEI}_{f(v)_{best}}(v) = \text{log_h}((\mu(v) - f(v)_{best})/\sigma(x)) + \log(\sigma(x)) \tag{10}$$

where log_h is mathematically equivalent to $\log \circ h$, and $f(v)_{best}$ is the best cost observed so far. This acquisition function ensures more stable gradients, leading to better results [28]. Meanwhile, we use a heuristic local search strategy to further improve the efficiency.

VI. Experimental Results

We demonstrate the performance of AutoRE from the perspectives of effectiveness and efficiency, respectively. All the experiments are carried out on an Intel(R) Xeon(R) Gold 6226R 2.90GHz Linux machine with 256 GB RAM.

A total of six testcases are used in our experiments: Syn1, Syn2 and Syn3 are synthesized based on the design in [29]; Real1, Real2 and Real3 are real chip designs from [10]–[12]. The reliability quantification models from [13] are utilized to evaluate the anti-blockage and anti-leakage reliabilities. According to our manufacturing experience, in the quantification models, pb_{unit}, the probability of a unit channel segment being blocked, is set as 2%; pl_{unit}, the probability of each unit channel segment leaking to any other unit channel segment at a unit distance, is set as 0.4%. For the settings of AutoRE, we let the initial variation direction to be along the y-axis, allow 150 explorations in each round of variation, and set the improvement threshold as 1%. For each testcase, we conduct three different experiments with w set as 0, 0.5, and 1, respectively.

A. Experiments on the Effectiveness

To start with, we test the effectiveness of AutoRE in enhancing the reliability of different layouts. The results are shown in TABLE I. It can be observed that AutoRE significantly enhances both the anti-blockage and anti-leakage reliabilities. Specifically, the anti-blockage reliability is improved by 42.53%, and the anti-leakage reliability is improved by 37.59% on average across all testcases.

TABLE I: Performance of Reliability Enhancement for Different Testcases

Testcase	Size	Channel Density	Improvement of Anti-Blockage Reliability				Improvement of Anti-Leakage Reliability				Average Runtime (s)
			$w = 0$	$w = 0.5$	$w = 1$	Average	$w = 0$	$w = 0.5$	$w = 1$	Average	
Syn1	15×11	20.00%	1.22%	1.22%	-0.35%	0.69%	4.07%	4.07%	6.64%	4.93%	48.47
Syn2	30×20	17.50%	152.15%	94.08%	33.44%	93.22%	-14.97%	25.31%	27.23%	12.52%	38.45
Syn3	65×40	13.10%	45.53%	37.63%	22.72%	35.29%	65.63%	188.74%	194.07%	149.48%	1425.57
Real1 [12]	39×31	14.89%	52.85%	52.85%	52.85%	52.85%	9.85%	9.85%	9.85%	9.85%	24.14
Real2 [10]	20×20	11.50%	19.99%	19.99%	-11.21%	9.59%	-0.02%	-0.02%	2.37%	0.78%	122.16
Real3 [11]	60×49	14.46%	126.09%	134.38%	-69.91%	63.52%	-23.80%	-1.43%	169.10%	47.96%	947.33
Average	1319	15.24%	66.31%	56.69%	4.59%	42.53%	6.79%	37.75%	68.21%	37.59%	434.40

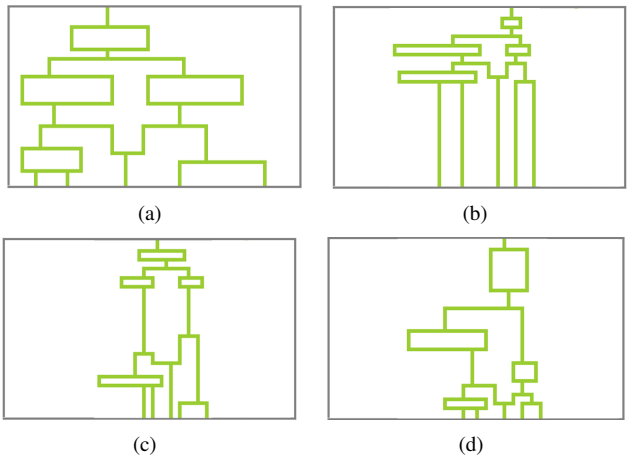


Fig. 6: Layouts of testcase Syn3. (a) The original layout. (b) The optimized layout with $w = 0$. (c) The optimized layout with $w = 0.5$. (d) The optimized layout with $w = 1$.

Additionally, the choice of w greatly influences the results. Generally, the closer w is to 0, the more AutoRE focuses on improving the anti-blockage reliability. This demonstrates AutoRE's flexibility in adapting to users' varying emphases on the two types of reliabilities. Conversely, as w increases, AutoRE tends more to enhance the anti-leakage reliability. Layout variants of Syn3 derived with different w settings are shown in Fig. 6. In extreme scenarios, such as Real3 with $w = 0$ and $w = 1$, AutoRE may even sacrifice one type of the reliability to achieve greater improvement in the other.

B. Experiments on the Efficiency

We also test the efficiency of AutoRE. According to the average runtime shown in TABLE I, AutoRE can complete the reliability enhancement for all testcases within 1500 s, which is a satisfactory speed for practical use.

To better demonstrate the efficiency of the BO-based exploration utilized by AutoRE, we compare it with the random exploration. Fig. 7 shows the result of the comparison using testcase Syn3. In the figures, each dot represents an exploration, with the y-axis value indicating the ratio between the current cost and the original cost, and the lines are drawn using the average of every ten explorations. It is evident that no matter what value w is set to adapt to users' different emphases on the two types of reliabilities, the BO-based exploration always consistently reduces the cost of

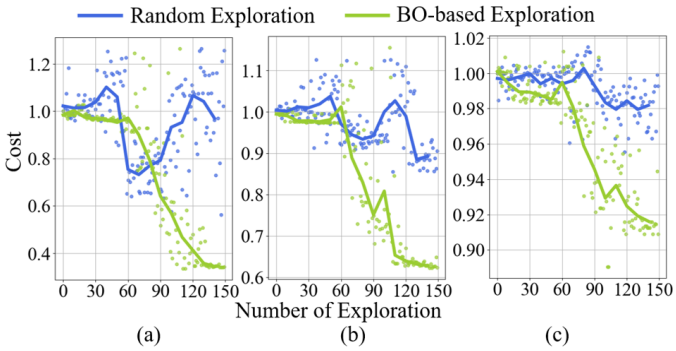

Fig. 7: Comparison of the efficiency between random exploration and the proposed BO-based exploration on testcase Syn3. (a) $w = 0$. (b) $w = 0.5$. (c) $w = 1$.

subsequent explorations, whereas the random exploration does not. Additionally, the lowest cost obtained through the BO-based approach are significantly better than those achieved by the random exploration. This demonstrates that the BO-based exploration is a more purposeful and efficient method for exploring within the feasible domain compared to the random exploration, proving AutoRE to be a highly efficient approach.

VII. Conclusion

In this paper, we have proposed the first automatic reliability enhancement tool for flow-based microfluidic biochips, named AutoRE. We have segmented the original layout and allowed segments to vary within a specified range while preserving the same topology. This approach has helped us identify a feasible domain, enabling us to explore among all feasible layout variants to achieve higher reliability. To improve the efficiency of our exploration, we have utilized Bayesian optimization (BO) and apply the reliability quantification models proposed [13] to evaluate the reliability of layout variants throughout the process. Experimental results have demonstrated that AutoRE is an efficient tool, effectively enhancing the reliability across all testcases by around 40% on average.

***Abstract*—FPGAs offer superior energy efficiency and performance in parallel computing but are vulnerable to remote power side-channel attacks. Existing attacks rely on assumptions of co-resident crafted circuits and shared power delivery networks, limiting their practicality in real-world scenarios. In this paper, we present AmpereBleed, a novel `current`-based side-channel attack that exploits widely available `INA226` sensors in ARM-FPGA SoCs, bypassing the aforementioned two assumptions. AmpereBleed achieves 261× greater variations to victim activities compared to the popular ring oscillator (RO) circuit, fingerprints DNN models on the Xilinx Deep Learning Processor Unit (DPU) with 99.7% accuracy, and distinguishes the Hamming weights of RSA-1024 keys.**

I. Introduction

Over the past few decades, Field Programmable Gate Arrays (FPGAs) have gained widespread adoption due to their superior energy efficiency and performance in parallel computing applications [14], [19], [20]. For example, when performing inference tasks on Llama 2 (a large language model), the Xilinx Virtex UltraScale+ VU9P FPGA achieves up to a 12.75× reduction in energy consumption per token compared to the Intel Xeon Broadwell E5-2686 v4 CPU, and an 8.25× reduction compared to the NVIDIA RTX 3090 GPU. In addition, it delivers up to 2.46× faster inference speeds than the CPU and reaches 53% of the GPU's speed, despite the GPU's significantly higher base clock rate [20].

Despite these advancements, FPGAs face various security threats, particularly from remote power side-channel attacks, which can extract sensitive information from a victim FPGA circuit without physical proximity to it [16], [22], [34], [37], [38], [43]. Specifically, an attacker crafts a circuit that can co-reside with a victim circuit on the same FPGA board, sharing the power delivery network (PDN). As the PDN supplies power to both circuits, increases in the victim's voltage (thus power consumption) cause transient voltage drops in the crafted circuit. Further, the voltage fluctuations in the crafted circuit lead to variations in signal propagation delays within itself and can be reflected in its output. For instance, as a representative circuit design, ring-oscillator (RO) [43] uses a combinational loop to increment a counter and sample the counter at fixed time intervals, thereby observing voltage through the increments of this counter.

Critical assumptions of state-of-the-arts: Notably, all the aforementioned power side-channel attacks rely on the assumption of co-residence between malicious and benign circuits, which is feasible only in multi-tenant FPGA scenarios where the PDN is shared among tenants. While FPGA multi-tenancy has gained significant attention from academia and industry as a promising approach to virtualize FPGA resources in the cloud [25], it is not yet adopted in real-world commercial practice [15]. Also, these attacks assume a shared PDN that fluctuates when the victim circuit is actively running, with voltage fluctuations observable by the attacker. To mitigate them, PDN stabilizers are implemented to ensure the FPGA supply voltage fluctuates within a limited range (e.g., 0.825 V to 0.876 V on the Zynq UltraScale+ series FPGAs). Additionally, recent works [10], [35] have proposed isolated PDN for each tenant (e.g., ISO-TENANT [10]).

As the critical assumptions significantly raise the bar for remote power side-channel attacks, this leaves an open research question: *Can a remote power side-channel attack against FPGAs still be feasible if these assumptions are voided?*

Our work: In this paper, we answer this question affirmatively by presenting AmpereBleed, a novel attack that bypasses these limitations. Our key observation is that many embedding devices are equipped with `INA226` sensors that provide measurements of `current`, `voltage`, and `power` for various hardware components. In the context of ARM-FPGA SoCs, these sensors monitor the FPGA board and provide fine-grained `current` measurements for the FPGA which are the most sensitive to FPGA activities among the three available measurements. Further, these measurements are accessible to an unprivileged process running on the ARM processor via the `hwmon` subsystem. Leveraging this, AmpereBleed constructs a `current`-based side channel to infer FPGA activities without relying on either crafted circuits or a shared PDN.

In our evaluation, we first compare AmpereBleed's `current` with the ring oscillator (RO) circuit [43] (a well-

† Co-first authors. * Corresponding authors.

known crafted circuit that senses voltage fluctuations), regarding 161 distinct victim activation conditions. The results indicate that AmpereBleed-based `current` measurements achieve 261× greater variations than RO. Further, we validate that AmpereBleed's `current` is much more sensitive than `voltage` and `power` under the same settings. Last, we exploit AmpereBleed in two case studies. First, we mount a DNN model fingerprinting attack to show that AmpereBleed can distinguish among 39 DPU accelerators with a high accuracy of 99.7%. Second, we successfully apply AmpereBleed to distinguish Hamming weights of secret keys from an RSA-1024 circuit operating at 100 MHz.

Summary of contributions: The main contributions of this paper are as follows:

- We present AmpereBleed, a new current-based remote power side-channel attack against ARM-FPGA SoCs, without relying on either crafted circuits or a fluctuating PDN. AmpereBleed highlights the need for secure power monitoring implementation.
- We characterize how `current` measurements leak fine-grained information about victim activities and compare them with crafted circuit (i.e., RO [43]), `voltage` measurements, and `power` measurements.
- We apply AmpereBleed to two case studies, which fingerprint different DPU accelerators and distinguish the Hamming weight of RSA keys.

The source code to reproduce our experiments is released at https://github.com/Skyofmine007/AmpereBleed-DAC.

II. Background and Related Work

A. ARM-FPGA SoCs

Recent years have seen a growing demand for both energy efficiency and high performance, which has significantly driven advancements in high-performance FPGAs. Unlike CPUs and GPUs, which accelerate by optimizing instruction streams, FPGAs provide substantial benefits for customized computing due to their inherent re-programmability and high-performance potential. For example, AMD Xilinx's high-end AI Adaptive Compute Acceleration Platform (ACAP) VCK5000 achieves 1.8× frames per second per watt compared to Nvidia's flagship Ampere GPU (A100 SXM) in a standard MLPerf [31] benchmark.

ARM-FPGA System-on-Chips (SoCs) integrate ARM processor cores with an FPGA to provide a versatile solution for embedded systems [14]. The ARM cores, akin to standalone ARM processors such as the STM32 series, are equipped with various peripherals including UART, CAN, and GPIO ports, while FPGA serves as a customizable peripheral. This tight integration allows for high-speed, low-latency communication between CPU and FPGA resulting in improved performance, reduced cost, and a smaller physical footprint compared to using separate chips. Today, ARM-FPGA SoCs have become increasingly popular in Internet of Things (IoT) applications for commercial purposes, including autonomous driving [4], [9], 5G telecommunications [11], and medical devices [3], [8]. Companies like Baidu [9] and Subaru [4] have adopted this architecture in their autonomous driving and driver-assistance systems, respectively. For instance, Subaru has sold over 1 million vehicles with over 50 different models, which are equipped with ARM-FPGA SoCs as a solution for driver-assistance systems [4], highlighting the practicality of these SoCs in real-world deployments.

B. Remote Power Side Channel Attacks against FPGAs

Power side channel attacks have long been recognized as a significant source of information leakage. By analyzing power consumption, an adversary can infer victim's activities and extract sensitive data. To enable remote power side channel attacks on FPGAs, existing studies have explored a number of crafted circuits [22], [34], [37], [38], [43] that can detect on-chip voltage fluctuations. Specifically, all these works assume that a crafted circuit co-resides with the victim circuit on the same FPGA board, thereby sharing the same PDN with the victim circuit. A fundamental vulnerability identified in these studies is the inverse correlation between signal propagation delay and voltage variations at gate level. When engineered with precision, a crafted circuit can exploit voltage fluctuations, resulting in varying bit flips in its output stream. This behavior enables the creation of a novel side channel. The adversary can then leverage this output to various end-to-end attacks, including extracting cryptographic keys [34], [38], [43], fingerprinting victim workloads [18], and stealing DNN model architectures [42].

III. AmpereBleed

A. Threat Model

Aligned with prior works [14], [30], [36], [44], we consider an unprivileged attacker controlling a user process without special privileges, achievable through malicious over-the-air (OTA) updates [28], [29] or malware installation [12], [24]. The attacker's process is co-located with the victim circuits on the same ARM-FPGA SoC equipped with `INA226` sensors. The victim is a victim circuit with full control over the FPGA board for circuit deployment.

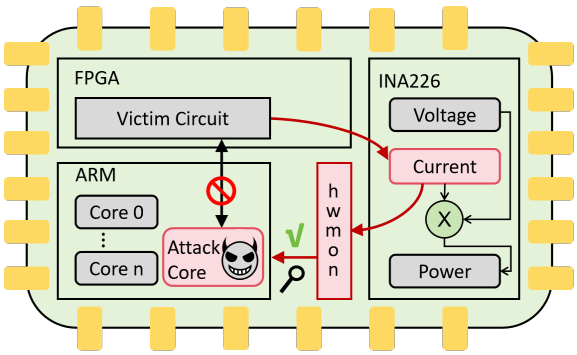

Fig. 1: Attack overview of AmpereBleed. The components inducing AmpereBleed's leakage are marked as red.

TABLE I: A comparison of the number of integrated INA226 sensors on various ARM-FPGA SoCs.

Property	ZCU102	ZCU111	ZCU216	ZCU1285	VEK280	VCK190	VHK158	VPK180

B. Current-based Side Channel

As a first step for our analysis, we set out to review how existing attacks [16], [34], [43] monitor dynamic power consumption. Specifically, in a shared PDN that ideally ignores the effect of the stabilizers and can be modeled as an equivalent RLC matrix, an increase in the victim circuit's power causes transient voltage drops in neighboring circuits:

$$V_{drop} = I \cdot R + L \cdot \frac{\Delta I}{\Delta t}, \tag{1}$$

where V_{drop} depends on both steady-state current ($I \cdot R$ drop) as well as short transients ($\frac{\Delta I}{\Delta t}$ drop) caused by switching logic on the FPGA. It can be seen that current serves as an intermediate quantity of voltage change in these studies.

While previous studies have crafted various circuits [16], [22], [34], [37], [38], [43] to capture the voltage drop in the shared PDN, we note that dedicated PDN stabilizers [21] have been implemented to ensure the FPGA supply voltage fluctuates within a limited range, e.g., from 0.825 V to 0.876 V on the board with Zynq UltraScale+ series FPGAs (as shown in Table I). Besides, there are improvements in academia [10], [35] that aim at maintaining a stable voltage supply to each tenant circuit. However, it remains unclear whether the remote power side-channel threats can be fully mitigated after the voltage is completely stabilized.

Foundation: The foundation behind our work is rooted in an essential law of physics, where the overall dynamic power can also be measured by the supply voltage and current [1], as represented in Equation 2.

$$P_{dyn} = V_{dd} \cdot \sum I(LE, RAM, DSP, Clocks, \ldots), \tag{2}$$

where P_{dyn} is the dynamic power, V_{dd} is the supply voltage, and I is the current drawn by different types of computing elements, e.g., logic elements (LE), random access memory (RAM), digital signal processing (DSP), and clocks. Thus, even if the voltage remains stable, significant changes in power still cause noticeable changes in current.

To this end, we propose AmpereBleed, a novel remote power side channel attack that exploits current measurement to infer victim activities. As shown in Figure 1, AmpereBleed works on an ARM-FPGA SoC platform. Our attacker is located on one of the ARM cores without any co-resident circuit involved. To monitor on-chip current, we exploit INA226 sensors, which are integrated into a wide range of embedding devices for system monitoring, including ARM-FPGA SoCs. By accessing unprivileged current driver (i.e., hwmon) of INA226 sensors, AmpereBleed infers the activities of victim circuits through the red path.

TABLE II: Sensitive sensors that allow unprivileged access through the hwmon interfaces on the ZCU102 board [5].

Sensor	Description
ina226_u76	current, voltage, and power for full-power domain of the ARM processor cores.
ina226_u77	current, voltage, and power for low-power domain of the ARM processor cores.
ina226_u79	current, voltage, and power for FPGA's logic and processing elements.
ina226_u93	current, voltage, and power for DDR memory.

C. Unprivileged Sampling of On-chip Current

In this section, we provide implementation details about the unprivileged sampling of current. First, to demonstrate the widespread availability of the exploited INA226 sensors, we have examined a range of SoC boards across two FPGA families (i.e., Zynq UltraScale+ and Versal). Table I lists 8 representative boards, all of which include INA226 sensors. Notably, AmpereBleed's applicability extends well beyond these examples. For instance, the ZCU106 board, featuring 14 INA226 sensors, is not listed due to its similarity in price and release date to the ZCU102. Besides, Table II showcases four sensitive INA226 sensors out of the 18 integrated on the ZCU102, providing on-chip monitoring for various components including CPU, FPGA, and DRAM.

The INA226 sensors provide current and voltage measurements at specific monitoring points. They also calculate power indirectly from these two measurements when properly calibrated [2]. We identify current as the most potentially exploitable for two key reasons: First, for the victim FPGA workload, its voltage measurements are constrained by a fixed resolution of 1.25 mV and exhibit minimal changes (as shown in Table I, resulting in a limited range of voltage variations. Second, the power measurements are derived from current and voltage, with their resolution fixed at a ratio of 25 relative to the current resolution [2]. Given the limited variability in voltage, the power measurements are almost synchronized to the current measurements, but the low bits are truncated. In our evaluation, we compare current measurements against voltage and power measurements to validate the identification.

We use the hardware monitoring (also known as hwmon) subsystem to access the INA226 sensors from the ARM side without requiring any privileges. The subsystem is also available in x86 processors [23]. We access the current measurements on each INA226 sensors through

Each INA226 sensor is equipped with a dedicated shunt resistor, enabling current to be measured based on its voltage and resistance.

`/sys/class/hwmon/hwmon[0-*]/curr1_input` in the Linux file system. Notably, these interfaces provide a resolution of ±1 mA and a configurable updating interval between 2 and 35 ms. The resolution is determined by the hardware sensors, and the default updating interval is set to 35 ms. Although the updating interval can be adjusted at runtime, modifying it requires root privileges. Since AmpereBleed assumes an unprivileged attacker, we use the default updating interval throughout this paper.

IV. Evaluation

Experimental machine: We evaluate AmpereBleed on a Xilinx ZCU102 SoC, which features four Cortex-A53 cores with a base frequency of 1200 MHz and an FPGA fabric operating at 300 MHz. The FPGA fabric includes 274,080 lookup tables, 548,160 flip-flops, and 2,520 digital signal processing blocks. We use PetaLinux to customize Linux-based operating system for a specific SoC, which is a popular approach for Xilinx ARM-FPGA SoCs. All system configurations, including `hwmon` settings and dynamic voltage and frequency scaling (DVFS) policies, are kept by default.

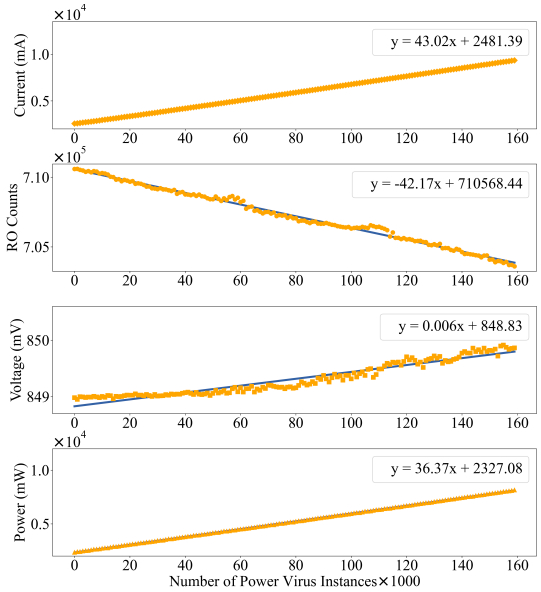
A. Characterizing AmpereBleed

As outlined above, our AmpereBleed attack leverages the unprivileged `hwmon` interface to acquire `current` measurements that are related to the victim's behavior in theory. Here, we demonstrate that these `current` measurements are sufficient to distinguish various activities of the victim FPGA.

Varying computing workloads: Then, we deploy 160 k power virus instances described in Gand et al. [17] to cover major routing places of our ZCU102 board. They serve as a victim to stress FPGA logic, aligned with Zhao et al. [43]. We then divide them into 160 groups and each group has 1 k evenly-distributed instances. After deploying the bitstream onto the FPGA board, we can dynamically activate different numbers of these groups from the ARM processor to make the `current` vary by 161 levels.

Distinguishing different victim activities: Our first experiment is to characterize the `hwmon`'s output under different FPGA workloads. To this end, we activate a varying number of power virus instances, making the victim activities vary from 161 levels. To construct a baseline, we follow Zhao et al. [43] to reproduce RO circuits and distribute them throughout the FPGA board to average dependence on spatial proximity to activated power virus instances. At each level, we collect 10 k samples about `current`, `voltage`, and `power` of FPGA logic from `hwmon` and the RO circuits, respectively, and compute the mean of these samples as the final value to derive the Pearson correlation coefficient which quantifies the strength and direction of the linear relationship.

Figure 2 illustrates the correlation between these measurements and the number of active power virus instances. FPGA `current` and `power` exhibit a strong linear relationship with the number of activated power virus instances, with a Pearson correlation coefficient of 0.999. Additionally, FPGA `voltage` achieves a Pearson correlation of 0.958,



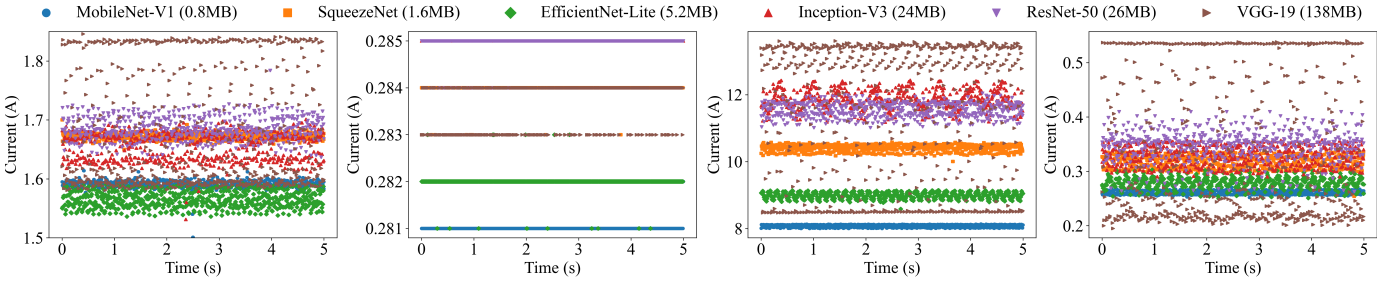


Fig. 2: The FPGA `current`, `voltage`, and `power` accessed via `hwmon`, along with RO counts, versus the number of activated power virus instances.

and RO achieves -0.996. This suggests that FPGA `current` and `power` readings, accessed via `hwmon`, correlate more strongly with victim activities under this experimental setup. Furthermore, we compute the linear function for each type of measurements. Due to `power` readings being updated at a maximum resolution of 25 mW, the difference between consecutive settings is limited to 1-2 least significant bits (LSBs). `voltage` measurements also show a limited linear correlation coefficient of 0.006 and support a fixed and coarse-grained resolution of 1.25 mV, leading to only slight LSB changes even under high workloads of 160 k activated power virus instances. In contrast, `current` measurements support a fine-grained resolution of 1 mA and vary approximately 40 LSBs per setting, enhancing their sensitivity to different victim activities and, consequently, improving attack performance as detailed in the following subsections. We clarify that the reason why `current` measurements do not start from 0 is due to the static workloads [26] caused by inactivated but deployed power virus instances.

B. Fingerprinting DPU Accelerators

Xilinx DPU is a commercial framework for deploying pre-trained DNN models on FPGA boards. To protect its confidentiality and intellectual property, DPU encrypts its hardware description language (HDL) files at the source code level, following IEEE-1735-2014 V2 standard [6]. Due to this encryption, attackers cannot determine how the model inference is performed, such as the sequence of matrix computations and intensive memory read-write activities, increasing the difficulty of attack. Till now, the only one attack against DPU is to reverse-engineer the encrypted implementation details about DPU, which requires a high-resolution probe and physical proximity to sample electromagnetic signals [19].

(a) Full-power CPU (b) Low-power CPU (c) FPGA (d) DRAM

Fig. 3: `current` patterns leaked from four sensors during different DNN model inferences.

In this subsection, we demonstrate a DNN model fingerprinting attack against the DPU framework, notably achieved without any specialized equipment. Our key insight is that distinct `current` variation patterns during inference can expose information about the underlying neural network operations. Knowledge of the DNN architecture poses a significant intellectual property risk [13], and can facilitate further AI attacks (e.g., adversarial example attack [27] and membership inference attack [40]).

Victim DPU accelerator: To deploy DPU framework on ZCU102 board, we utilize its official image provided by AMD-Xilinx [7]. This image incorporates Python version 3.9.9, Linux kernel version 5.15, and Vitis AI version 3.0. To minimize the impact of process scheduling interference, we schedule the task of triggering DPU inference onto CPU core 0, and the sampling tasks onto CPU core 3. We select a complete suite of image recognition models from Vitis AI Library as victim accelerators, including 39 architectures over 7 diverse architecture families. We conduct inference using the ImageNet ILSVRC Test set, resizing the input images to comply with the specifications of the victim accelerators. By default, the victim runs each model in series for 5 seconds.

Experimental setup: Aligned with previous work [27], [41], our model fingerprinting attack has two distinct phases: an *offline preparation* phase and an *online classification* phase. In the *offline preparation* phase, we collect traces of `current`, `voltage`, and `power` by separately sampling each interface to build a series of well-trained classifiers, each of which can classify a specific type of side channel traces to their corresponding model architectures. In the *online classification* phase, we issue queries to a black-box accelerator running on our FPGA board, triggering its model inference. Concurrently, we collect side-channel traces from `hwmon`. With the collected traces, we then use the corresponding classifier to fingerprint the architectures of encrypted DPU accelerators.

Since our fingerprinting attack is essentially a classification task with straightforward features, we use random forest (RForest) to conduct the evaluation, due to its suitability for handling high-dimensional data and identifying feature importance. We configure RForest with 100 trees and set the maximum depth to 32. The model uses Gini impurity as the splitting criterion, measuring class impurity within nodes to assess the quality of splits. We apply bootstrap sampling to build each decision tree, ensuring each tree is trained on a unique subset of data by selecting samples with replacement. For validation, we perform a 10-fold cross-validation where, in each iteration, 9 folds serve as training data and the remaining fold is used for testing.

TABLE III: Classification accuracy for encrypted accelerator fingerprinting. The baseline of random guess is 0.0256.

Sensor \ Duration		1 s	2 s	3 s	4 s	5 s (Full-length)
Current (Full-power CPU)	Top-1	0.823	0.830	0.832	0.834	0.837
	Top-5	0.981	0.980	0.982	0.981	0.982
Current (Low-power CPU)	Top-1	0.429	0.498	0.548	0.557	0.557
	Top-5	0.870	0.905	0.914	0.915	0.915
Current (DRAM)	Top-1	0.953	0.961	0.960	0.959	0.958
	Top-5	0.998	0.999	0.999	0.999	0.999
Current (FPGA)	Top-1	**0.980**	**0.985**	**0.997**	**0.997**	**0.997**
	Top-5	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
Voltage (FPGA)	Top-1	0.080	0.099	0.116	0.118	0.116
	Top-5	0.317	0.323	0.327	0.326	0.330
Power (FPGA)	Top-1	0.929	0.973	0.989	0.991	0.989
	Top-5	0.997	0.997	0.997	0.996	0.996

Experimental results: Figure 3 illustrates examples of `current` traces collected via four `hwmon` interfaces while the DPU executes 6 DNN models separately, including MobileNet-V1, SqueezeNet, EfficientNet-Lite, Inception-V3, ResNet-50, and VGG-19, with their respective model sizes indicated. Each of the selected models produces a unique `current` patterns, influenced by the computing activities during the inference phase. The DPU's activity, involving the CPU, FPGA, and DRAM, is reflected in these `current` traces from these components, effectively captured by the `hwmon` interfaces and highlighting significant model fingerprinting vulnerabilities.

Table III presents the fingerprinting results of four sensitive `current` sensors, an FPGA `voltage` sensor, and an FPGA `power` sensor captured by `hwmon`, with each sensor's top-1 accuracy displayed in the first row and top-5 accuracy in the second row. We observe that all the `current` sensors achieve a high accuracy when the duration exceeds 3 s. Notably, FPGA `current` measurements reach a high accuracy of 99.7%, indicating a strong correlation between FPGA `current` variations and DPU activities. Given the greatly varied workloads of different DPU accelerators on the FPGA logic (as shown in Figure 3(c)), indirect `power` measurements that are computed from `current` and `voltage` also achieve a high success

rate of 98.9%. In contrast, the FPGA `voltage` measurements achieve a significantly lower accuracy of 11.6%.

C. Example Attack on an RSA

Beyond fingerprinting attacks, we present a concrete attack example that shows how AmpereBleed can infer the Hamming weight of secret keys from an RSA module implemented on an FPGA. Specifically, we assume an unprivileged attacker running on ARM cores targets a victim circuit performing RSA encryption. Till now, the only one attack against RSA-1024 circuit is Zhao et al. [43], where a malicious process samples the RO outputs with a high sampling frequency of 2 MHz. However, their victim RSA circuit operates at a low frequency of 20 MHz and RO circuits have been banned by commercial cloud providers (e.g., AWS [33]).

Victim RSA accelerator: We follow Zhao et al. [43] to implement an RSA-1024 circuit as the victim, and modify it to operate at 100 MHz. This circuit employs the Square-and-Multiply algorithm, which consists of two dedicated modular multiplication modules and a state machine. The state machine iterates through each bit of the 1024-bit input exponent, starting from the least-significant bit. One multiplication module is used for computing the square term and the other module is used for the multiplication operation. For every iteration, if the current least-significant bit of the iteratively-shifted exponent is '1', both the two modules are activated to compute the square, inducing high switching activities. Otherwise, only a square operation will be activated. Both multipliers are synchronized to complete computation within the same cycle for each iteration of the loop. To protect the secret key, this implementation embeds the key within the encrypted bitstream. Once the circuit is deployed on an FPGA, the private key remains inaccessible, even to privileged users.

Experimental setup: To perform power side channel attack, our attack program continuously records the FPGA `current` measurements from the `hwmon` interface, using the sampling frequency of 1 kHz to collect 100,000 samples. During the `current` collecting, the RSA modular repeatedly encrypts a random plaintext. To demonstrate that FPGA `current` measurements can indeed leak information about private keys, we construct 17 distinct keys whose Hamming weights increase in intervals of 64, except for the first key that is chosen as 1 (since the RSA circuit does not support exponentiation with a value of 0). To make a comparison, we also use the FPGA `power` measurements to repeat the above procedure.

Experimental results: Figure 4 shows the statistical distribution of FPGA `current` and `power` measurements during RSA-1024 execution. Clearly, the attacker can use the FPGA `current` measurements to infer the Hamming weights of these private keys. As a comparison, the `power` measurements could only categorize the 17 keys into 5 groups. We note that knowledge of the Hamming weight can greatly reduce the search space of RSA's key brute force attack, and serves as a precursor for statistical analysis attacks [32].

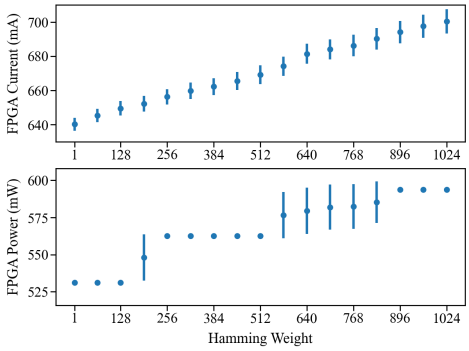

Fig. 4: The impact of the Hamming weight of RSA-1024 keys on FPGA `current` and `power` measurements.

V. Discussion

Mitigation: Since AmpereBleed exploits unprivileged access to `INA226` sensors, restricting their access to privileged users can effectively mitigate the unprivileged attacks that are demonstrated in this paper. However, this restriction may badly affect benign programs that rely on these interfaces for performance monitoring, fault detection, and system management purposes. Besides, it requires driver or kernel updates for all affected devices, and cannot protect the legacy systems.

Future work: While this study primarily focuses on the Xilinx ARM-FPGA platforms, it raises the question of whether similar vulnerabilities exist in other FPGA SoCs (e.g., Intel's ARM-FPGA SoC products) as more FPGA boards are integrating a CPU as well as on-chip sensors within a single die. Besides, this paper only considers unprivileged attack scenarios, whether these `INA226` sensors could be exploited to attack trusted execution environments (TEEs) implemented on FPGA [39] remains an open question. Last, as the on-chip `current` can also be measured by physical devices [26], we are also interested in its security implications as a physical side channel.

VI. Conclusion and Acknowledgments

In this work, we propose AmpereBleed, a new type of remote power side channel attack to infer FPGA activities. Specifically, AmpereBleed targets the ARM-FPGA SoC architectures and exploits the unprivileged `hwmon` subsystem to acquire `current` measurements. To demonstrate the viability of AmpereBleed, we first characterize the behavior of `current` measurements under varying power consumption conditions, experimental results of which show that fine-grained victim activities can be distinguished. We then successfully apply AmpereBleed to fingerprint DPU accelerators and infer the Hamming weights of different RSA private keys.

We thank the anonymous reviewers for their feedback. In addition, we thank Yuhui Zhang and Yusi Feng for their valuable comments that helped us to improve the work. ***Abstract*—Merkle Tree is a fundamental cryptographic primitive in Zero-Knowledge Proof (ZKP) protocols, sharing significant computational workloads with the Number Theoretic Transform (NTT) in zk-STARK schemes. Merkle Tree is a tree structure where nodes are primarily generated through hash computations. Among them, Poseidon Hash, as a ZK-friendly hash function, has emerged as one of the most widely adopted choices. Therefore, hardware acceleration of building Merkle Tree based on Poseidon Hash can significantly enhance the performance of ZKP protocols. We propose AcclMT, a highly resource-efficient and flexible Poseidon Hash-based Merkle Tree architecture. Our design employs hardware-software co-design and optimizes the hashing data flow, resulting in an area-efficient Poseidon Hash engine that improves modular multiplication resource utilization. Furthermore, AcclMT uses these engines alongside hierarchical on-chip cache and optimized task scheduling for building large Merkle Trees. It also supports flexible parameter configurations for various requirements. Experimental results show that our proposed Poseidon Hash engine achieves a 14.3 × speedup compared to the latest FPGA-based work. By improving resource utilization, it also reduces area usage by 14.8% compared to unoptimized design. AcclMT achieves up to 1665 × speedup over software implementations in building Merkle tree, with average utilization of 95.9% and 99.2% for the two hash engines.**

***Index Terms*—Zero-Knowledge Proof, Merkle Tree, Poseidon Hash, Hardware Acceleration**

I. INTRODUCTION

The Merkle Tree is a key primitive in Zero-Knowledge Proof (ZKP), a commonly used privacy-preserving algorithm. It is often utilized in zk-STARK-based ZKP [1] schemes for polynomial commitments. Unlike the Multi-Scalar Multiplication-based commitment schemes in zk-SNARK [2], Merkle Trees offer higher computational and spatial efficiency. When building a Merkle Tree, a large sequence of elements is first hashed to generate leaf nodes, which are then repeatedly hashed and combined layer by layer until the root node is obtained. The trend has shifted toward choosing ZK-friendly arithmetic hash functions like Poseidon Hash [3]. Unlike traditional hashes such as SHA, Poseidon Hash offers higher computational efficiency and fewer constraints, making it widely applied in various scenarios [4]–[6]. In zk-STARK and some newer zk-SNARK schemes, hash functions—primarily in the form of Merkle Trees—represent the largest computational workload alongside the Number Theoretic Transform, with the two accounting for over 65% of total computation [7]. Poseidon Hash, being more computationally expensive, may further increase this proportion. Previously, hardware acceleration efforts for ZKP mainly focused on Multi-Scalar Multiplication (MSM) [8]–[11] and the Number Theoretic Transform (NTT) [10]–[12], while neglecting improvements in hash computations and Merkle Tree. According to Amdahl's Law [13], exclusively accelerating MSM and NTT would leave ZK system performance severely bottlenecked by the unoptimized hash operations, which dominate the remaining computation overhead [14].

However, building a Poseidon Hash-based Merkle Tree presents significant challenges. One is efficiently managing the computational workload, as a single Poseidon Hash may require hundreds or thousands of modular multiplications, while a Merkle Tree can involve millions of such computations. Another challenge lies in handling the vast, temporally sparse intermediate data generated during computation. Despite their space efficiency, Merkle Trees can produce several gigabits of intermediate data, whose sparse distribution reduces computational unit utilization. Keeping extensive intermediate data on-chip is expensive, while frequent transfers to off-chip storage further impact efficiency.

To address these challenges, accelerating Poseidon Hash-based Merkle Tree implementations becomes crucial. ZPrize [15] introduces a track for Poseidon Hash hardware acceleration, and Ingonyama develops ICICLE [16], a cryptographic library optimized for hardware platforms, including Poseidon Hash-based Merkle Trees. TRIDENT [17], a Poseidon Hash accelerator for FileCoin on FPGA, delivers significant performance gains over advanced CPUs. Irreducible also proposes the first fully pipelined FPGA architecture for ZKP-friendly Merkle Trees using Poseidon Hash [18].

However, we believe that the above works have limitations that make them unsuitable as reference paradigms or lack practical considerations, as detailed below:

- **Lack of Flexibility and Generalizability:** Their implementations are often tailored to specific protocols, such as Irreducible's approach [18] for Plonky2 and TRIDENT [17] for the FileCoin protocol.
- **Low Resource Utilization:** The most expensive modular multipliers are not fully utilized. We estimate that nearly half of TRIDENT's [17] modular multipliers remain idle most of the time, resulting in reduced area efficiency.
- **Imbalanced Performance and Resource Overhead, with Limited Optimization Strategies:** Irreducible's approach [18] fully unrolls the Poseidon Hash for optimal performance in 64-bit Goldilocks fields. However, for ZKP protocols using larger finite fields, the hardware cost of full unrolling becomes unsustainably high.

In this paper, we present AcclMT, a highly resource-efficient and flexible Poseidon Hash-based Merkle Tree architecture. Our proposed flexible design supports the configuration of several typical parameters, catering to diverse application contexts. We optimize the proposed Poseidon Hash engine through software-hardware co-design, efficiently allocating different types of Poseidon permutations to two

*Corresponding author: yangfan@fudan.edu.cn, wusy@safit.org.cn

sub-engines, achieving higher resource utilization than unoptimized architectures. In Merkle Tree optimization, our approach efficiently decomposes and schedules tasks, using a limited hierarchical on-chip cache to build Merkle Trees of various sizes. Although our design uses a 256-bit data width, it can be adjusted for specific applications. Our key contributions are:

- We propose a Poseidon Hash engine combining a resource-efficient partial-round engine with a resource-intensive full-round engine. We optimize the scheduling of different rounds in Poseidon Hash across two sub-engines, reducing resource consumption and improving modular multiplier utilization. Compared to an unoptimized design with two full-round engines, our approach reduces area by 14.8% with just 7.04% extra time overhead and achieves a 14.3 × speedup over FPGA design.
- We develop a Merkle Tree architecture with efficient on-chip cache management and high resource utilization. Large-size Merkle Trees are broken into standard tasks requiring minimal cache for hierarchical processing. By efficiently managing around 200KB of limited on-chip cache, our design supports building large-size Merkle Trees. Merging multiple standard tasks further improves Poseidon Hash engine utilization. AcclMT can achieve up to 1665 × speedup over CPU-based implementation with an average Poseidon Hash utilization of 97.6%.
- Our proposed design natively supports flexible configuration of key parameters for the Poseidon Hash engine and Merkle Tree, enhancing its versatility across a broader range of applications.

II. Background

A. Poseidon Hash Function

Poseidon is a novel arithmetic hash function designed for the ZKP algorithm. While its native computation is more expensive than traditional hash functions like SHA, it offers greater efficiency in circuits, resulting in fewer constraints and reduced complexity for both provers and verifiers. Poseidon Hash employs a sponge/squeeze structure to map arbitrary-length strings over F_p to a fixed-length output, using iterations of the Poseidon permutation. The input, state (S), is divided into rate (R) and capacity (C) bits, with R-sized blocks absorbed into the sponge state. In the squeeze state, part of the state is output as the hash digest. The Poseidon permutation consists of a full round for higher security or a partial round for greater efficiency, with the number of rounds varying by scenario. We present an overview of the Poseidon Hash computation data flow in Fig. 1. In both cases, the algorithm includes three stages: adding round constants (ARC); an S-box layer for nonlinear diffusion using low-degree polynomials; and maximum-distance separable (MDS) matrix multiplication. In partial rounds, all S-box layers except the first are replaced with identity functions.

B. Merkle Tree in zk-STARK

A Merkle Tree (MT) is a tree structure in which each node is constructed using a collision-resistant hash function. It commits to an element sequence, allowing verification of an element's presence. The leaf nodes are obtained by hashing the elements, while non-leaf nodes are derived by concatenating and hashing their child nodes. The root node of the MT serves as a commitment to the sequence, as finding different sequences with the same root is computationally infeasible. Fig. 1 shows a simple schematic of the MT. We focus on binary MT (arity = 2), where each non-leaf node has exactly two child nodes, which is a common structure, though our proposed architecture can be configured to higher arity structures.

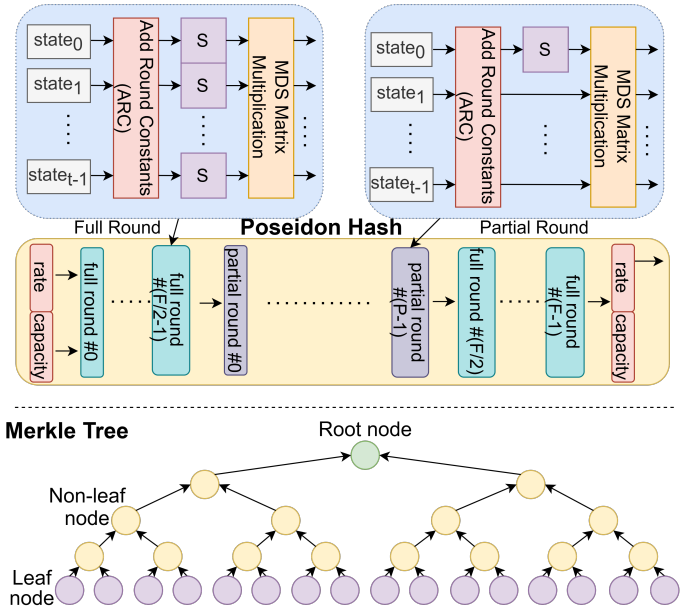

Fig. 1: Flowchart of Poseidon Hash (top) and Merkle Tree (down). For the Poseidon Hash, we assume F full rounds and P partial rounds. The case example features a 4-layer, size-16 Merkle Tree with an arity of 2.

In the zk-STARK protocol, MT is used for polynomial commitments. Fig. 2 outlines the proof generation phase, starting with converting the program into computational integrity (CI) declarations, followed by representing them as polynomials, including trace and constraint polynomials. Multiple constraint polynomials are then combined into a composition polynomial (CP), extended using the low-degree extension (LDE), and evaluated/interpolated via NTT/INTT. The composition and trace polynomials are then committed on the extended domain using MT. After the Deep operation, the polynomial undergoes low-degree testing using the FRI method. During the polynomial folding process, MT is used to commit to the polynomial at each stage. Additionally, this process encompasses querying nodes within the MT and the BCS method [19]. As these topics are not central to this paper, they are not detailed further.

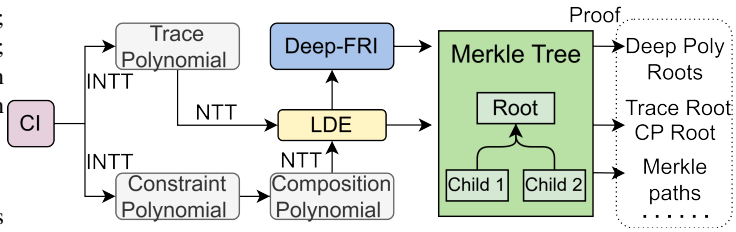

Fig. 2: Flowchart of the Proof Generation Phase in a Typical zk-STARK Protocol.

III. Proposed Design

In this section, we first present the overall architecture of AcclMT. Subsequently, we detail the microarchitecture of the Poseidon Hash engine built with two sub-engines, along with the optimizations of inter-sub-engine data flow. Finally, we present our insights at

the Merkle Tree and optimization strategies for on-chip cache and scheduling mechanisms.

A. Overall Architecture

Our proposed design, AcclMT, consists primarily of two Poseidon Hash engines along with several on-chip caches for specific purposes and a dispatch scheduler. Fig. 3 illustrates the overall architecture of AcclMT. The leaf hash engine, a Poseidon Hash engine, receives the raw element sequence and performs hash computations, storing the leaf nodes in the leaf hash buffer. The root hash engine, also a Poseidon Hash engine, constructs the non-leaf nodes through concatenation and hashing, ultimately deriving the root node of the Merkle Tree. The root hash buffer, scratch pad, and hierarchical intermediate data memory store the intermediate results of the root hash engine or provide inputs to it, with the dispatch scheduler managing the scheduling and distribution of inputs and outputs for the root hash engine. Each of these data storage units has distinct roles, and we will elaborate on the employed design strategies in Sec. III-C.

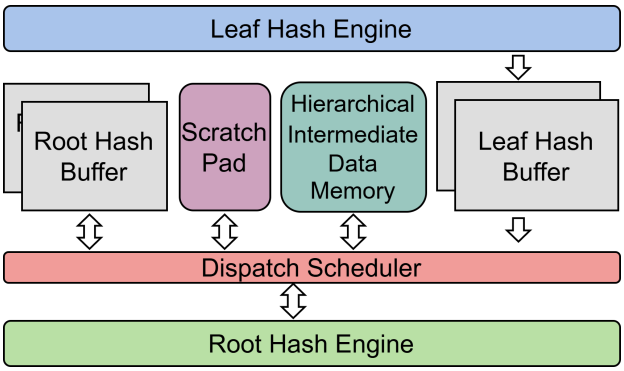

Fig. 3: Overall Architecture of AcclMT.

B. Microarchitecture of Poseidon Hash Engine

We have examined the typical parameters within the Poseidon Hash function, which mainly include the exponent in the S-box (the S-box typically utilizes an exponential function for nonlinear diffusion), the number of states in the Poseidon Hash, and the number of full rounds and partial rounds. Our goal is to develop a highly efficient and flexible Poseidon Hash engine with configurable parameters to enhance versatility.

To achieve this, we first observe the range of these typical parameters and make the following simple insights, focusing on hardware feasibility rather than delving into mathematical principles:

1) The exponent in the S-box is generally greater than or equal to 3, with 3 being almost the most common choice. Some applications may opt for 5 or 7 [3].
2) The number of states in the Poseidon Hash, which is arity + 1, often tends to be multiples of 3. Typical values for arity include 2, 4, 8, and 11 [3], [17].
3) Although the number of full and partial rounds varies across different applications, we observe that the number of partial rounds is generally significantly larger than that of full rounds.

Given these insights, we see great potential for optimizing the Poseidon Hash engine in hardware. Our solutions are as follows: For Insight 1), we design a configurable S-box with three modular multipliers for exponents 3 and 5, and it can also handle exponent 7 with an Initial Interval (II) of 2; higher exponents are not supported due to their rarity. For Insight 2), the Poseidon Hash engine, starting at a state of 3, leverages the vector multiplication and self-adder to support up to the state of 12, accommodating various arities. For Insight 3), we develop a resource-intensive full-round engine for full rounds in full mode and an area-efficient partial-round engine for partial rounds; the full-round engine can also operate in partial mode, enabling both engines to prioritize partial rounds, in line with our observations on round quantities.

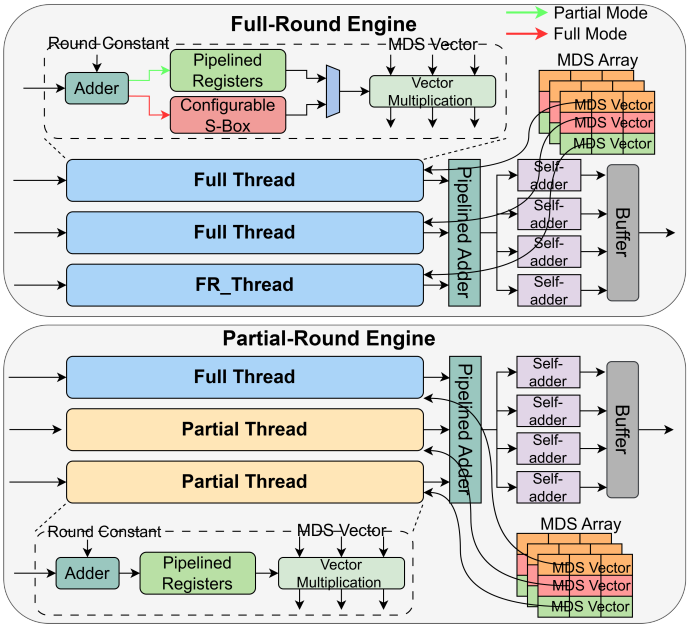

Fig. 4: Microarchitecture of Two Types of Sub-engines in Poseidon Hash Engine. The partial thread utilizes half the modular multiplication resources of the full thread. The full-round engine supports both partial-round and full-round computation, indicated by different colored arrows.

Fig. 4 displays the microarchitectures of our proposed full-round and partial-round engines. The partial-round engine includes two partial threads and one full thread, while the full-round engine comprises three full threads. The partial thread, lacking an S-box, uses half the modular multiplication modules of the full thread. The partial-round engine is dedicated to partial-round computations, while the full-round engine supports full-round computations in full mode and partial-round computations in partial mode. The sub-engine natively supports Poseidon permutation with state = 3. For higher states, an outer product algorithm improves vector-matrix multiplication efficiency. Each thread processes MDS vectors derived from the MDS matrix, and results are aggregated via an adder tree. The self-adder unit handles accumulation and outputs longer vectors in chunks for higher states.

We improve the scheduling mechanism for the two sub-engines to develop the Poseidon Hash engine. It can support arbitrary numbers of full and partial rounds by reusing the full-round engine and partial-round engine through iterative looping. Optimizing the data flow between sub-engines results in higher area efficiency and resource utilization for the Poseidon Hash engine. Fig. 5 compares our Poseidon Hash engine's optimized scheduling with an unoptimized design that uses two full-round engines, as in TRIDENT [17]. The unoptimized design keeps most S-boxes bypassed in partial mode (where partial rounds dominate), leading to considerable modular

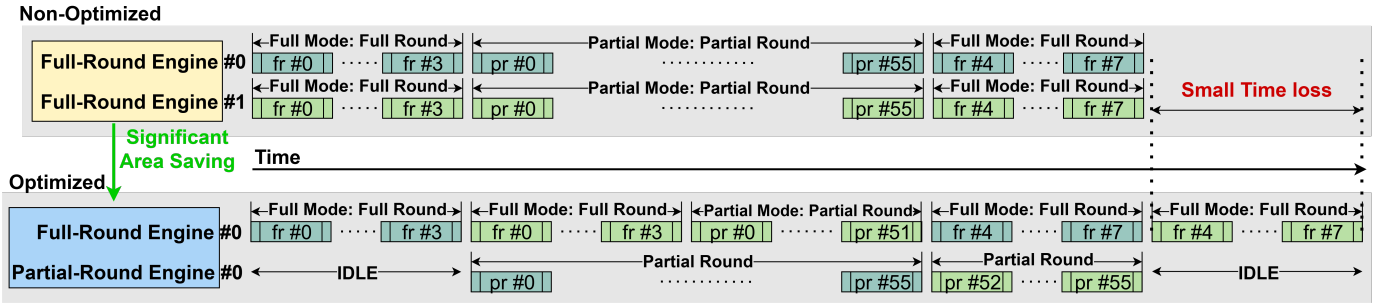

Fig. 5: Optimized Data Flow of Poseidon Hash Engine with Dual Sub-engines. We use typical parameters, with 8 full rounds and 56 partial rounds, as a case. Two different colors are used to illustrate the data flow of Poseidon Hash from different batches. 'pr' stands for partial round, 'fr' represents full round, and the symbol # followed by a number indicates the round sequence number. The partial-round engine consumes only $\frac{2}{3}$ of the modular multiplication resources compared to the full-round engine.

multiplication waste. We find it inefficient to allocate excessive resources to infrequent full rounds. So we assign more full rounds to the full-round engine and allow the more efficient partial-round engine to focus solely on partial rounds, reducing the number of modular multiplication modules.

In our scheduling mechanism, the Poseidon Hash data is divided into two batches. The full-round engine first performs half of the full rounds for both batches, then switches to partial mode for the second batch's partial rounds, while the partial-round engine completes the first batch's partial rounds. The partial-round engine then processes the second batch, with the full-round engine finishing the remaining full rounds in full mode. While the partial-round engine incurs brief idle times, adding minimal latency due to the round count difference, it provides significant area savings, as detailed in Sec. IV-B.

C. Optimization for Merkle Tree

We utilize two Poseidon Hash engines as the Leaf Hash Engine (LHE) and Root Hash Engine (RHE), along with a limited on-chip cache, to construct AcclMT. We observe that during the building of Merkle Tree, two key issues need to be addressed:

1) Merkle Tree sizes are often variable, with larger trees requiring more input and intermediate data. However, relying solely on larger intermediate caches is both inefficient and impractical.
2) The process of building the Merkle Tree involves aggregating multiple child nodes into a parent node. At higher layers of the tree, data distribution becomes sparser, leading to underutilization of the Poseidon Hash engine and reduced computational efficiency.

To address the first challenge, we propose the following solution: as shown in Fig. 6, We use a 128KB Leaf Hash Buffer for LHE-processed values and a 64KB Root Hash Buffer for RHE intermediate results, with a 256-bit data width. These buffers fully support a 4096-size Merkle Tree with arity = 2. To handle larger Merkle Trees in various applications, we decompose them into groups of standard Merkle Trees, each sized at 4096. Instead of computing the entire tree at once, which generates and requires storing gigabits of intermediate data, we pipeline each standard Merkle Tree group, reducing the on-chip cache to about 100KB for a single standard Merkle Tree's intermediate data. The root of the standard Merkle Tree will be stored in an 8.5KB hierarchical intermediate data memory (HIDM). HIDM has two levels: Level 0 stores roots of standard Merkle Trees, which are aggregated when full (corresponding to Merkle Tree layers 13 to 19), with the new root stored in Level 1. When Level 1 is full, a final aggregation is performed for layers 20 to 23, with the final root

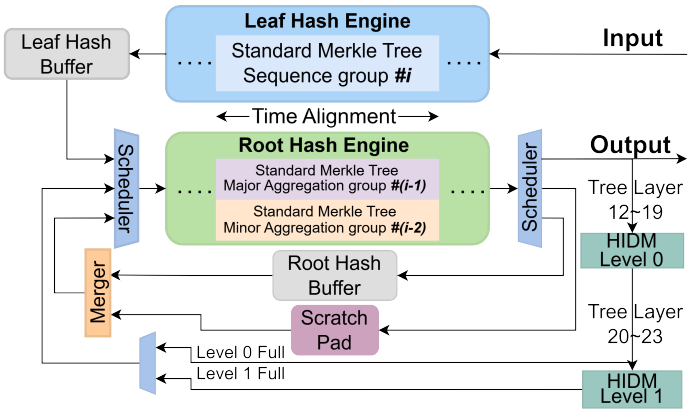

Fig. 6: Optimized Computational Flow of the Merkle Tree in AcclMT. AcclMT can leverage a limited on-chip cache and hierarchical intermediate data memory (HIDM) to efficiently build large-size Merkle Trees through an optimized task scheduling mechanism.

outputted. This hierarchical design supports building the Merkle Trees up to a size of 2^{23}. RHE processes each standard Merkle Tree group by reading data from the leaf hash buffer, and repeatedly writing and accessing intermediate results in the root hash buffer for incremental aggregation. The scheduler manages both RHE's data read and write-back operations.

To address key issue 2, we optimize the data scheduling mechanism within AcclMT. LHE efficiently handles compactly arranged input data, but as Merkle Tree layers deepen, RHE's inputs and outputs become sparser due to data dependencies, which limits its utilization and creates backpressure, reducing LHE's efficiency. We observe that RHE's pipeline utilization drops with each additional Merkle Tree layer; pipeline bubbles in RHE significantly increase by the fifth layer. As shown in Fig. 6, a 4KB scratch pad mitigates this: when aggregating leaf nodes for each standard Merkle Tree, we use root hash buffer as a data buffer, aggregating only up to 128 nodes, a process we call "major aggregation". The final step to reach the root of standard Merkle Tree is referred to as "minor aggregation". Proceeding directly with minor aggregation introduces pipeline bubbles, greatly reducing the efficiency of the Poseidon Hash engine. To improve this, we temporarily store the previous group's intermediate major aggregation results in a scratch pad and use a merger to combine these intermediate data with the next group's major aggregation sequence, effectively filling pipeline bubbles left

by the major aggregation sequence in the RHE. This optimization substantially alleviates sparsity in the RHE pipeline, improving RHE utilization and balancing it with LHE, thereby creating an efficient computational pipeline. Fig. 7 illustrates the optimized data scheduling for the RHE, further boosting the computation efficiency for each standard Merkle Tree. In experiments, the pipeline data flow between RHE and LHE limits minor aggregation to the 11^{th} layer, leaving only the final hash (12^{th} layer). To avoid inefficiency from performing a single hash, both values are stored in HIDM's Level 0, which manages tree layers 12 to 19.

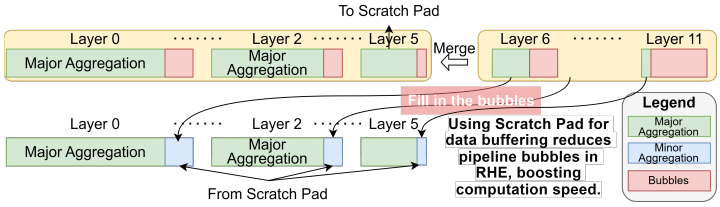

Fig. 7: Optimizing Data Scheduling for the RHE Pipeline. The pipeline combines the Merkle Tree's minor aggregations from the previous group with the major aggregations from the current group, significantly improving RHE utilization.

IV. EVALUATION

A. Experiment Setup & Overhead

In this section, we present the implementation results and performance analysis of AcclMT. AcclMT is implemented in System Verilog HDL and is based on a typical 256-bit data width. The typical parameters in Poseidon Hash, including the S-box exponent, state size, the number of full and partial rounds, and the size of the Merkle Tree, are all configurable at runtime. We synthesize AcclMT using the TSMC 28nm process library and Synopsys Design Compiler, targeting a frequency of 500 MHz. The area report from the synthesis tool indicates AcclMT has a total area of 20.87 mm^2, with the two Poseidon Hash engines taking up 93.7%, and memory occupying about 1.31 mm^2, which is roughly 6.3%. Our Merkle Tree decomposition strategy allows handling several gigabits of data with just nearly 200KB of on-chip cache.

B. Evaluation of the Poseidon Hash Engine

We compare the performance of our proposed Poseidon Hash engine with existing FPGA-based work, TRIDENT [17], and CPU-based work, NEPTUNE [4]. Using the Poseidon Hash configurations from FileCoin [4] as benchmarks, we determine the specific parameters based on Ingonyama's tool [20]. Tab. I details the data, measuring performance by hashes computed per second.

Compared to FPGA-based work, our Poseidon Hash engine offers up to a 14.3 × speedup, achieving a throughput of 14.11M hashes per second. To ensure a fair comparison, excluding frequency differences and focusing solely on clock cycles, the maximum speedup is about 2.85 ×. Notably, TRIDENT uses two units equivalent to our proposed full-round engine. However, during partial round computation, its S-box modules are bypassed and left idle, resulting in lower resource utilization compared to our design. In contrast, We optimize utilization by efficiently distributing tasks between the full-round and partial-round engines, reducing modular multiplication resource consumption by 16.7%. NEPTUNE is an optimized Rust-based open-source implementation of Poseidon Hash for FileCoin. Compared to NEPTUNE, our design offers a speedup of up to 145 ×.

TABLE I: Comparison of Poseidon Hash Computation Speed: AcclMT vs. FPGA and CPU-based Works.

Work		Ours	TRIDENT [17]	NEPTUNE [4]
Platfrom		TSMC 28nm	Xilinx Varium C1100	Intel i7-13700F 32GB
Frequency		500 MHz	100 MHz	2.1 GHz
Hash Rate (hash / sec)	Arity = 2	**14.11M**	0.99M (**14.3 × / 2.85 ×**)[a]	97.00K (**145 ×**)
	Arity = 4	5.93M	-	57.67K (103 ×)
	Arity = 8	3.79M	358K (10.6 × / 2.12 ×)	30.29K (125 ×)
	Arity = 11	2.69M	305K (8.82 × / 1.76 ×)	20.96K (128 ×)

a: The left side of the parentheses indicates the time-based speed up, while the right side represents the clock cycle-based speedup.

Our speedup is optimal at arity = 2, while performance degrades at higher arity levels. This is because, in our Poseidon Hash engine, the two sub-engines support pipelined input and output at arity = 2, resulting in the smallest initiation interval (II). However, at higher arity, the sub-engines are no longer fully pipelined, requiring block processing for input and output, which increases the II and diminishes the overall speedup of the Poseidon Hash engine. Additionally, there is space for further improvements in the scheduling mechanism of the Poseidon Hash engine at higher arity.

Significant Reduction in Area: We conduct experiments to validate that our Poseidon Hash engine, built with a full-round engine and a partial-round engine, achieves higher area efficiency than the baseline with two full-round engines. Based on the four benchmarks from FileCoin shown in Tab. I, our proposal incurs an average time loss of 7.04% relative to the baseline, primarily due to the idling of the partial-round engine, as illustrated in Fig. 5. We also synthesize a baseline design using two full-round engines. Compared to this baseline, our proposed Poseidon Hash engine achieves a 14.8% reduction in area, which closely aligns with our theoretical estimate of 16.7% area reduction. Notably, this area savings is fixed, while the time loss diminishes as the ratio of partial rounds to full rounds increases. When the full round count is 8 and the partial round count is 120 [3], the time loss drops to only 3.55%, nearly negligible, while the reduction of area overhead remains at 14.8%.

C. Evaluation of the Merkle Tree

In Tab. II, we evaluate the performance of AcclMT in building Merkle Trees of various sizes, comparing it to CPU-based implementations with an arity = 2, a common parameter. The CSF '24 [21] uses the libff [23] library in C++ and builds Poseidon Hash-based Merkle Trees with sizes up to 2^{18}. We also utilize the Rust-based library from Dusk-network [22] for another benchmark.

The results show that AcclMT achieves up to a 245 × speedup over CSF '24 and a 1665 × speedup compared to Dusk-network. As the size of the Merkle Tree increases, the speedup of AcclMT becomes more pronounced. The execution time also includes initial data loading and final aggregation in HIDM. When the size of the Merkle Tree is small, the time to build the standard Merkle Tree with AcclMT becomes shorter, and the proportion of time spent on initialization and post-processing increases. As the Merkle Tree size increases, the latency from subsequent data loading is masked by the ping-pong mechanism of data transfer, and the proportion of time spent on data aggregation in the HIDM decreases. At larger sizes, the time for initialization and post-processing can be negligible. Thus, AcclMT's execution time grows sublinearly. Compared to CPU implementations, which exhibit linear growth, AcclMT demonstrates

TABLE II: Comparison of Time (ms) Spent by AcclMT and Other Works for Building Merkle Trees of Various Sizes.

Work	Platform	Merkle Tree Size											
		2^{12}	2^{13}	2^{14}	2^{15}	2^{16}	2^{17}	2^{18}	2^{19}	2^{20}	2^{21}	2^{22}	2^{23}
Ours	TSMC 28nm 500 MHz	0.91	1.22	1.83	3.04	5.45	10.3	19.8	39.0	77.4	154	308	615
CSF'24 [21]	Intel i9-13900KF @ 6.0 GHz	75.8 (83.3 ×)	152 (125 ×)	303 (166 ×)	607 (200 ×)	1213 (223 ×)	2426 (235 ×)	4852 (**245** ×)	-	-	-	-	-
Dusk-network [22]	Intel Xeon Platinum 8358@ 2.6 GHz	498 (547 ×)	1.01 s (828 ×)	2.00 s (1093 ×)	4.00 s (1316 ×)	7.99 s (1466 ×)	16.0 s (1553 ×)	32.0 s (1616 ×)	64.0 s (1641 ×)	128 s (1654 ×)	256 s (1662 ×)	512 s (1662 ×)	1024 s (**1665** ×)

greater advantages in building larger Merkle Trees, making it particularly suited for building large-size Merkle Trees.

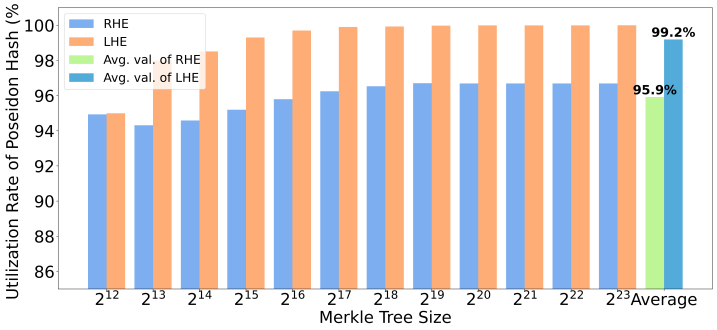

Fig. 8: Utilization Rate of the Leaf Hash Engine (LHE) and Root Hash Engine (RHE) in AcclMT for Building Merkle Trees of Various Sizes.

We also analyze the utilization rates of the LHE and RHE in AcclMT during the building of Merkle Trees of various sizes, as shown in Fig. 8. As the core component of AcclMT, one optimization goal is to improve the Poseidon Hash engine's utilization, which typically correlates with higher computational throughput. The utilization rates of LHE and RHE are quite similar, indicating that data organization for standard Merkle Tree computations is pipelined. Both engines maintain utilization rates above 95%, with RHE reaching 96.7% and LHE nearing 100% as the Merkle Tree size increases. This is expected, as RHE incurs more scheduling overhead, increasing latency. With larger Merkle Trees, both engines' utilization approaches saturation due to the higher computational workload of standard Merkle Tree computations. AcclMT achieves 99.2% and 95.9% average utilization for LHE and RHE, significantly exceeding the pre-optimization average of under 85%.

V. Conclusion

In this paper, we introduce AcclMT, a highly resource-efficient and flexible Poseidon Hash-based Merkle Tree architecture. We implement the Poseidon Hash engine through hardware-software co-optimization and data flow optimization, making it suitable not only for Merkle Trees but also for various purposes in ZKP. We also optimize the scheduling mechanism to ensure efficient acceleration of Merkle Tree computation using limited on-chip cache. The parameters of the Poseidon Hash engine and Merkle Tree size are configurable, offering AcclMT high flexibility for practical use in diverse ZKP scenarios.

ABSTRACT

A review of recent studies on up-to-date IC shows that electromigration (EM) has become one of the major challenges for 2.5D and 3D chiplet heterogeneous integration (CHI) systems. However, most existing researches on EM are focusing on 2D power delivery network without taking Through Silicon Via (TSV) and non-uniformly thermal distribution condition between dies into consideration. To address this problem, this article proposes a novel EM simulation tool ChipletEM for 2.5D and 3D CHI systems. A finite volume method (FVM) based electrical-thermal co-simulation model is employed to get initial temperature and current density inside TSV. And a finite difference time domain (FDTD) solver is used for hydrostatic stress simulation for both nucleation and post-voiding phases. Thermal migration (TM) effect is also considered in the solver. An analytical TSV thermal solver is employed for temperature distribution simulation and thermal dependent current simulation. The FDTD EM solver and TSV thermal solver are coupled together at each time step so that the interaction among EM stress, thermal stress, void growth, resistance change, IR drop and Joule heating effects can be simulated within a single simulation framework. Simulation results show that compared with Finite Element Method (FEM) tool, average error is 0.61% in nucleation phase and 2.4% in growth phase. And the error of proposed method is reduced from 22.22% to 5.24% compared with state of art atomic flux divergence (AFD) method.

1 INTRODUCTION

With emergence of high performance AI algorithms, Through Silicon Via (TSV) based 2.5D and 3D chiplet heterogeneous integration (CHI) systems have become one of the most promising technology to achieve the requirement of excessive data communication [1–3]. The architecture of a 2.5D CHI systems is shown in Fig. 1.

However, due to the high current density and non-uniformly distributed high temperature on TSV, a number of reliability issues

This work was supported in part by the National Natural Science Foundation of China under Grant 92373113, in part by the National Key Research and Development Program of China (Grant 2024YFB4405401), in part by the Strategic Priority Research Program (A) of Chinese Academy of Sciences (CAS) under Grant XDA0330401, and in part by the CAS Youth Interdisciplinary Team under Grant JCTD-2022-07. (Corresponding authors: Qinzhi Xu; Zhiqiang Li.)

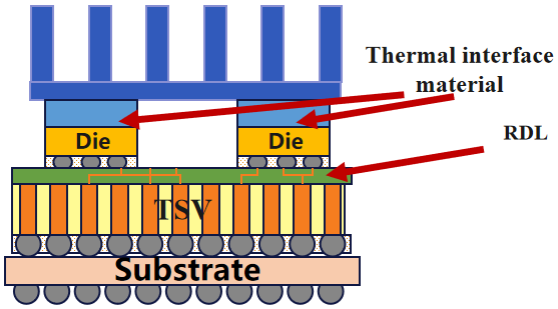

Figure 1: Architecture of a 2.5-D CHI system.

,including electromigration (EM), Joule heating, thermomigration (TM), time-dependent-dielectric-breakdown(TDDB), have become the main threaten to the advanced CHI systems[4–6]. Among these reliability issues, EM is one of the major reliability concerns in the back-end-of-line (BEOL) interconnects, especially in the advanced sub-10nm 2.5D and 3D CHI systems. According to the ITRS 2015 report, EM lifetime will be significantly reduced due to increasing current density and shirking size of net cross sections[7]. Therefore, a fast and accurate EM model is essential for advanced 2.5D and 3D CHI systems. However, existing models cannot meet the requirement of efficiency and accuracy sign-off. Traditional mean-time-to-failure (MTTF) models such as black's equation [8] and blech's product [9] are empirical fitting-based models, which are not scalable and robust enough for the modern 2.5D and 3D CHI systems. The models based on the experiment data of simple one-segment metal line cannot get an accurate EM failure prediction of complicated multi-segment wires and TSVs. Besides, these models are over conservative, bringing unnecessary constraint and increasing the difficulty of IC design.

In order to mitigate the disadvantages of traditional empirical models, a number of physics-based models are proposed [4, 10–14], which considers general interconnect for the 2D interconnect. These models are compact and can solve the stress based partial different equation (PDE) effectively. And the work in [10] has considered the TM and Joule heating effect. However, these methods focus on SoC systems and only consider the Joule heating effect of interconnects and local thermal distribution. As presented by [15–18], global thermal effect is critical and can be one of the dominant factors for EM. In the advanced 2.5D and 3D CHI systems, due to unique

topology and non-uniformly distributed temperature of TSV, a specific EM analysis tool needs to be developed.

In order to address aforementioned issues, this paper proposes a novel physics-based stress and thermal coupling analysis tool for TSV based 2.5D and 3D ICs. Specifically, the contributions are summarized up as follows:

•A finite difference time domain (FDTD) based EM-TM model, including both nucleation and post-voiding phases, is applied to TSV. Hydro-static stress is calculated by the extended Korhonen's equation combined with both EM and TM flux.

•A global thermal model of CHI system is employed in order to get the accurate temperature distribution. A realistic CHI model ,including heat sink, is implemented. And a finite volume method (FVM) is used for the global electrical-thermal co-simulation for high simulation efficiency while retaining the conservation principles inside thermal conduction equation.

•A coupled EM-TM and Joule heating simulation is employed, so that the simulator can consider the interplay among stress, void growth, resistance change and Joule heating effect in a single simulation framework.

•Simulation result shows that the accuracy of the proposed tool is very high. Compared with commercial finite element method (FEM) based tool, average error is 0.61% in nucleation phase and 2.4% in growth phase. And the error of the proposed method is reduced from 22.22% to 5.24% compared with state of art atomic flux divergence (AFD) method. The error rate is reduced by 76.4%.

•The proposed tool is applied to a 2.5D CHI system. And the simulation result shows that EM issue is more critical when power consumption is high. It can also be observed that in the early stage the dominant factor for EM is temperature while in the late stage the dominant factor is current density.

This paper is organized as follows: Section 2 reviews state of art EM models. Section 3 presents the background of EM. Section 4 introduces the proposed EM thermal co-simulation method. Section 5 demonstrates numerical results obtained from the proposed method. Section 6 concludes this paper.

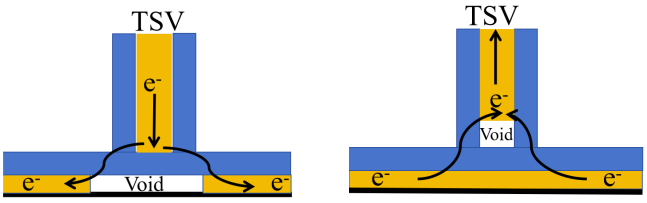
2 RELATED WORKS

A few EM analysis for TSV based 2.5D and 3D ICs have been proposed recently[4, 13, 19–21]. Specifically, Frank *et al.*[19] and Pak *et al.*[4] put forward AFD based approaches for the TSV. They investigate the mechanism of the EM failure in TSV, showing that the EM void is in the adjacent metal level. Pak's model points out that the resistance change is related to the current density, temperature, cross section area of the TSV and redistribution layers (RDL) interconnect thickness. And a recent AFD based study [13] points out that the EM void is also possible to be nucleated inside the TSV instead of the the junction with RDL interconnects when TSV diameter is small and its aspect ratio is large. Wang's work[20] has considered recovery effect by converting the time variant current into an equivalent square waveform. A response surface methodology based algorithm taking current density, duty cycle and temperature as input parameter is proposed in that work. Nevertheless, the physics mechanisms of EM are not well studied by these methods since internal stress evolution inside the TSV is not counted. Thus the models, not scalable and too conservative, will lead to design redundancy. Besides, as one of the key factors of EM failure, thermal effect and Joule heating need to be taken into consideration. Liu's work[21] studies the relationship between self heating effect and EM of the TSV. The experiment result shows that increased temperature has a positive feedback on the EM effect and will cause thermal run-away effect due to the small cross section area between TSV and RDL. However, this work only focuses on the local Joule heating of TSV lacking the consideration of global thermal effect.

To address the aforementioned issues, a novel coupled EM and thermal simulation tool is proposed in the work, employing Korhonen's equation based physics models to achieve fast and accurate EM lifetime estimation. Also the proposed method has taken global thermal effect of actual complex structure with heat sink of 2.5D and 3D CHI systems into consideration.

3 A REVIEW OF STRESS BASED THREE PHASE EM MODEL

EM is a physical phenomenon of the migration of metal atoms along the direction of the applied electrical field due to momentum exchange between electrons and atoms. During the migration process, hydro-static stress, as well as the stress gradient, generated inside the embedded metal wire due to momentum exchange between lattice atoms will act as a counter-force for atomic migration along the metal line. Before the void nucleated, the stress distribution in the interconnect can be described as follows:



$$\begin{aligned}
&\frac{\partial \sigma}{\partial t} = \frac{\partial}{\partial x}\left[\frac{D_a B\Omega}{k_B T\,(x)}\left(\frac{\partial \sigma}{\partial x} - \frac{eZ\rho j}{\Omega} - \frac{Q}{\Omega T}\frac{\partial T}{\partial x}\right)\right] \\
&BC: \frac{D_a B\Omega}{k_B T\,(x_b)}\left(\left.\frac{\partial \sigma}{\partial x}\right|_{x=x_b} - \frac{eZ\rho j}{\Omega} - \frac{Q}{\Omega T}\frac{\partial T}{\partial x}\right) = 0 \quad 0 < t < t_{nuc} \\
&IC: \sigma\,(x,0) = \sigma_T
\end{aligned} \tag{1}$$

Here, σ is the EM hydrostatic stress, x is the coordinate along the segment length, t is time, $T(x)$ is the temperature at corresponding position, D_a is the effective atomic diffusivity, eZ is the effective charge of migrating atoms, B is the effective bulk elasticity modulus, Ω is the atomic lattice volume, ρ is the copper resistivity, j is the current density, k_B is the Boltzmann constant, T is the temperature, σ_T is initial thermal stress, and x_b is coordinate of boundary node.

When the stress at the cathode exceeds the critical level at t_{nuc}, a void will be nucleated and start growth which is called incubation phase. The normal component of stress at the void boundary is typically zero. Stress gradient between the zero stress void surface and the surrounding is shown as follows:

$$\nabla\sigma(x,t) = \frac{\sigma(x+\delta,t)}{\delta} \qquad on \quad \partial\Omega_L \cap \Gamma_{void} \tag{2}$$

Here δ is effective thickness of the copper-void boundary, Ω_L is the volume of the remaining interconnect wire, Γ_{void} denotes the void boundary, which can be a union of several discrete voids, the $\nabla\sigma(x,t)$ essentially serves as a force to move the void boundary toward the atomic flux direction. The void volume is determined by the stress distribution on the remaining section of the wire and

(a) Void nucleated in RDL junction (b) Void nucleated inside TSV

Figure 2: Location of EM void in TSV. (2a) is the condition that the void nucleated in the RDL layer and (2b) is the condition that the void nucleated inside TSV

it can be calculated by the following atom conservation equation:

$$V_{void}(t) = -\int_{\Omega_L} \frac{\sigma(t)}{B} dV \tag{3}$$

Here $V_{void}(t)$ is time dependent void volume. When the void volume is larger than critical volume (V_{crit}) which mainly depends on the cross section of the wire, the resistance starts change. That phase is called growth phase.

For the TSV, the void location depends on the directions of electron flow. Based on the experiment result in [13], the location of the void can be nucleated at the junction of TSV and RDL line or inside the TSV with different current directions. Fig. 2a shows the condition that the void nucleated at the junction with the electron flow from TSV to RDL line. The resistance can be calculated with the following equation:

$$\Delta R = \frac{\rho_B}{2 \times \pi \times t_B} \times ln\left(\frac{r_{void}}{r_{TSV}}\right) \tag{4}$$

Here ρ_B is resistivity of the barrier material(Ta/TaN). t_B is thickness of the barrier. r_{void} is radius of void and r_{TSV} is radius of TSV. And Fig. 2b shows the condition that the void nucleated inside TSV with the electron flow from RDL line to TSV. The resistance can be calculated with the following equation:

$$\Delta R = \frac{\rho_B V_{void}}{r_{TSV}^2\left((r_{TSV} + t_B)^2 - r_{TSV}^2\right)} \tag{5}$$

The work focuses on the condition that the void nucleated inside TSV shown in Fig. 2b. And the other conditions will be studied in the future work.

4 METHODOLOGY

4.1 The New Coupled TSV EM Check Flow

In this part, the flow of proposed ChipletEM tool is presented as shown in Fig. 3. The whole flow mainly consists of three major parts: *CHI system electrical-thermal co-simulation model, Fast EM solver* and *TSV thermal solver*. CHI system electrical-thermal co-simulation model is employed in order to get the initial temperature distribution in the CHI systems and current density of each TSV. Fast EM solver is implemented with a FDTD based method. Thermal migration effect is also considered in the model. TSV thermal solver use an analytical model to get temperature distribution and temperature dependent current density inside TSV. Joule heating effect and temperature dependent electrical conductivity are combined together. EM and TSV thermal solver are coupled together. EM induced resistance change will change the Joule heating condition so that the corresponding temperature distribution is also changed. And the time dependent temperature acts as one of the dominant factors in the EM simulation. The time dependent IR drop of CHI systems considering global thermal effect can be demonstrated to the users for further design optimization. The following section will present aforementioned steps in details.

4.2 CHI electrical-thermal co-simulation model

In order to get the thermal distribution and the current density in TSV, an efficient electrical-thermal co-simulation model [18] for CHI systems is employed in this work. Due to the complexity of CHI systems, detailed circuit level based power analysis is not time efficient. Thus, the employed model abstracts the parameters and maps the circuit level thermal model to system level. The Joule heating power is calculated as follows:

$$\begin{aligned} \nabla \cdot [\kappa(x,y,z)\nabla T(x,y,z)] &= -P_{total} \\ P_{Joule} &= \frac{1}{\rho(x,y,z,T)}|\nabla\varphi(x,y,z)|^2 \\ P_{total} &= P_{init} + P_{Joule} \end{aligned} \tag{6}$$

Here κ is thermal conductivity of the solid medium, P is the power consumed by interconnect, x, y, z are the coordinate of CHI system, T is temperature, ρ is the temperature dependent resistivity and φ is the potential distribution, P_{init} is the initial power consumption without Joule heating.

As can be seen, P_{Joule} is affected by temperature dependent resistivity ρ. Meanwhile, P_{Joule} is a part of heat source leading to temperature increasing.

And the temperature dependent resistivity of RDL, bump array, TSV and other interconnects are estimated with the equivalent model to improve the computational efficiency [15–17, 22]. The equivalent model can reduce the impact of complex structure and the composite material of these interconnects and get an estimated resistivity efficiently which is close to the actual resistivity. And the model is discretized by FVM method.

With the presented model, the global thermal effect of CHI system considering convective heat transfer effects and Joule heating effects can be estimated. Individual TSV initial temperature can be obtained from the global thermal distribution.

4.3 Coupled Thermal and Electromigraiton Multi-Physics Simulation

In order to get accurate EM stress for IR-drop analysis, a coupled thermal and EM simulation method is proposed. Temperature is one of the dominant conditions for the EM failure mechanism. It contributes to both stress evolution and TM effect. Meanwhile current induced Joule heating is one of the major heat sources of interconnects. So it is essential to do coupled simulation to get an accurate and EM stress evolution process. In order to improve the accuracy of the EM stress estimation in the full-chip power grid level, we have to consider multi-physics effects and their interaction.

For the Korhonen's equation based EM model from Eq. 1, a finite difference based model is employed for detailed stress analysis over time. Employed method follows the similar work [11, 12, 14]

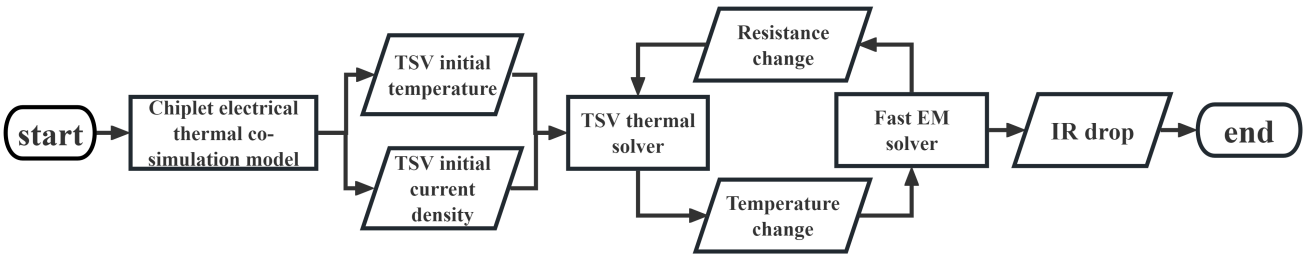


Figure 3: Simulation flow for proposed ChipletEM tool

without the model order reduction feature as shown in the following equation:

$$C\dot{\sigma}(t) = A\sigma(t) + PI(t) - D \tag{7}$$

Here C and A are $n \times n$ matrices. P is the np input matrix. D is $n \times 1$ constant matrix corresponding to TM effect, n is the number of discretization and p is the size of driving current density sources $I(t)$.

For the TSV thermal model, a close form equation from [23] considering Joule heating induced current. And the Joule heating is calculated by the following TSV thermal model in Eq. 8.

The equation is shown as follows:

$$T_{TSV}(x) = \frac{\alpha^2 T_{sub} + \theta}{\lambda^2} + \frac{(\lambda^2 - \alpha^2)T_{sub} - \theta}{\lambda^2(1 + e^{\lambda H})} \times \left[e^{\lambda(H-x)} + e^{\lambda x} \right] \tag{8}$$

Here the T_{sub} is the temperature of substrate, H is height of TSV, x is coordinate of the TSV. And the λ^2, α^2 and θ is presented as follows:

$$\lambda^2 = \frac{1}{k_m}\left[\frac{2k^*_{ins}}{t_{ins} r_{Cu}} - \frac{I^2(x)\rho_m \beta}{\pi^2 r^4_{Cu}}\right]$$

$$\alpha^2 = \frac{2k^*_{ins}}{k_m t_{ins} r_{Cu}}$$

$$\theta = \frac{I^2(x)\rho_m \left[1 - \beta T_{ref}\right]}{k_m \pi^2 r^4_{Cu}}$$

$$I(x) = \frac{V(0) - V(H)}{\int_0^H R_E(x)dx}$$

$$\int_0^H R_E(x)dx = R_0(1 - \beta T_{ref})H + R_0\beta\left[\frac{\alpha^2 T_{sub} + \theta}{\lambda^2} \cdot H + \frac{(\lambda^2 - \alpha^2)T_{sub} - \theta}{\lambda^3(1 + e^{\lambda H})} + \frac{(\lambda^2 - \alpha^2)T_{sub} - \theta}{\lambda^3(1 + e^{\lambda H})} \cdot 2(e^{\lambda H} - 1)\right] + R_{EM} \tag{9}$$

Here $I(x)$ is current, $\int_0^H R_E(x)dx$ is temperature dependent resistance, k_m is thermal conductivity of copper, R_0 is resistance under reference temperature T_{ref}, β is temperature coefficient of copper, ρ_m is resistivity of copper, r_{Cu} is ratio of copper inside TSV, t_{ins} is thickness of insulator, T_{sub} is temperature of substrate, $V(0)$ is the bottom voltage of TSV, $V(H)$ is the top voltage of TSV and R_{EM} is the EM induced resistance.

As can be seen in equation 9, $I(x)$ and $\int_0^H R_E(x)dx$ are coupled together to get the steady state solution of corresponding working condition. And the resistance changed due to EM can be calculated by Eq. 5 and 7. The resistance is updated with the change of EM conditions.

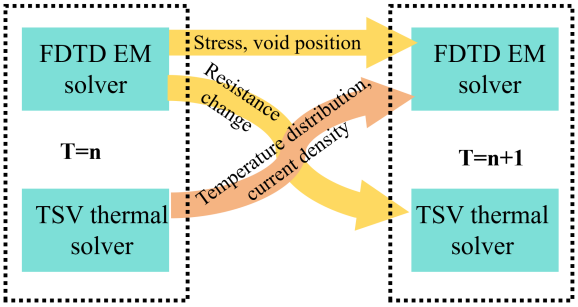

Figure 4: Block diagram of coupled FDTD EM and TSV Joule heating simulator.

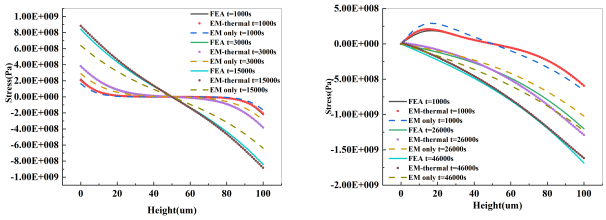
As can be seen, Eq. 7, 5 and 9 are coupled together as shown in Fig. 4. Since thermal solver is static, EM simulation time step is used as the coupled simulation time step here. FDTD EM solver passes resistance change to TSV thermal solver and gets temperature distribution and Joule heating induced current density from it. Accurate EM and thermal information can be achieved with the coupled simulation at each time step.

5 NUMERICAL RESULTS AND DISCUSSION



This section presents numerical experiments of the proposed ChipletEM tool which is carried out on a Windows-based simulation platform with an 3.70GHz AMD Ryzen5 5600X processor which has 6 cores. FDTD EM solver and TSV thermal solver are prototyped in MATLAB and C, respectively. The experiment is performed on a 2.5D CHI system published in [18]. This section will first validate the proposed tool with a state-of-art EM model and experiment result; then present global chiplet scale resistance change result.

5.1 Accuracy comparison against existing EM analysis methods and experiment results on single TSV

This part first compares the result of the proposed method and FEA tool, then compares the proposed method with state-of-art EM models and experiment result.

Table 1: Failure rate of high and low power mode

	Nucleation phase	Growth phase
EM-thermal average error	0.61%	2.4%
EM-thermal max error	2.62%	6.67%
EM only average error	3.48%	10.03%
EM only max error	12%	26.79%
TM contribution	11.4%	15.83%

(a) Nucleation phase (b) Growth phase

Figure 5: Coupled EM-thermal simulation result

5.1.1 Validation with FEM tool. Fig. 5 shows the comparison result between FEA tool, EM-thermal co-simulation method and EM only simulation method in nucleation phase and growth phase. Experiment is performed on a single TSV with 100*um* height. As can be seen in Table 1, the average error is 0.61% in nucleation and 2.4% in growth phase. And if only EM is considered without coupled thermal simulator, average error is 3.48% for nucleation phase and 10.43% for growth phase. Max error can reduce from 26.79% to 6.67% with the coupled EM-thermal simulation. It draws a conclusion that Joule heating is one of the key factor for EM and EM-thermal co-simulation can significantly improve the accuracy.

Besides, Table 1 also shows the stress contribution of TM effect. Simulation result shows that TM effect contributes 11.4% in the nucleation phase stress evolution and 15.83% in growth phase stress evolution. And this agrees with the conclusion from experiment in [13] saying that TM effect is relatively weak.

5.1.2 Validation with experiment data. This part validates the simulation result with published experiment data from [13]. Based on the experiment result, $\frac{\Delta R}{R}$ reaches 20% at 32.4 hours with $200°C$ and $1.5MA/cm^2$ current density. Fig. 6 compares the simulation result of the proposed method and AFD method from [13] with real EM experiment result.

It can be seen that in the experiment the TSV reaches 20% resistance change in 32.5 hours. And the simulation result of proposed method is 30.7 hours and AFD method is 25.2 hours. The error of proposed method is 5.24% and the error of AFD method is 22.22%. The error rate is reduced by 76.4%.

5.2 Simulation results on the CHI System

This part demonstrates the simulation results on a 2.5D CHI system which has nine chiplets. The parameters of the system is shown in Table 2 and its layout of the system is in Fig. 7.

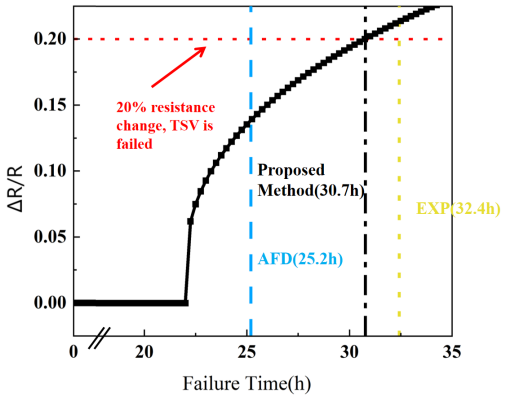


Figure 6: Resistance change trend of TSV

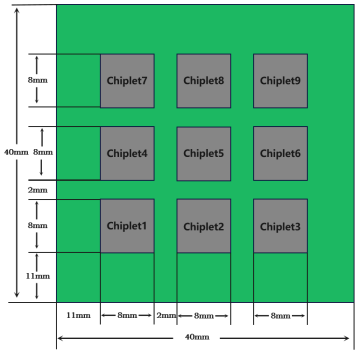
Table 2: Parameters of the CHI system

Name	Number	Size (mm)
Chiplet	9	$8 \times 8 \times 0.15$
Heat Sink	1	$40 \times 40 \times 0.18$
TSV	1600	Diameter = 0.01 Height = 0.1
MicroBump	2500	/



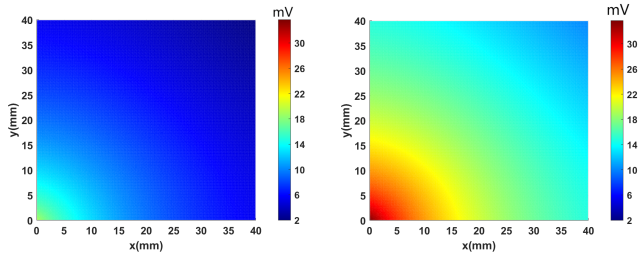


Figure 7: Layout of CHI system

There are low and high working modes for the CHI system. The voltage distribution of both modes are shown in Fig. 8. And temperature distribution results from CHI system electrical-thermal co-simulation model is shown in Fig. 9. It can be seen that the left corner of the chip has high voltage and the medium of the chip has high temperature.

The resistance change distribution of the CHI system of low and high power modes is shown in Fig. 10 and 11, in which the EM issue in the high power mode is more critical than that in the low power mode. And we can see current density and thermal are both critical issues for the EM. It can be observed that in the early stage the high temperature part has more critical EM issue. In the late stage EM issue is more critical in the high current density part.

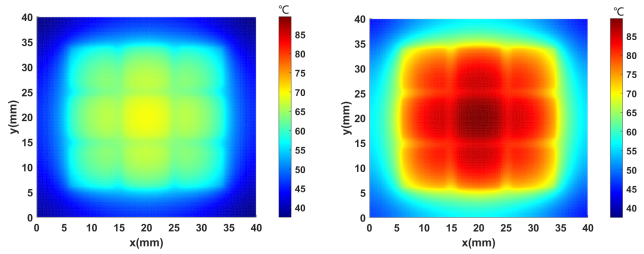

Table 3 displays that the percentage of failed TSVs is increasing over time. In the low power mode, there is no TSV failed in the first year since most TSVs are still in nucleation phase. And 47%

(a) Voltage distribution for low power mode

(b) Voltage distribution for high power mode

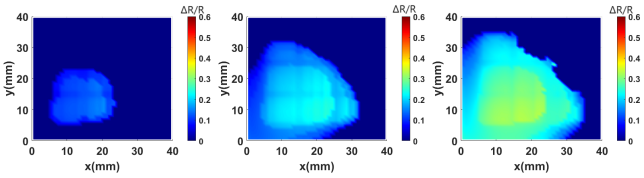

Figure 8: Voltage distribution of CHI system

(b) Temperature distribution for high power mode

Figure 9: Temperature distribution of CHI system

(a) 1 year (b) 3 years (c) 6 years

Figure 10: Resistance change distribution of low power mode in 1, 3 and 6 years

(a) 1 year (b) 3 years (c) 6 years

Figure 11: Resistance change distribution of high power mode in 1, 3 and 6 years

TSVs failed in 6 years. EM issue is more critical in high power mode. 54.25% TSVs failed in first year and all the TSVs failed in 6 years.

Table 3: Failure rate of high and low power mode

	6 month	1 year	3 years	6 years
Low power	0%	0%	16.75%	47%
High power	26.19%	54.25%	91.5%	100%

6 CONCLUSION

This paper has proposed a novel EM simulation tool ChipletEM for 2.5D and 3D CHI systems. A FVM based electrical-thermal co-simulation model is employed to get initial temperature and current density inside TSV. A FDTD EM solver and a compact TSV thermal solver is employed for coupled simulation for interaction among EM stress, thermal stress, void growth, resistance change, IR drop and Joule heating effects. Accuracy of the proposed tool is validated with FEM tool and published experiment data. Compared with state of art AFD method the error rate is reduced by 76.4%. In the future the EM failure between RDL and TSV junction will also be taken into consideration.

***Abstract*—With the widespread deployment of long-context large language models (LLMs), efficient and high-quality generation is becoming increasingly important. Modern LLMs employ batching and *key-value (KV) cache* to improve generation throughput and quality. However, as the context length and batch size rise drastically, the KV cache incurs extreme external memory access (EMA) issues. Recent LLM accelerators face substantial processing element (PE) under-utilization due to the low arithmetic intensity of attention with KV cache, while existing KV cache compression algorithms struggle with hardware inefficiency or significant accuracy degradation. To address these issues, an algorithm-architecture co-optimization, KVO-LLM, is proposed for long-context batched LLM generation. At the algorithm level, we propose a KV cache quantization-aware pruning method that first adopts salient-token-aware quantization and then prunes KV channels and tokens by attention guided pruning based on salient tokens identified during quantization. Achieving substantial savings on hardware overhead, our algorithm reduces the EMA of KV cache over 91% with significant accuracy advantages compared to previous KV cache compression algorithms. At the architecture level, we propose a multi-core jointly optimized accelerator that adopts operator fusion and cross-batch interleaving strategy, maximizing PE and DRAM bandwidth utilization. Compared to the state-of-the-art LLM accelerators, KVO-LLM improves generation throughput by up to 7.32×, and attains 5.52∼8.38× better energy efficiency.**

***Index Terms*—Large language model, Long-context, Batching, KV cache, Algorithm-architecture co-design**

I. Introduction

Long-context large language models (LLMs) show exceptional dexterity across a spectrum of natural language processing tasks with notable proficiency, especially in long-context generation [1]. With the increasing demand for long-context generation, the maximum context length has increased dramatically from 2K to millions of tokens. To improve the generation throughput, a prevalent strategy is to batch requests, exploiting data sharing [2], [3]. Moreover, LLMs broadly employ the pivotal *key-value (KV) cache* technique, which stores the intermediate attention keys and values to avoid heavy re-computation during long-context generation [4], [5].

However, with a drastic increase in batch size and context length, KV cache incurs extreme memory issues. As depicted in Fig. 1(a), the KV cache external memory access (EMA) increases linearly with batch size. Taking Llama-2-7B [6] as an example, as the batch size rises, the EMA of KV cache exceeds that of the model weights under 4K context length. Furthermore, as shown in Fig. 1(b), the KV cache related operations predominantly influence the generation throughput under large batch size. With the increase of context length, the challenges become more pronounced. For example, the EMA of KV cache even increases to 128 GB when the context length reaches 32K, becoming more than 20× the weight size. This extreme EMA accounts for 96% of the generation latency for Tender [7], forming a distinct bottleneck to throughput.

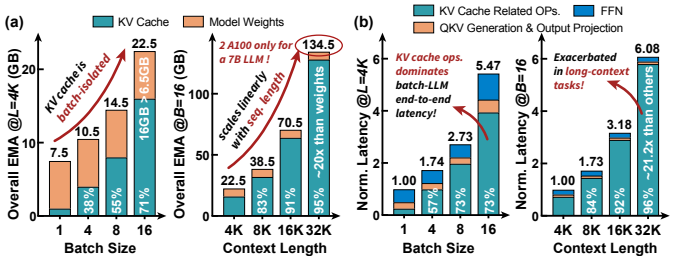

Fig. 1. Breakdown of EMA and latency for Llama-2-7B generating one token under different batch size B and context length L. Weights, activations, and KV cache are in INT8 format. The latency is measured on Tender [7] with a peak throughput of 2048GOPS@INT8 and a DRAM bandwidth of 256 GBps.

The above *KV cache issues have not been adequately addressed* in existing LLM accelerators [7]–[9]. Though they focus on lessening computational workload, there seems to be a common oversight regarding the low arithmetic intensity issues of KV cache. For example, Tender [7] and OPAL [8] quantize the LLMs into low precision to boost the processing element (PE) efficiency. MECLA [9] addresses the similar issue by compressing the weight matrices through fine-tuning. Nonetheless, in attention layers, their generation throughput is severely hindered by intensive EMA and low arithmetic intensity which causes serious PE under-utilization (e.g., only ≈25% of Tender under 16-batched Llama-2-7B decoding [7]).

Many previous algorithms have been dedicated to compressing the KV cache through *KV quantization (KV-Q)* or *KV eviction (KV-E)*. The state-of-the-art (SOTA) KV-Q works [10], [11] involve extra element-wise floating-point (FP) multiplication and accumulation (MAC) during matrix operations, which significantly degrades hardware efficiency. Meanwhile, other works of KV-E aim to retain a limited budget of important tokens, while evicting the trivial ones [12], [13]. However, discarded tokens might cause huge semantic information loss

†: Equal contribution.

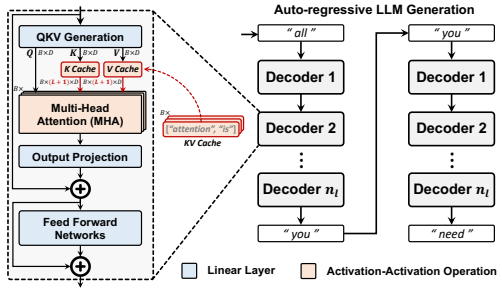

Fig. 2. Model architecture and auto-regressive inference of LLMs. As decoder layers focus on matrix computation, we exclude the layer normalization and position embedding in the diagram.

[14]. Despite its significant EMA savings, KV-E leads to noticeable accuracy loss on long-context generation [15].

In summary, KV cache emerges as a key barrier to high-throughput LLM inference while existing works leave a clear gap away from the memory-efficient design with high generation quality. Therefore, we consider three key requirements: ❶ *hardware efficiency* of the compression policy; ❷ *generation quality* under KV cache compression; and ❸ *utilization maximization* of PE and DRAM bandwidth. To meet these requirements, we propose an algorithm-architecture co-optimization, **KVO-LLM**. The key contributions are as follows:

1) We propose an effective KV cache quantization-aware pruning algorithm, which adopts differential and salient-token-aware quantization (DSQ) firstly. Then based on the identified salient tokens, it employs historical-current attention guided pruning (HCAP) to prune KV channels and tokens. Our method not only achieves *substantial savings on hardware overhead* ❶, but also delivers *high-quality generation comparable to that with full KV cache* ❷ under a high KV cache compression ratio (CR). This algorithm is open-sourced and available for public use.
2) We design a multi-core jointly optimized architecture with operator fusion and cross-batch interleaving strategy (OFBI) to schedule the compute flow wisely. Compared to naively scheduling our algorithmic flow, OFBI improves *PE utilization from 25% to 93% for multi-head attention and DRAM bandwidth usage from 25% to 67% for Query-Key-Value generation on average* ❸, thus achieving up to 1.72× throughput improvement.
3) We implement our design on TSMC 28nm technology and extensively evaluate it on various long-context generation tasks. KVO-LLM achieves comparable performance under a CR of over 91% as the model with full KV cache, while SOTA KV-Q and KV-E works still exhibit a notable accuracy loss even with a smaller CR. Compared with SOTA LLM accelerators, KVO-LLM improves generation throughput by up to 7.32× and achieves 5.52∼8.38× gain in energy efficiency.

II. Background and Motivation

A. Large Language Models

The LLM inference flow is typically organized into two phases: the *prefilling* phase and the *decoding* phase. The former calculates and stores the KV cache of the input prompt,

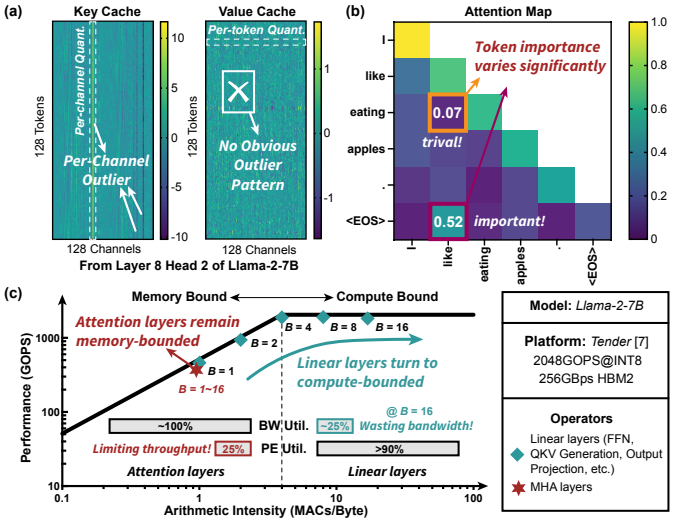

Fig. 3. (a) Magnitude of key and value cache from layer 8 head 2 of Llama-2-7B [6]. (b) The attention map of the input prompt "I like eating apples." (c) Roofline model of the Tender [7] for the decoding phase of Llama-2-7B when L is 4096, where BW represents the DRAM bandwidth.

and generates the first token. The latter phase, as illustrated in Fig. 2, generates the output tokens one by one, updating the KV cache during each regression loop. Since the prefilling phase is widely researched [7]–[9] and accounts for a minor portion of latency under long-context generation relatively [1], this paper focuses primarily on the *decoding* phase.

Fig. 2 shows that LLM is mainly constructed by several stacked decoder layers, each comprising four major parts: (1) Query($\mathbf{Q}$)-Key($\mathbf{K}$)-Value($\mathbf{V}$) generation, (2) multi-head attention (MHA), (3) output projection, and (4) feed forward networks (FFNs). (1), (3), and (4) are composed of linear layers, while the MHA primarily involves multiplication between activations. Denote the batch size, current context length, and embedding dimension by B, L, and D, respectively. After QKV generation, the newly generated $\mathbf{K}_i$, $\mathbf{V}_i \in \mathbb{R}^{B\times D}$ need to be concatenated with the cached $\mathbf{K}_C$, $\mathbf{V}_C \in \mathbb{R}^{B\times L\times D}$:

$$\begin{aligned} \mathbf{K},\mathbf{V} &= \texttt{Concat}(\mathbf{K}_C,\mathbf{K}_i),\texttt{Concat}(\mathbf{V}_C,\mathbf{V}_i),\\ \mathbf{K}_C,\mathbf{V}_C &= \mathbf{K},\mathbf{V}, \end{aligned} \tag{1}$$

where $\mathbf{K}$ and $\mathbf{V}$ participate in the following MHA: attention score computation $\mathbf{S} = \texttt{Softmax}(\mathbf{Q}_i\mathbf{K}^T)$, and $\mathbf{x}_{out} = \mathbf{SV}$.

B. Motivations

To compress KV cache, the most effective method is to reduce the total bytes it occupies, i.e., KV-Q. We profile the magnitude distribution of KV cache in Llama-2-7B [6] in Fig. 3(a). It could be observed that some $\mathbf{K}$ channels demonstrate large absolute magnitudes. Such features suggest a natural preference of per-channel $\mathbf{K}$ quantization [10]. However, this incurs an expensive overhead of FP MACs, as the $\mathbf{Q}_i\mathbf{K}^T$ computation of MHA is along the token dimension. Nevertheless, the per-token method, which is relatively hardware-friendly, introduces significant accuracy loss when quantizing vastly volatile channels [10]. Additionally, KV-E is an effective KV cache compression method by identifying and eliminating tokens with trivial context. However, as demonstrated in Fig.

3(b), the importance of tokens varies significantly across different context positions. Although research like H_2O [13] relies on historical accumulated attention scores to distinguish trivial tokens as precisely as possible, evicted tokens may become important in future generation, causing significant loss of semantic information [14]. Above all, the challenge for current KV cache compression lies in *ensuring both hardware efficiency and generation quality*.

Compared to the aforementioned algorithmic optimization, existing LLM accelerators often neglect the KV cache compute issues. We conduct a roofline analysis on Llama-2-7B in Fig. 3(c) based on Tender [7]. For the linear layers, batching improves the arithmetic intensity with weight sharing, whereas attention layers remain memory-bound consistently regardless of how batch size and context length increase. Divergent features determine that Tender suffers severe DRAM bandwidth or PE under-utilization in these two types of LLM layers respectively. As exhibited in Fig. 1(b), while KV cache scaling up with B and L, it exacerbates the aforementioned bottlenecks. Therefore, there is an urgent need for *the approach for PE efficiency and memory bandwidth maximization in batched LLM inference* to achieve high generation throughput.

III. Proposed KV Cache Compression Approach

In this section, we propose an effective quantization-aware pruning algorithm combining differential and salient-token-aware quantization (DSQ) with historical-current attention guided pruning (HCAP). DSQ identifies salient tokens and achieves extremely low-bit KV cache quantization. Based on the identified salient tokens, HCAP prunes a great number of trivial channels and tokens to enhance the KV cache CR. In Sec. III-A, we first introduce the DSQ. Then the HCAP will be described in Sec. III-B. Finally, Algorithm 1 details each step of our KVO-LLM algorithm combining DSQ with HCAP.

A. Differential and Salient-Token-Aware Quantization

To minimize the FP MACs, it is essential to ensure that the quantization dimension align with the accumulation. Therefore, we should employ per-token $\mathbf{K}$ and per-channel $\mathbf{V}$ quantization. However, using it naively causes huge accuracy drop [10]. To overcome this dilemma, the DSQ is proposed.

1) Differential Per-Token $\mathbf{K}$ Quantization. As illustrated in Fig. 3(a), adjacent $\mathbf{K}$ exhibit high numerical similarity along the channel dimension. This property indicates that the differences between adjacent tokens are minimal. Leveraging this opportunity, we propose a differential quantization method that partitions all tokens into groups, each containing one base token ($\mathbf{K}_{base}$) and several Δ tokens ($\mathbf{K}_{\Delta}$). When quantizing each group, the $\mathbf{K}_{base}$ is directly quantized to INT8, while the $\mathbf{K}_{\Delta}$ are represented by the low-bit quantized differential values relative to the $\mathbf{K}_{base}$:

$$\texttt{Quant}(\mathbf{K}_{\Delta}) = \texttt{Quant}(\mathbf{K}_{\Delta} - \mathbf{K}_{base}, \texttt{INT2}) \tag{2}$$

A new challenge arises in selecting the $\mathbf{K}_{base}$ and implementing effective grouping strategies. According to [13], selecting tokens with the highest accumulated attention scores as base tokens like H_2O [13] is the most appropriate approach. However, this can lead to an uneven distribution in memory, resulting in irregular memory access. Therefore, we propose a window-based $\mathbf{K}_{base}$ selection strategy at line 18-20 in Algorithm 1. Every n_{win} tokens form a group, and within each group, the token with the highest accumulated score from the most recent R generations is identified as the salient token, with its corresponding attention key serving as $\mathbf{K}_{base}$.

2) Salient-Token-Aware Per-Channel $\mathbf{V}$ Quantization. As shown in Fig. 3(a), $\mathbf{V}$ does not exhibit an obvious outlier pattern like $\mathbf{K}$. As a result, for per-channel quantization, the precision of salient tokens is susceptible to the quantization process imposed on trivial tokens. Given that the result ($\mathbf{x}_{out}$) of $\mathbf{SV}$ primarily depends on the combination of a few important tokens, compared to $\mathbf{K}$ quantization, we do not employ a differential process on $\mathbf{V}$ to mitigate interactions between tokens. We allocate high bit-width (8-bit) for salient tokens, and assign low bit-width (2-bit) to trivial tokens.

Algorithm 1: Proposed KVO-LLM Algorithm

Input: Query $\mathbf{Q} \in \mathbb{R}^{L\times D}$, KV cache $\mathbf{K}$, $\mathbf{V} \in \mathbb{R}^{L\times D}$, KV cache budget $k \in \mathbb{N}$, recent generation observation length R, window size n_{win}, pruning ratio P

B. Historical-Current Attention Guided Pruning

Further reduction in quantization bit-width can significantly impair accuracy. To enhance the CR, it is necessary to prune the trivial information within the KV cache. We rely on both historical accumulated attention scores and current attention scores, i.e., current $\texttt{Softmax}(\mathbf{Q}_i\mathbf{K}_{base}^T)$ results, to guide the pruning process and mitigate semantic information loss.

1) Historical Attention Guided Pruning. Evicting tokens thoroughly based on historical accumulated attention scores causes significant loss of semantic information. However,

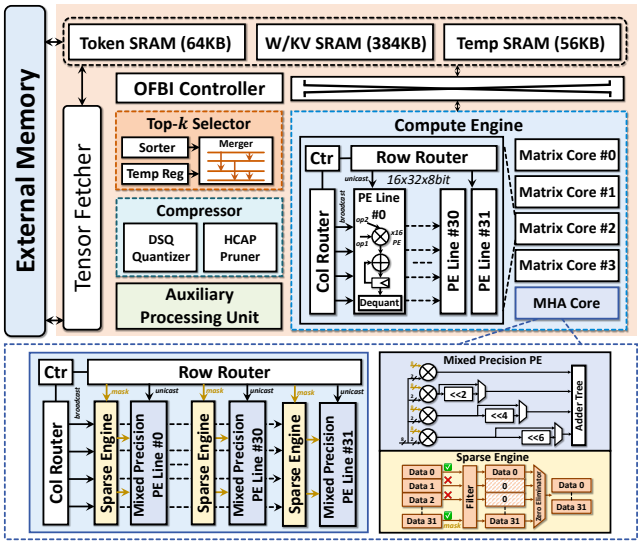

Fig. 4. Overview of the KVO-LLM accelerator.

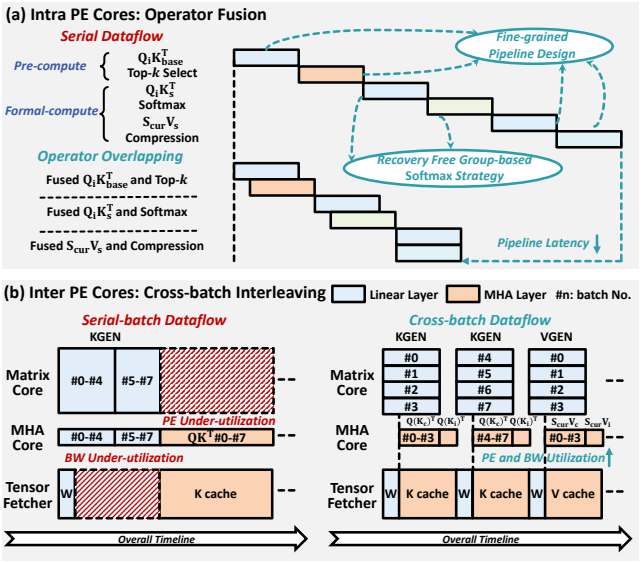

Fig. 5. Proposed operator fusion and cross-batch interleaving (OFBI) dataflow. (a) Intra PE cores operator fusion to reduce pipeline latency. (b) Inter PE cores cross-batch interleaving to improve PE and DRAM bandwidth utilization.

there are many channels with small magnitudes of trivial tokens delivering negligible contribution to the final results. Therefore, we selectively prune these trivial channels at line 25 in Algorithm 1. Based on the absolute values, we adopt a structured pruning method that eliminates the lowest N values in each quantization group. When pruning ratio is $1-P$, the compression ratio (CR) of one group is reduced to:

$$G_{CR}(P) = (8D + 2DP(n_{win} - 1))/16DL \tag{3}$$

2) Current Attention Guided Pruning. Large pruning ratio (>75%) solely based on historical attention scores results in significant accuracy degradation. Fortunately, prior research demonstrates the inherent sparsity in attention scores [14]. Therefore, to mitigate accuracy loss while achieving a high CR, we propose to estimate the current attention scores and utilize them to select a small portion of tokens participating in current computation at line 7-8 in Algorithm 1. First, instead of multiplying $\mathbf{Q}_i$ with all $\mathbf{K}$, we approximate attention scores by multiplying $\mathbf{Q}_i$ and $\mathbf{K}_{base}$. The scores estimate the importance of each KV group. Then, given a KV cache budget k, only the top-(k/n_{win}) groups with the largest $\mathbf{Q}_i\mathbf{K}_{base}^T$ results participate in the following computations.

When $L\%R = 0$, the $\mathbf{K}$ cache EMA CR using our approach is reduced to

$$\mathbf{K}_{CR} = 1 - (\underbrace{R/L}_{recent} + \underbrace{G/2L}_{base} + \underbrace{(k/n_{win})G_{CR}(P)}_{k\ budget}), \tag{4}$$

where $G = (L-R)/n_{win}$, which is # of groups. For $\mathbf{V}_{CR}$, it only includes the EMA of recent tokens and k budget tokens.

IV. Proposed Generative LLM Accelerator

As depicted in Fig. 3(c), existing LLM-specific designs face severe PE or DRAM bandwidth under-utilization issues. We design a multi-core jointly optimized architecture which schedules the compute flow wisely leveraging operator fusion and cross-batch interleaving (OFBI) strategy. We first present the overview of our accelerator in Sec. IV-A. Then, we show how operators are fused within one core in Sec. IV-B. The cross-batch interleaving strategy is described in Sec. IV-C.

A. Overview

Fig. 4 depicts the overall architecture of KVO-LLM. It primarily consists of 504KB on-chip buffer, an auxiliary processing unit, a compute engine, and specialized functional units. The on-chip buffer is divided into three main parts for input feature maps, weights/KV cache, and temporary results respectively. The auxiliary processing unit is mainly responsible for `Softmax` and other non-linear functions. The compute engine is composed of five PE cores focused on matrix multiplication, including one MHA core dedicated to multi-head attention. The specialized functional units include a top-k selector and a compressor to support our KV cache quantization-aware pruning algorithm.

B. Intra PE Cores: PE Design and Operator Fusion

As shown in Fig. 4, each PE core consists of 32 PE lines, and each PE line is composed of 16 PEs. Each PE core performs $(1 \times 16) \times (16 \times 32)$ matrix-vector multiplication per cycle, and it follows an output stationary dataflow, where partial sums are accumulated in each PE line. The MHA core is composed of precision-configurable PEs and sparse engines based on zero elimination to support mixed-precision quantization and pruning respectively.

When performing MHA in a single batch, our algorithm necessitates data recovery of $\mathbf{Q}_i\mathbf{K}_{\Delta}^T$ because of DSQ, top-k selection because of HCAP, and compression of new KV tokens. Naively performing these operations in a serial manner causes long pipeline latency, which could be seen in Fig. 5(a). We propose a fine-grained fusion dataflow to improve PE cores utilization significantly. In the pre-compute stage, once a valid $\mathbf{Q}_i\mathbf{K}_{base}^T$ result is finished, the top-k selector compares it with previous results. In the formal-compute stage, the `Softmax`

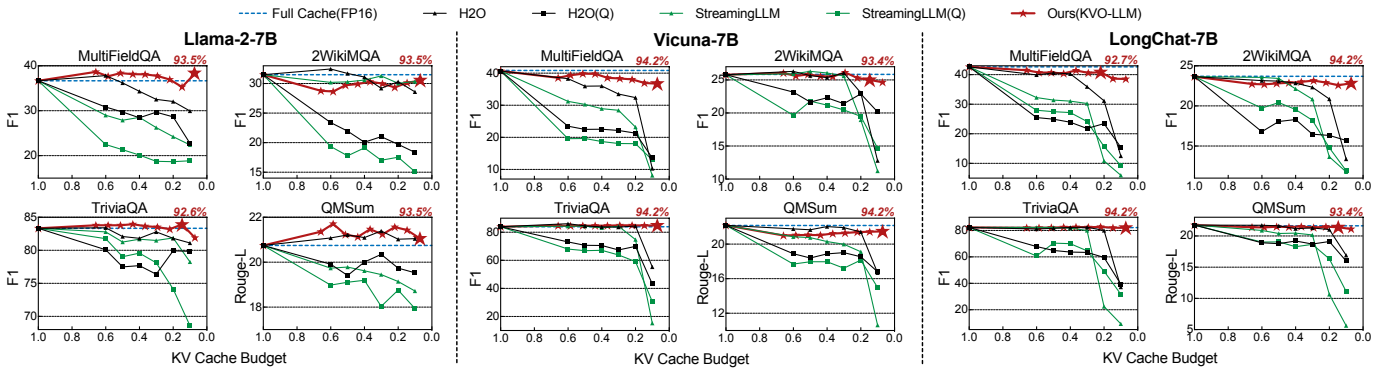

Fig. 6. Comparsion results between the baseline model with full cache, our KVO-LLM algorithm, and the existing KV-E methods [12], [13] with or without quantization. We choose 4 representative datasets for distinct tasks: single-document QA, multi-document QA, synthetic tasks, and summarization, respectively, from the extensively utilized LongBench [15]. For each diagram, we highlight one point with significant CR and high accuracy compared to SOTA works, and we present the actual CR. Our method could compress the KV cache EMA over 91% while demonstrating negligible accuracy loss.

can overlap with $\mathbf{Q}_i\mathbf{K}_s^T$ by fusing data recovery process with the `Softmax` operation and utilizing a group-based `Softmax` strategy. More specifically, we implement `Softmax` for each group of $\mathbf{Q}_i\mathbf{K}_s^T$, i.e., n_{win} results. By designating $\mathbf{Q}_i\mathbf{K}_{base}^T$ as the `Softmax` maximum, we eliminate the necessity for completing data recovery. After finishing $\mathbf{Q}_i\mathbf{K}_s^T$, we update group-based `Softmax` results accordingly. Then the compute engine begins $\mathbf{S}_{cur}\mathbf{V}_s$. Compression on new KV tokens can be operated simultaneously on the specially designed compressor.

C. Inter PE Cores: Cross-Batch Interleaving

As shown in Fig. 3 (c), in the linear layers, batching enhances arithmetic intensity, while attention layers consistently exhibit memory bound, irrespective of batch size and context length. Fig. 5(b) presents an unoptimized execution timeline for the multi-batch computational process, which executes the QKV generation and MHA serially. This execution flow leads to severe under-utilization of both PE and DRAM bandwidth.

Therefore, we introduce a cross-batch interleaving approach. Fig. 5(b) illustrates an example of this technique, which is accomplished by partitioning the compute cores into separate matrix and MHA cores to accommodate distinct workloads. Since there is no dependency between KV generation and MHA with cached $\mathbf{K}_C, \mathbf{V}_C$, MHA is divided into two computational segments: MHA with cached $\mathbf{K}_C, \mathbf{V}_C$ and MHA with new $\mathbf{K}_i, \mathbf{V}_i$. We dispatch them with other batches to optimize resource utilization. To be specific, because of the compute-bounded property in batched KV generation, there is a long period of DRAM idleness. Instead of scheduling all compute cores to operate on KV generation, we schedule one MHA core for MHA with cached $\mathbf{K}_C, \mathbf{V}_C$, fully utilizing the wasted DRAM bandwidth. Cross-batch interleaving facilitates the concurrent execution of compute-intensive linear layers alongside memory-bound attention layers, and thus effectively improves PE and DRAM bandwidth utilization.

V. Evaluation

A. Evaluation Methodology

We evaluate KVO-LLM on four datasets in the widely-used *LongBench* [15] to demonstrate our superiority over diverse tasks, e.g., document QA, summarization, and synthetic tasks. *LongBench* provides a holistic evaluation of long-context generation abilities of LLMs across various lengths, distributions, and long dependency patterns [15]. Detailed configurations and implementation are derived from the official repository of H_2O [13] and KIVI [10]. Meanwhile, three representative long-context LLMs are chosen for our evaluation: Llama-2-7b-chat-4k (*Llama-2-7B*) [6], LongChat-v1.5-7b-32k (*LongChat-7B*) [16], Vicuna-7b-v1.5-16k (*Vicuna-7B*) [17]. When evaluating accuracy, we use the PyTorch [18] framework and the Hugging Face library [19].

For hardware implementation, we implement the compute and control logic of KVO-LLM with SystemVerilog and estimate the area and energy consumption of on-chip memory with CACTI [20]. The prototype is synthesized with Synopsys Design Compiler under TSMC 28nm CMOS technology. Logic power consumption is estimated using Synopsys PrimeTimePX by annotating switching activity from the datasets above. For off-chip DRAM, we use an HBM2 with 256GB/s bandwidth, which consumes 1.2pJ/b for data access [21].

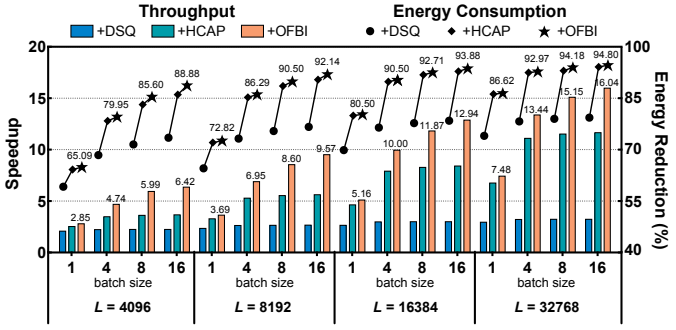

Fig. 7. Normalized throughput and energy consumption improvements through DSQ, HCAP and OFBI. Note that "+" means this method is appended on the previous approach. Baseline has the same hardware architecture with these functions deactivated.

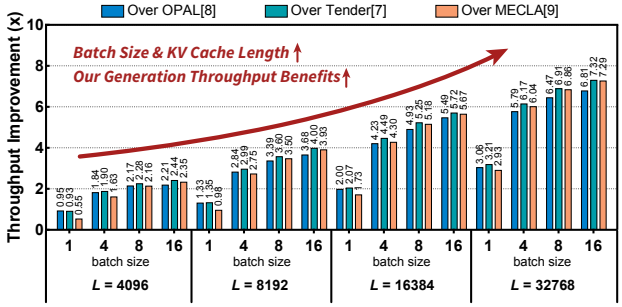

Fig. 8. Normalized throughput improvements of KVO-LLM with SOTA LLM accelerators [7]–[9]. We ensure the peak throughput is consistent across all works to make a fair comparison.

B. Evaluation on Proposed Algorithm

We first evaluate our method with SOTA KV-Q works, such as KIVI. As shown in Table I, NINT2 suffers from significant accuracy loss due to the outlier channels in $\mathbf{K}$. Although KIVI mitigates the quantization error by adjusting the quantization dimensions, it introduces inefficient FP MACs. Compared to KIVI with up to a 14.82% accuracy drop and an 86.10% KV cache CR, KVO-LLM only has up to a 5.76% accuracy drop despite achieving up to 91.93% CR. KVO-LLM outperforms existing methods on both accuracy and KV cache CR.

We further compare our algorithm with SOTA KV-E works across different KV cache budget in Fig. 6. To clearly demonstrate our strengths, the KV cache budget shown in the figure is calculated as k/L. However, with the inclusion of DSQ and HCAP, the CR using our method significantly surpasses $1 - k/L$, as calculated in (4). We can observe that: (1) KVO-LLM with a CR above 91% can achieve comparable accuracy to the model with full KV cache (FP16). (2) KVO-LLM shows increasingly significant accuracy advantages under high CR. (3) Combining DSQ and HCAP, KVO-LLM demonstrates consistent and significant accuracy improvements over KV-E works with quantization.

C. Evaluation on Proposed Hardware Accelerator

Fig. 7 presents the throughput and energy consumption evaluations over three key techniques: DSQ, HCAP, and OFBI. We set $k = L/8$ for the following evaluations.

When compared to the baseline, DSQ and HCAP yield over 3.72× enhancement in throughput and over 86.3% reduction in power consumption under $B = 16, L = 4096$. The introduced OFBI strategy further improves throughput by up to 1.72× and decreases power consumption by up to 1.24×. Additionally, as illustrated in Fig. 7, the performance improvement is typically greater with larger batch size and context length, as these conditions elevate the latency and EMA contribution from the MHA stage within the processing flow.

TABLE II
COMPARISON WITH OTHER LLM ACCELERATORS

	OPAL [8]	Tender [7]	MECLA [9]	Ours

† Technology normalized to 28nm as follows: s = Technology/28nm, $f \sim s$, and $P \sim (1/s)$, where f and P is denoted as frequency and power, respectively.

D. Comparison with SOTA LLM Accelerators

We conduct a comparison of KVO-LLM with leading LLM accelerators [7]–[9], and ensure the peak throughput is consistent across all works. Compared with them, KVO-LLM effectively reduces the EMA of KV cache with a CR >91% by employing DSQ and HCAP. Moreover, utilizing the OFBI, KVO-LLM significantly improves PE utilization from 25% to 93% for MHA and DRAM bandwidth usage from 25% to 67% for QKV generation. As a result, KVO-LLM improves throughput by up to 7.32× in Fig. 8.

Table II presents the detailed implementation results. Utilizing TSMC 28nm technology, the KVO-LLM prototype demonstrates an effective performance of 4584.38 GOPS/W at 500 MHz, with a power consumption of 717 mW. The accelerator occupies an area of 4.83 mm^2. We also reconstruct the method of [7]–[9] for the LLM generation phase to evaluate their energy efficiency. Leveraging DSQ, HCAP and OFBI, KVO-LLM shows a 5.52∼8.38× increase in energy efficiency compared to these accelerators.

VI. Conclusion

This paper introduces an algorithm-architecture co-optimization, KVO-LLM. The key insight is to alleviate the significant KV cache EMA and improve the throughput for long-context batched LLM generation. Through quantization-aware pruning, KVO-LLM not only achieves substantial savings on hardware overhead, but also compresses KV cache EMA by over 91% with high generation quality. Besides, KVO-LLM hardware accelerator integrates the OFBI strategy to maximize PE and DRAM bandwidth utilization. Comprehensive evaluations demonstrate KVO-LLM surpasses SOTA works in various metrics such as accuracy, throughput, and energy efficiency across diverse tasks and model types.

***Abstract*—Analog/mixed-signal circuit design encounters significant challenges due to performance degradation from process, voltage, and temperature (PVT) variations. To achieve commercial-grade reliability, iterative manual design revisions and extensive statistical simulations are required. While several studies have aimed to automate variation-aware analog design to reduce time-to-market, the substantial mismatches in real-world wafers have not been thoroughly addressed. In this paper, we present GLOVA, an analog circuit sizing framework that effectively manages the impact of diverse random mismatches to improve robustness against PVT variations. In the proposed approach, risk-sensitive reinforcement learning is leveraged to account for the reliability bound affected by PVT variations, and ensemble-based critic is introduced to achieve sample-efficient learning. For design verification, we also propose μ-σ evaluation and simulation reordering method to reduce simulation costs of identifying failed designs. GLOVA supports verification through industrial-level PVT variation evaluation methods, including corner simulation as well as global and local Monte Carlo (MC) simulations. Compared to previous state-of-the-art variation-aware analog sizing frameworks, GLOVA achieves up to 80.5× improvement in sample efficiency and 76.0× reduction in time.**

***Index Terms*—Analog circuit synthesis, PVT variation, Reinforcement learning**

I. Introduction

Analog/mixed-signal circuit design is an extremely labor-intensive process, relying on human expertise, experience, and intuition. As CMOS technology continues to scale down, it has become increasingly challenging to meet the demand for higher performance and shorter design cycles. Consequently, both industry and academia are driven toward developing advanced design automation tools. Over the years, numerous studies have incorporated machine learning to mitigate reliance on manual design. [1], [2] utilize genetic algorithms with deep neural network-based models for optimization. Bayesian optimization (BO) [3]–[5] and reinforcement learning (RL) [6]–[9] are also widely used to efficiently explore large design space.

A key challenge in analog circuit design is dealing with performance degradation caused by process, voltage, and temperature (PVT) variations. In particular, process variations during manufacturing introduce substantial silicon mismatches. As shown in Fig. 1, these variations are classified into global mismatches, which occur broadly across the entire wafer, and local mismatches within individual dies [10], [11]. Voltage variation results from non-idealities of external voltage sources, while temperature variation arises from changes in operating conditions. Since the performance of analog circuits under PVT variations is highly sensitive and unpredictable, addressing these effects is crucial. In industry, where maintaining yield is paramount, this challenge is even more pressing. Therefore, extensive verification across various PVT conditions is conducted to ensure chip reliability, even though it is time-consuming and costly.

*These authors contributed equally to this work.

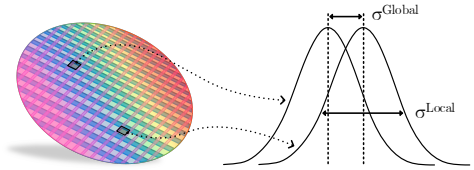

Fig. 1. Schematic of global (die-to-die) and local (within-die) variations on a wafer [11]. The median difference between two dies is determined by global variation (σ^{Global}), while variations within each die occur around its median due to local variation (σ^{Local}).

Existing design automation tools primarily focus on typical condition and cannot effectively account for diverse variations [1]–[5], [12]. Although [4], [12] introduce PVT corners, they merely test all PVT conditions every iteration, which limits sample efficiency. To tackle this, [8] employs multi-task RL, treating each PVT corner as a separate task, and improves efficiency by testing only the dominant corners identified through clustering. Nonetheless, using random initial sampling limits both the sample efficiency and success rate of the optimization process. To overcome this, [9] incorporates TuRBO [13] for the initial sampling, enhancing optimization efficiency.

While [4], [7]–[9], [12] provide insights into addressing PVT variations, their focus remains primarily on global process corners, leaving the impact of extensive random mismatches both across and within dies underexplored. Although [9] examines transistor-level mismatches, it is limited to a few cases, making it difficult to reflect the comprehensive impact of mismatches. Additionally, the consideration of mismatches is handled separately from the optimization process, requiring additional iterations and reducing overall design efficiency. In terms of verification, ensuring chip reliability necessitates a large number of statistical simulations to address the significant impact of random mismatches in real-world wafers [14]. Nevertheless, prior works have not considered comprehensive verification in the design process. Therefore, it is essential to thoroughly address these factors within the design flow to overcome the challenges in both optimization and verification processes.

In this paper, we present GLOVA, an efficient optimization and verification framework for variation-aware analog circuit design automation. Experimental results demonstrate that the proposed GLOVA efficiently and effectively manages diverse PVT conditions and a wide range of mismatch cases compared to previous state-of-the-art approaches.

Our contributions are summarized as follows,

- We propose an automated optimization and verification framework for PVT-aware analog circuit design, accounting for broad and diverse global and local mismatches via risk-sensitive reinforcement learning.
- Ensemble-based critic is proposed to estimate the bound of

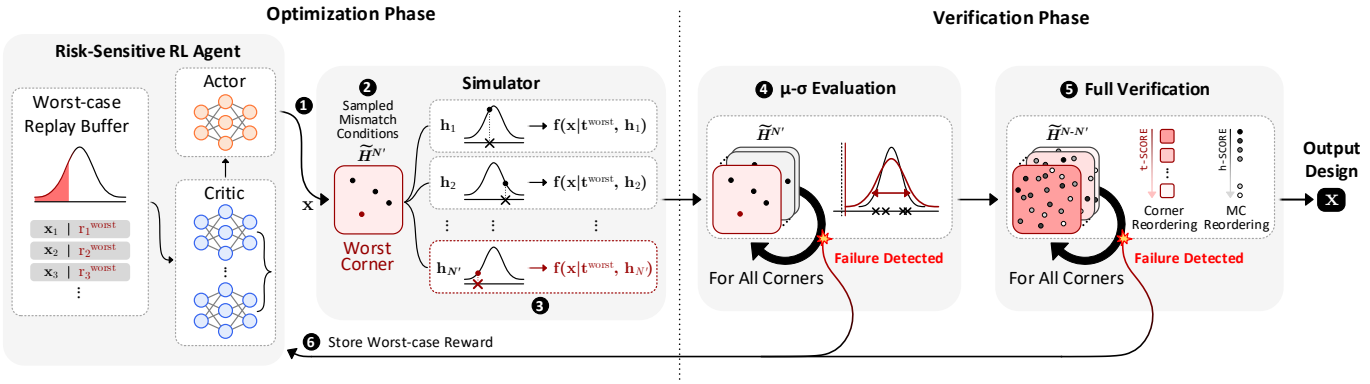

Fig. 2. Framework overview of the proposed GLOVA.

uncertain worst-case variations, improving sample efficiency and optimization convergence.

- μ-σ evaluation method is proposed to determine if an optimized design is feasible and whether to further verify it, improving sample efficiency and reducing overall runtime.
- Simulation reordering method is proposed, significantly reducing the verification cost of a large number of statistical simulations.
- The produced designs are verified through real-world simulation scenarios, including corner simulation, corner with local Monte Carlo (MC) simulation, and corner with global-local MC simulation.
- Extensive experimental results demonstrate that GLOVA achieves up to 80.5× improvement in sample efficiency and 76.0× runtime reduction compared to state-of-the-art tools.

II. Preliminaries

A. Simulation Methods for Analyzing PVT Variation Effects

Corner and Monte Carlo (MC) simulations are commonly used to evaluate analog circuit performance under varying process, voltage, and temperature (PVT) conditions. Corner simulation tests extreme conditions by analyzing predefined PVT corners, such as process corners $\{\mathrm{TT}, \mathrm{SS}, \mathrm{FF}, \mathrm{SF}, \mathrm{FS}\}$, voltage levels $\{0.8\mathrm{V}, 0.9\mathrm{V}\}$, and temperatures $\{-40\,^\circ\mathrm{C}, 27\,^\circ\mathrm{C}, 80\,^\circ\mathrm{C}\}$. Regarding process variation, corner simulation primarily reflects global variation between dies. In contrast, MC simulation statistically assesses process variations by evaluating numerous random parameter combinations. By exploring a large number of combinations, it can probabilistically reveal worst-case scenarios. In practical design, corner simulation and MC simulation can be appropriately combined to experiment with a wide range of mismatch cases under various PVT conditions [15]. To ensure robust circuit design, thorough verification using these methods is the fundamental requirement.

B. Risk-Sensitive Reinforcement Learning

Deep reinforcement learning (RL) is an emerging field used to optimize decision-making in complex environments. In traditional RL, the goal is typically to maximize the expected cumulative reward. In contrast, environments with significant uncertainty introduce unexpected occurrences of negative outcomes that can lead to potential risks. Thus, to focus not only on reward maximization but also on risk management, risk-sensitive RL [16]–[18] aims to balance the expected reward and risk by penalizing deviations from the expected outcomes during simulated rollouts. The objective function J in risk-sensitive RL, referred to as risk-sensitive criterion [18], modifies the standard objective to prioritize stability in worst-case scenarios under stochastic uncertainty, and it is expressed as:

$$J = \mathbb{E}[R] + \beta\sigma[R] \tag{1}$$

where $\mathbb{E}[R]$ is the expected reward, $\sigma[R]$ is the standard deviation of reward, and β is the risk-sensitivity parameter. Adjusting β controls the level of risk, with $\beta > 0$ for risk-seeking, $\beta < 0$ for risk-avoidance, and $\beta = 0$ for risk neutrality [17]. By modeling and carefully accounting for worst-case scenarios in the optimization process of stochastic and unpredictable systems, this approach helps to minimize failure costs. As a result, it allows desired targets to be reached more efficiently, especially when the cost of failure is high.

III. Framework Overview of Proposed GLOVA

A. Problem Formulation

Our goal is to find a sizing vector ensuring that the circuit's performance meets the design targets under PVT variations. Therefore, the problem can be formulated as a constraint satisfaction problem:

$$\begin{aligned} &\text{minimize} \quad 0 \\ &\text{subject to} \quad \max_{\mathbf{h}\in\widetilde{H}_j^N} \mathcal{F}_i(\mathbf{x}|\mathbf{t}_j,\mathbf{h}) < c_i, \quad i=1,...,m, \quad j=1,...,k, \end{aligned} \tag{2}$$

where $\mathbf{x} \in \mathcal{X}^p$ represents the design solution in a p-dimensional design space $\mathcal{X}$, and $\mathcal{F}_i(\mathbf{x}|\mathbf{t}_j,\mathbf{h})$ denotes the i-th performance metric under the j-th PVT corner $\mathbf{t}_j$ and mismatch condition $\mathbf{h}$. The term c_i represents the i-th target constraint. The function $\mathcal{F}(\mathbf{x}|\mathbf{t},\mathbf{h})$ nonlinearly maps $\mathbf{x}$ to performance metric, relying on SPICE simulation to reflect circuit's physical behavior. The PVT corner $\mathbf{t} \in T$ is an element of the predefined set T of PVT corner conditions. The vector $\mathbf{h} \in \widetilde{H}^N$ represents a r-dimensional mismatch condition, and the mismatch condition set $\widetilde{H}^N$ is obtained by randomly sampling N times from the distribution over $\mathbb{R}^r$, as follows:

$$\begin{aligned} \mathbf{h}^{(1)} &\sim \mathcal{N}(0, \Sigma^{Global}(\mathbf{x})) \\ \widetilde{H}^N &:= \{\mathbf{h}_1^{(2)}, \mathbf{h}_2^{(2)}, \ldots, \mathbf{h}_N^{(2)} \mid \mathbf{h}^{(2)} \sim \mathcal{N}(\mathbf{h}^{(1)}, \Sigma^{Local}(\mathbf{x}))\}. \end{aligned} \tag{3}$$

Eq. (3) outlines a hierarchical process for generating the set $\widetilde{H}^N$. Initially, a global variation sample $\mathbf{h}^{(1)}$ is drawn from a normal distribution $\mathcal{N}\big(0, \Sigma^{\text{Global}}(\mathbf{x})\big)$, where $\Sigma^{\text{Global}}(\mathbf{x})$ is a diagonal matrix containing the variances of each global process variation parameter. Subsequently, conditional on $\mathbf{h}^{(1)}$, local mismatch parameters $\mathbf{h}^{(2)}$ are sampled from $\mathcal{N}\big(\mathbf{h}^{(1)}, \Sigma^{\text{Local}}(\mathbf{x})\big)$. Here, $\Sigma^{\text{Local}}(\mathbf{x})$ is a diagonal matrix containing the variances of the device-specific variations, which depend on the design solution $\mathbf{x}$ [19]. Finally, the mismatch

TABLE I
OPERATIONAL CONFIGURATION OF THE FRAMEWORK

Verif.	Predefined Corner $\mathbf{t}$			Var. of Mismatch $\mathbf{h}$		# of Samples	
Method	P	V	T	Global	Local	Optim.	Verif.
C	Y	Y	Y	0	0	1	k
C-MC$_{\mathrm{L}}$	Y	Y	Y	0	Σ^{Local}	N'	$k \times N$
C-MC$_{\mathrm{G\text{-}L}}$	N	Y	Y	Σ^{Global}	Σ^{Local}	N'	$k \times N$

condition $\mathbf{h}$ is sampled by combining global and local variations for given design configuration [11], [15].

B. Operational Configuration

The GLOVA framework provides flexibility in selecting the target verification method (e.g., corner simulation, MC simulation, or a combination of both). With this adaptability, GLOVA efficiently adjusts the sampling methods and quantity during the optimization process. The configuration of the operational variables based on the chosen verification method is summarized in Table I.

C: Corner simulation. Predefined corners are considered without including mismatch conditions.

C-MC$_{\mathrm{L}}$: Corner and local MC simulation. Mismatch conditions are sampled from the local variation distribution for predefined corners.

C-MC$_{\mathrm{G\text{-}L}}$: Corner and global-local MC simulation. Mismatch conditions are sampled from the combined distribution of global and local variations for predefined corners.

C. Overall Workflow

An overview of the GLOVA framework is provided in Fig. 2. Initially, it utilizes TuRBO [13] to generate design solutions that meet constraints under the typical condition. This initial sampling is adopted from [9]. Each design solution is then simulated across sampled mismatch conditions under all PVT corners. The worst-case reward from these simulations is stored in the worst-case replay buffer, forming the initial dataset. Additionally, the last worst-case buffer records the last worst reward of each PVT corner. In each iteration, the following steps are executed. ❶ **Generate a design solution.** Put the last design solution into an actor to get a new design solution. ❷ **Sample PVT conditions.** Select the worst PVT corner by comparing the last worst-cases of corners, and sample N' mismatch conditions from the distribution via Eq. (3). ❸ **Simulate the design solution under the sampled conditions.** Get performance metrics under the sampled N' mismatch conditions given the worst PVT corner. ❹ **Evaluate the design solution via μ-σ metric. If it is decided not to verify further, go to Step 6.** ❺ **Fully verify with reordered PVT conditions.** Simulate the design solution under the targeted verification method. If the design meets all constraints in all cases, the framework terminates. Otherwise, continue the optimization process. ❻ **Store the worst reward in the replay buffer and update RL agent with data stored in the buffer.** Only the worst reward is stored across PVT conditions.

IV. OPTIMIZATION PHASE OF PROPOSED GLOVA

A. Risk-Sensitive Reinforcement Learning Agent

Risk-sensitive RL [18] is an approach that accounts for stochastic uncertainty within a system. To avoid uncertain and costly failures, agents are trained to maximize the worst-case robustness of the reward. This risk-sensitivity potentially leads to faster learning for unpredictable systems. In GLOVA, a risk-sensitive RL agent is employed to find the desired design solution in a situation where performance metrics fluctuate by various PVT conditions. By treating each variation as a potential risk and adopting a risk-avoidance policy, this approach reduces the cost of numerous simulations required by industrial-level verification methods, such as corner and MC simulations.

Algorithm 1: Risk-sensitive RL in GLOVA

Given replay buffer B^{worst} and the last design $\mathbf{x}_{last}$;
Given actor network $A(\mathbf{x}|\theta^A)$ and critic network $Q(\mathbf{x}|\theta^Q)$ with a set of base models $\{Q_i(\mathbf{x}|\theta_i^Q)\}$;
Given the number of samples N' and the worst corner $\mathbf{t}^{worst}$;
for *iteration = 1, M* **do**
  Sample a batch of $(\hat{\mathbf{x}}, \hat{r})$ from B^{worst};
  for *i = 1, ensemble size* **do**
    Update the base model by minimizing the loss: $\mathcal{L}_{Q_i} = MSELoss(\hat{r}, Q_i(\hat{\mathbf{x}}|\theta_i^Q) + bias)$;
  end
  Update the actor by minimizing the loss: $\mathcal{L}_A = MSELoss(0.2, Q(A(\hat{\mathbf{x}}|\theta^A)|\theta^Q) + bias)$;
  Select a new design according to the current policy and exploration noise: $\mathbf{x}_{new} = A(\mathbf{x}_{last}|\theta^A) + noise$;
  Sample mismatch conditions $\widetilde{H}^{N'}$ via Eq. (3);
  Simulate the $\{\mathbf{x}_{new}|\mathbf{t}^{worst}, \widetilde{H}^{N'}\}$ to get rewards $\{r\}$;
  Select the worst-case reward: $r^{worst} = \min\{r\}$;
  Store the data ($\mathbf{x}_{new}$,r^{worst}) in B^{worst};
end

Reward. The actor-critic agent, which is a widely used method in RL [20], is trained to optimize the multiple performance metrics to meet constraints. To simplify this process, we use a reward function that consolidates multiple objectives into a single target. The reward is defined as follows:

$$r = \begin{cases} r', & r' < 0 \\ 0.2, & r' \geq 0 \end{cases} \tag{4}$$

with r' calculated as:

$$r' = \sum_{i=1}^{m} \min\left(f_i, 0\right) \tag{5}$$

where f_i is the normalized current simulated i^{th} performance metric, defined as $f_i = (c_i - \mathcal{F}_i)/(c_i + \mathcal{F}_i)$, and c_i is the corresponding constraint. As we want $f_i \leq c_i$, a smaller reward indicates a worse design. If all constraints are satisfied, the reward is set to 0.2. This reward formulation is modified from [8], [9].

Actor and critic. The actor is a 4-layer neural network. The actor's input is the previous design $\mathbf{x}_{last}$, a p-dimensional normalized design solution, where each dimension represents a design parameter (e.g. width or length in a transistor). The output of the actor is the next design $\mathbf{x}_{new}$, a p-dimensional normalized design solution. On the other hand, the critic includes a set of 4-layer neural networks, which are called base models. The input of the critic is also a p-dimensional normalized design solution. The critic outputs a scalar value representing the input's predicted reliability bound under various PVT conditions. The process of predicting uncertain design reliability bounds using the base models is detailed in Section IV. B.

Training. Algorithm 1 outlines agent's training procedure. Here, M is the maximum number of optimization iterations. The training process is modified from DDPG [21]. Unlike risk-neutral training, the risk-avoidance process evaluates each design iteration based on worst-case scenarios under sampled PVT conditions. In other words, while multiple rewards are obtained from simulations, only the worst

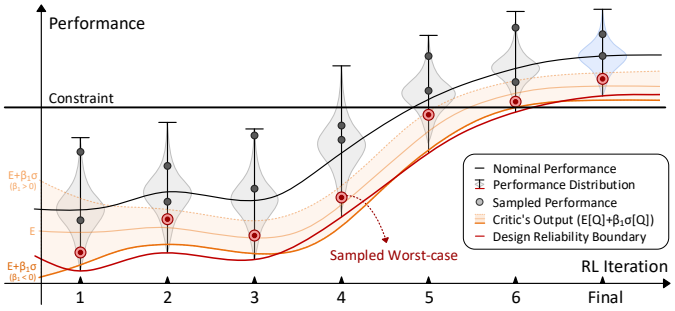

Fig. 3. Design reliability bound estimation under PVT variations using an ensemble-based critic trained on sampled worst-case scenarios.

reward is stored in the replay buffer and used for training. Each of the critic's base models is independently trained with a distinct batch sampled from the replay buffer. The actor is trained to find the desired design solution using the predicted reliability bound, which is derived by aggregating the outputs of the critic's base models.

B. Ensemble-based Critic

In risk-sensitive RL, modeling worst-case scenarios is crucial, yet impractical due to the need for over 1,000 samples per iteration to determine reliability bounds under PVT variations [22], [23]. Therefore, to achieve sample-efficient risk management, we propose an ensemble-based critic that approximates design reliability bounds for variation by sampling worst cases. This approach allows the actor to explore a wide range of variations without simulating each scenario individually, improving sample-efficiency.

The proposed critic extends the risk-sensitive criterion [18] by employing an ensemble of base models. Fig. 3 qualitatively illustrates the modeling of the design reliability boundary with the ensemble-based critic during the optimization process. First, in each iteration, a small number N' (typically 2 to 5) of mismatch conditions $\widetilde{H}^{N'}$ are sampled and simulated under the worst-case corner to capture performance variability. The critic then learns from the worst-case among N' sampled variations, using an ensemble to estimate design reliability bound with awareness of uncertainty. Each base model is trained with different data batches, benefiting from randomness and varying initialization. This process allows the critic to compensate for the uncertainty in the design reliability bound caused by limited statistical samples. The output of critic is defined as follows:

$$Q(\mathbf{x}|\theta^Q) = \mathbb{E}[Q_i(\mathbf{x}|\theta_i^Q)] + \beta_1 \sigma[Q_i(\mathbf{x}|\theta_i^Q)] \tag{6}$$

where $Q_i(\mathbf{x}|\theta_i^Q)$ represents the output of the i^{th} base model with weights θ_i^Q, $\mathbb{E}[\cdot]$ denotes the average of the base model outputs, $\sigma[\cdot]$ refers to the standard deviation of the base model outputs, and $\beta_1 < 0$ is the risk-avoidance parameter. The critic manages risk and provides reliability bounds to guide the actor in finding a feasible design solution.

V. Verification Phase of Proposed GLOVA

Extensive simulations, which are time-intensive, are inevitable to ensure circuit reliability under PVT variations. If a design fails to meet its target during the verification process, a large number of simulations can become an inefficient use of resources. Therefore, to achieve sample-efficient verification, it is crucial to detect failures early and halt the verification process, returning to the optimization phase. To address this, we propose a hierarchical verification algorithm comprising the μ-σ evaluation and the simulation reordering method. The verification workflow of GLOVA is presented in Algorithm 2.

Algorithm 2: Verification Algorithm of GLOVA

```
Given the number of samples N for full verification and a
  subset of samples N';
Sort T based on the last worst-case buffer;
for each t_j in sorted T do
    Sample H̃_j^{N'} from the distribution via Eq. (3);
    Simulate {x|t_j, H̃_j^{N'}} to obtain {r, f_i(x|t_j, H̃_j^{N'})};
    if μ-σ evaluation passes then
        Calculate t-SCORE_j;
        Calculate Pearson correlation coefficient vector ρ_j;
    end
    else
        Verification failed;
    end
end
Sort T by {t-SCORE_j};
for each t_j in sorted T do
    Sample H̃_j^{N-N'} from the distribution via Eq. (3);
    Calculate h-SCORE_{j,n} for each h_{j,n} ∈ H̃_j^{N-N'} and ρ_j;
    Sort H̃_j^{N-N'} by {h-SCORE_n}_j;
    for each h_{j,n} in sorted H̃_j^{N-N'} do
        Simulate {x|t_j, h_{j,n}} to obtain {r, f_i(x|t_j, h_{j,n})};
        if r ≠ 0.2 then
            Verification failed;
        end
    end
end
```

A. μ-σ Evaluation Method

The μ-σ evaluation first analyzes a subset N' of the total N MC simulations under the given corner conditions. Based on this analysis, it determines whether it is worthwhile to proceed with the remaining $N - N'$ simulations for full verification. Specifically, it statistically estimates the performance distribution of the full mismatch condition set $\widetilde{H}^N$ using the pre-sampled subset $\widetilde{H}^{N'}$. The μ-σ evaluation is conducted sequentially across all given corners, starting with the worst corner from the last worst-case buffer. Note that, during the optimization phase, the $\widetilde{H}^{N'}$ for the worst corner has already been simulated and can be reused. If the evaluation fails to pass the criteria set in Eq. (7), the design is deemed to have failed verification. The evaluation criterion is provided by the following equation:

$$e_i = \mathbb{E}[f_i] + \beta_2 \sigma[f_i] \leq c_i \tag{7}$$

where f_i represents the i^{th} normalized performance metric and β_2 is a reliability factor. The reliability factor β_2 is set to a positive value of 4 or higher, as higher values in the performance metric, unlike rewards, indicate worse performance. This reliability factor compensates for the incomplete nature of the distribution caused by a lack of samples. The μ-σ evaluation method conservatively assesses whether a given design is feasible for full verification, reducing the likelihood of verification attempts that would ultimately result in failure. Consequently, this approach saves valuable resources and reduces overall runtime.

B. Simulation Reordering Method

If the design passes the μ-σ evaluation for the N' samples across all given corners, full verification is performed for the remaining $N - N'$ samples for each corner. To detect failure early and halt

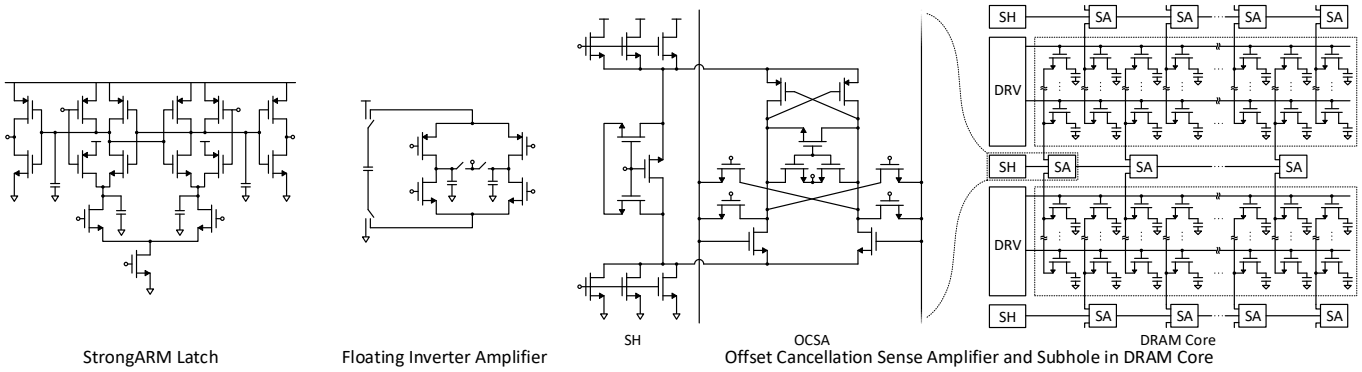

Fig. 4. Schematics of three analog/mixed-signal testcase circuits.

the verification process, the simulation sequence is determined by the proposed corner and MC reordering methods, prioritizing simulations with a higher likelihood of failure.

Corner reordering. For the pre-sampled mismatch condition set $\widetilde{H}_j^{N'}$ of each corner $\mathbf{t}_j$, the $\texttt{t-SCORE}_j$ is calculated to rank the severity of degradation caused by mismatch conditions as follows:

$$\texttt{t-SCORE}_j = \sum_{i=1}^{m} e_{j,i} \tag{8}$$

where e_i is computed by Eq. (7). Corners with a higher t−SCORE, indicating a greater potential for failure, are selected for simulation first.

MC reordering. For the given corner, the simulation list for the remaining mismatch condition set $\widetilde{H}_j^{N-N'}$ is determined. To prioritize the mismatch conditions most likely to result in failure, the Pearson correlation coefficient is introduced to assess the relationship between the mismatch parameters and performance. Specifically, for each $\mathbf{h}_{j,n}$ vector in the pre-sampled set $\widetilde{H}_j^{N'}$, the Pearson correlation coefficient vector ρ_j is calculated between each element of $\mathbf{h}_{j,n}$ and the corresponding performance metric $g_{j,n}$, where $g = \sum_i f_i$, as defined by the following equation:

$$\rho_j = \frac{\sum_{n=1}^{N'}(\mathbf{h}_{j,n} - \bar{\mathbf{h}_j})(g_{j,n} - \bar{g_j})}{\sqrt{\sum_{n=1}^{N'}(\mathbf{h}_{j,n} - \bar{\mathbf{h}_j})^2}\sqrt{\sum_{i=1}^{N'}(g_{j,n} - \bar{g_j})^2}}. \tag{9}$$

Then, the $\texttt{h-SCORE}_{j,n}$ is defined as the weighted sum of the mismatch condition vector $\mathbf{h}_{j,n}$ from the mismatch condition set $\widetilde{H}_j^{N-N'}$ and correlation vector ρ_j, as follows:

$$\texttt{h-SCORE}_{j,n} = \sum_{i=1}^{r} \left[(\mathbf{h}_{j,n})_i \circ (\rho_j)_i\right]. \tag{10}$$

Mismatch conditions with a higher h−SCORE, indicating a greater potential for failure, are prioritized for simulation for the given corner.

By reordering both the corners and mismatch conditions, failures in the verification process can be detected early, effectively reducing the number of unnecessary simulations. This simulation reordering method reduces the verification cost and improves the overall efficiency of the framework.

VI. Results

A. Analog/mixed-signal Circuits

Real-world designs from previous work [8], [9] are adopted as testcases to compare the design efficiency of GLOVA. The testcases include the strongARM latch (SAL) [24] and the floating inverter amplifier (FIA) [25]. These circuits are selected due to their fully dynamic operation, which makes them highly sensitive to PVT variations. Additionally, we include the offset cancellation sense amplifier (OCSA) [26] and subhole (SH) in DRAM core with an $6F^2$ open bitline architecture, which consists of 2K wordlines and peripherals for memory operation [27]. This testcase is particularly challenging due to large parasitic array capacitance and extensive mismatches, which necessitate a significantly higher number of statistical simulations to achieve a high yield. The topologies are presented in Fig. 4.

All testcases are designed using advanced $28\mathrm{nm}$ CMOS technology and simulated with a SPICE-based simulator [15] under 30 PVT conditions, given by $\{\mathrm{TT}, \mathrm{SS}, \mathrm{FF}, \mathrm{SF}, \mathrm{FS}\} \times \{0.8\mathrm{V}, 0.9\mathrm{V}\} \times \{-40\,^\circ\mathrm{C}, 27\,^\circ\mathrm{C}, 80\,^\circ\mathrm{C}\}$. Each circuit comprises multiple transistors and capacitors, where the transistors are defined by parameters such as gate width and length, and the capacitors by their capacitance values. Mismatch parameters are considered for each device, with variances following the PDK rules for the same technology.

StrongARM latch. The sizing vector of this circuit consists of 14 parameters: 6 transistor widths, 6 transistor lengths, and 2 capacitances. The range for each parameter is $[0.28, 32.8]\,\mu\mathrm{m}$ for width, $[0.03, 0.33]\,\mu\mathrm{m}$ for length, and $[0.005, 5.5]\,\mathrm{pF}$ for capacitance with a total design space of 10^{28}. The mismatch parameter includes all devices in the circuit. The performance metrics are power, set delay, reset delay, and noise. The design targets are as follows, which are the same as [9]:

$$c = \begin{cases} \text{Power} \leq 40\,\mu\mathrm{W} \\ \text{Set delay} \leq 4\,\mathrm{ns} \\ \text{Reset delay} \leq 4\,\mathrm{ns} \\ \text{Noise} \leq 120\,\mu\mathrm{V}. \end{cases}$$

Floating inverter amplifier. The sizing vector of this circuit consists of 6 parameters: 2 transistor widths, 2 transistor lengths, and 2 capacitances. The range for each parameter is the same as those of the strongARM latch with a total design space of 10^{12}. The mismatch parameter includes all devices in the circuit. The performance metrics are energy consumption per conversion and noise. The design targets are as follows, taking technology scaling into account in [9]:

$$c = \begin{cases} \text{Energy/conv.} \leq 0.1\,\mathrm{pJ} \\ \text{Noise} \leq 130\,\mathrm{mV}. \end{cases}$$

Offset cancellation sense amplifier and subhole in DRAM core. The sizing vector of this circuit consists of 12 parameters: 6 transistor widths and 6 transistor lengths. The range for each parameter is $[0.28, 1.028]\,\mu\mathrm{m}$ for the transistor width in the OCSA, $[5, 15]\,\mu\mathrm{m}$ for the transistor width in the SH, and $[0.03, 0.06]\,\mu\mathrm{m}$ for all transistor length, resulting in a total design space of 10^{24}. These

parameter ranges are determined with consideration for cell pitch, as the transistors need to be integrated near the cell array. The mismatch parameter includes all devices in the DRAM core. The simulation methods and metrics are based on [27]. The performance metrics are low data sensing voltage ΔV_{D0}, high data sensing voltage ΔV_{D1}, and energy consumption per 1-bit sensing. Note that since both the low and high data sensing voltages are metrics that need to be maximized, their signs are inverted. The design targets are as follows:

$$c = \begin{cases} \Delta V_{D0} \geq 85\,\mathrm{mV} \;\rightarrow -\Delta V_{D0} \leq -85\,\mathrm{mV} \\ \Delta V_{D1} \geq 85\,\mathrm{mV} \;\rightarrow -\Delta V_{D1} \leq -85\,\mathrm{mV} \\ \text{Energy/bit} \leq 30\,\mathrm{fJ}. \end{cases}$$

B. Evaluation and Analysis

To validate GLOVA's design solution across various PVT corner conditions and extensive mismatches, we incorporate three verification scenarios: 30 PVT corner simulations (C), 0.1K local Monte Carlo simulations on 30 PVT corners (C-MC$_L$), and 1K global-local Monte Carlo simulations on 6 VT corners (C-MC$_{G\text{-}L}$). Each method requires 30, 3,000, and 6,000 simulations, respectively, to complete full verification. In our setting, simulations are conducted in parallel with a sample size of 3 during the optimization phase, while the verification phase utilizes the maximum available resources. For training, the batch size is set to 10, and the risk-avoidance parameter β_1 and reliability factor β_2 are set to -3 and 4, respectively.

The optimization results across three real-world circuits are shown in Table II. GLOVA achieves the highest success rate, with up to 80.5× greater sample efficiency and 76.0× lower time consumption compared to PVTSizing and RobustAnalog. Notably, for the OCSA and SH in the DRAM core case, which is verified using the C-MC$_{G\text{-}L}$ method, GLOVA demonstrates 1.9× improvement in success rate and 10.3× improvement in sample efficiency over PVTSizing and RobustAnalog. However, this case appears to consume more RL iterations and simulations than other cases. This is due to the challenge of designing a solution that simultaneously satisfies low data sensing voltage and high data sensing voltage—two conflicting metrics—in scenarios where the DRAM core circuit is highly sensitive to mismatch cases across numerous devices within the cell array.

Table III presents the results of an ablation study conducted on a DRAM core to assess the contributions of the proposed methods. The ensemble-based critic facilitates the derivation of feasible design solutions during the optimization process, improving in both success rate and sample efficiency. Additionally, the μ-σ evaluation and simulation reordering methods effectively reduce the number of simulations required in the verification process, thereby lowering verification costs and enhancing the overall efficiency of the framework.

VII. CONCLUSION

We present GLOVA, an efficient optimization and verification framework that effectively manages diverse PVT conditions and extensive mismatches. GLOVA employs risk-sensitive reinforcement learning and introduces an ensemble-based critic for variation-aware optimization. Incorporating μ-σ evaluation and simulation reordering methods significantly alleviates the simulation burden during verification, improving the overall efficiency of the framework. The proposed GLOVA supports industrial-level corner and Monte Carlo simulations for design verification. Experimental results on real-world circuits, including challenging DRAM core, demonstrate that GLOVA substantially reduces simulation and time costs compared to previous state-of-the-art frameworks.

REMU: Memory-aware Radiation Emulation via Dual Addressing for In-orbit Deep Learning System

Longnv Xu†, Meiqi Wang†, Han Qiu*, Jun Liu, Yuanjie Li, Hewu Li*

***Abstract*—The deployment of commercial-off-the-shelf (COTS) GPUs in space has emerged as a promising approach for supporting in-orbit deep neural network (DNN) inference. However, unlike terrestrial environments, understanding the impact of space radiation on COTS GPU-enabled DNNs is critical. This is challenging because existing methods, such as real-world radiation testing and software emulation, fail to link radiation-induced memory errors to runtime DNN behaviors. In this paper, we propose `REMU`, a memory-aware Radiation EMUlator to fill this gap. `REMU` introduces a dual addressing mechanism across virtual, physical, and DRAM memory spaces, enabling precise mapping and efficient injection of radiation-induced errors from DRAM to runtime DNN inference. Extensive evaluations across 10 well-known DNN models and 2 typical in-orbit computing tasks demonstrate the effectiveness of `REMU`, providing valuable insights for understanding the resilience of runtime DNN inferences on space radiations.**

***Index Terms*—Deep learning, AI on satellites, memory emulation.**

I Introduction

In-orbit computing [1], [2] has emerged as a novel form of "edge computing", where data is processed directly on satellites to reduce downlink bandwidth [3], [4] or to perform latency-sensitive tasks in orbit, such as wildfire monitoring [5]. In order to support complex data processing tasks like deep neural networks (DNNs), a promising trend [6] is to launch commercial-off-the-shelf (COTS) GPUs into space (see statistics from public information in Fig. 1) instead of relying on radiation-harden chips which are not only 10× more expensive [7] but also unable to support DNN inference [8].

However, different from terrestrial edge computing scenarios, COTS GPUs (e.g., NVIDIA NX) without radiation hardening are vulnerable to radiation-induced errors in space. On the one hand, both ESA's 10-year in-orbit experimental records [9] and various ground-based radiation tests [10], [11] have demonstrated that space radiation particles can induce bit flips in COTS memory. These include single-event upsets (SEUs), which flip a single bit, and multiple-cell upsets (MCUs), which flip multiple spatial-correlated bits, occurring at a non-negligible rate (e.g., at least 1×10^{-7}/bit/day [12]). On the other hand, runtime DNN models are especially susceptible since their memory-intensive data flow amplifies the probability of error accumulation during critical computations. Current efforts to investigate radiation-induced errors can be classified into two approaches. (1) Real-world validation rely on beam tests [11] or in-orbit flight experiments [12], which requires significant resources and time (e.g., years in [9]), to obtain physical error distributions on memory cells. However, there is still a huge gap between memory hardware errors and the DNN inference behaviors. (2) Software-based error injection offers a cost-effective alternative [13] but existing tools cannot be directly adopted to evaluate how radiation-induced errors influence COTS GPU-based DNN inference. Particularly, they either rely on complex instrumentation close to the hardware [14]–[16] or adopt naïve error injection in static DNN models [17]–[19], regardless of the characteristics of hardware errors and the runtime dynamics of DNN inference. Therefore, we summarize the challenge as follows: *how to rigorously understand the radiation-induced errors' impact on those COTS GPU-enabled runtime DNN's performance.*

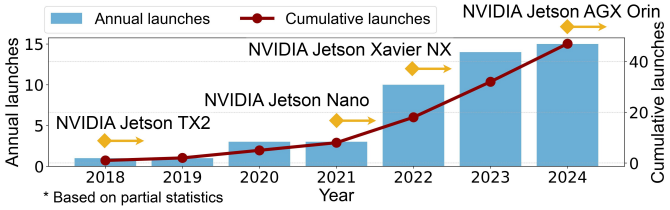

Fig. 1: COTS GPUs launched into space in recent years.

In this paper, we tackle the above challenge by proposing `REMU`, a memory-aware Radiation EMUlator that bridges radiation-induced memory hardware errors to runtime DNN's behavior. (1) `REMU` can *precisely* trace memory bit errors across the system (i.e., from low-level DRAM to high-level process space) to realize an end-to-end error mapping. (2) To *efficiently* navigate error tracking in massive DNN memory usage, we develop a novel dual-addressing mechanism using bitmap-based trees, reducing error injection overhead from $\sim 100\times$ to $\sim 3\times$. (3) `REMU` supports mainstream satellite payload platforms (e.g., TensorRT on NVIDIA Jetson series [20]) but can also be *extended* with other configurations.

Based on `REMU`, we investigate how COTS GPU-enabled DNN inference's performance is influenced by radiation-induced memory errors with 10 well-known DNN models on 2 typical in-orbit computing tasks. Our 3 key findings are as follows. (1) Different DNN model structures exhibit different inherent error-tolerance to radiation-induced errors (i.e., lightweight models such as EfficientNet [21] are more sensitive while compacted models such as ViT [22] are robust). (2) Some uncovered sensitivities in runtime DNN inference can lead to a more severe accuracy collapse (i.e., degrading decision-making to a random guess) than the DNN model's parameter errors. (3) Hardware-layer spatial-correlated errors (i.e., MCU) in memory *cannot* be simplified as multiple single-bit errors (i.e., SEU) since the sensitivity in DNN inference manifests as clustered bits.

II Preliminaries

A. Space radiation is a threat

Harsh space radiation has emerged as a potent "adversary" for in-orbit computing. Satellites in space are surrounded by radiation particles mainly consisting of trapped protons, secondary neutrons from nuclear interactions, and high-energy cosmic rays [13]. Radiation affects in-orbit electronic components, especially the COTS devices that are rarely hardened for lower cost, causing permanent damage (e.g., degradation and burning) or transient damage (e.g., logical state flip) in the unprotected memory[1] [24]. The transient damages,

†Co-first authors.
*Corresponding authors.

[1]The main memory chips in current in-orbit COTS devices mostly lack support for error-correcting code (ECC) and are not protected by other hardening techniques, such as triple modular redundancy and shielding [23].

although seemingly trivial, are more prevalent and threatening for in-orbit computing since they can stealthily inject wrong control logic and data values into the computing process and disrupt the outcomes, such as the decision-making results of DNN inference. These errors in memory can be classified into two categories.

Single-event upset (SEU) is induced by ionizing radiation striking that makes electron-hole pairs in transistor gates generate and diffuse, causing a state alteration in a memory cell, i.e., a single-bit error. The probability of SEUs can reach 10^{-7} to 10^{-6}/bit/day [9]. Even one SEU may damage the performance of in-orbit DNN inference.

Multiple-cell upset (MCU) occurs when neutron particles react with impurities and produce a large number of secondary particles with sufficient energy [25], leading to multiple memory cells flipped simultaneously as shown in Fig. 2, i.e., a spatial correlated multi-bit error. In space, MCUs happen more frequently in COTS due to the advanced nanotechnology and more compact chips in size [25].

Existing research [26] has shown that the reliability of DNN inference is fragile as bit-flips can result in *stealthy* wrong inference results without crashes, which may compromise safety-critical in-orbit applications, such as disaster monitoring and ship detection [27]. Thus, a practical emulation of SEU/MCU errors in DNN inference is significant to discover its sensitivity at scale.

B. Memory system of COTS GPUs on satellites

To emulate the radiation-induced errors, especially spatial correlated MCUs from the low-level memory cells to the upper process space of DNN inference, precise memory system modeling is essential. We consider a commonly-used payload, NVIDIA Jetson Xavier NX [28] with 16GB 128-bit LPDDR4 (JESD209-4 [29]) as its main memory. The modeling bridges the process space to the dynamic random access memory (DRAM) via hierarchical addressing. First, the memory management unit (MMU) translates virtual addresses in the process space into physical addresses by mapping virtual pages to physical frames using memory paging. Second, the memory controller (MC) translates physical addresses into DRAM and accesses the data.

As shown in Fig. 2, DRAM typically consists of six hierarchies, including die, channel, rank, bank, array, and cell. LPDDR4 [29] defines dual-channel dies with 16DQ (data I/O pins for parallel data transfer) per channel of varying memory densities, such as 16Gb. To enhance data parallelism, multiple dual-channel dies can be employed (e.g., 128-bit LPDDR4 utilizes 8 dual-channel dies). Each DARM channel consists of multiple banks, and each bank contains three-dimensional arrays: row-, column-, and DQ-dimension. DRAM cells are organized into arrays, with each cell using a capacitor to store logical states (charging to represent logic 1 and discharging to represent logic 0) and a transistor to control access to the capacitor during read and write operations. Besides, MCU's adjacency manifests in three dimensions: consecutive rows sharing the same bitline, consecutive columns sharing the same wordline, and consecutive DQ bits in a logical word.

C. Existing emulation methods

The practical emulation of radiation-induced errors requires addressing the complex interaction between hardware errors and application behavior, making it challenging to balance *efficiency* and *extensibility*. Most existing emulations focus on injecting errors closer to the hardware (mainly targeting registers and computing pipelines rather than DRAM), such as at the intermediate representation [14], the low-level assembly [15], or the microarchitecture [16]. Although these methods are extensible to most upper applications, the complexity of use leads to inefficient error injection and limits their adaptability for sensitivity analysis of runtime DNN inference.

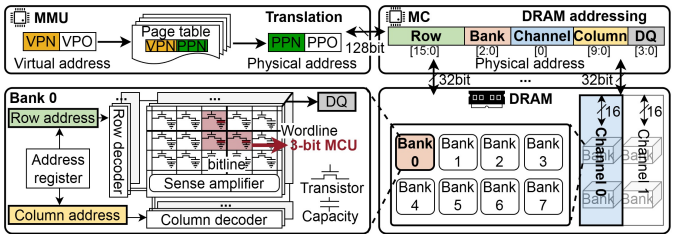

Fig. 2: Hierarchical addressing from process space to DRAM by two steps: translation and DRAM addressing. Detailed organization in a DRAM bank shows MCU's adjacency in three dimensions.

To be more specialized, many error injection tools tailored for deep learning (DL) frameworks have been proposed with expert knowledge, such as TensoFI [17], PyTorchFI [18], and Ares [19]. These methods inject random bit-flip errors directly in DNN models' weights and feature maps for different DL frameworks (e.g., TensorFlow [30] and PyTorch [31]). Although these methods are efficient due to targeted injection in small-scale values, the *offline* model-level error injection lacks critical insights into the runtime process space, such as optimized data flow and actual memory allocation. Thus, it fails to extend to other applications and also misses sensitive points in DNN inference. Besides, all existing methods overlook the impact of spatial correlated MCUs in memory, causing a lack of *correctness*. Thus, we fill the gap to balance the efficiency and extensibility, and also intensify the correctness in our emulation (Sec.III).

III REMU framework

A. Overview

To explore reliable DNN inference under space radiation, emulation of radiation-induced bit-flip errors (i.e., SEUs/MCUs) is imperative. However, existing error injection tools [17]–[19] overlook the spatial correlation of MCUs, leading to impractical error models. To address the gap, we propose `REMU` (see overview of `REMU` in Fig. 3) to precisely trace SEU/MCU errors from low-level DRAM to high-level process space. `REMU` has three main goals to achieve. (1) Correctness: SEU/MCU errors occurring in the DRAM must be precisely addressed in the upper DNN inference (Sec.III-B). (2) Efficiency: error injection should be fast to facilitate large-scale testing (Sec.III-C). (3) Extensibility: the emulation should extend to various DRAMs and radiation-induced error models (Sec. III-D).

B. DNN to DRAM mapping

To precisely inject SEU/MCU errors during runtime DNN inference, the DNN should be first mapped to DRAM. We observe that the process space of DNN inference is vast and radiation-induced SEU/MCU errors are unpredictable. Thus, we simplify the mapping by focusing exclusively on the *inference-critical*, *time- and memory-intensive* DNN engine (i.e., an optimized runtime DNN model used to execute inference, more details are in Sec.IV-A), which is allocated in the main memory. We realize the mapping via two steps.

First, we leverage the kernel interface (e.g., */proc/pid/pagemap*[2]) to translate the userspace virtual addresses to physical addresses (❶ in Fig. 3). In modern memory management, such as memory paging, allocations are separate due to the fragmented and limited physical memory left when the process is running. Thus, a contiguous virtual memory space of the DNN engine is typically allocated to scattered physical frames (constituting a huge space) with the order varying

[2]https://www.kernel.org/doc/Documentation/vm/pagemap.txt in Linux.

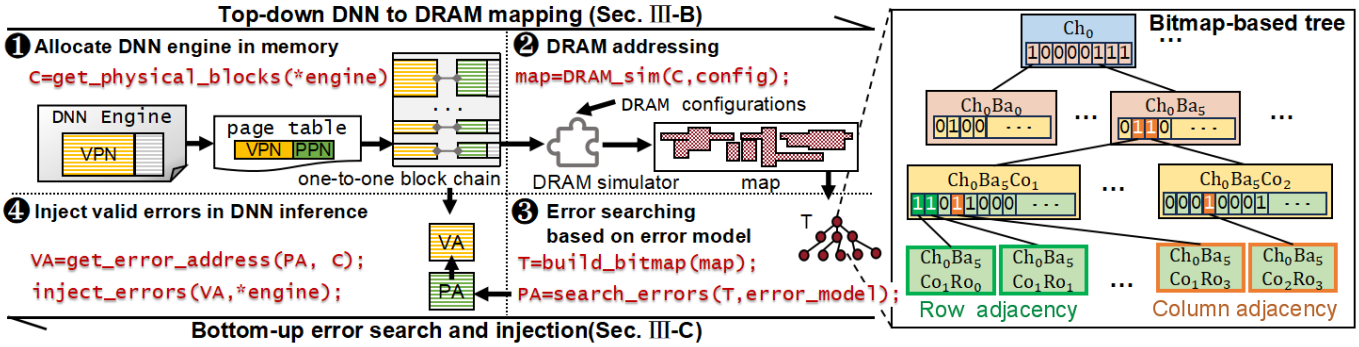

Fig. 3: Overview of REMU for four-step error injection: ❶ Allocate DNN engine's process space to physical blocks and construct a one-to-one mapping chain of virtual and physical blocks. ❷ Configure the DRAM simulator and perform DRAM addressing based on the addresses in physical blocks to get a vast memory space (i.e., map). ❸ Build the bitmap-based tree based on the physical blocks and search spatial adjacent errors in DRAM via traversal. ❹ Reveresely convert valid error physical addresses (PA) to DNN inference's process space (VA).

from the virtual pages. We construct a one-to-one mapping chain of virtual and physical blocks via the process-context page table.

Second, we leverage the correctness-verified extensible DRAM simulator, Ramulator [32], to address the translated physical memory space in DRAM (❷ in Fig. 3). This benefits from generalized modeling of the DRAM system and extending by configurable DRAM standards (e.g., LPDDR4 [29] in this paper) and DRAM addressing. We improve it to further support the emulation of error injection in DRAM. Specifically, we determine the range of each DRAM level based on the target physical memory space. For example, in a 4KB space, only the lowest 12 bits of the physical address serve for addressing, typically containing 2^0 row and 2^8 columns in LPDDR4. Then, SEUs/MCUs can be emulated in the range and flip the corresponding bit in the virtual memory space. The above two-step extraction from a real memory system can achieve the correct mapping from DNN inference to DRAM.

C. Dual addressing

When executing DNN inference, memory accesses follow a top-down manner from the virtual memory space, translating to the physical memory space, and finally addressing the DRAM cells (Sec.III-B). However, when radiation-induced errors occur in DRAM, their impact on DNN inference flows in an opposite direction. The fragmented physical blocks cause those random errors to get lost in the wilderness (i.e., a vast physical memory space irrelevant to DNN inference). Thus, REMU introduces a dual addressing mechanism utilizing bitmap-based trees to optimize the addressing process and narrow the searching space of relevant errors, which can efficiently inject SEU/MCU errors in DNN inference among the tremendously vast physical memory space (❸ in Fig. 3).

Bitmap-based tree. We establish the bitmap-based tree by traversing all physical address blocks and performing DRAM addressing of these addresses, in which each level of the tree represents a DRAM level and each node in the level contains a bitmap to index the next level. For example, the bitmap 10000111 in Ch_0 indexes $Ba_{0,5,6,7}$, indicating that these banks in the channel are associated with the physical blocks allocated by the DNN inference engine, in which errors are valid. As mentioned in Sec.II-B, MCU's adjacency manifests in three dimensions: rows, columns, and DQs. For a fast search, we place the *static* bank and channel levels closer to the root and the *dynamic* row, column, and DQ levels closer to the leaves. Thus, the subsequent adjacency checks of low-level nodes (i.e., row and column) will not impact the initial fast selection of high-level nodes (i.e., channel and bank) in a *depth-first traversal*. The search for a valid error mainly consists of two steps as illustrated in Fig. 3.

First, randomly select a high-level node based on its parent's bitmap. For example, select Ba_0 based on the bitmap in Ch_0. Second, select a low-level node based on the error type. 1) For SEU, the selection of a row and column is the same as the high-level node. 2) For column- and row-adjacent MCUs, the selection of columns and rows is based on the adjacency indices (i.e., 11) in their parent's bitmap. If no adjacency is found in the bitmap, the adjacency check will be continuously performed on the parent's sibling nodes adhering to the depth-first principle. Once the adjacent columns are determined, the rows at the next level can be selected based on the bitwise *AND* operation of these columns' bitmaps. This two-step search can efficiently identify a valid SEU/MCU error in DRAM. However, if only one error is searched per traversal, injecting multiple errors remains costly. Thus, we calculate the memory size of the sub-tree for each high-level node and assign the number of errors layer by layer, starting from the root. For example, Ch_0 has 10M address space and Ch_1 has 20M, approximately 1/3 of the SEUs/MCUs falling in Ch_0 and 2/3 in Ch_1. Therefore, all errors can be searched in a single depth-first traversal.

After error searching in physical memory space, we obtain a series of valid physical addresses that store data relevant to DNN inference, which should be further converted into valid virtual addresses using the previously mentioned one-to-one mapping chain between virtual and physical blocks (❹ in Fig. 3). Additionally, We optimize the mapping by combining several consecutive physical blocks into a large one, thereby further reducing the search complexity.

Complexity analysis. By decomposing the vast linear physical memory space into a nonlinear, bitmap-based tree, the complexity of error searching is significantly reduced. The reasons are two-fold. First, building a tree based on valid physical addresses and searching within it can eliminate the time overhead caused by rechecking invalid errors. Second, spatially adjacent MCUs in DRAM may span distant addresses due to data parallelism and row addressing by high bits of the physical address, making them tricky to map with a simple linear structure. Specifically, the complexity of error searching consists of two parts: error searching in the bitmap-based tree, and error converting from physical address space to virtual address space. The first one reduces from $O(mn)$ to $O(n)$, where n represents the number of valid physical addresses and M denotes the number of attempts on invalid addresses (e.g., for $k = 100$, m typically exceeds 30,000). The second one reduces from $O(n)$ to $O(s)$, where s represents the number of physical blocks (typically thousands in practice) with $O(1)$ addressing within each block using offsets.

D. Extension for usage

REMU requires extensive characterization of the target DRAM device and error model, which is achieved by user-friendly configurations. Following [32], we use external files of the target DRAM device (e.g., *DRAM standard file* and *DRAM addressing file*) as inputs to set up the DRAM simulator. For the default error model evaluated in this paper, we statistically configure SEUs and MCUs based on the extensive in-orbit and ground radiation tests [11]. SEUs are spatially independent and thus can be modeled as random bit-flips. MCUs are spatial adjacent along three dimensions (i.e., row, column, and DQ) with varying multiplicity (e.g., typically ranging from 2-bit to 8-bit), proportions, and patterns. For instance, the probability of flipping two DRAM cells along one wordline is higher (80%) than along one bitline (20%) [11]. The default error model is a combination of SEUs and MCUs with more details in Sec.IV-A. Finally, we pursue REMU in ease of use via source code instrumentation linking with $libREMU_mem.so$ library to automate memory addressing and inject SEUs/MCUs in the runtime DNN inference.

IV Experiments and results

A. Setup

DNN models. We describe the DNN baselines used for evaluating the effectiveness of REMU in uncovering radiation-induced sensitivities. Table I lists 10 commonly-used DNN models we evaluate. We target the classical Earth observation dataset, RESISC45 [33], and 7 DNN models for image classification tasks in orbit. We perform an extensive evaluation of diverse DNN backbones, covering traditional CNN-based (e.g., ResNet-50 [34], DenseNet-161 [35]), recent transformer-based structures (e.g., ViT [22]), also the lightweight models widely used on resource-constrained edge (e.g., EfficientNet [21] and MobileNet [36]), and later CNN/MLP variants (e.g., ConvNext [37] and MLPMixer [38]). Furthermore, we leverage a large-scale dataset, DOTA [39], and 3 variants (i.e., small, medium, large) of a practical DNN detector, YOLOv5 [40], for object detection tasks in orbit.

DNN engines. All evaluated DNN models are converted into TensorRT engines [20] and inferred on real satellite payloads, NVIDIA Jetson Xavier NX [28] with 16GB 128-bit LPDDR4 [29], using TensorRT runtime [20]. A prerequisite step of inference is to convert the trained DNN model from a DL framework (e.g., PyTorch) into optimized data flow graphs and build inference engines (in the main memory[3]). The TensorRT runtime then creates an execution context from the engine with input and output buffers in preparation for inference. Thus, the engines are crucial for the reliability of DNN inference. Table I shows the size of each engine allocated in memory in preparation for processing one input, which is a good indicator of the memory intensity of each DNN inference. Additionally, the accuracy of all DNN models' inferences without any error is listed in Table I. We further employ low-precision INT8 types to represent quantized floating point values (both parameters and activations) and utilize posting-training quantization to create quantized DNN engines. This can achieve faster execution speed ($\approx 4\times$) and lower memory usage ($\approx 1/4$) than full-precision, although incurring a slight accuracy degradation, which is not the priority of our study.

REMU configurations. We account for the bit error rate (BER) and the error model when injecting errors in runtime DNN inference via REMU. We set BER at 10^{-7} and 10^{-6} based on the statistics of existing real-world radiation tests [11], and the number of bit errors depends on the memory intensity of each inference, i.e., the size of each engine in this paper. The radiation-induced error model is a configurable input of REMU. In Sec.IV-B, we use the default one (Sec.III-D), to evaluate the error tolerance, which is a mixture of SEUs and MCUs. Fig. 5 shows the detailed proportion of SEUs/MCUs and multiplicity of MCUs for each BER and DNN model. Typically, the proportion of SEUs is higher than 90% and the proportion of $\geq$3-bit MCUs is significantly less than SEUs and 2-bit MCUs. In Sec.IV-C, we apply six additional error models to illustrate the impacts of MCUs. To better understand REMU's memory-aware error injections, we show a case in Fig. 4. We locate the emulated SEUs and MCUs in both the virtual and physical address space. Specifically, we visualize the lifecycle of two MCU examples during REMU's emulation from the DRAM cells to the inference process, which benefits the precise location of MCUs. Note that we use the default DRAM addressing without interleaved mode [41], thus the bits in an MCU will be kept in one contiguous physical address block. Other address mappings can be customized in REMU like [32].

TABLE I: DNN models used in our evaluations. The listed engines are optimized by TensorRT [20] for both FP32 full-precision and INT8 low-precision quantization.

Dataset	Model	Engine size		Baseline accuracy	
		FP32	INT8	FP32	INT8
RESISC45	ResNet-50	115MB	24MB	96.7%	96.6%
	DenseNet-161	144MB	32MB	96.0%	95.0%
	EfficientNet	18MB	6.9MB	91.8%	87.2%
	MobileNet	9.6MB	3.6MB	93.0%	92.2%
	ViT	328MB	107MB	97.1%	95.6%
	MLPMixer	227MB	63MB	95.7%	93.8%
	ConvNext	108MB	30MB	96.8%	93.1%
DOTA	YOLOv5s*	48MB	11MB	81.2%	76.2%
	YOLOv5m*	129MB	28MB	80.4%	75.8%
	YOLOv5l*	294MB	54MB	76.6%	77.3%

*Object detection uses mean average precision (mAP) instead of accuracy.

B. Error tolerance of DNN baselines

To better understand the error tolerance of each DNN model and explore the effectiveness of REMU in identifying sensitivities during each DNN inference, we conduct an extensive evaluation under millions of REMU's error injection. This shows us how differences in BERs, quantization, DNN models, error locations, and error models (Sec.IV-C) can potentially affect the reliability of DNN inference. To our knowledge, this is the first demonstration of DNN inference's error tolerance on runtime memory under near-to-real radiation-induced error emulation, which benefits from REMU's *practical error models* and *precise memory addressing*.

Avoid crashes. Fig. 7 illustrates the impact of SEU and MCU errors on the accuracy of DNN inference. We use REMU to execute 1000 error-injected inferences per BER per DNN model and show the average accuracy. However, we observe a high probability of crashes (e.g., aborts, CUDA failures) during runtime error injections when considering the entire space of the inference engine, which is not our concern. Our concern is a more stealthy error behavior with seamlessly completed inference but wrong results, making errors more difficult to discover. By dumping the engine, we find that errors at the end of the engine[4] are more likely to activate a crash. Therefore, we additionally omit these areas from the engine and evaluate the error tolerance of DNN inference when errors are located in the remaining space (the majority), denoted as *parameter space*

[3]In NVIDIA Jetson Xavier NX, the main memory and GPU memory are physically unified. So no typical data copy/transfer between them is needed.

[4]Engine's serialized format is close-sourced. By dumping the engine, We infer that its end likely contains network definition, engine metadata, executable code of CUDA kernel, etc., associated with inference.

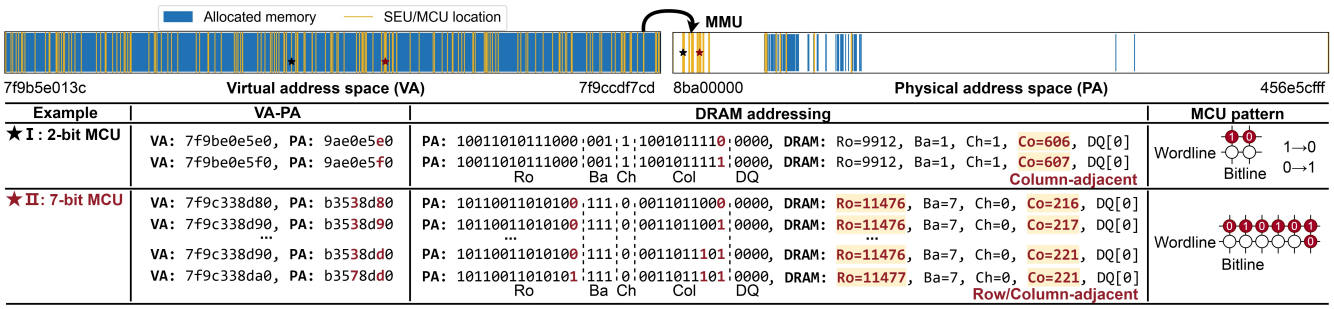

Fig. 4: A case of REMU's error injection. We use REMU to inject SEUs/MCUs in ResNet-50's runtime inference under 10^{-6} BER and the default error model. We show the continuous virtual address space of the inference engine allocated in the main memory and the corresponding discrete physical address space. The seemingly scattered SEUs/MCUs are more clustered in the physical address space. Besides, we give two MCU examples (e.g., 2-bit and 7-bit MCUs) to illustrate the REMU's precise memory addressing from the upper-level process space to the low-level DRAM cells in both row- and column-adjacency.

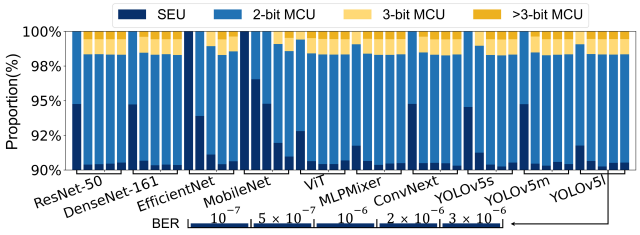

Fig. 5: The proportion of SEUs and the MCUs with different multiplicity in the default error model used for each DNN model and BER. The y-axis is the proportion and the x-axis corresponds to the DNN models (5 BER settings for each).

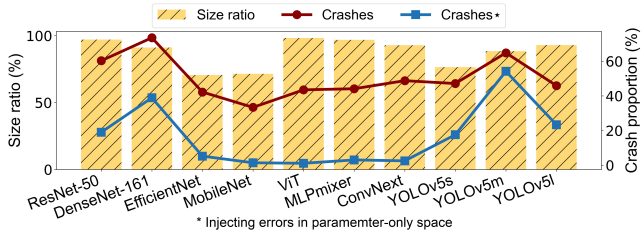

Fig. 6: The left y-axis represents the ratio of the parameter space size to the overall engine size. The right y-axis is the proportion of crashes observed in 1000 inferences. The x-axis corresponds to the DNN models.

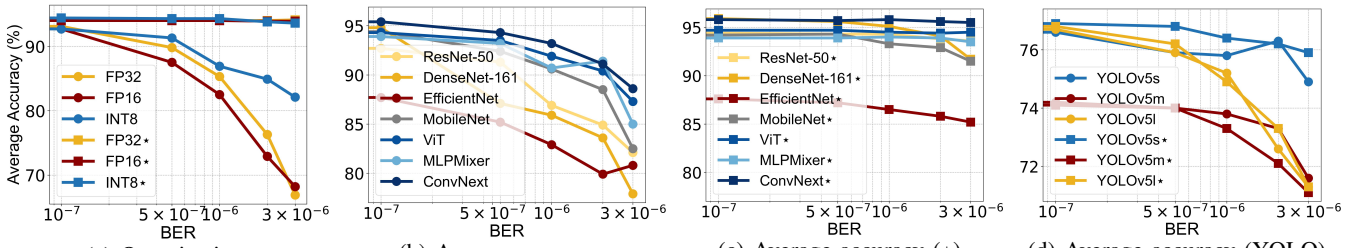
(⋆), which results in fewer crashes. Fig. 6 lists the size and crash occurrence of the parameter space compared to the overall engine for each DNN model. Even with this additional evaluation, we underscore that injecting the overall engine is more realistic, as radiation can affect any memory space. When evaluating the overall engine, we skip the crashes and only record the completed inferences.

Quantization. Fig. 7a shows that precision affects the error tolerance of DNN inference, however, the results are not as expected when injecting errors solely in parameter space (⋆), indicating that the engine additionally holds critical data related to inference beyond the parameter space, which is overlooked in previous model-level error injection tools [17]–[19]. FP32 and FP16 precision exhibit a weaker error tolerance than INT8 precision due to the larger data range and fragile exponent bit. In the following, we focus on INT8 precision as a more challenging case for error attribution.

Accuracy collapse. Fig. 7 shows that the average accuracy declines across almost all DNN models as the BER increases. We observe a significant accuracy drop when injecting errors in the overall engine. For example, the average accuracy drops 18% in DenseNet-161 under 3×10^{-6} BER. If the BER continues increasing, the average accuracy will drop dramatically. Besides, Table II lists the minimum accuracy that occurred during tests, which means DNN inference may experience severe accuracy collapse under radiation-induced errors. Almost all DNN models may be degraded as random guesses (i.e., below 5%) even under a very low BER.

Takeaways. We demonstrate REMU 's effectiveness in robust model selection and sensitivity discovery, providing insights for radiation testing and hardening before in-orbit deployment.



First, REMU can support all DNN models and select a better one balancing efficiency, accuracy, and tolerance. In Fig. 7b, REMU reveals that different DNN models exhibit varying sensitivity, e.g., DenseNet-161 (-18%) is more sensitive than ViT (-6%). We observe that the smaller the model, the more sensitive it is. ViT and MLPMixer are relatively more robust but less efficient than the lightweight EfficientNet and MobileNet. Conversely in YOLOv5, the small variant is less sensitive but may suffer a more severe accuracy collapse (i.e., 5.4%) than the medium/large. Therefore, when in-orbit edges lean towards smaller models due to resource constraints, we advocate greater efforts on the error tolerance of these models.

Second, REMU can effectively expose the undiscovered sensitivity in the engine. The accuracy collapse in Table II can be located in the engine for further protection. In the parameter space, different models have different locations. For instance, the collapse (27%) occurs in the No.4 layer of EfficientNet but in the No.2 layer of ResNet-50. Beyond the parameter space, the most severe collapse below 5% consistently occurs between two layers in the network definition at the end of the engine as illustrated in Table IIa. These special errors are not intuitively in parameters but auxiliary runtime logic related to the computation of inference. The collapse of 4% highlighted in blue results from the final output buffer not being processed and remaining initialized 0 due to errors. For YOLOv5, such collapse is rare because the post-processing in object detection will further filter out the abnormal output.

C. One MCU does not equal to multiple SEUs

To further investigate the superiority of REMU's memory awareness over previous random error injection [17]–[19], we evaluate the in-depth impact of MCUs that rely on precise addressing of adjacency. If MCUs are not considered (i.e., the proportion is 0), REMU will effectively degrade to random error injection. This is the first to exploit the MCU's impact on DNN inference.

The proportion of MCUs considered in the above default error model is 4%, among which 2% 2-bit MCUs, and 2% 3-bit MCUs. In this evaluation, we set six additional error models with different MCU multiplicities and proportions under the same BER: no MCUs, 50% 2-bit MCUs, 33% 3-bit MCUs, 25% 4-bit MCUs, 20% 5-bit MCUs, and 14% 7-bit MCUs. Fig. 8 shows that the increase in MCU proportion and multiplicity intensifies the reduction of average accuracy. These results are due to aggregated MCUs hitting nearly continuous sensitive bits of DNN inference, especially when the MCU

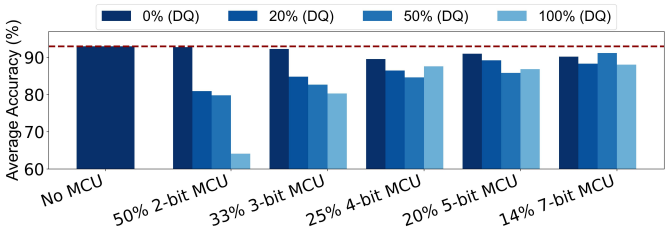

Fig. 8: MCUs' impact on ResNet-50's inference: x-axis is the 6 novel error models with different MCU multiplicities and proportions. For each error model, we set 4 probabilities of MCUs that occur along DQ. The y-axis is the 1000 inferences' average accuracy (10^{-7} BER).

TABLE III: Example of a byte in ResNet-50 inference engine: the accuracy under an SEU error at each bit and the accuracy under a 5-bit MCU error along the DQ-dimension.

Byte (01000001): Accuracy								
0	1	2	3	4	5	6	7	5-bit MCU
94%	42%	42%	42%	42%	42%	94%	94%	**9%**

diffuses along DQ, in addition to the DRAM rows and columns. We find that bits within a byte (i.e., along DQ) always exhibit identical high sensitivity. For example in Table III, almost every bit in some byte can lead to an accuracy drop, and together resulting in a more severe collapse 9%. To explore these sensitivities, we configure REMU to enable DQ-dimensional MCUs (i.e., set the probability of DQ-dimension greater than 0). Fig. 8 compares MCUs without DQ-dimension and with DQ-dimension of different probabilities for each novel error model. Please note that the proportion of MCU's DQ-dimension diffusion can be modeled via radiation tests. We propose preliminary insights and set the proportion to 0%, 20%, 50%, and 100% in this paper. DNN inference under increased errors along DQ generally shows a worse average accuracy. These results underscore that the introduction of memory addressing in REMU substantially supports the MCU's precise emulation, which is not equal to multiple SEUs and, therefore, can effectively expose more sensitive locations for further protection, such as aggregated sensitive bits.

D. Other results and discussions

Benefiting from the optimization via the bitmap-based tree, the efficiency of error injection is greatly improved. We test the completion time of DNN inference before/after error injection, also with/without the optimization. The result shows that error injection without optimization introduces a $67.1 - 99.8\times$ completion time increase while the overhead reduces to $3.1 - 3.5\times$ with the optimization. The above findings reveal that runtime DNN inference is highly sensitive to spatially correlated MCU errors and runtime logic. We hope our lessons can foster more academic and industrial efforts on reliable orbital DNN inference, such as allocating critical bits into different memory banks and leveraging detection on output buffers. Our future work will evaluate the sensitivity of DNN inference beyond DRAM and the engine, focusing on instructions and intermediate results.

V Conclusion

This paper designs a memory-aware emulator, REMU, to emulate radiation-induced bit-flip errors, i.e., SEUs and MCUs, and investigate their impact on in-orbit DNN inference. We demonstrate that existing emulation tools either lack easy usage or fail to precisely trace spatially correlated bit errors in memory across hierarchical systems. REMU achieves both correctness and efficiency by precise modeling of the memory system and leveraging the bitmap-based tree for dual addressing to reduce the complexity of large-scale error searching. Based on REMU, extensive experiments are conducted to understand the error behavior of runtime DNN inference, which can benefit the selection of robust model, and sensitivity discovery of the DNN before deployed in orbit.

***Abstract*—Thermal management in 3D ICs is increasingly challenging due to higher power densities. Traditional PDE-Solving based methods, while accurate, are too slow for iterative design. Machine learning approaches like FNO provide faster alternatives but suffer from high-frequency information loss and high-fidelity data dependency. We introduce Self-Attention U-Net Fourier Neural Operator (SAU-FNO), a novel framework combining self-attention and U-Net with FNO to capture long-range dependencies and model local high-frequency features effectively. Transfer learning is employed to fine-tune low-fidelity data, minimizing the need for extensive high-fidelity datasets and speeding up training. Experiments demonstrate that SAU-FNO achieves state-of-the-art thermal prediction accuracy and provides an 842× speedup over traditional FEM methods, making it an efficient tool for advanced 3D IC thermal simulations.**

***Index Terms*—Thermal modeling, Self-Attention, Fourier Neural Operator, Transfer Learning.**

I. Introduction

Thermal simulation in Electronic Design Automation (EDA) is essential as integrated circuit technology advances. Compared to traditional 2D and 2.5D designs, 3D integration has higher power density, making it more susceptible to overheating and hot spots, which can degrade performance and shorten chip lifespan [1]–[4]. Efficient thermal management and rapid simulation tools are therefore vital for layout optimization and reliability [5].

3D chip thermal simulation involves solving the 3D heat conduction PDE. Traditional methods like the Finite Element Method (FEM) and Finite Difference Method (FDM), as used in tools like Ansys Icepak, Celcius, COMSOL, and MTA, are accurate but often too slow due to the complexity of mesh partitioning and PDE solving, limiting their use in iterative design optimization [6]–[8].

With the rise of artificial intelligence, ML-based approaches have gained attention in thermal simulation [9]–[14]. For example, [15] introduced a CNN model for temperature field prediction, but purely data-driven methods lack physical interpretability and need extensive training data.

PINN [16], which parameterizes PDE solutions directly through neural networks, has been used for various heat transfer problems [17], [18]. Its main advantage is embedding physical laws into the learning process for consistent results. However, PINN models require retraining for different system instances due to their fixed geometry, limiting scalability in 3D IC thermal simulations. DeepOHeat [19] improved this by combining PINN with operator learning to map power distribution and heat transfer, though at the cost of long training times. Despite leveraging DeepONet's [20] grid-invariance, training duration remains a significant challenge.

FNO uses Fast Fourier Transform (FFT) [21] to approximate PDEs, making it more consistent with physical laws than CNNs. It performs well in the Darcy flow and the Navier-Stokes equation. The resolution-invariant capability ensures FNO's adaptability to different chip sizes, a key advantage in thermal simulations [22], [23]. Recent work, such as MLA-FNO [24], improves precision and speed by combining active learning and FNO. However, FNO methods are limited by two significant challenges. First, its tendency to neglect high-frequency components results in notable errors. Secondly, FNO still demands considerable high-fidelity simulation data for effective model training.

Inspired by U-Net's ability to preserve multi-scale features through skip connections [25], [26] and self-attention's [27] capacity to capture long-range dependencies, we integrated these mechanisms with the FNO for 3D IC thermal modeling. This combination significantly improves the accuracy of thermal predictions, particularly in capturing local temperature variations and high-frequency details, leading to more precise thermal management and design. Additionally, we leverage transfer learning [28] by fine-tuning the model trained with low-fidelity data, further improving performance and reducing the data requirements. This approach enhances the accuracy of thermal predictions, particularly in capturing local temperature variations and high-frequency details, and addresses the inherent challenge of data scarcity in machine learning applications. Our key contributions are as follows:

- We propose a novel operator learning architecture, **S**elf-**A**ttention **U**-Net **F**ourier **N**eural **O**perator (**SAU-FNO**), that integrates attention mechanisms and U-Net with FNO to enhance 3D IC thermal modeling, particularly in capturing high-frequency information, making it better suited for 3D IC thermal simulations.

[†] Corresponding authors. This work was partially supported by "Science and Technology Innovation in Yongjiang 2035" (2024Z283) and by research support from BTD Inc.

- We incorporate transfer learning to fine-tune the model with low-fidelity data, which avoids reliance on high-fidelity data while achieving competitive accuracy.
- Extensive experiments demonstrate that our method achieves state-of-the-art (SOTA) results, with metrics Mean Squared Error (MSE) reduced by over 50% compared to other approaches.
- SAU-FNO achieves significant computational acceleration, delivering over 842× speedup compared to mainstream commercial software such as COMSOL and MTA, while maintaining comparable accuracy.

The rest of the paper is structured as follows. Section II provides the background and preliminaries of thermal modeling and related technology. Section III describes the proposed SAU-FNO in detail. Section IV presents the experimental results, and Section V summarizes the paper.

II. Background

A. Thermal modeling of 3D IC

The core of 3D IC thermal analysis is simulating heat conduction. Thermal analysis tools compute temperature distribution across the chip based on power routing and key physical parameters like chip layout and stack geometry, enabling accurate heat distribution evaluation and thermal management optimization. The main challenge lies in solving the global heat conduction PDEs:

$$\sum_{i=1}^{3} \frac{\partial}{\partial y_i}\left(k\frac{\partial T}{\partial y_i}\right) + Q_g = \rho c_p \frac{\partial T}{\partial t}, \tag{1}$$

Where C_p, ρ, and k are the capacity, mass density, and thermal conductivity of the material, respectively. Q_g and T stand for the rate of internally generated energy per unit volume at any spatial-temporal location and the temperature.

For simplicity, we consider a steady temperature field of isotropic materials, simplifying the equation as follows:

$$C_v \frac{dT}{dt} = k\nabla^2 T + Q_g, \tag{2}$$

Where C_v represents the volume heat capacity of a substance, $\frac{dT}{dt}$ represents the rate of change of temperature with time, k represents the thermal conductivity, $\nabla^2 T$ represents the Laplacian operator, and Q_g the rate of production of heat inside the control volume represents the volume heat generation rate.

We consider the steady-state simulation problem and get the following simplified formula:

$$k \cdot \nabla^2 T + Q_g = 0 \tag{3}$$

the temperature distribution $t(x)$ of 3D IC is governed by the boundary condition, where Robin condition and Neumann condition are adopted:

$$\begin{aligned} \kappa(x)\nabla t(x) \cdot n &= g(x) \\ \kappa(x)\nabla t(x) \cdot n &= \eta(t_a - t(x)) \end{aligned} \tag{4}$$

where $t(x)$ represents the temperature at position x, η is the thermal transmissivity. $f(x)$ denotes power trace distribution.

B. Fourier Neural Operators

Neural networks excel at learning mappings in finite-dimensional spaces but struggle with parameter or boundary condition variations, limiting generalizability. Neural operators address this by learning mappings between function spaces. The Fourier Neural Operator (FNO) efficiently maps initial conditions to PDE solutions, making it valuable for complex physical problems.

The operator mapping is mathematically described as:

$$\mathcal{G} : \mathcal{U} \to \mathcal{V}, \tag{5}$$

where $\mathcal{G}$ maps inputs from the function space $\mathcal{U}$ to outputs in $\mathcal{V}$. This mapping generalizes across various input scenarios within these spaces, not confined to single instances.

FNOs leverage FFT to map PDE solutions into the frequency domain, enhancing generalization and computational speed compared to traditional models like CNNs. Their resolution invariance and scalability make them ideal for fluid mechanics (e.g., Navier-Stokes equations) and efficient for large-scale 3D IC thermal simulations across varying chip sizes and grid resolutions.

The core functionality of FNOs involves transforming the input function $u_\ell(x)$ through a series of layers, each performing the operation:

$$u_{\ell+1}(x) = \sigma\left(W u_\ell(x) + \mathcal{F}^{-1}\left(\rho(\xi) \cdot \mathcal{F}\left(u_\ell(x)\right)\right) + b\right). \tag{6}$$

Here, $\mathcal{F}$ and $\mathcal{F}^{-1}$ denote the Fourier and inverse Fourier transforms, respectively. The term $\rho(\xi)$ represents a learnable convolution kernel in the frequency domain, W is a linear operator (weight matrix), b is a bias term, and σ is the Gaussian Error Linear Unit (GELU).

By using Fourier transforms, FNOs capture global and local patterns critical for modeling complex PDE behaviors, enabling generalization across resolutions and geometries for various physical problems. In summary, FNOs advance neural network architectures for PDE modeling with their operator-learning capability, resolution invariance, and computational efficiency, making them powerful for complex simulations, including thermal modeling.

C. Self-attention

Self-attention, first popularized in NLP [27], captures global information and long-distance dependencies more effectively than traditional networks. By dynamically adjusting data relationships through queries, keys, and values, it excels with complex, high-dimensional data. Unlike CNNs focusing on local fields, self-attention learns global interdependencies, enhancing recognition of broad patterns and fine details.

In applications such as 3D IC thermal modeling, self-attention not only tracks regional temperature correlations but also identifies local temperature spikes, adapting seamlessly to large-scale data. This capability enhances detail capture, particularly of high-frequency components, thus boosting both the accuracy and efficiency of simulations.

D. Transfer learning

Transfer learning transfers knowledge from pre-trained models to solve new tasks, particularly useful when data is scarce or costly [28]. It leverages features learned from a related task and fine-tunes them for the target task, reducing reliance on large amounts of high-fidelity data while improving model performance and convergence speed.

In 3D IC thermal simulation, obtaining high-fidelity data is expensive and time-consuming. We addressed this by initially training a model with low-fidelity data to learn basic heat transfer patterns and global features quickly. The model was then fine-tuned with a small set of high-fidelity data to capture detailed features, like local hot spots and junction temperatures. This strategy enhances complex temperature distribution prediction, reduces high-fidelity data requirements, and accelerates convergence, offering an efficient solution for large-scale simulations.

III. Proposed Method

Our method **SAU-FNO** consists of three stages: lifting the input to a higher-dimensional space, passing it through iterative U-Fourier layers, and projecting the result back into the original space. Each U-Fourier layer employs a combination of kernel integral transformations, U-Net and CNN operators, and linear operators, enhancing feature extraction.

Additionally, we introduce a self-attention mechanism to capture long-distance dependencies, which is crucial for tasks like 3D thermal simulations. This setup also supports transfer learning, allowing training on low-resolution data and fine-tuning with high-resolution data for improved generalization.

A. Fundamental U-FNO Design

As described in Section 2, FNO consists of multiple superimposed Fourier layers. We enhance the original Fourier layers by integrating a U-Net bypass in each U-FNO layer, as illustrated in Figure 1. The U-Net processes local convolutions, enhancing the representation of high-frequency information. The specific steps of our proposed method are as follows:

1) **Lifting:** Lift the input observation $a(x)$ to high dimensional space using a neural network transformation P.
2) **Iterative Layers:** Apply iterative Fourier layers followed by iterative U-Fourier layers:

$$v_{l_0}(x) \to \cdots \to v_{l_L}(x) \to v_{m_0}(x) \to \cdots \to v_{m_M}(x), \tag{7}$$

where $v_{l_k}(x)$ for $k = 0, 1, \ldots, L$ and $v_{m_k}(x)$ for $k = 0, 1, \ldots, M$ are sequences of functions taking values in $\mathbb{R}^c$, with channel dimension c.
3) **Projection:** Project $v_{m_M}(x)$ back to the original space using a fully connected neural network transformation Q, yielding $z(x) = Q(v_{m_M}(x))$.

Within each newly proposed U-Fourier layer, we define:

$$v_{m_{k+1}}(x) = \sigma\left(\mathcal{K}v_{m_k}(x) + \mathcal{U}v_{m_k}(x) + Wv_{m_k}(x)\right), \forall x \in D, \tag{8}$$

where $\mathcal{K}$ is the kernel integral transformation, $\mathcal{U}$ is a U-Net CNN operator, and W is a linear operator; all are learnable parameters. The activation function σ is GELU, which introduces strong non-linearity into each U-Fourier layer. Other settings are detailed in Section IV, Experiment Settings.

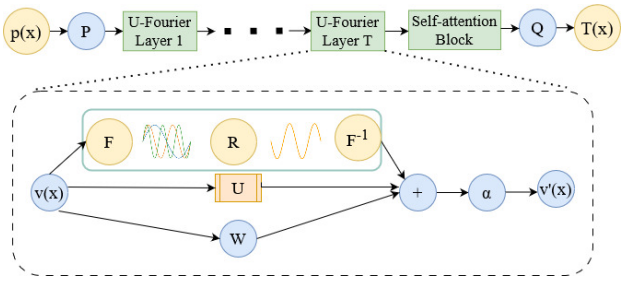

Fig. 1. Our SAU-FNO model architecture. $p(x)$ is the input, P and Q are fully connected neural networks, and $T(x)$ is the output. $\mathcal{F}$ denotes the Fourier transform, R is the parameterization in Fourier space, $\mathcal{F}^{-1}$ is the inverse Fourier transform, W is a linear bias term, and α is the activation function. U denotes a U-Net.

B. Attention-Enhanced U-FNO

Attention mechanisms, widely used in computer vision models like Vision Transformer (ViT), excel at capturing key spatial relationships. Similarly, thermal fields exhibit complex spatial temperature variations. By leveraging self-attention, models can capture long-range dependencies, enhancing the understanding of global heat conduction effects. Inspired by this, we integrate a self-attention module to improve feature extraction in 3D IC thermal simulation tasks.

The overall self-attention block architecture is shown in Figure 2. We perform a 1×1 convolution on the feature map $V_t(x)$ obtained from the U-FNO to compute the spatial attention map A_s and the channel attention map A_c sequentially. The computations are as follows:

$$\begin{aligned} A_c &= W_h V_t(x), \quad Q = W_q V_t(x), \\ K &= W_k V_t(x), \quad s_{ij} = Q_i^\top K_j, \\ A_s &= \text{softmax}(s_{ij}) = \frac{\exp(s_{ij})}{\sum_{k=1}^{N} \exp(s_{ik})}, \end{aligned} \tag{9}$$

where W_h, W_q, and W_k are learnable parameters representing the embeddings for the value, query, and key, respectively. The softmax function ensures that the attention weights are properly normalized. These parameters are trained jointly with the U-Fourier layer during training.

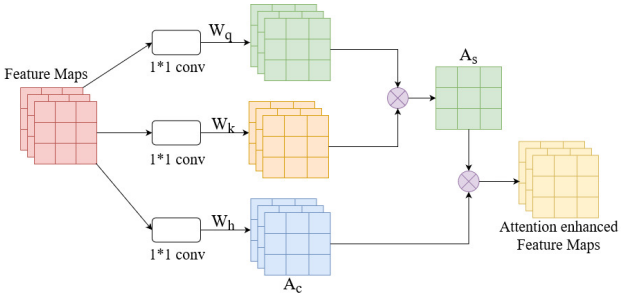

Fig. 2. The self-attention block architecture.

By using 1×1 convolutions in the attention block, we retain the mesh-invariant property of the original U-FNO, preserving its ability to generalize from coarse grid training to high-resolution grid inference. This approach also facilitates transfer learning using multi-fidelity data.

The final attention-enhanced feature map is obtained by combining the spatial and channel attention maps:

$$V_t'(x) = A_s \otimes A_c, \tag{10}$$

where $\otimes$ denotes element-wise multiplication.

As described in Section III-A, the architecture of our proposed U-FNO layer is:

$$v_0 \to v_1 \to v_2 \to \cdots \to v_t, \tag{11}$$

which directly affects the final thermal modeling performance. We refine the U-FNO layer by inputting the feature map $V_t(x)$ to obtain the attention-enhanced feature map $V_t'(x)$, as shown in Figure 2.

The experiments show that adding self-attention blocks after all U-FNO layers yields similar performance to adding them only after the last one or two layers. We attribute this to the multi-layer architecture of U-FNO, where features are gradually transmitted and accumulated. Moreover, the U-Net's skip connections facilitate the propagation of key information, even when attention is applied only in the last layer.

Therefore, to reduce computational complexity, we introduce the attention block only in the last layer, in the $V_t(x) \to V_t'(x)$ step. Refer to Section IV for other detailed settings.

C. Training with Transfer Learning

SAU-FNO effectively models 3D ICs and, with its mesh invariance, can train on low-resolution data and infer on high-resolution data, enabling better generalization than traditional networks. However, large grid resolution differences between training and testing may reduce performance, as low-resolution data often misses complex local and high-frequency details.

Training directly with high-resolution data is costly and impractical. Transfer learning addresses this by pre-training on low-resolution data and fine-tuning with a small amount of high-resolution data, boosting prediction accuracy and reducing reliance on extensive high-fidelity datasets, thus improving efficiency.

1) **Pre-training:** First, a large amount of low-resolution data $D_l = \{X_l, Y_l\}$ is used to train a low-fidelity model M_l. Here, Y_l is the prediction obtained by M_l to the input X_l. We use the L2 loss function to optimize the parameters of the model:

$$L_2 = \frac{1}{N} \sum_{i=1}^{N} \left(T_{\text{pred},i} - T_{\text{true},i}\right)^2, \tag{12}$$

where N is the number of samples, $T_{\text{true},i}$ represents the true value for sample i, and $T_{\text{pred},i}$ represents the model's prediction for sample i.

2) **Fine-tuning:** In the second stage, the pre-trained model M_l is fine-tuned using a relatively small amount of high-fidelity data $D_h = \{X_h, Y_h\}$. The training process is similar to the pre-training stage. The learning rate lr_2 during fine-tuning is about an order of magnitude smaller than that used in the pre-training stage. The rest of the settings are detailed in the experimental section.

IV. EXPERIMENTAL RESULTS

A. Experiment Settings

Experimental Setup: We adopted the Alpha 21264 EV6 microprocessor architecture [29] as the core structure and selected three different 3D ICs for our experiments. These ICs share the same face-to-back stacking structure, including device layers, Thermal Interface Material (TIM), Through-Silicon Vias (TSVs), packaging, and a heatsink. Specifically, Chip1 is a single-core processor consisting of two device layers: one layer contains the core, two L1 caches, and one L2 cache, while the other layer comprises three L2 caches. Chip2 is a three-layer quad-core processor, with the top layer closest to the heatsink consisting of four cores, and the remaining two layers identical, each containing two L2 caches. Chip3 is an octa-core two-layer microprocessor with an architecture similar to Chip1, where the upper layer is composed of eight cores and L1 caches, and the lower layer consists of four L2 caches. In all chips, the address and data bus between the L2 cache and the processor core are connected via TSVs. The 3D structure is illustrated in Figure 3. To simplify the figure of the floorplan, TSVs passing through each layer have been omitted. Additionally, Table I provides detailed structures of the 3D ICs.

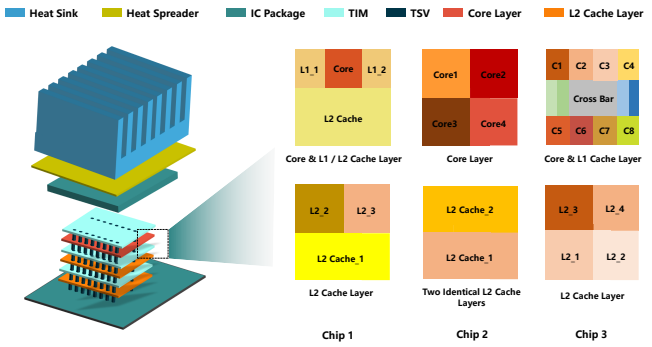

Fig. 3. The stacking structures and floorplan of three 3D chips examined in this work.

Data Generation: We randomly assigned power levels to different functional blocks while ensuring the total power remained within an appropriate range. By varying the power distribution, we aimed to achieve significant and reasonable temperature differences in the simulation results, reflecting real-world scenarios. The model output is a three-dimensional temperature distribution; due to the slow processing speed of commercial software such as Celsius, Icepak, and COMSOL, we adopted MTA [30] as the solver to derive the training data outputs. For each of the three types of chips, we generated

5,000 sets of distinct power distributions. Unless otherwise specified, the data was divided into training and testing sets at a ratio of 4:1.

Model Setting: We referenced the settings from previous work and used Optuna and W&B for hyperparameter tuning. For Chip1 and Chip2, the SAU-FNO was configured with a width of 2 and a model structure of [12, 12, 2]. For Chip3, the width was doubled to 64, resulting in a model structure of [24, 24, 2], to accommodate its larger data scale and grid size. The U-Net encoder has 4 layers of 3×3 convolution with ReLU activations, producing feature maps of [64, 128, 256, 512], while the decoder restores them to [512, 256, 128, 64] using bilinear interpolation and 3×3 convolutions. The self-attention module processes inputs of shape [Bs, 64, 64, 64] into Q, K, and V matrices with dimensions [Bs, 64, 64, d] (d=64). Further settings follow [31] and [32].

Training and Testing: We utilized a decaying learning rate with the Adam optimizer. The initial learning rate was set to 1e-4, and a weight decay of 1e-5 was applied to mitigate model overfitting. For fine-tuning, an initial learning rate of 1e-5 was used to ensure training stability. Each training process ran for over 200 epochs to guarantee convergence. All experiments were conducted on an RTX 3090 GPU with CUDA 11.3, using PyTorch version 1.10.1 and Python 3.7.

B. Compared to Latest ML methods

Recently, numerous studies have applied machine learning to 3D IC thermal modeling, but these methods have various limitations. Our approach, as a neural operator method, offers unique properties like mesh invariance not found in traditional neural networks. Direct comparisons of accuracy or time are not entirely fair, so we only benchmarked against recent neural operator methods, including FNO, U-FNO, and DeepOHeat.

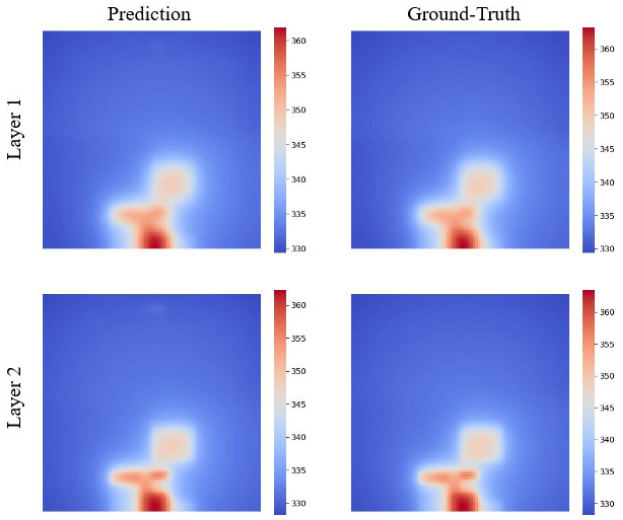

Fig. 4. Comparisons between our SAU-FNO predictions and Ground-Truth on Case 1 of Chip1.

We selected two representative cases with significant power distribution variations from Chip1 for visualization, as shown

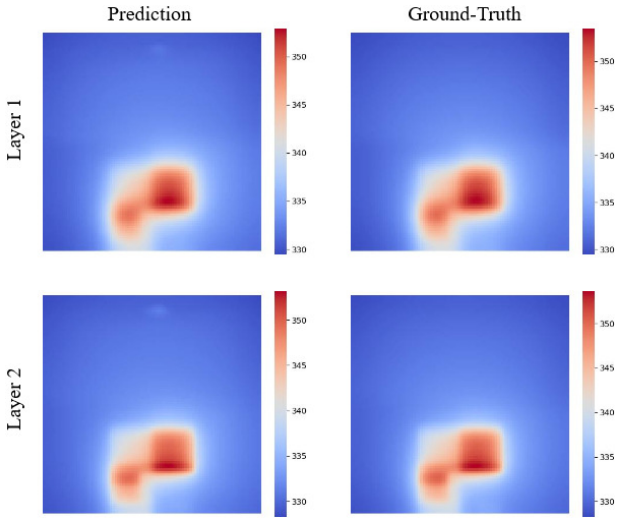

Fig. 5. Comparisons between our SAU-FNO predictions and Ground-Truth on Case 2 of Chip1.

in the heatmaps Figure 4 and Figure 5. The chips have two heating layers, labeled as layer 1 and layer 2. The visualizations show that our thermal simulation results closely match the ground truth, demonstrating strong performance in average temperature difference and excelling in junction temperature.

For quantitative evaluation, we used metrics such as RMSE, average temperature error (Mean), and maximum temperature error (Max), along with MAPE and PAPE. As shown in Table II, SAU-FNO significantly outperforms the commonly used DeepOHeat and FNO, with RMSE and junction temperature reductions of over 50% compared to FNO. While methods like U-Net lack resolution invariance and were not extensively compared for fairness, our results demonstrate clear advantages, including significant improvements over GAR, highlighting the superior performance and robustness of our approach. Additionally, the comparison between our method and U-FNO demonstrates the effectiveness of the self-attention module, while the improvements from FNO to U-FNO further highlight the contribution of the U-Net architecture. These comparisons effectively serve as an ablation study validating the importance of each component in our method.

We found that the structural differences among chips lead to variations in absolute accuracy. However, our method consistently achieves significant improvements and reaches SOTA performance across all chips. Therefore, we only report the average quantitative results for Chip2, with results for other chips provided in the supplementary material.

C. Validation of Transfer Learning

We implemented transfer learning by pre-training the model on extensive low-fidelity data and fine-tuning it with a small amount of high-fidelity data. This approach achieves nearly the same effectiveness as training from scratch with large-scale high-fidelity data, while significantly reducing the need for such data and accelerating training.

TABLE I
GEOMETRIC STRUCTURES AND THERMAL PARAMETERS OF 3D-ICS

	size (mm)			Thermal Attributes	
	Single-Core	Quad-Core	Octa-Core	Thermal Conductivity (W/m·K)	Volumetric Heat Capacity (J/m^3K)
L2 Cache Layers	16×16×0.15	12.4×12.76×0.15	10×10×0.1	100	1.75×10^6
Core layer	16×16×0.15	12.4×12.76×0.15	10×10×0.1	100	1.75×10^6
TIM	16×16×0.02	12.4×12.76×0.02	10×10×0.052	4	4.00×10^6
Heat Spreader	30×30×1	30×30×1	30×30×1	400	3.55×10^6
Heat Sink (Base)	60×60×6.9	60×60×6.9	60×60×6.9	400	3.55×10^6
Heat Sink (Fins×21)	1×60×50	1×60×50	1×60×50	400	3.55×10^6
TSV	diameter:0.01 ; pitch:0.01			100	1.75×10^6

TABLE II
COMPARISON OF OUR METHOD WITH OTHER ML METHODS, MAX STANDS FOR JUNCTION TEMPERATURE AND MEAN STANDS FOR AVERAGE TEMPERATURE.

Method	Resolution	RMSE	MAPE	PAPE	Max	Mean
DeepOHeat [19]	40∗40	0.457	0.093	0.811	2.936	0.297
	64∗64	0.473	0.097	0.914	4.355	0.312
FNO [21]	40∗40	0.438	0.086	0.730	2.774	0.329
	64∗64	0.409	0.077	1.073	4.081	0.292
U-FNO [31]	40∗40	0.221	0.049	0.195	0.741	0.185
	64∗64	0.278	0.065	0.275	1.046	0.253
GAR [33]	40∗40	0.576	0.127	0.893	4.639	0.153
	64∗64	0.598	0.145	0.917	5.132	0.170
Ours	40∗40	0.197	0.041	0.168	0.650	0.146
	64∗64	0.203	0.043	0.179	0.773	0.162

As shown in Table III, RMSE and junction temperature metrics showed minimal accuracy loss with fine-tuning compared to full high-fidelity training. The low-fidelity model used 4,000 cases, while fine-tuning the high-fidelity model required only 1,000 cases, achieving a 4:1 ratio of low-resolution to high-resolution data, which we determined to be optimal after multiple experiments. A high-fidelity model trained from scratch with 4,000 cases served as a benchmark. Given that high-resolution data collection is 4 to 6 times slower, total training time was reduced by about 2.5 times. Increasing fine-tuning data to 4,000 cases slightly improved accuracy. Transfer learning was also effective on other ML methods like FNO and U-FNO, proving its suitability for efficiency-critical 3D IC thermal simulations.

TABLE III
THE COMPARISON BEFORE AND AFTER TRANSFER LEARNING ON CHIP1, TRANSFER MEANS TRANSFER LEARNING.

Method	Transfer	RMSE	MAPE	PAPE	Max	Mean

D. Compared to Professional Thermal Simulation Tool

We compared the accuracy and speed of our model with mainstream 3D IC thermal simulation tools, including commercial software like COMSOL and open-source tools such as MTA [30] and Hotspot [34]. COMSOL, based on FEM, is suited for complex engineering, while MTA is an academic FEM tool, and Hotspot uses fast thermal network analysis based on FDM and empirical models. For simplicity, we only compared junction temperature and minimum temperature here, while other metrics such as MAPE are provided in the supplementary material. To achieve a certain degree of fairness in comparison, we conducted simulation experiments with them using the finest mesh and maximum resolution available.

Using the method in Section IV, we generated 20 power distributions for chip1-chip3 high-fidelity data and ran simulations to measure the maximum temperature and distribution, comparing average errors with our approach. Junction temperature was the primary comparison metric. Table IV shows that SAU-FNO predictions are close to baseline methods, with a maximum error within 0.25K, proving its practical usability. While COMSOL is slower, MTA and Hotspot performed faster. Our SAU-FNO method averaged 0.27s per prediction, compared to 227.31s for MTA and 98.47s for Hotspot, achieving speedups of 842x and 365x, respectively.

TABLE IV
MAXIMUM AND MINIMUM TEMPERATURE COMPARISONS AMONG COMSOL, MTA, HOTSPOT AND SAU-FNO ON FIVE STEADY-STATE SAMPLES.

		COMSOL	MTA	Hotspot	Ours	Error*
$chip_1$	Max(K)	381.257	381.173	391.051	381.159	-0.098
	Min(K)	328.032	328.107	334.970	328.139	+0.107
$chip_2$	Max(K)	380.065	380.134	392.015	380.195	+0.130
	Min(K)	325.259	325.450	336.290	325.473	+0.214
$chip_3$	Max(K)	422.207	422.079	432.017	422.091	-0.108
	Min(K)	347.496	347.330	348.019	347.353	-0.143

* Error refers to the difference between SAU-FNO and COMSOL.

V. CONCLUSION

We present SAU-FNO, an advanced thermal modeling framework that addresses key challenges in 3D IC thermal management. By integrating self-attention and U-Net architectures into the FNO, SAU-FNO effectively captures both global and local thermal dynamics. Our results demonstrate significant accuracy improvements and an 842× reduction in computation time compared to traditional methods. Transfer learning further boosts performance, reducing reliance on extensive high-fidelity datasets. Future work will expand SAU-FNO's capabilities to support a broader range of thermal analysis tasks, promoting more efficient design processes in advanced semiconductor technologies.

***Abstract*—In advanced technology nodes, benefits from scaling have become limited in terms of power, performance, and area (PPA), necessitating improvements through design-technology co-optimization (DTCO). While the standard-cell methodology is widely used in modern VLSI design, it inherently constrains the potential of DTCO due to its abstraction at the logic level, limiting optimization at the physical level. To bridge this gap, transistor-level design methodology is desired to break the abstraction of standard cells. Existing research has explored large-scale transistor placement, but a gap remains in developing a routing framework that efficiently addresses transistor-level routing challenges. This paper proposes a pioneering transistor-level routing framework for large-scale transistor placements, along with an efficient CP-SAT (Constraint Programming-SATisfiability) formulation for routing in lower layers. Experimental results demonstrate that the proposed routing framework enables transistor-level designs to achieve significantly reduced total wirelength and high utilization rates for designs with hundreds to thousands of transistors, outperforming traditional standard-cell-based approaches in advanced technology nodes.**

I. Introduction

In advanced technology nodes, the PPA benefits from scaling have become limited, highlighting the growing importance of advancements through DTCO. DTCO involves three critical stages: technology, design enablement, and design [1]. Among these, the design enablement stage is critical for bridging technology and design by providing essential inputs to the design phase, including standard cell libraries, intellectual properties (IPs), and signoff environments. Standard cell libraries are fundamental to the VLSI design process due to their scalability, reusability, and seamless integration with electronic design automation (EDA) tools. Each library comprises pre-defined logic functions with fixed physical implementations that standardize the design framework. However, while the standard-cell methodology simplifies design and supports PPA improvement, the fixed physical layouts of standard cells impose constraints on further optimizing the physical design and achieving maximum PPA potential.

To fully unleash the potential of DTCO, it is crucial to move beyond the abstraction of standard cells by adopting a transistor-level physical design approach [2], rather than relying on pre-defined physical implementations in standard cells. Eliminating the abstraction provides greater optimization flexibility, leading to a smaller design area and reduced total wirelength compared to traditional standard-cell-based design. Furthermore, achieving a high utilization rate is challenging with the standard-cell-based approach, as it often struggles to produce LVS/DRC-clean results within a compact design area. A key limitation arises from the fixed physical implementations of standard cells, which hinder the full utilization of lower-layer routing resources (e.g., Metal0) that follow the "use it or waste it" principle. Breaking the standard-cell abstraction allows these lower-layer routing resources to be fully explored and utilized, further enhancing design optimization.

Existing work on transistor-level placement and routing primarily focuses on automating standard cell design. As design rule complexity continues to grow in advanced nodes, manual standard cell design has become increasingly challenging, necessitating advanced automation to address these complexities. Standard cell design automation is categorized into two major approaches: concurrent and sequential. Concurrent approaches [3]–[5] address transistor placement and routing simultaneously for a cell. In contrast, sequential approaches [6]–[10] divide the process into two stages: transistor placement and in-cell routing. Transistor placement [11]–[14] minimizes cell area and enhances routability by leveraging diffusion sharing, while in-cell routing [15]–[17] ensures net connectivity without design rule violations and guarantees pin accessibility. However, existing in-cell routing research primarily focuses on standard-cell-scale transistor-level routing and faces scalability challenges when applied to large-scale placements with hundreds or thousands of transistors.

Recently, TransPlace [18] proposed a transistor-level placement framework that directly places all transistors of a design without standard-cell abstraction, achieving a compact design area and reducing total half-perimeter wirelength. However, existing transistor-level routing approaches are limited to standard-cell scales, typically fewer than 50 transistors, due to scalability issues. To the best of our knowledge, no prior work has addressed the challenges of transistor-level routing for transistor placements with hundreds or even thousands of transistors. Therefore, a new transistor-level routing framework is needed to efficiently route large-scale placements.

In this paper, we present a novel hierarchical transistor-level routing framework capable of routing large-scale transistor placements with high utilization, while optimizing the total wirelength and via count, and handling various complex design rules. The main contributions of this paper are summarized as follows:

- We present the first transistor-level routing framework for a large-scale transistor placement, consisting of three main steps: partitioning, lower-layer routing, and upper-layer routing.
- We propose a transistor partitioning technique that leverages transistor placement results. This approach prioritizes the physical locations of transistors over their logical relationships (those within a standard cell), potentially yielding greater enhancements in PPA.
- We propose an efficient CP-SAT connectivity formulation for transistor-level routing, which controls the flow of each net on a grid-based routing graph while enforcing node exclusiveness through integer encoding at each vertex.
- Experimental results show that the proposed routing framework achieves LVS/DRC-clean transistor-level designs, with an average 22% reduction in wirelength and 14% reduction in via count compared to standard-cell-based designs, while maintaining a high utilization rate of around 90%.

The remainder of this paper is organized as follows. Section II gives the preliminaries and the problem formulation. Section III illustrates our proposed transistor-level routing framework, and Section IV details the proposed CP-SAT formulation for lower-layer routing within a partition. Section V shows the experimental results, and Section VI concludes the paper.

II. Preliminaries and Problem Formulation

This section presents an overview of transistor placement. Then, we formulate the transistor-level routing problem.

A. Transistor Placement

A legal transistor placement requires all transistors of a given transistor-level netlist are placed within a design canvas without overlap. When two transistors that are placed adjacently in the same row, the nets of their shared diffusion must be the same, known as diffusion sharing. Figure 1 shows a legal transistor placement with four standard-cell rows.

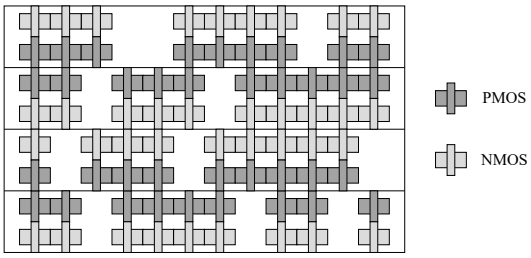

Fig. 1. A transistor placement.

B. Problem Formulation

Problem 1 (Transistor-Level Routing): Given a transistor placement and its corresponding transistor-level netlist, generate a routing solution such that all nets are routed without design rule violations, and the total wirelength and via count are minimized.

III. Transistor-Level Routing Framework

Large-scale transistor-level routing is challenging since we need to consider numerous complex design rules while optimizing total wirelength and via count. The overall flow of our proposed transistor routing consists of three stages as shown in Fig. 2: (1) partitioning, (2) lower-layer routing, and (3) upper-layer routing. First, the layout is partitioned into several partitions based on the transistor placement. From these partitions, we categorize all nets into two types: intra-partition nets and inter-partition nets. An intra-partition net has all its terminals within a single partition, while an inter-partition net has terminals across multiple partitions. Intra-partition nets are routed entirely within their corresponding partitions in the lower routing layers (typically Metal1 and below). For an inter-partition net, we connect its terminals in the lower routing layers and also create an *escape pin* in each of its partitions. These escape pins are then used to connect the inter-partition nets in the upper routing layers (typically Metal1 and above).

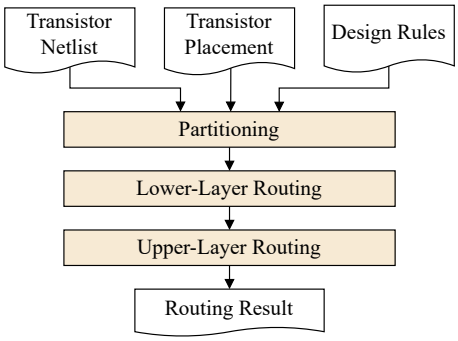

Fig. 2. The overall flow of our proposed transistor-level routing framework.

A. Partitioning

Routing all transistors directly within a macro design can lead to extremely long runtime. To address this challenge, we propose a layout partitioning strategy, where the layout is divided into partitions, each containing a set of transistors. Based on transistor placement, the layout is divided into several partitions according to transistor locations, with each partition being of similar size. Partition size plays a crucial role. If the partitions are too small, they can lead to severe routing congestion in the upper layers. On the other hand, if a partition is too large, connections within the partition may fail. In practice, we use partitions that are 2–4 standard-cell rows by 15–25 contacted poly pitches (CPPs), which are larger than individual standard cells. Furthermore, we use an Euler path (a sequence of diffusion-shared transistors without breaks) as a fundamental component for partitioning, meaning that an Euler path cannot be split across multiple partitions. As a result, partitions are not necessarily rectangular and can take on any rectilinear shape.

Fig. 3 shows the partitioning of the transistor placement in Fig. 1. It is important to emphasize that the partitioning of transistors within a design occurs at the physical level, unlike

the standard-cell methodology, which partitions transistors at the logic level. Such a distinction is crucial as partitioning at the logic level may limit PPA optimization.

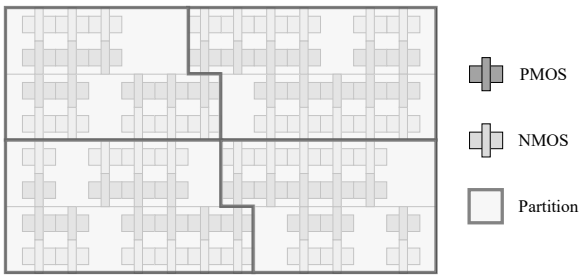

Fig. 3. Four partitions of the transistor placement.

B. Lower-Layer Routing

Lower-layer routing involves net routing for all nets and the creation of escape pins for inter-partition nets within a partition. This stage is particularly challenging due to limited routing resources, the high density of terminals, and complex design rules. Therefore, we formulate lower-layer routing of each partition into a CP-SAT problem and solve the problem by the CP-SAT solver [19], which is detailed in Section IV. Fig. 4 shows the lower-layer routing results of the four partitions in Fig. 3.

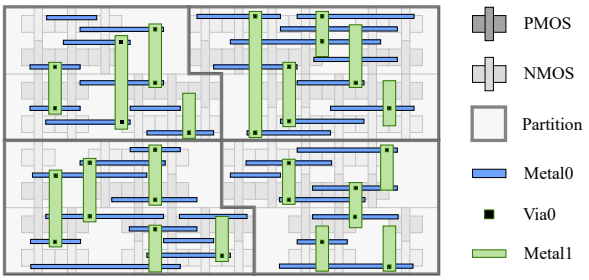

Fig. 4. Lower-layer routing for the four partitions.

C. Upper-Layer Routing

For upper-layer routing, we need to connect all inter-partition nets through their escape pins, with each net guaranteed to have one escape pin in each of its partitions. Since routing resources are more abundant in upper layers, efficiency becomes our primary concern. Connecting all escape pins is similar to the traditional routing problem for standard-cell-based design. Therefore, we could use a conventional router for standard cells to complete the upper-layer routing across all partitions.

IV. CP-SAT Formulation for Lower-Layer Routing

This section details our proposed CP-SAT formulation for lower-layer routing for each partition. We first introduce the grid-based routing graph, followed by the construction of the corresponding flow network. Based on the flow network, we then formulate the CP-SAT constraints and define the objective function.

A. Grid-Based Routing Graph

For lower-layer routing, we use a grid-based routing graph [20]. In advanced technology nodes, routing on each layer is unidirectional with routing directions alternating between layers. Each layer contains multiple tracks, and the grid points on the routing graph represent the intersection points projected from both the layer above and the layer below. Furthermore, due to the non-uniform configuration of tracks, edges in a grid graph can have varying physical lengths on each layer. In this paper, we allow the escape pins created only on the Metal1 layer. Fig. 5 shows a grid-based routing graph from the diffusion/poly layers to the Metal1 layer.

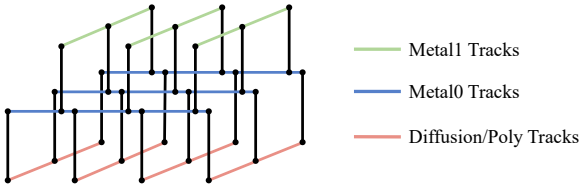

Fig. 5. A grid-based routing graph.

B. Flow Network Construction

To ensure connectivity, we construct a flow network from the grid-based routing graph, with each grid point as a vertex and each edge forming a pair of bidirectional arcs [20]. A terminal pin (diffusion/gate pin) typically has multiple access grid points. A *super-node* is created for each terminal pin. For each net, one of its terminal pins is selected as the source, while the remaining pins are designated as sinks. For the source terminal pin, arcs are constructed from its super-node to each of its access grid points. Conversely, for sink terminal pins, arcs are created from each access grid point to their super-node.

For an inter-partition net, it is necessary to create an escape pin on the escape layer (e.g., Metal1), enabling connections to pins in other partitions. To achieve this, an *escape node* is constructed, and an arc is constructed from each of the grid points on the escape layer to the escape node. Additionally, the escape node is also a sink to each inter-partition net. Fig. 6 shows the flow network based on a routing grid graph.

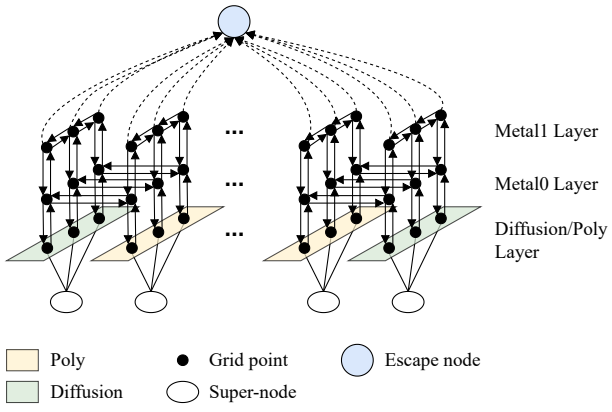

Fig. 6. The flow network based on a grid-based routing graph.

C. Constraints

The CP-SAT constraints for lower-layer routing are divided into two categories: connectivity and design rules. Connectivity constraints ensure the connection of all nets and the generation of an escape pin for each inter-partition net, with these constraints formulated based on a flow network. On the other hand, the design rule constraints are dedicated to preventing any violations of design rules, which are based on an undirected graph derived from the flow network by removing arc directions. Table I summarizes the notations used in this paper.

TABLE I
NOTATIONS USED IN THIS PAPER

Symbol	Description
N	The set of nets in a partition.
N_{inter}	The set of inter-partition nets in a partition.
V/A	The set of vertices/arcs.
V_u^i/V_u^o	The set of vertices where vertex u has an in/out-arc.
s_n	The source node for net n.
T_n	The set of sink nodes for net n.
$t_{n,i}$	The i^{th} sink node for net n.
v_e	The escape node.
$a_{u,v}$	Boolean. Indicate if arc (u,v) is selected.
$f_{u,v}$	Integer. Flow on arc (u,v).
c_u	Integer. The encoding of vertex u.

1) Connectivity: The net routing problem can be formulated as a terminal Steiner forest problem. To construct terminal Steiner forest, we can leverage network flow by controlling the flow between nodes and the flow directions. For a net to be fully connected, there must be a flow from the source node to each of its sink nodes without overlapping with the flows of other nets.

- *Flow Conservation Constraint*: For each vertex in the flow network, the inflow and outflow must be the same for flow conservation:

$$\forall u \in V, \text{inflow}(u) = \text{outflow}(u), \tag{1}$$

where

$$\text{inflow}(u) = \begin{cases} |T_n|, & \text{if } u = s_n, n \in N \\ \sum_{v \in V_u^i} f_{v,u}, & \text{otherwise,} \end{cases}$$
$$\text{outflow}(u) = \begin{cases} 1, & \text{if } u \in T_n \setminus \{v_e\}, n \in N \\ |N_{inter}|, & \text{if } u = v_e \\ \sum_{v \in V_u^o} f_{u,v}, & \text{otherwise.} \end{cases} \tag{2}$$

The inflow of a source node is fixed to the number of sinks, the outflow of each sink node (except the escape node) is fixed to one, and the outflow of the escape node is fixed to the number of inter-partition nets. Note that the domain of each flow variable $f_{u,v}$ is $[0, \max_{n \in N} \deg(n) - 1]$.

- *Selected Arc Constraint*: Arc (u,v) is selected if and only if it has non-zero flow:

$$\forall (u,v) \in A, a_{u,v} \leftrightarrow (f_{u,v} \geq 1). \tag{3}$$

- *In/Out-Arc Count Constraint*: To ensure that each net is connected by a tree, at most one of the in-arcs can be selected for each node, except the escape node:

$$\forall u \in V \setminus \{v_e\}, \sum_{v \in V_u^i} a_{v,u} \leq 1. \tag{4}$$

For each source node, at most one out-arc can be selected to ensure that the source node is a leaf node of a tree:

$$\forall n \in N, \sum_{v \in V_{s_n}^o} a_{s_n,v} \leq 1. \tag{5}$$

- *Vertex and Edge Exclusiveness Constraint*: The flow conservation ensures the connectivity of all nets, but each node or edge can be assigned to at most one net. To enforce vertex exclusiveness, each vertex u has an integer encoding c_u, typically set to the net index (i.e., $1, \ldots, |N|$). The encoding of all the source and sink nodes (except the escape node) is fixed to their net index. Moreover, if an arc (u,v) is selected, then its two vertices must have the same encoding:

$$\forall (u,v) \in A, v \neq v_e, a_{u,v} \rightarrow (c_u = c_v). \tag{6}$$

Note that only node exclusiveness needs to be constrained since edge exclusiveness is implicitly ensured.

Fig. 7 shows an example of terminal Steiner forest construction for two nets, n_1 and n_2, using network flow. Net n_1 includes a source s_1 with three sinks $t_{1,1}$, $t_{1,2}$, and $t_{1,3}$. Similarly, net n_2 has a source s_2 and four sinks $t_{2,1}$, $t_{2,2}$, $t_{2,3}$, and $t_{2,4}$. The inflows of s_1 and s_2 are fixed to 3 and 4 respectively, while the outflow of each sink is fixed to 1.

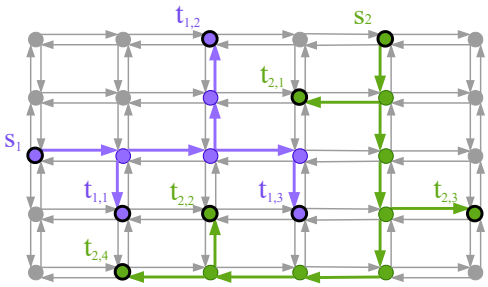

Fig. 7. Terminal Steiner forest construction using network flow.

Our proposed CP-SAT formulation is more efficient than the SAT-friendly integer linear programming (ILP) formulation in [20], which uses only 0-1 integer variables. Unlike [20], which decomposes a k-pin net into $(k-1)$ source-to-sink pairs connected by independent commodity flows, our approach directly generates a Steiner tree by controlling the flow of a net. This allows implicit edge exclusiveness through a single integer variable for node encoding, whereas [20] requires n 0-1 variables per edge, with constraints ensuring at most one is active for edge exclusiveness, where n is the net count.

2) Design Rules: Connectivity constraints ensure all nets are connected with node and edge exclusiveness, but design rules are not addressed. To handle design rules, we add CP-SAT constraints based on the undirected graph derived from a directed graph used for connectivity. Several common design rules are considered, such as minimum area, end-of-line spacing, via spacing, etc. Based on the undirected graph, we can formulate CP-SAT constraints for the design rules, following a similar approach to that in the works [3], [20].

D. Objective

The objective of lower-layer routing is to minimize the total wirelength and via costs. Each arc in the routing graph, excluding those connected to super-nodes or the escape node, represents either a wire or a via. Wire costs are calculated as the product of wirelength and a layer-specific unit cost, while via costs are determined by a user-defined parameter. Thus, the objective in the CP-SAT formulation is $\sum_{a \in A} \text{cost}(a)$.

V. Experimental Results

The proposed partitioning and lower-layer routing methods were implemented in the C++ programming language with the CP-SAT solver [19]. For upper-layer routing, we used the OpenROAD project [21] and the Cadence Innovus tool [22]. This section describes the benchmark generation process and provides a detailed comparison of standard-cell-based designs versus transistor-level designs, along with an evaluation of the efficiency of the proposed CP-SAT connectivity formulation.

A. Benchmarks

Our transistor-level netlists are generated from standard-cell-based designs. First, we synthesize an RTL design using a standard-cell library to obtain a gate-level netlist. The gate-level netlist is then flattened by replacing each standard cell with its corresponding SPICE transistor-level netlist. The resulting transistor-level netlist includes all transistors from the original standard-cell-based design, but with the hierarchy fully eliminated.

Table II gives the benchmark statistics, where "Tech.", "#Trans.", "#Net", "#SDC", and "SDC Area" denote the technology, transistor count, signal net count, standard cell (SDC) count, and total standard cell area (μm^2), respectively. To evaluate the proposed transistor-level routing framework, there are totally eight designs across two advanced industry technology nodes: Tech1 (Design1 to Design4) and Tech2 (Design5 to Design8).

TABLE II
Benchmark statistics

Benchmark	Tech.	#Trans.	#Net	#SDC	SDC Area
Design1	Tech1	72	40	15	0.41
Design2	Tech1	162	90	23	0.87
Design3	Tech1	666	300	76	3.38
Design4	Tech1	684	314	84	3.51
Design5	Tech2	286	129	28	1.14
Design6	Tech2	633	282	55	2.49
Design7	Tech2	656	336	77	2.68
Design8	Tech2	1969	936	180	7.72

B. Overall Quality Comparison

To evaluate transistor-level routing, we compare the post-routing results of transistor-level designs with their corresponding standard-cell-based designs. Two different placement and routing flows are used for the standard-cell-based designs, depending on the technology node. The open-source OpenROAD [21] design flow is used for Tech1 (Design1 to Design4), while the commercial Cadence Innovus flow is employed for Tech2 (Design5 to Design8). Furthermore, transistor-level placements for each design are generated using a placement framework based on TransPlace [18]. All the transistor-level designs are LVS/DRC-clean.

Table III summarizes a comprehensive comparison of the post-routing results, where "Total WL", "Total Via", "Design Area", and "Util." represent the total wirelength (μm), via count, design area (μm^2), and utilization rate, respectively. The design area refers to the bounding box of all standard cells or transistors, and the utilization rate, equivalent to that in standard-cell-based designs, is calculated by dividing the total SDC area by the design area. The transistor-level designs consistently exhibit significantly less total wirelength and via count compared to the standard-cell-based designs, with an average wirelength reduction of 23% for Tech1 and 21% for Tech2, and via count reductions of 25% for Tech1 and 2% for Tech2. These improvements can be attributed to two key factors. First, transistor-level placement, without the constraints of standard-cell abstraction, allows for more diffusion sharing opportunities, enabling designs to fit into a smaller area and reducing the overall HPWL. Second, the absence of standard-cell abstraction enables more nets to be routed in the lower layers, minimizing the need for detours into upper layers. Furthermore, transistor-level designs achieve significantly smaller design areas, with reductions of 29% for Tech1 and 31% for Tech2. As a result, these designs reach a high utilization rate of around 90%, which is challenging to achieve with DRC-clean results in standard-cell-based designs.

C. Wirelength Breakdown

Fig. 8 presents the breakdown of wirelength by layers for both the standard-cell-based design and transistor-level (T-level) design of Design3, Design4, Design7, and Design8. For Design3 and Design4, the transistor-level designs show significantly reduced wirelength in the upper layers (Metal2 and above), while the lower layers have slightly more wirelength compared to the standard-cell-based designs. However, the total wirelength in the transistor-level designs remains lower. It is important to note that lower-layer routing resources follow the "use it or waste it" principle. In standard-cell-based designs, routing on Metal0 is restricted due to fixed routing within standard cells. In contrast, transistor-level designs can fully leverage the lower-layer routing, as they are not constrained by the fixed physical implementations of standard cells. For Design7 and Design8, the transistor-level designs have significantly less wirelength across all layers, except for a slight increase in Metal3. This minor increase helps avoid congestion in lower layers due to the smaller design area compared to standard-cell-based designs.

TABLE III
OVERALL COMPARISON BETWEEN STANDARD-CELL-BASED DESIGNS AND TRANSISTOR-LEVEL DESIGNS

Benchmark	Standard-Cell-Based Design				Transistor-Level Design			
	Total WL	Total Via	Design Area	Util.	Total WL	Total Via	Design Area	Util.
Design1	15.71	67	0.81	0.51	8.79	26	0.41	1.00
Design2	36.37	150	1.38	0.63	26.50	100	0.97	0.89
Design3	167.76	618	4.70	0.72	155.40	609	3.85	0.88
Design4	181.20	646	4.79	0.73	153.80	611	3.76	0.93
Avg. Ratio	1.00	1.00	1.00	-	0.77	0.75	0.71	-

D. Connectivity Formulation Comparison

To evaluate the efficiency of our proposed CP-SAT connectivity formulation, we implemented both the SAT-friendly ILP formulation [20] and our CP-SAT formulation using the CP-SAT solver. We generated five synthetic graphs with various grid sizes and net counts for terminal Steiner forest construction, as given in Table IV, where "#Nets", "#Nodes", and "Max Deg." represent the net count, total node count, and maximum net degree, respectively. A time limit was set for each graph based on the problem size. The CP-SAT solver finds an initial feasible solution and continues optimizing until it reaches an optimal solution or the time limit. Due to the solver's non-deterministic nature, each formulation was run 10 times per graph to measure the average time to find the first feasible solution and the average total length.

Table IV compares the performance of the SAT-friendly ILP and CP-SAT formulations. For graph4 and graph5, the solver timed out in 4 and 6 out of 10 runs, respectively, without finding a feasible solution when using the SAT-friendly ILP formulation. On average, the proposed formulation finds the first feasible solution 61% faster and reduces total net length by 18% within the time limit compared to the SAT-friendly ILP formulation. The results demonstrate that the proposed CP-SAT formulation allows the solver to find a feasible solution more efficiently, enabling it to achieve a better-optimized solution within the given time limit.

VI. CONCLUSION

In this paper, we have presented an innovative transistor-level routing framework capable of routing all nets within large-scale transistor placements. The layout partitioning method has been proposed to accurately reflect the proximity of transistors at the physical level, rather than relying on logic-level relationships, facilitating the optimization of the ultimate layout. Furthermore, our proposed CP-SAT-based lower-layer routing algorithm efficiently routes all nets with a novel connectivity formulation, optimizing both wirelength and via costs while handling complex design rules in cutting-edge technology nodes. Experimental results have demonstrated the transistor-level design's significant improvements over standard-cell-based designs in wirelength, via count, and design area. Transistor-level routing is the final step toward achieving complete transistor-level design for macro designs, and this work marks the first attempt to fully realize this goal. As DTCO becomes increasingly important in advanced technology nodes, we believe that the transistor-level design approach, beyond standard-cell methodology, can fully exploit the potential of DTCO.

***Abstract*—To accelerate AI applications, numerous data formats and physical implementations of matrix multiplication have been proposed, creating a complex design space. This paper studies the efficient MAC implementation of the integer, floating-point, posit, and logarithmic number system (LNS) data formats and Microscaling (MX) and Vector-Scaled Quantization (VSQ) block data formats. We evaluate the area, power, and numerical accuracy (evaluated as signal-to-quantization noise ratio) of >25,000 MAC designs spanning each data format and several key design parameters such as the inner product size and accumulation width. We find that for the same numerical accuracy, pareto optimal MAC designs with emerging data formats (LNS16, MXINT8, VSQINT4) achieve 1.8×, 2.2×, and 1.9× TOPs/W improvement compared to FP16, FP8, and FP4 dot product implementations.**

I. Introduction

The computational requirements of modern artificial intelligence (AI) applications have given rise to an entire industry for hardware acceleration. While there exist several different system-level architectures for processing these applications, all leading AI processors leverage quantization and custom hardware for matrix multiplication.

Quantization enables narrower data formats by casting higher precision (FP32) weights and activations to lower precision data formats such as INT8 or FP8 [10], [13], [26]. Using fewer bits per weight or activation yields a linear improvement in effective memory capacity and bandwidth and a quadratic improvement in area and energy efficiency. From these improvements, quantization has achieved fast and widespread adoption in commercial designs. NVIDIA's recent addition of FP4 and FP6 to Blackwell is one such example [37]. With both commercial interest and success, a myriad of new data formats and so-called *block data formats* [7], [9] have been proposed. Together, these data formats form a rich design space with improved dynamic range at low area and power overhead.

A second factor contributing to improved performance is custom matrix multiplication hardware. Most modern commercial AI accelerators feature some type of matrix multiplication accelerator such as the Tensor Core in NVIDIA's GPUs [1] or Google's Tensor Processing Unit (TPU) [20]. Within these matrix multiplication accelerators, special fused dot product units can be used that are more efficient than conventional multipliers and adders [16]. In addition to reduced logic complexity, custom matrix multiplication units process more operations in parallel reducing the processor datapath overhead.

The combination of new data formats and physical implementations of matrix multiplication creates a complex design space warranting exploration. The trend towards narrower data formats and reduced precision hardware is ultimately a trade-off between numerical accuracy and hardware efficiency. Therefore, to effectively evaluate the design space, it is necessary to compare data formats and their hardware implementations based on both numerical accuracy and area and energy efficiency.

In this work, we evaluate the efficient MAC implementation of the integer, floating-point, posit [15], and logarithmic number system (LNS) data formats and Microscaling (MX) [9] and Vector-Scaled Quantization (VSQ) [7] block data formats. We design, implement, verify, and evaluate over 25,000 MAC implementations across these data formats and various MAC design parmeters: inner product size, outer product size, accumulation width, etc. Next, we present the pareto optimal MAC designs considering power, performance, and numerical accuracy across several large language model (LLM) benchmarks. First, we find that at the same numerical accuracy, LNS, MX, and VSQ achieve higher area and energy efficiency than integer and floating-point. Second, we find that choosing the optimal MAC design parameters, especially inner product size and accumulation width, is essential to strong area and energy efficiency. Lastly, we show that at the same numerical accuracy, pareto optimal MAC designs with emerging formats at different bit-widths (LNS16, MXINT8, VSQINT4) achieve 1.8×, 2.2×, and 1.9× TOPs/W improvement compared to FP16, FP8, and FP4 dot product implementations.

II. Background and Related Work

A. Data Formats for AI

To evaluate the design space of data formats, we study and evaluate four common data formats with unique properties: integer, floating-point, posit, and logarithmic number system (LNS). To introduce the key differences between the data formats, we visualize the 16 real values (representations) of each data format with 4-bit precision in Fig. 1. Each data format yields a different dynamic range (maximum value divided by minimum value) and step sizes. A large dynamic range is necessary for when the distribution of weights or activations has a large variance, however when the data format's dynamic range is unnecessarily large, many bit patterns will be wasted. Therefore, it is ideal for the target data format's dynamic range to match the variance of the data distribution as closely as possible.

The **integer** (INT) and **floating-point** (FP) data formats are the commonly used data formats in AI models. For both integer and floating-point, we follow the specification in [32]. For integer, an implicit scale factor and symmetric range is used such that the raw value range is: $[-1\frac{63}{64}, +1\frac{63}{64}]$. For floating-point, we follow [32] for E5M2, E4M3, E3M2, and E2M1 and [2] for FP32 and FP16.

The **posit** data format [15] is a relatively new alternative to floating-point with a larger dynamic range, fewer wasted bit patterns, and a tapered distribution to allocate more bit patterns near zero. Similar to floating-point, posit has a sign, exponent (of size "*es*"), and fraction - which operates similar to a mantissa but has no subnormal behavior. Posit also adds a regime field that is run-length encoded. This means the field sizes and locations are dynamic, requiring complex decoding logic [24]. However, these dynamic fields create a *tapered* distribution with higher dynamic range and more bit patterns allocated near zero. Fig. 1 includes a 4-bit posit with a 1-bit exponent field (E1).

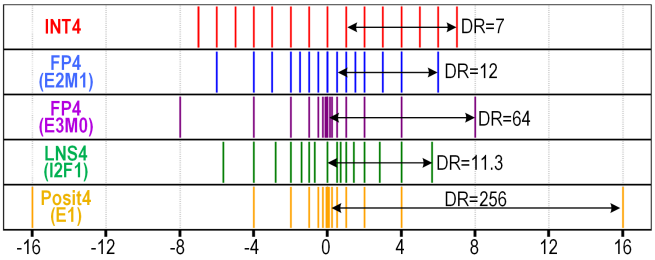

Fig. 1. The 16 real values for INT4, FP4 E2M1 & E3M0, LNS4, and posit4. Dynamic range (DR) varies between data formats.

The **logarithmic number system** (LNS) was originally used to simplify multiplications by moving them to the logarithm domain where they become additions [35]. Since then, several works [19], [29], [41] have applied the same idea to reduce the cost of matrix multiplication in AI applications. In floating-point terms, LNS uses a sign bit (*s*) and exponent to encode a number and neglects having a mantissa or fraction field. To improve the precision of LNS, recent work proposes the multi-dimensional logarithmic number system (MDLNS) [41] or multi-base logarithmic number system [19]. For this work, we follow a special case of MDLNS demonstrated in [41], where the exponent is replaced with a fixed-point number containing an integer and fraction component. For example, the 8-bit (I4F3) LNS with an exponent of 4 integer bits (*int*) and 3 fraction bits (*frac*) can be modeled as a two-base MDLNS of the following form:

$$(-1)^s \cdot 2^{int} \cdot \sqrt[8]{2}^{frac}$$

B. Block Data Formats

A relatively new type of data formats proposed to improve accuracy at low-precision are called block data formats [9]. At a high level, block data formats use a shared scale or exponent for a *block* of data, where a block is typically 32 to 64 adjacent weights or activations from the same matrix or vector. The advantage of a shared scale is that it gives a higher effective dynamic range for a block of data at a low memory, area, and power overhead. The two block data formats we evaluate are **Microscaling** (MX) [33] and **Vector-Scaled Quantization** (VSQ) [7]. MX defines a standard where an 8-bit exponential scale factor (E8M0) is shared amongst a block of 32 weights or activations. VSQ applies a linear scale for a vector of 64 weights or activations [7], [22]. Although prior work uses FP32 [7] and INT8 [22] scales, we use an FP8 (E5M2) scale because it achieves the best tradeoff between hardware cost and numerical accuracy in our evaluations. The key advantage of VSQ, over MX, is that the scale is not constrained to a power of 2 and thereby offers higher precision. However, re-scaling the data is more expensive and requires multiplication instead of shift operations. Although several other works fit the criteria of block data formats [8], [12], [23], [36], we conclude each is similar in design to either MX and VSQ in that they use a shared exponent or linear scale for a block of data.

C. Matrix Multiplication Unit Design

Modern AI processors utilize specialized matrix multiplication hardware to benefit from both instruction-level parallelism and improved area and energy efficiency. Traditionally, GPUs perform single-instruction multiple-data (SIMD) operations on a *warp* or 32 threads executing the same operation on different data. In this execution model, 32 independent multiply-and-accumulate instructions operate on 32 different data. While this model provides the programmer with generality, it fails to exploit the area and energy efficiency advantage of a fused operation. The simplest example of this is the DP4 (4-input dot product) instruction, that implements: $C = \sum_{n=1}^{4} A_i \cdot B_i$, where A and B are 4-input vectors.

The implementation of the dot product and how various factors contribute to power, performance, area, and accuracy has been the subject of several studies [14], [17], [21], [27], [30], [34]. The dot product unit was conventionally implemented as a network of multipliers and adders, but the initial implementation of the so-called "fused" dot product demonstrated how area and power could be reduced by up 40% by fusing the network of multipliers and adders [34]. In Fig. 2, we illustrate the design of the 4-input FP8 (E4M3) dot product unit with MX scaling and FP32 (or FP16) accumulation. In the fused dot product, multiplication is performed similar to the baseline approach, but the alignment and accumulation of all four products is done together before any normalization or rounding. Following accumulation, only a single normalization and rounding step is performed, thereby reducing area, power, latency. Two designs from Intel [17], [21] extend this idea to 32 input terms which further amortizes the cost of alignment and normalization, effectively improving the area and energy efficiency.

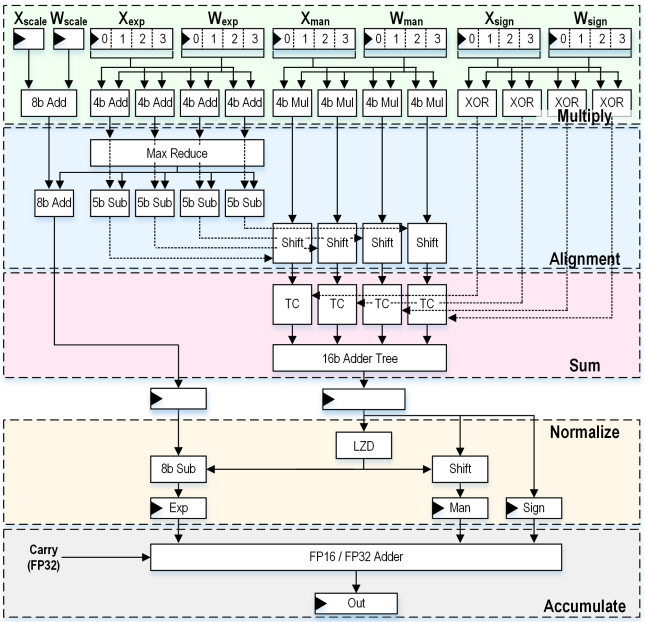

Fig. 2. Schematic of a 4-input fused FP8 (E4M3) dot product unit. Color coding corresponds to area and power breakdown in Fig. 4.

As an extension of the dot product operation (vector-vector multiplication), several commercial designs have introduced dedicated hardware to execute vector-matrix multiplication and matrix-matrix multiplication as a single operation. The Tensor Core, introduced in NVIDIA's Volta architecture [1], is the best known example. The first version of the Tensor Core executes a single 4×4×4 matrix multiplication per clock and improves FP16 throughput by 6× (21.2→125 TOPs) over the previous generation (Pascal) that used only CUDA cores. Subsequent versions of the Tensor Core increased the dimensions from 4×4×4 (Volta) to 8×8×4 (Ampere) to 16×8×4 (Hopper), resulting in throughput improvement. While the primary advantage of performing fused matrix-matrix multiplication is instruction-level parallelism, both pre-processing logic and input registers can be shared resulting in modest area and power savings.

The fused dot product can achieve higher numerical accuracy than the conventional design because it avoids truncation between each operation. However, most implementations of the fused dot product truncate the products following alignment to avoid an unnecessarily large internal datapath (over 90-bits for FP16). There exists a wide range of accumulation widths across commercial designs ranging from 22-bits in Samsung's mobile processor [31], 24-bits in NVIDIA's Tensor Core [16], 37-bits [17] in Intel's accelerator, and 69-bits in ARM's DP4 IP [27]. However, for machine learning applications, [4] demonstrates that truncation as low as 16-bits (for FP16) avoids any significant numerical accuracy loss.

With the emergence of block data formats such as MX and VSQ, several designs [9], [27], [37] have implemented block scaling as part of the MAC design. Conventional layer-wise or channel-wise quantization, where one scale may be shared by thousands of values

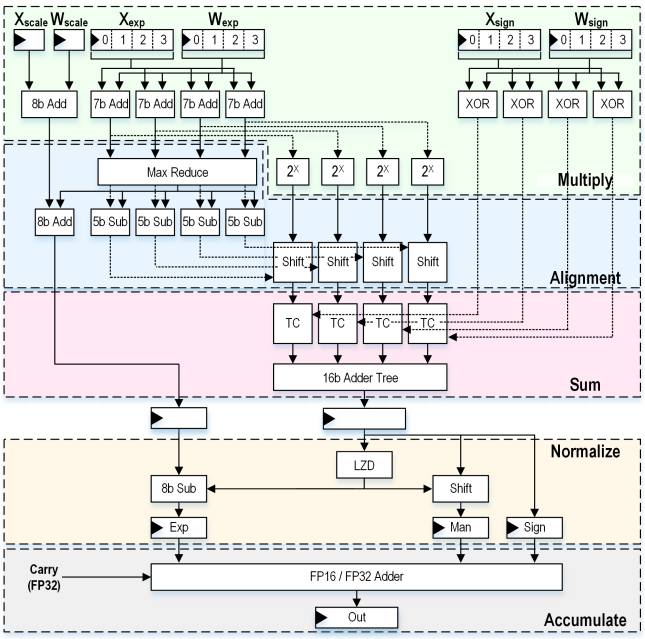

Fig. 3. Schematic of a 4-input fused LNS8 (I4F3) dot product unit. Color coding corresponds to area and power breakdown in Fig. 4.

in a tensor, can be executed efficiently in software. However, the fine-grained scaling requirements of block data formats necessitate integration of the scale inside the MAC operation to maximize efficiency [9], [39]. In Fig. 2, we show how MX scaling can be integrated into the dot product by first adding the scales in parallel, and then adding them to the maximum exponent prior to normalization.

III. MAC Design and Evaluation

A. MAC Architecture

In Fig. 2 we presented the architecture for a configurable 4-input floating-point dot product unit. For posit and LNS, we adapt this design so we can fairly evaluate the design optimizations applied to each data format. Following prior work [24], [30], we find that the posit dot product is most efficiently implemented by first converting posit to floating-point, and then performing the dot product in floating-point. It should be noted that the posit to floating-point conversion is costly in terms of both area and power, and recent work redefines posit such that the decoding step is not as expensive [18]. Posit also has dynamic field sizes requiring higher precision multipliers and adders.

Fig. 3 shows our 4-input dot product design for LNS. To implement 8-bit (1-bit sign, 4-bit integer, 3-bit fraction or I4F3) LNS, 7-bit addition replaces the mantissa multiplication and exponent addition blocks. Next, the fraction component of the result (3 LSBs) is converted from the log domain using a base-2 fixed point exponential function. For our Verilog implementation, we use the associated fixed-point Synopsys Designware IP (DW_exp2). The integer component of the result (5 MSBs) can be processed by shifting the fraction component. The summation, normalize, and accumulate portion of the dot product remains mostly similar to floating-point.

B. Evaluation Methodology

To evaluate the MAC implementations of the various data formats, we consider three key figures of merit: area efficiency, energy efficiency, and numerical accuracy. To evaluate area and energy efficiency, we design, implement, verify, and optimize Verilog models for each data format at different bit precisions. The Verilog model for each data format is parameterized so we can sweep the various optimization parameters studied in the following section (inner product size, accumulation width, pipeline stages, etc). To verify each MAC design, we create a Python emulator and verify against 10,000 test vectors with special attention to special cases such as NaN, infinity, sub-normal, and zero. We synthesize each MAC design in 5nm CMOS at 1 GHz using 750mV VDD (TT corners) and collect area (um^2) and critical path (ns) results. Next, we simulate the synthesized MAC designs using 100 vectors sampled from 4 LLM benchmarks and extract power (mW) using Synopsys PrimePower. In Fig. 5 to Fig. 10 we alternate between TOPs/W and TOPs/mm^2 to address both figures of merit. We find improvements in TOPs/W and TOPs/mm^2 have strong correlation, especially at fixed VDD.

While area efficiency and energy efficiency are common figures of merit for evaluating AI hardware, numerical accuracy is equally important for a fair comparison. This is because the major trade-off when moving to lower precision data formats or efficient MAC designs is numerical accuracy. Following [9], we evaluate numerical accuracy using signal-to-quantization noise ratio (SQNR). However, we compute SQNR using the result of quantized matrix multiplication to account for numerical error introduced by the MAC design. We compute SQNR of each MAC design based on the following equation:

$$SQNR = -10\log(\frac{||Q(X)\cdot Q(W) - X\cdot W||^2}{||X\cdot W||^2})$$

where X and W are activations and weights in FP32, Q is the quantization function that maps FP32 to the quantized data format (ex. FP8), and $||X|| = (\sum_{i=1}^{N} x_i^2)^{1/2}$.

SQNR is a simple yet powerful figure of merit because it scales linearly with the number of bits in the data format and allows us to compare the data formats and their MAC implementation fairly. However, the relationship between SQNR and application accuracy is model and task dependent and typically non-linear. But if we assume the relationship between SQNR and application accuracy is mostly monotonic, then we can effectively compare data formats achieving similar SQNR. To evaluate the SQNR of each MAC design, we sample random vector-vector products from each layer in OpenELM-1B [28] and Llama3.2-1B [38] on the Hellaswag dataset [40] and BERT-Large [25] and RoBERTa-Large [25] on the STSB dataset [6]. We first compute the FP32 result of the vector-vector products as reference. Next, we scale the vectors by the ratio of the max value in the target data format and the max value in the tensor they are sampled from. This ensures the full range of the target data format is used. Then, we quantize the vectors to the target data format and compute the vector-vector product with each MAC design. To execute a large vector-vector product with a smaller MAC design, we break it down into several operations and accumulate the partial sums in FP32 precision. Lastly, we compute the SQNR against the FP32 reference.

C. MAC Design Characterization

In Fig. 4, we present a baseline evaluation (area, power, and SQNR) of each data format with a nominal MAC design to serve as reference for the design optimizations in the following section. For each data format we use a 16-input MAC, with an accumulation width of 16, and 1 pipeline stage. To characterize area and power, we show the block-level breakdown of each MAC implementation in 5nm CMOS. Based on the results in Fig. 4, we make the following initial observations: ① INT8, FP8 (E4M3), and LNS8 (I4F3) consume similar area and power because of the design parameters. INT4 is visibly more power and area efficient than FP4 (E2M1) and LNS4 (I2F1) because accumulation width is fixed at 16-bits. In the

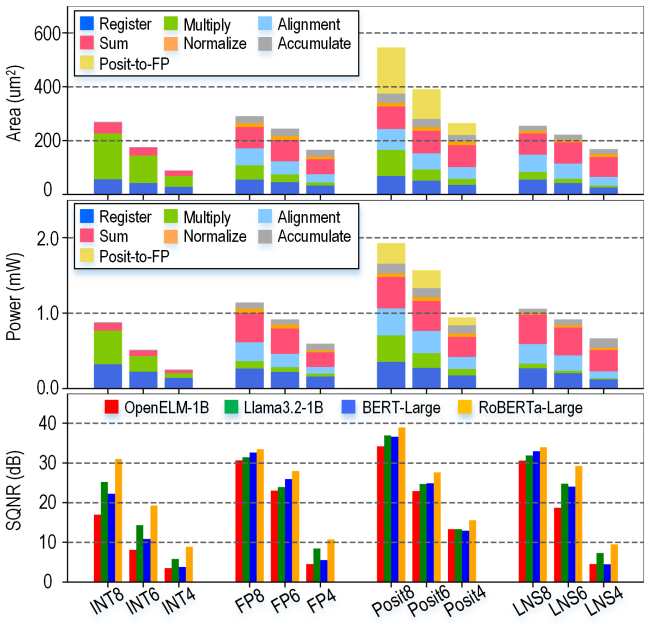

Fig. 4. Area, power, and SQNR of 8-bit, 6-bit, and 4-bit MAC designs for integer, floating-point, posit, and LNS.

following sections, we show how changing design parameters will cause large variations in area and power. ② Posit (E1) consumes nearly 2× more area and power than the other data formats because of the FP conversion overhead. However, it also achieves the best SQNR because of the higher dynamic range. ③ Multiplication makes up a significant fraction of the INT design, but FP (E4M3) only needs a 4-bit multiplier and the base-2 exponent logic in 4/6/8-bit LNS is negligible. ④ A single pipeline stage (register component in Fig. 4) consumes significant area and power overhead for 4/6/8-bit data formats. ⑤ On average the complex data formats (FP, posit, LNS) achieve higher SQNR than INT because they have higher dynamic range which is necessary for the considered transformer models.

D. MAC Design Optimization

Inner Product Size: In section II, we discussed how the inner product size (number of input terms) of the fused dot product can have a significant impact on area and energy efficiency. To understand how each data format benefits from a larger inner product size, we sweep the inner product size of a nominal MAC design and evaluate the energy efficiency (TOPs/W) in Fig. 5. First, we find that increasing the inner product size of the MAC improves the energy efficiency of all data formats. To better understand this observation, we plot the normalized per-MAC area breakdown for the FP8 MAC in Fig. 6. The improvement comes from amortizing the cost of normalization, accumulation, and registers after accumulation. However, the improvement saturates when normalization and accumulation become

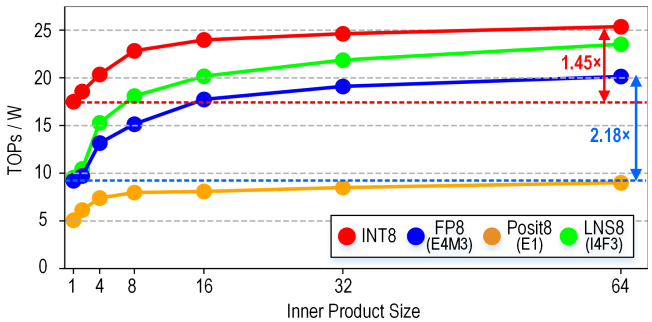

Fig. 5. TOPs/W versus the inner product size for 8-bit data formats.

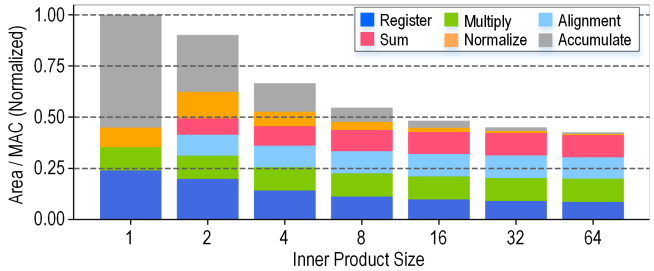

Fig. 6. Normalized area breakdown for the FP8 (E4M3) fused dot product as a function of inner product size.

a negligible fraction of the MAC area. Second, we find that the complex data formats (FP8, LNS8, posit8) benefit more from the increased number of input terms than INT8 because normalization is not performed in the integer dot product and accumulation is significantly cheaper (FP32 vs INT24 addition). Lastly, it should be noted that although peak TOPs/W can be improved by increasing the inner product size, it does not necessarily mean application performance will improve because under-utilization is more likely to occur depending on the specific layer size.

Outer Product Size: In section II, we identified how several commercial designs have extended the dot product instruction (vector-vector multiplication) to both vector-matrix and matrix-matrix multiplication. While this is done primarily to improve instruction-level parallelism, it also has logic-level implications for area and energy efficiency. To understand how each data format benefits from performing matrix-matrix multiplication (as opposed to vector-vector multiplication), we synthesize a 16-input dot product with outer product shapes of 1×1, 2×2, and 4×4 and evaluate the area efficiency (TOPs/mm^2) in Fig. 7. First, we find that increasing the outer product size for FP8, INT8, and LNS8 gives a modest improvement of ∼11% because only the input registers and pre-processing logic (sub-normal, zero, infinity, NaN) are amortized. Second, we find that posit improves visibly more than the other formats, because it's costly decoding logic can be shared across outer products. Posit8 achieves 1.35× TOPs/mm^2 for an outer product of 4×4 versus 1×1.

Accumulation Width: In section II, we identified how floating-point dot products implemented in several AI accelerators truncate the aligned products prior to addition in order to improve area and energy efficiency. To understand how each data format benefits from a reduced accumulation bit-width, we sweep the accumulation width of a nominal MAC design and evaluate the energy efficiency (TOPs/W) in Fig. 8. Because reducing the accumulation bit-width negatively impacts numerical accuracy, we also evaluate SQNR in Fig. 8. First, we find that FP8 and LNS8 achieve similar energy efficiency improvement before SQNR begins to reduce. Second, we find that INT8 is more sensitive to reducing the accumulation bit-width because it is fixed-point (not floating-point). For this reason, the accumulation bit-width of integer is rarely (if ever) truncated, but it is included here for completeness.

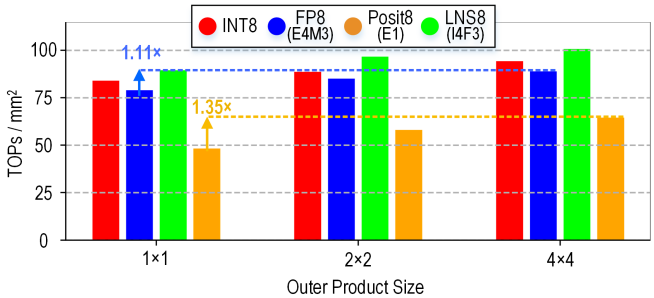

Fig. 7. TOPs/mm^2 versus the outer-product size for 8-bit data formats.

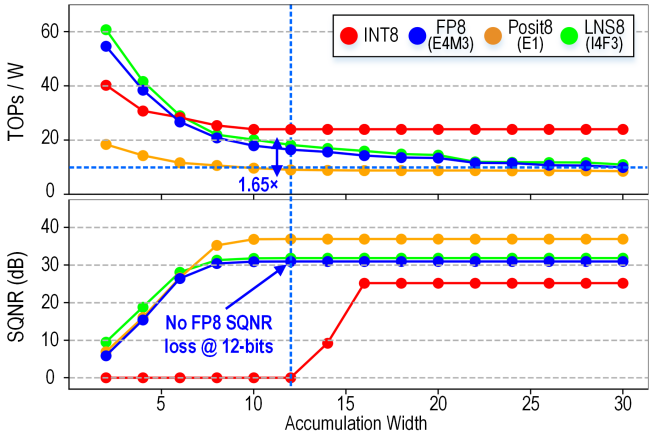

Fig. 8. TOPs/W versus the accumulation width for 8-bit data formats.

Block Data Formats: In section II, we identified an industry trend towards block data formats for effective low-precision quantization. To understand how MX and VSQ can impact the tradeoff space between area efficiency and numerical accuracy, we design and simulate their pairings with the integer, floating-point, posit, and LNS data formats. In Fig. 9, we compare a design without block scaling versus designs with a block size of 32 and 64. First, we find that block scaling yields a significant improvement in SQNR for INT4, FP4, and LNS4 while the area overhead is negligible. However, because posit4 has a large dynamic range it may not need block scaling even at 4 bits. Second, we find that decreasing the block size (64→32) improves SQNR and reduces area efficiency marginally. Third, we observe that VSQ has slightly higher overhead than MX and yields slightly higher SQNR. Because VSQ sets the scale more precisely, it achieves ∼3dB higher SQNR corresponding to $\frac{1}{2}$ bit precision.

Fixed-Point Accumulation: In section II, we described how a fused dot product aligns all mantissa products to the maximum exponent prior to accumulation. Under this topology, the products of floating-point multiplication are accumulated in floating-point; they are represented using the maximum exponent and N mantissa products, where N is the inner product size. If instead, we were to represent the products of floating-point multiplication as fixed-point numbers it would require >90 bits in FP16 [5]. However, for FP4, the products of floating-point multiplication can be represented in fixed-point using only 8-bits, and the cost of global alignment outweighs the benefits of truncation. In Fig. 10, we plot energy efficiency for both floating-point and fixed-point accumulation on FP16, FP12, FP8, FP6, FP4, and FP3. We find that floating-point accumulation is significantly better for FP16, FP12, and FP8. However, we find

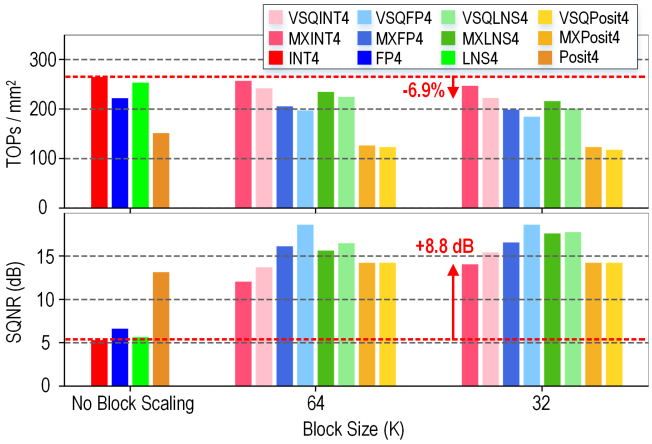

Fig. 9. TOPs/mm^2 versus block size for MX & VSQ 4-bit data formats.

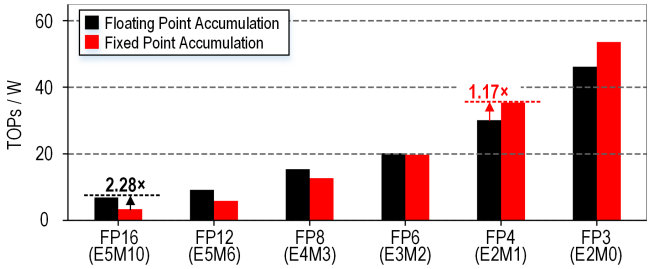

Fig. 10. TOPs/W versus floating-point and fixed point accumulation.

that FP4 with fixed-point accumulation achieves 17% better energy efficiency than the floating-point accumulation implementation.

Pipeline Stages: The last design parameter we evaluate is the number (and location) of pipeline stages. In our floating-point Verilog model we have 6 pipeline stages that can be enabled or disabled giving a total of 64 (2^6) permutations. For each design, we find the subset of pipeline configurations that yields the best area and energy efficiency. Ultimately, we find that the optimal pipeline configuration changes based on the data format and other design parameters (inner product size, accumulation width, etc).

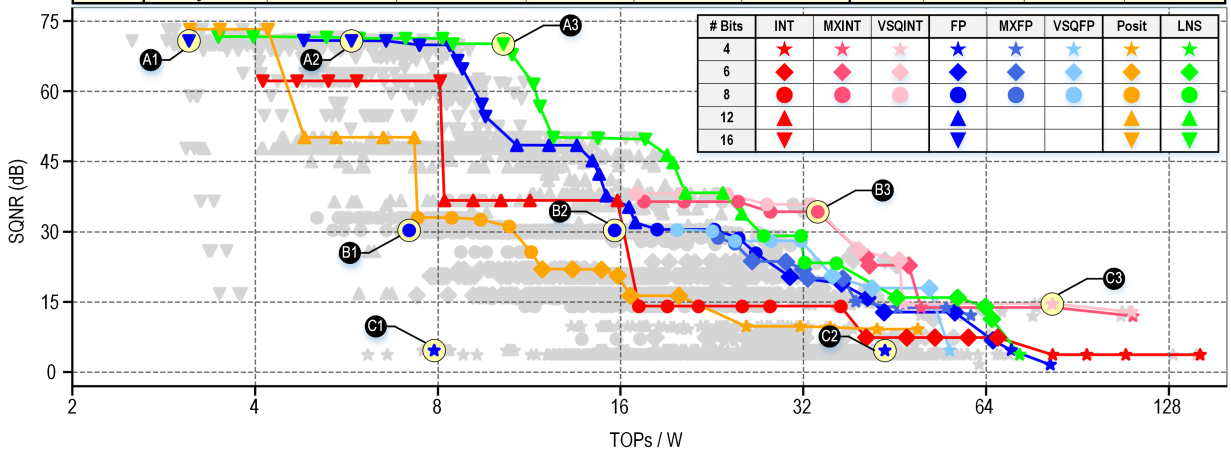
IV. Design Space Exploration

A. Experimental Results

In Fig. 11, we plot the numerical accuracy versus energy efficiency design space for INT, FP, LNS, posit and the MX and VSQ variants of INT and FP. For each data format, we evaluate MAC implementations for 4-bit, 6-bit, 8-bit, 12-bit, and 16-bit variants. We evaluate several configurations of the FP (ex. E5M2, E4M3), LNS (ex. I5F2, I4F3), and posit (ex. E0, E1) data formats at each bit-width. We sweep a wide range of the MAC design parameters presented in section III, resulting in over 25,000 total designs. We color only the pareto optimal designs for each data format, and the gray points represent the sub-optimal designs. It should be noted that we do not consider the area and power overhead of quantization in our evaluation.

In Fig. 11, we inspect three sets of data points corresponding to three different levels of SQNR. The first set (A1, B1, C1) are baseline 1-input MAC designs that resemble the implementation of the fused-multiply add (FMA) instruction in a CPU or NVIDIA CUDA cores. The second set (A2, B2, C2) are fused dot product designs with an outer product size of 4×8 to model the Tensor Core in NVIDIA's H100 [3]. The inner product size increases from 16 (FP16) to 32 (FP8) to 64 (FP4) to model the Tensor Core in NVIDIA's H100 [3]. The third set (A3, B3, C3) are the pareto optimal designs resulting from our design space evaluation. It should be noted we limit the inner product size to 64 and outer product size to 4×4 (except for A2, B2, C2) in our evaluation to constrain the design space. It should also be noted that not all pareto optimal design points may be suitable for commercial implementation due to other factors. Instead, this design space exploration is intended to show the current upper bound that can be achieved with new data formats and custom MAC design. Starting with the 16-bit (∼70dB) data formats, we find that the FP16 dot product design (A2) achieves 2.0× TOPs/mm^2 and 1.9× TOPs/W over the baseline 1-input MAC (A1). The pareto-optimal 16-bit LNS data point (A3) achieves 1.8× TOPs/mm^2 and 1.8× TOPs/W over the FP16 dot product (A2) at nearly the same SQNR. These improvements come from the larger inner product size, smaller sum (accumulation) width, and area savings LNS obtains by avoiding multiplication. Next, we evaluate 8-bit (∼30dB) data formats. We find that the pareto-optimal MXINT8 data point (B3) can achieve 1.8× TOPs/mm^2 and 2.2× TOPs/W over the FP8 dot product (B2) while achieving higher SQNR. Lastly, we evaluate 4-bit (∼15dB)

ID	MAC Design						Figure of Merit			
	Data Format	Inner Product	Outer Product	Sum Width	# Pipeline	Block Size	#Bits	TOPs/W	TOPs/mm^2	SQNR (dB)
A1	FP16	1	-	37	2	-	16	3.1	22.0	70.8
A2	FP16	16	4×8	24	2	-	16	5.8	43.9	70.8
A3	LNS16	64	4×4	16	2	-	16	**10.3**	**78.1**	70.2
B1	FP8 (E4M3)	1	-	37	2	-	8	7.1	43.7	30.3
B2	FP8 (E4M3)	32	4×8	24	2	-	8	15.6	90.8	30.3
B3	MXINT8	64	4×4	16	1	64	8.125	**33.8**	**164.7**	**34.2**
C1	FP4 (E2M1)	1	-	37	2	-	4	7.9	59.1	4.6
C2	FP4 (E2M1)	64	4×8	24	2	-	4	43.6	238.7	4.6
C3	VSQINT4	64	4×4	8	1	32	4.25	**82.2**	**413.9**	**14.6**



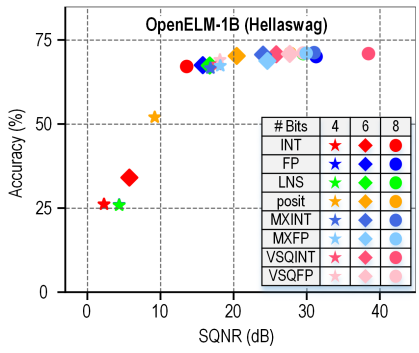


Fig. 11. Energy efficiency versus numerical accuracy design space for INT, MXINT, VSQINT, FP, MXFP, VSQFP, posit, and LNS.

data formats. We find that the pareto-optimal VSQINT4 data point (C3) can achieve 1.7× TOPs/mm^2 and 1.9× TOPs/W over the FP4 dot product (C2) while achieving higher SQNR.

From Fig. 11 we can also make several other observations. ① The pareto optimal data format for >8-bit is LNS. LNS has a marginal advantage over FP is because it avoids multiplication which is a large fraction of the energy consumed by FP when the number of mantissa bits is large (FP16, FP12). ② The pareto optimal data formats for ≤8-bit are MXINT and VSQINT. Both MX and VSQ boost the accuracy of low precision data formats at low hardware overhead. ③ Posit appears sub-optimal despite having a high SQNR compared to data formats with a similar number of bits (ex. posit8 vs FP8). This is because posit requires hardware overhead for decoding and dynamic field sizing. ④ INT has sub-optimal SQNR because it has insufficient dynamic range for the data distribution in the LLMs. This challenge is resolved by pairing INT with MX or VSQ. ⑤ At various points in the scatter plot, we see designs that improve in TOPs/W with no cost to SQNR. This observation occurs because the inner product size, outer product size, and pipeline configuration can improve TOPs/W at no impact to SQNR. ⑥ For each data format there are *steps* at various points in the pareto curve. These steps correspond to transitions from a higher precision format to a lower precision format (ex. INT12→INT8) or changes in parameters like the accumulation width and block size that trade TOPs/W for SQNR.

B. Application Benchmarks

To correlate the numerical accuracy with application accuracy, we benchmark on four representative LLMs. We evaluate two decoder-only transformer models, OpenELM-1B [28] and Llama-3.2-1B [38], and two encoder-only transformer models, BERT-Large [11] and RoBERTa-Large [25]. For OpenELM-1B and Llama-3.2-1B, we run inference on the HellaSwag dataset [40] where the model selects one of four answers. For BERT-Large and RoBERTa-Large, we run inference on the STSB dataset [6] where the model predicts a similarity score between 0 and 1. To evaluate the different data formats on each model, we implement custom PyTorch kernels to quantize FP32 weights and activations of each matrix multiplication operation to the target data format. The actual matrix multiplication executes in FP32, but the underlying weights and activations are constrained to the target data format such that it emulates custom hardware. Fig. 12 presents the accuracy achieved across our set of transformer benchmarks on the target data formats at 4-bit, 6-bit, and 8-bit precision. The results are green if <1% accuracy loss is achieved from the FP32 baseline, otherwise red. We observe a positive trend towards MX and VSQ, similar to results in Fig. 9 and Fig. 11. In Fig. 12, we also plot SQNR versus accuracy for OpenELM-1B on Hellaswag and empirically confirm a mostly monotonic (and non-linear) relationship between SQNR and application-level accuracy. A similar relationship occurs for the other benchmarks.

Task	Language Decoder						Language Encoder					
Dataset	Hellaswag						STSB					
Model	OpenELM-1B			Llama3.2-1B			BERT-Large			RoBERTa-Large

***Abstract*—Model checking is an automated method used to formally verify systems by checking them against properties. However, a major problem in model checking is the state explosion. To overcome this challenge, one approach is to utilize parallel processing capabilities to either speed up computations or handle larger-scale problems. Explicit model checking has lower computational complexity and can be easily parallelized. There are numerous parallel explicit model checking algorithms available in the literature. Symbolic model checking offers significant advantages over explicit model checking in terms of problem scalability and verification speed. However, treating states encountered during the search as sets poses a challenge in devising efficient parallel algorithms. As a result, current research on parallelizing symbolic model checking has primarily focused on reachability analysis or safety properties, rather than attempting to parallelize the nested fixpoint calculations. In this paper, we propose a novel property-driven approach for parallel symbolic model checking of full LTL. Our algorithm introduces a fair model state labelling function that forms a partition of the nested fixpoint across the product combining the model and the property Büchi automaton. The experimental results demonstrate significant speedup, ranging from 2.81 to 17.19 times compared to sequential approaches on a 32-core machine. Moreover, in comparison to existing parallel model checking methods, our approach not only surpasses those relying on BDD libraries with a maximum improvement of up to 134% and an average improvement of 33.1% but also demonstrates significant superiority over the state-of-the-art parallel explicit model checker.**

I. Introduction

Model checking is an automated method for formally verifying systems against temporal properties [1]. However, the state space must be exhaustively explored either explicitly or symbolically, leading to the state explosion problem that has plagued model checking since its inception [2]. To address this issue, researchers have developed clever methods such as abstractions [3] and symbolic representations [4]. Another approach is to leverage the rapid development of computing, storage, and communication technologies by parallelizing sequential model checking using multi-core [5], distributed systems [6], GPGPU [7], and other modes of computation.

Explicit model checking is amenable to parallelization, and extensive parallel algorithms exist in the literature. In explicit model checking, each state encountered during BFS, DFS, or some variants is explicitly stored and individually manipulated. Explicit model checking algorithms based on BFS or the detection of strongly connected components (SCC) belong to the Nick class [8], which theoretically have highly parallel algorithms [9]. Although DFS is inherently sequential, and thus the classic nested DFS model checking algorithm [10] based on finding an accepting and fair cycle does not belong to the Nick class, there are also many efficient parallel explicit model checking algorithms based on DFS [8].

Symbolic model checking offers significant advantages, compared to explicit model checking, in terms of the scale of problems and verification speed. Symbolic model checking uses characteristic functions to represent a set of states. Symbolic representations, such as BDDs [11], are normally more compact than explicit representations, making it possible to verify problems with larger scales. Modern symbolic model checking algorithms are variants of the Emerson-Lei algorithm [12], which includes nested fixpoint calculations.

However, treating states encountered as sets poses a challenge in devising efficient parallel symbolic algorithms. The most challenging task lies in devising an efficient algorithm for computing the nested fixpoint when the symbolic state space is divided into slices. As a result, current research on parallelizing symbolic model checking has primarily focused on reachability analysis or safety properties, avoiding the parallelization of nested fixpoint calculations. Building upon distributedly partitioned BDDs, a parallel symbolic model checking algorithm for safety properties was introduced in [13]. There have been also various studies on parallel symbolic model checking of systems with specific structures. For instance, research has been conducted on the reachability analysis of security protocols with a bounded number of sessions [14] and the verification of split-invariants for asynchronously composed processes communicating through shared-memory [15]. Unlike these studies, which do not focus on full model checking, [16] proposed a symbolic algorithm for the model checking of propositional μ-calculus based on distributively evaluating subformulas. However, formulas to be verified are generally not large in scale, the degree of parallelism is limited.

In this paper, we present property-driven parallel symbolic model checking of full LTL. The contributions is summarized as follows:

- We propose a property-driven state space partition method for nested fixpoint computation. This algorithm utilizes a fair model state labelling function that ensures the labeling of a model state s in an automoton state q if and only if there exists a fair path starting from (s, q) in the product. The fair model state labelling function naturally forms a partition of the nested fixpoint. Therefore, by computing the labelling function, we effectively implement the symbolic model checking of LTL.
- We propose a parallelize algorithm to compute the state labelling function. This algorithm takes advantage of the labelling function can be computed using a backward BFS manner, which is well-suited for parallelization. In our approach, the computation is performed by a group workers. The number of workers used in this process is equal to the number of states in the automaton, denoted as n. However, we have also devised mechanisms to increase the degree of parallelization beyond n, allowing for more workers to be utilized. To ensure efficient usage of resources, we have also introduced load balancing techniques.
- We conduct a comprehensive evaluation of our parallel algorithm and compared it to existing approaches. The results highlight the effectiveness and efficiency of our proposed method. The experimental results on a 32-core machine demonstrate significant speedup, ranging from 2.81 to 17.19 times compared to sequential approaches. Moreover, in comparison to existing parallel methods, our approach not only surpasses those relying on BDD libraries with a maximum improvement of up to 134%

and an average of 33.1% but also demonstrates superiority over the parallel explicit model checker LTSMin [5].

II. Preliminaries

Kripke structure: Without loss of generality, we assume the system is modelled as Kripke structure. Specifically, a Kripke structure is represented by a tuple $M = (S, S_0, R, AP, L)$ in which S denotes the set of states, $S_0 \subseteq S$ represents the set of initial states, $R \subseteq S \times S$ denotes the transition relation, AP is the set of atomic propositions, and $L : S \to 2^{AP}$ is a function that labels each state with the set of atomic propositions that are true in that state [1]. A path of length l is defined as a sequence of states $s_0, \cdots, s_{l+1}$ where $s_0 \in S_0$ and for all $0 \leq i \leq l$, $(s_i, s_{i+1}) \in R$.

Linear temporal logic (LTL) is a formalism for specifying temporal properties derived from Kripke structures. It extends propositional logic with temporal operators such as $\mathbf{X}$ (next), $\mathbf{F}$ (eventually), $\mathbf{G}$ (globally), and $\mathbf{U}$ (until), allowing the expression of time-dependent behaviors [1]. The properties expressed in LTL can be classified into safety and liveness.

Büchi automaton: LTL model checking typically involves negating the formula, converting it to a Büchi automaton, and checking the emptiness of its product with the Kripke model. As the Büchi automaton generated from an LTL formula normally has an alphabet over the power set of AP and includes atomic propositions as labels in each state, in addition to the standard definition, we have incorporated a state labeling function in the following definition. A Büchi automaton is defined as $\mathcal{B} = (\Sigma, Q, \Delta, Q_0, \mathcal{L}, F)$, where $\Sigma = 2^{AP}$ is the finite alphabet, Q is the finite set of states, $\mathcal{L} : Q \to 2^{AP}$ is the state labelling function, $\Delta \subseteq Q \times \Sigma \times Q$ is the transition relation such that if $(q, \sigma, q') \in \Delta$ then $\sigma = \mathcal{L}(q)$, Q_0 is the set of initial state, and $F = \{P_1, P_2, \cdots, P_k\}$ where for every $1 \leq i \leq k$, $P_i \subseteq Q$. Similarly, an infinite path ρ is a sequence states $q_0, \cdots, q_i, \cdots$ such that $q_0 \in Q_0$ and, for all $i \geq 0$, $(q_i, \nu(i), q_{i+1}) \in \Delta$, where $\nu(i)$ denotes the i-th input letter of the word sequence $\nu \in \Sigma^*$. A Büchi automaton accepts only infinite ***illustrate*** paths in which there exist at least one state from each P_i that appears infinitely often. Given a Kripke structure $M = (S, S_0, R, AP, L)$ and a Büchi automaton $\mathcal{B} = (2^{AP}, Q, \Delta, Q_0, \mathcal{L}, F)$, their synchronized product is denoted as $M \otimes \mathcal{B} = (2^{AP}, Q_\otimes, \Delta_\otimes, Q_{\otimes 0}, F_\otimes)$. Here, $Q_\otimes = S \times Q$, $Q_{\otimes 0} = S_0 \times Q_0$, and $((s_1, q_1), \sigma, (s_2, q_2)) \in \Delta_\otimes$ if and only if $(s_1, s_2) \in R$, $L(s_1) = \mathcal{L}(q_1)$, and $(q_1, \sigma, q_2) \in \Delta$. Furthermore, $F_\otimes(s_1, q_1) = F(q_1)$.

III. Problem Formulation

The formula $\mathbf{EG}\varphi$ expresses the existence of a path in which φ holds globally. When fairness is considered, the set of states satisfying $\mathbf{EG}\varphi$ can be obtained through the following nested fixpoint:

$$[\mathbf{EG}\varphi]_M^{Fair} = \nu Z.\varphi \wedge \bigwedge_{k=1}^{n} \mathbf{EXE}(\varphi \mathbf{U}(Z \wedge P_k)) \tag{1}$$

Here, ν represents the greatest fixpoint, and $\{P_1, \cdots, P_n\}$ represents the fairness. If any of the initial states of M belongs to $[\![\mathbf{EG}\varphi]\!]_M^{Fair}$, then $M \models \mathbf{EG}\varphi$. Consequently, the formula $\mathbf{EG}true$ characterizes the set of states from each of which there exists a fair path.

The symbolic model checking of LTL based on the computation of $\mathbf{EG}true$, assuming $F = P_1$ without loss of generality, is presented in Algorithm 1. When the fixpoint is reached, only the states from which there exists a fair path are kept. The procedure above heavily relies on the use of symbolic state representation, utilizing sets of states in every iteration. This approach significantly enhances its effectiveness and clarity. However, it also makes decision procedures employed in explicit parallel model checking, such as loop detection based on nested DFS [10], or loop detection based on BFS [17], impractical.

Algorithm 1: Symbolic algorithm for LTL model checking

Input: a Kripke structure M, a Büchi $\mathcal{B}_{\neg\varphi}$ automaton corresponding to the LTL formula to be verified.
Output: a boolean result indicating whether the language accepted by $M \otimes \mathcal{B}_{\neg\varphi}$ is empty.

```
1  begin  /* Compute EGtrue = νZ.EXEF(Z ∧ F⊗) */
2      S1 ← S × Q, Q' ← S1;
3      do
4          Q ← Q';
5          begin /* EF(Q ∧ F⊗) = μZ.(Q ∧ F⊗) ∨ EXZ */
6              W' ← ∅;
7              do
8                  W ← W';
9                  W' ← (Q ∧ F⊗) ∨ Pre⊗(W);
10             while W ≠ W';
11         begin                          /* Compute EX */
12             Q' ← Pre⊗(w);
13     while Q ≠ Q';
14 begin                                  /* Check emptiness */
15     if ∃(s0, q0) ∈ S0 ⊗ Q0 such that (s0, q0) ∈ Q then
16         return false
17     else
18         return true
```

As discussed previously, the current research on parallelizing symbolic model checking primarily focuses on reachability analysis and safety properties, while neglecting the parallelization of nested fixpoint calculations. Therefore, there is a gap in this research area as no investigations have been conducted on parallelizing the nested fixpoint calculation process. Our paper aims to present an effective approach for parallelizing the nested fixpoint computation process, enabling parallel symbolic model checking of full LTL.

IV. Property-driven Parallel Symbolic Model Checking

The term *property-driven* refers to the transformation of nested fixpoint computation into the parallel computation of n smaller fixpoints, where n is the number of states of the property automaton.

A. Sequential algorithm

Given a Kripke structure $M = (S, S_0, R, AP, L)$, a Büchi automaton $\mathcal{B} = (2^{AP}, Q, \Delta, Q_0, \mathcal{L}, F)$ and their synchronous product, we have the following definitions:

Definition IV.1 (Model state labelling function)**.** *Let $\mathcal{L}_\mathcal{M}$ be a function: $Q \to 2^S$. It should be noted that any subset of S can be characterized by a predicate over AP.*

Definition IV.2 (Projection)**.** *For a subset $Q' \subseteq Q$ and a model state labelling function $\mathcal{L}_\mathcal{M}$, the projection of $\mathcal{L}_\mathcal{M}$ over Q' is denoted as $\mathcal{L}_{\mathcal{M}\restriction Q'}(q) = \mathcal{L}_\mathcal{M}(q)$ if $q \in Q'$, and $\emptyset$ otherwise.*

Definition IV.3 (Fair model state labelling function)**.** *A model state labelling function $\mathcal{L}_\mathcal{M}$ is considered fair if and only if for any state s in the set $\mathcal{L}_\mathcal{M}(q)$, there exists a fair path starting from (s, q) in the product.*

Theorem IV.1. *For a state labeling function, the set $\{\mathcal{L}_\mathcal{M}(q) |$ for all $q \in Q\}$ forms a partition of the nested fixpoint $\mathbf{EG}true$.*

Algorithm 2: Sequential property-driven symbolic algorithm

Input: a Kripke structure M; a Büchi $\mathcal{B}_{\neg\varphi}$ automaton corresponding to the LTL formula to be verified.
Output: a boolean result indicating whether the language accepted by $M \otimes \mathcal{B}_{\neg\varphi}$ is empty.

/* Compute fair $\mathcal{L}_\mathcal{M}$ */
1 $\mathcal{L}^0_\mathcal{M}(q) \leftarrow true,\ for\ all\ q \in Q$;
2 **do**
3 $\quad \mathcal{L}^1_\mathcal{M} \leftarrow \mathcal{L}^0_\mathcal{M}$;
4 $\quad \mathcal{L}^0_\mathcal{M}(q) \leftarrow \mathcal{L}(q) \cap \mathcal{L}^1_\mathcal{M}(q)$ if $q \in P_1$, $\emptyset$ otherwise;
/* $s \in \mathcal{L}^0_\mathcal{M}(q)$ *if and only if* $(s,q) \in$ **EF**$(\mathcal{L}(q) \cap \mathcal{L}^1_\mathcal{M}(q))$ */
5 $\quad FIFO\ queue \leftarrow P_1$;
6 $\quad$ **while** $queue \neq \emptyset$ **do**
7 $\quad\quad q \leftarrow queue.remove$;
8 $\quad\quad$ **for** *each* $q' \in Pre_\mathcal{B}(q)$ **do**
9 $\quad\quad\quad update \leftarrow Pre_M(\mathcal{L}^0_\mathcal{M}(q)) \cap \mathcal{L}(q') \cap \overline{\mathcal{L}^0_\mathcal{M}(q')}$;
10 $\quad\quad\quad$ **if** $update \neq \emptyset$ **then**
11 $\quad\quad\quad\quad \mathcal{L}^0_\mathcal{M}(q') = \mathcal{L}^0_\mathcal{M}(q') \cup update$;
12 $\quad\quad\quad\quad$ *add* q' *to queue*;
/* *Compute* **EX**$(\mathcal{L}^0_\mathcal{M})$ */
13 $\quad \mathcal{L}^{EX}_\mathcal{M}(q) \leftarrow false,\ for\ all\ q \in Q$;
14 $\quad FIFO\ queue \leftarrow Q$;
15 $\quad$ **while** $queue \neq \emptyset$ **do**
16 $\quad\quad q \leftarrow queue.remove$;
17 $\quad\quad$ **for** *each* $q' \in Pre_\mathcal{B}(q)$ **do**
18 $\quad\quad\quad \mathcal{L}^{EX}_\mathcal{M}(q') = \mathcal{L}^{EX}_\mathcal{M}(q') \cup (Pre_M(\mathcal{L}^0_\mathcal{M}(q)) \cap \mathcal{L}(q'))$;
19 $\quad \mathcal{L}^0_\mathcal{M} = \mathcal{L}^{EX}_\mathcal{M}$;
20 **while** $\mathcal{L}^1_\mathcal{M} \neq \mathcal{L}^0_\mathcal{M}$;
/* Check emptiness */
21 **if** $\exists s_0 \in S_0, q_0 \in Q_0\ such\ that\ s_0 \in \mathcal{L}^0_\mathcal{M}(q_0)$ **then**
22 $\quad$ **return** *false*
23 **else**
24 $\quad$ **return** *true*

In Algorithm 2, we propose a sequential property-driven symbolic algorithm for model checking LTL. The main objective of the algorithm is to compute the fair model state labeling function. When line 4 is first executed, each accepting state q is labeled with the model states that satisfy $\mathcal{L}(q)$. The code between line 5 and line 12 performs backward labeling on the Büchi automaton's states. This ensures that a model state s is labeled in some state q if and only if $(s,q) \in$ **EF**$(\mathcal{L}(q) \cap \mathcal{L}^1_\mathcal{M}(q))$. In line 11, the code ensures that if a model state s' is added to the labeling of q', there must exist a state $s \in \mathcal{L}^0_\mathcal{M}(q)$ such that $((s',q'),\mathcal{L}(q'),(s,q)) \in \Delta_\otimes$. The subsequent steps in lines 13 to 19 calculate the **EX** operation. This operation involves removing a state's label s from some accepting state q under the following conditions: either (s,q) is not part of any loop, or it cannot reach any other accepting states.

A Kripke structure and an automaton are presented in Figure 1. Initially, $\mathcal{L}_\mathcal{M}(d) = \mathcal{L}(d) = \{x,y,z\}$, $\mathcal{L}_\mathcal{M}(a) = \mathcal{L}_\mathcal{M}(b) = \mathcal{L}_\mathcal{M}(c) = \emptyset$, and $queue = \{d\}$. Then get d from the $queue$, and calculate the pre-image of $\mathcal{L}_\mathcal{M}(d)$, $Pre_M(\mathcal{L}_\mathcal{M}(d)) = \{x,y,z\}$. And then transfer it to the predecessor states in the automaton, $Pre_\mathcal{B}(d) = \{b,c,d\}$. For state b, calculate all states that belong to $Pre_M(\mathcal{L}_\mathcal{M}(d)) \cap \mathcal{L}(b)$ and do not belong to $\mathcal{L}_\mathcal{M}(b)$, $Pre_M(\mathcal{L}_\mathcal{M}(d)) \cap \mathcal{L}(b) \cap \overline{\mathcal{L}_\mathcal{M}(b)} = \{x,z\}$. If it is not empty, add these states to $\mathcal{L}_\mathcal{M}(b)$ and enqueue b. The same for c and d, then $\mathcal{L}_\mathcal{M}(a) = \emptyset$, $\mathcal{L}_\mathcal{M}(b) = \{x,z\}$, $\mathcal{L}_\mathcal{M}(c) = \{y,z\}$, $\mathcal{L}_\mathcal{M}(d) = \{x,y,z\}$ and $queue = \{b,c\}$. Continue this process until the $queue$ becomes empty, indicating the occurrence of the fixpoint of **EF**. Then, proceed to calculate **EX** and repeat the entire process until $\mathcal{L}_\mathcal{M}$ is no longer updated(line 30). Finally, $\mathcal{L}_\mathcal{M}(a) = \{y\}$, $\mathcal{L}_\mathcal{M}(b) = \{x,z\}$, $\mathcal{L}_\mathcal{M}(c) = \{y,z\}$, $\mathcal{L}_\mathcal{M}(d) = \{x,y,z\}$, which is the fixpoint of **EG**$true$. The property is safe because the only initial state $x \notin \mathcal{L}_\mathcal{M}(a)$.

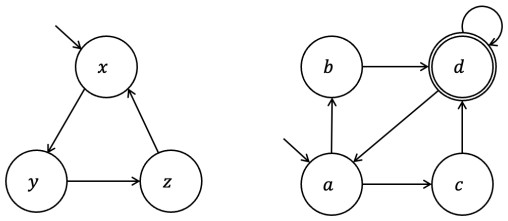

Fig. 1: A Kripke structure $S_0 = \{x\}$, and a Büchi automaton, $Q_0 = \{a\}$, $P_1 = \{d\}$, $\mathcal{L}(a) = \{y\}$, $\mathcal{L}(b) = \{x,z\}$, $\mathcal{L}(c) = \{y,z\}$, $\mathcal{L}(d) = \{x,y,z\}$

Algorithm 3: Parallel property-driven symbolic algorithm

Input: a Kripke structure M; the Büchi $\mathcal{B}_{\neg\varphi}$ automaton corresponding to $\neg\varphi$, where φ is the LTL formula to be verified. Let $n = |Q|$.
Output: a boolean result indicating whether the language accepted by $M \otimes \mathcal{B}_{\neg\varphi}$ is empty
Data: $\mathcal{L}^0_\mathcal{M}(q)$ with each element initialized to true, $\mathcal{L}^1_\mathcal{M}(q)$.

1 **do**
2 $\quad \mathcal{L}^1_\mathcal{M} = \mathcal{L}^0_\mathcal{M}$;
3 $\quad$ **for** *each* $q \in Q$ **do** /* Compute EXEF */
4 $\quad\quad Spawn\ Labelling_q(\mathcal{L}^0_{\mathcal{M}\uparrow P_1}(q))$;
5 $\quad$ **for** *each* $q \in Q$ **do**
6 $\quad\quad \mathcal{L}^0_\mathcal{M}(q) \leftarrow Sync\ Labelling_q$;
7 **while** $\mathcal{L}^0_\mathcal{M} \neq \mathcal{L}^1_\mathcal{M}$;
/* Check emptiness */)
8 **if** $\exists s_0 \in S_0, q_0 \in Q_0\ such\ that\ s_0 \in \mathcal{L}^0_\mathcal{M}(q_0)$ **then**
9 $\quad$ **return** *false*
10 **else**
11 $\quad$ **return** *true*

Theorem IV.2. *Algorithm 2 computes the fair model state labelling function.*

Proof. In the algorithm, a model state s is marked in a particular state q if and only if (s,q) is an accepting state of the product or can reach an accepting state within a finite number of steps. It is important to note that the algorithm will eventually terminate since the **EX** operations cannot run indefinitely. Upon termination, the nested fixpoint computation guarantees that s is marked in a state q if and only if there exists a fair path that starts from (s,q). □

B. Parallel algorithm

The algorithm 2 effectively labels each Büchi state in a backward BFS manner, making it well-suited for parallelization. The parallel version is presented in Algorithm 3 and Algorithm 4.

In Algorithm 3, lines 1-7 compute the **EXEF** formula in parallel, continuing in an iterative manner until a fixed point is reached. More specifically, line 4 of the code spawns a separate worker for each state in the Büchi automaton, and each worker executes Algorithm 4. The projection of $\mathcal{L}^0_\mathcal{M}$ onto P_1 in line 4 will assign labels to each

state q in P_1 based on the modeling states that satisfy q, leaving all other states labeled with the empty set. In line 6, the algorithm is blocked until all workers have completed their tasks, subsequently retrieving the results of their computations.

Algorithm 4: Labelling$_q$

Input: $\mathcal{L}^0_{\mathcal{M}}(q), \mathcal{L}(q)$.
Output: a set of states indicating fair model state labelling function over q

1 $\mathcal{L}^{EF}_{\mathcal{M}}(q) = \mathcal{L}(q) \cap \mathcal{L}^0_{\mathcal{M}}(q)$;
2 **if** $\mathcal{L}^{EF}_{\mathcal{M}}(q) \neq false$ **then**
3 **for** *each* $q' \in Pre_{\mathcal{B}}(q)$ **do**
4 *Send EF message* $\mathcal{L}^{EF}_{\mathcal{M}}(q)$ *to Labelling*$_{q'}$;
5 **do**
6 **if** *all other Labelling*$_q$ *blocked in receiving* **then**
7 *Notify other Labelling*$_q$ *stopping receiving and breaking*;
8 **Break**;
9 *Wait until an EF message arrives*;
10 *Receive a Set message ef_message*;
11 $update = Pre_M(ef_message) \cap \mathcal{L}(q) \cap \overline{\mathcal{L}^{EF}_{\mathcal{M}}(q)}$;
12 $\mathcal{L}^{EF}_{\mathcal{M}}(q) = \mathcal{L}^{EF}_{\mathcal{M}}(q) \cup update$;
13 **if** $update \neq false$ **then**
14 **for** *each* $q' \in Pre_{\mathcal{B}}(q)$ **do**
15 *Send EF message update to Labelling*$_{q'}$;
16 **while** *true*;
17 **for** *each* $q' \in Pre_{\mathcal{B}}(q)$ **do**
18 *Send EX message* $\mathcal{L}^{EF}_{\mathcal{M}}(q)$ *to Labelling*$_{q'}$;
19 $\mathcal{L}^{EXEF}_{\mathcal{M}}(q) = false$;
20 **do**
21 **if** *all other Labelling*$_q$ *blocked in receiving* **then**
22 *Notify other Labelling*$_q$ *stopping receiving and breaking*;
23 **Break**;
24 *Wait until an EX message arrives*;
25 *Receive a Set message ex_message*;
26 $\mathcal{L}^{EXEF}_{\mathcal{M}}(q) = \mathcal{L}^{EXEF}_{\mathcal{M}}(q) \cup (Pre_M(ex_message) \cap \mathcal{L}(q))$;
27 **while** *true*;
28 **Return** $\mathcal{L}^{EXEF}_{\mathcal{M}}(q)$;

In Algorithm 4, lines 5-20 collaboratively compute the **EF** with other workers. At each stage, the algorithm continuously processes incoming messages from workers associated with its successors in the Büchi property automaton, updating its own set of labeled fair states. Upon receiving a message containing the newly labeled fair states from one of the successors, the algorithm labels state q with the predecessors of those fair states in the Kripke structure, ensuring that these predecessors also satisfy the state q, as shown in lines 12-13. If the set of newly discovered states, denoted as $update$, is not empty, the algorithm sends them to its predecessors as indicated by lines 15-16 of the code. Lines 21-30 compute the **EX** in the same way. After *EX* is computed, the result is returned to Algorithm 3. Before waiting for new messages, the algorithm checks whether all other workers are also waiting for incoming messages. If so, it indicates that there are no more messages being sent, and the worker notifies others to stop receiving messages and exit.

Algorithm 5: Increase Parallelism

Input: $desired_parallelism$, $LTL_original$
Output: an automaton with desired size

1 $LTL = LTL_original$;

7 $LTL = \mathbf{G}(LTL_{sr}) \rightarrow LTL$;
8 $automaton$ = $generate_automaton_from_ltl(\neg LTL)$;
9 **Return** $automaton$;

C. Optimizations

1) Increase parallelism: According to Algorithm 3, the number of workers is set equal to the number of states of the automaton. However, it is worth noting that the size of the automaton exhibits exponential worst-case complexity relative to the size of the formula itself [18]. Despite this exponential complexity, it does not pose a disadvantage for our approach. Despite the exponential worst-case complexity, our experiments with the algorithms described in [18] have demonstrated that they often yield automaton that are smaller in size. Nevertheless, to overcome this limitation, we have developed a solution that involves expanding the size of the automaton beyond the number of states in the original automaton. This enhancement improves the parallelism of our algorithm. Intuitively, by augmenting the complexity of the LTL formula, we can also amplify the size of the corresponding automaton.

Usually, the transition relation R of a *Kripke structure* is represented as a conjunction of some sub-relations $R_1, ..., R_n$ such that:

$$R = \bigwedge_{i=1}^{n} R_i, \ where \ R_i \ has \ the \ form \ R_i \ \equiv v' = f(\overline{v}) \quad (2)$$

We can select a set of sub-relations, denoted as $R_s = \{R_i | R_i \ is \ selected\}$, and incorporated them into the LTL formula, which has led to an increase in its size. However, a problem arises due to the presence of primed variables v' in R_i, as these are not valid in LTL expressions. To address this issue, we need to first replace the primed variables v' with the LTL next operator $\mathbf{X}\ v$, resulting in a new set of sub-relations denoted as R_{sr}. Let $LTL_{sr} = \bigwedge_{r \in R_{sr}} r$. Consequently, the new LTL formula will be formulated as follows:

$$LTL_{new} = (\mathbf{G}\ LTL_{sr}) \rightarrow LTL_{original} \quad (3)$$

To establish the relationship between the conjunction of the selected relations and the original LTL, an implication is used. This implies that if a model satisfies the selected transition relations globally, then LTL_{new} will be equisatisfiable with $LTL_{original}$.

Algorithm 5 outlines the procedure for increasing parallelism. It begins by checking if the size of the generated automaton is smaller than the desired parallelism. If it is, another sub-relation is added to construct a new LTL formula, and this process is repeated until the size reaches or exceeds the desired value.

2) Load balancing: As described in Algorithm 2, the workers collaboratively calculate the fair model state labeling function using a backward BFS approach. Generally, parallelizing a BFS-based algorithm provides inherent load balancing advantages. However, it is inevitable that load imbalance may occur in parallel algorithms due

to various factors. For example, in our approach, if only a few threads are performing BDD computation while other threads are blocked, waiting for incoming messages, load imbalance may arise.

To achieve load balancing in a scenario where some workers are blocked, waiting for incoming messages, the work-stealing strategy [19] allows these workers to assist other workers by stealing BDD operations and adding them to their own queue. Instead of developing a proprietary system to support this work-stealing approach, we utilize Sylvan [20], which is a multi-core BDD library. In Sylvan, the work-stealing strategy is employed to facilitate the stealing of BDD operation tasks from other workers when a worker becomes blocked. By leveraging the capabilities of Sylvan, the BDD operations in lines 12-13 and 28 are inputted into the library for effective load balancing.

V. Experimental Results

A. Experiment Setup

We implemented the proposed property-driven parallel algorithm using Sylvan for BDD operations and ltl2tgba for automaton generation. The artifact is available at [21]. Experiments were conducted on a 32-core AMD EPYC 7532 machine with 128GB RAM.

The available benchmarks of model checking are mostly focused on invariant properties, whereas our approach focuses on LTL. We evaluated our method using cases from the examples provided in the NuSMV tool. All of the models and properties were represented in SMV format. The key parameters of the cases are outlined in Table III, where the column *Hold* signifies whether the model checking problem holds, *Variables* represents the count of boolean state variables, and *Assignments* indicates the number of next-state variable assignments, as illustrated in Equation (2).

B. General Observation

Baseline Table I presents the experimental results obtained from evaluating our proposed property-driven algorithm. The sequential property-driven algorithm, outlined in Algorithm 2 and denoted as PSMC, is employed as the baseline for parallel performance evaluation. To establish its comparability to state-of-the-art symbolic model checkers, the column *NuSMV* showcases the performance data of NuSMV on the cases. It becomes evident that the baseline algorithm outperforms NuSMV in nearly all cases.

Scalability The performance of the parallel version of PSMC on various numbers of cores, denoted as $PPSMC_{XX}$, is detailed in Table I. In particular, PPSMC achieves a parallel speedup ranging from 2.81 to 17.19 times compared to PSMC in a 32-core environment, with an average speedup of 8.18 times. Figure 2 further illustrates the speedup of PPSMC at various core counts on average. It is evident that as the number of cores increases, there is no significant slowdown in the upward trend. This observation validates the near-linear scalability of PPSMC, affirming its efficient handling of larger workloads.

Increase parallelism Table II presents the sizes of automaton generated using different numbers of sub-relations on specific models. As the number of sub-relations increases, more intricate LTL formulas are constructed, leading to larger automaton. This size increase is instrumental in enhancing the parallelism of our method. The results show that our method effectively improves parallelism by constructing complex automaton through sub-relation selection.

Load balancing In Table I, we also presents the runtime of PPSMC without load balancing. The result shows that load balancing leads to a significant improvement in performance, with an average improvement of 61%. This result clearly demonstrates the effectiveness of load balancing in our method.

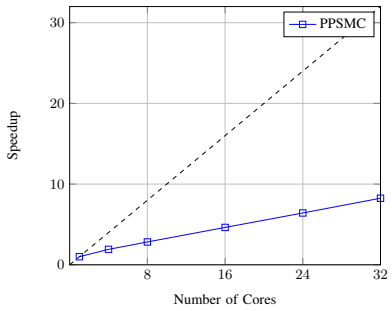

Fig. 2: PPSMC Average Speedups

TABLE II: Parallelism Increase

Model	$\lvert R_s \rvert$	0	1	2	3	4

prod-cons-p0	$\lvert Q_{\mathcal{B}} \rvert$	4	19	39	71	

C. Comparison

Compare to Sylvan To our knowledge, the only existing parallel symbolic model checking approach for full LTL relies solely on parallel BDD libraries like Sylvan [20]. The advantage of this approach is that the high-level model checking algorithm remains unchanged, and all that needs to be done is to invoke the Sylvan library. The strength of our approach lies in an additional level of property-driven parallelization, which not only enhances the overall level of parallelism but also contributes to improved load balancing. We evaluated Algorithm 1 implemented by Sylvan in a 32-core environment. The results are presented in the column labeled $Sylvan_{32}$ of Table III. It is evident from the column labeled *Improv.*, when comparing the column $Sylvan_{32}$ against the column $PPSMC_{32}$, that PPSMC consistently outperforms parallel Sylvan SMC in most cases. The improvement reaches a maximum of up to 134%, with an average improvement of 33.1%.

Compare to LTSmin We also evaluated LTSmin [22], which is a state-of-the-art parallel explicit model checker. We input SMV models into LTSmin through the PINS interface since LTSmin does not support SMV frontend. The results are shown in the column $LTSmin_{32}$. It is apparent that LTSmin has encountered difficulties in solving numerous instances, highlighting the superior scalability of symbolic model checking over explicit methods.

Compare to NuXmv We conducted an evaluation of the k-liveness algorithm [23] implemented in NuXmv [24], a variant of the IC3 algorithm designed for checking full LTL properties. The experimental results are presented in Table III. While it may be unfair to directly compare PPSMC32 with NuXmv, it's noteworthy that PPSMC32 outperforms NuXmv in ten out of twenty cases. In particular, in the case of *cuhanoi10ro*, NuXmv experienced a timeout, whereas BDD-based methods successfully solved it. Despite the prevalent advantages of SAT-based methods in recent years, certain problem classes still rely on BDD-based techniques as the sole method for achieving automated solutions. BDD-based techniques are often considered as part of a diverse range of methods.

VI. Related Work

Explicit parallel model checking individually stores and processes each state encountered during the state space exploration. This approach facilitates the design and implementation of various parallel algorithms. In the case of DFS, the existing research mainly revolves around variants of the classical nested DFS, where a back edge indicates the presence of a loop [25]. On the other hand, in BFS, loop detection is achieved using methods such as back-level edges [17]. The issue with explicit parallel model checking is that, despite the involvement of additional resources

in the parallel environment, its capability to handle large-scale problems remains limited [8].

Symbolic parallel model checking involves processing states as sets. However, treating states encountered during the search as sets poses a challenge in devising efficient nested fixpoint computing algorithms. As a result, current research primarily focuses on reachability analysis or safety properties. For instance, some studies have focused on verification of split-invariants for asynchronously processes communicating through shared-memory [15], and reachability analysis based on partitioned BDDs [26]. In contrast to these studies that primarily focus on safety properties or invariants, [16] proposed a symbolic algorithm for propositional μ-calculus by distributively evaluating subformulas. However, this approach is limited in terms of parallelism due to the relatively small scale of the formulas. The work presented in [27] concentrates on a fragment of CTL utilizing partitioned BDDs and fixpoint computation, as opposed to nested fixpoint computation. Moreover, there exist symbolic parallel techniques that exclusively focus on parallelizing supporting BDD libraries [20]. Nevertheless, these approaches overlook the parallelization of the high-level model checking itself. Our previous experimental results highlight the need for further significant improvement in their speedup. In our work, we concentrate on the Kripke structure and the LTL automaton. We propose a fully parallelized algorithm, while the approach does not incorporate any parallelization techniques.

VII. Conclusion

This paper introduces a novel approach for parallel LTL symbolic model checking. Departing from product computation between the model and the automaton, our approach computes images on the automaton states in parallel. Experimental results showcase the scalability of our method, outperforming existing methods that rely solely on parallel BDD library or are based on explicit parallel method.

***Abstract*—JPEG is the most widely-used image compression method on low-cost cameras which cannot support learning-based compressors. One promising approach to enhance JPEG aims to drop DC coefficients at the cameras' ends (without extra computation) and reconstruct those DC coefficients after receiving them. They all face the challenge that their DC reconstruction relies on a statistical property, which will cause deviation-introduced errors and propagate. In this paper, we propose `DCDiff`, a novel end-to-end DC estimation method to tackle the above challenge. Instead of using statistical methods to recover DC coefficients and then fix errors, we directly leverage a generative model to estimate DC coefficients in an end-to-end manner. In the meantime, we generate masks to correct certain image locations that do not satisfy the statistical distribution to suppress error propagation. Extensive experiments show that `DCDiff` not only outperforms all baselines on compression performance but also introduces a tiny impact on downstream tasks and is fully compatible with 2 typical low-cost processors with JPEG support.**

***Index Terms*—JPEG, Image compression, Diffusion model**

I. Introduction

The deployment of numerous low-cost front-end cameras enables the development of smart Internet of Things (IoT) systems such as security surveillance [1], smart cities [2], and intelligent transportation [3]. Due to the limited computing and power capacity, front-end cameras capture large volumes of images but transmit them to cloud servers for further processing [4], which generates an increasing need for efficient image compression on front-end sensors. Many image compression approaches are proposed such as transformation-based ones (e.g. JPEG2000 [5], WebP [6], etc.) and learning-based ones (e.g. compressive sensing [7], neural image codec [8], etc.). However, many actual cameras tend to use JPEG [9] still due to JPEG's real-time capability, low computational requirements, and high compatibility. For example, ESP32-CAM, a widely-used low-power camera [10]–[12], has a max power of 1.55 Watt and can only support JPEG [13] instead of learning-based encoders.

JPEG is a tunable method to compress images block by block (e.g. 8×8 block) that allows users to choose a lower quality factor (i.e. Q table [14]) to enhance compression ratio on high-frequency (AC) coefficients [15]. However, using a lower-quality factor decreases image quality at decompression. As shown in Fig. 1, another idea [16] to enhance JPEG compression is to preserve AC coefficients but drop the direct current (DC) coefficients at the sender's end and recover them at the receiver's end. This is based on 3 reasons (details in Section II-B). First, DC coefficients are the average pixel values of each image block, which means after discarding DC, the difference between each pixel value within a block remains unchanged. Second, DC coefficients usually have large values, which need more bits to present when coding. Third, dropping DC coefficients does not require any modifications to the JPEG implementation, making it compatible with any low-cost cameras.

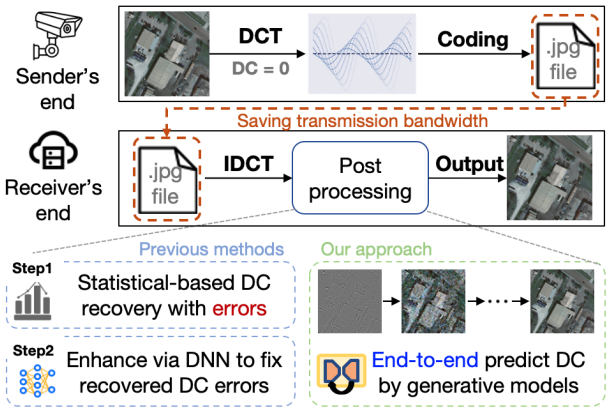

Fig. 1: Pipeline for DC recovery enhanced JPEG compression: existing methods (statistical-based DC recovery with errors need fixing) and our novel approach (i.e. a learned end-to-end method).

Various works [16]–[21] propose different approaches to tackle the challenge: *how to recover the DC coefficients more accurately from rest AC coefficients*. The fundamental idea is based on a statistical property: the differences between neighboring pixel values in natural images generally follow a Laplacian distribution [22]. Thus, based on this property, they recover one unknown DC coefficient from the known neighbor block to iteratively recover all DC coefficients. However, certain locations in natural images (e.g. less than 1% as pointed in [18]) deviate from this distribution, which causes an error when recovering the DC coefficient and will further propagate this error to limit the reconstructed image quality. Even though [19], [20] use deep neural networks (DNNs) to revise the errors after this iterative-based DC recovery, these two-step methods are still suboptimal since deviation-introduced errors are hard to fix.

In this paper, to avoid deviation-introduced errors, we propose `DCDiff` *to enhance JPEG via a learned end-to-end DC estimation*. Our basic idea is to avoid statistical recovery but directly leverage a pre-trained generative model (i.e., Stable Diffusion [23]) to utilize its knowledgeable priors for images to generate DC coefficients based on remaining AC coefficients. This is an end-to-end prediction process that can be optimized using learning methods with more data. Different from existing methods, `DCDiff` is not an iterative computation method block by block, so a deviation of image pixel values does not affect the whole image. However, as the generative model is not specifically designed for DC estimation, it faces challenges in predicting the content consistent average pixel value for each image block. To fill this gap, we propose a novel loss function to constrain the predicted image and the four corner blocks where the DC coefficients are retained to satisfy the Laplacian distribution while generating a mask to filter the image regions that deviate from the statistical property. What's more, to guide the diffusion model in

generating the DC coefficients, we propose a frequency modulation sampling strategy to enhance low-frequency generation.

We compare DCDiff with 3 state-of-the-art (SOTA) baselines across 6 datasets considering 4 metrics. Extensive experiments prove that DCDiff significantly outperforms baselines across different metrics on all datasets such as improving the reconstructed image quality with 3 $\sim$ 6.7 dB more PSNR. DCDiff also has minimal impact on typical downstream tasks such as image classification and can be fully compatible with 2 typical low-cost devices.

II. Preliminaries

A. JPEG compression in IoT system

Due to the broad compatibility and low computational requirements, JPEG is irreplaceable in IoT scenarios, such as safety and security monitoring [24]–[26]. For example, [25] use JPEG for image compression in resilient smart cities, monitoring in real time, and transmitting images to the cloud for processing. Figure 1 shows the workflow of JPEG in IoT systems. The sender's end is often equipped with IoT devices with limited memory and computing capacity, such as surveillance, which can only perform simple mathematical transformations on captured images. The process of JPEG compression includes Discrete Cosine Transform (DCT), quantization according to a quantization table, which determines the quality of compressed image, and entropy coding, typically Huffman coding. The compressed JPEG files are transmitted to the receiver's end, which are often cloud servers with powerful computing resources, for different applications.

Enhanced JPEG compression methods are proposed to save transmission bandwidth. [27] build a JPEG encoder for high visual quality of compressed image with high compression ratio, but introduces significant computation and memory overhead, which is infeasible for resource-constrained devices. [16]–[21] follows the pipeline that drops the DC coefficients at the sender's end to save the transmission bandwidth (see Fig. 2, DC coefficients are generally larger) without any overhead and recover the image at the receiver's end. In this paper, we follow this setting of saving transmission bandwidth by dropping DC coefficients and focus on the post-processing stage at the receiver's end to recover higher-quality images.

B. DC coefficient estimation

DC estimation was first proposed in [22], which demonstrated that it is possible to recover DC coefficient from AC coefficient with reasonable image quality in JPEG encryption systems to provide higher protection for DC coefficient. This method is based on the Laplacian property that the difference between two neighboring pixels follows a Laplacian distribution with zero mean and small variance, as shown in Figure 4. The blue line "w/o mask" means the difference between adjacent pixels across the entire image. Denote $B(i,j)$ as the 8×8 blocks at the $i-th$ row and $j-th$ column of the image. DC value is the average of $B(i,j)$, which is the same for all pixels in $B(i,j)$. Assuming the AC value of $B(i,j)$ and the neighbor block $B(i,j-1)$ is known and DC value of $B(i,j-1)$, $dc_{i,j-1}$, is also known. Based on the Laplacian property, it is highly likely that the pixel values between two adjacent blocks are very similar. [22] minimizes the differences of pixels between two adjacent blocks from three directions to identified DC values.

Recently, some other works have applied DC estimation methods to enhance JPEG compression and further improve DC estimation accuracy. [18] improved the DC estimation from minimizing the value between adjacent pixels to minimizing the distribution trends of the last two columns and the first column of $B(i,j)$ and $B(i,j+1)$.

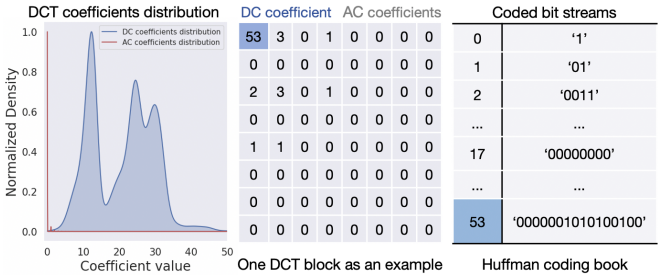

Fig. 2: An example of AC and DC coefficients distribution and corresponding Huffman coding.

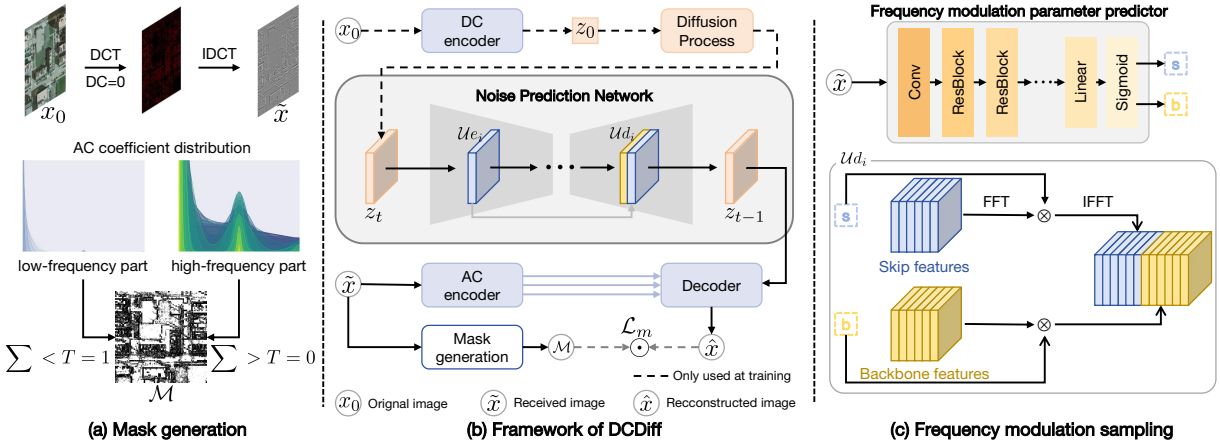
With the development of the neural network, [19] proposed a residual network to improve the image quality after calculating the DC coefficient using the methods proposed in [18]. Observing that the optimal prediction direction of each boundary pixel pair is inconsistent, [20] proposed a novel prediction pattern, which chooses pixel pairs from different directions, to improve the DC estimation.

Although the above methods use different pixel pair patterns to suppress the error propagation caused by the region deviated from Laplacian distribution, there are still some pixels that exhibit a significant difference compared to adjacent pixels in any three directions. Furthermore, the iterative process between blocks will amplify this error. To solve the above problems, we first analyze the characteristics of the region deviated from the Laplacian distribution. In addition, instead of using a block-by-block iterative approach, we directly predict the value of each pixel using a neural network, which can avoid the error propagation between adjacent pixels.

III. Method



A. Overview

In this section, we describe in detail our end-to-end post-processing method based on generative models. Figure 3 shows our major component. Compared with previous methods [19], DCDiff no longer relies on mathematical methods to iterate between DCT blocks to calculate the DC coefficients, but directly predicts the entire image using the diffusion model (section III-B). To constrain the reconstructed image to have content consistency with the origin image, DCDiff is trained using a masked Laplacian distribution loss to ensure the reconstructed images satisfy the Laplacian property while filtering the regions that may cause error (section III-C). Finally, to enhance the DC coefficients generated by the diffusion model, DCDiff uses a frequency modulation sampling strategy during the inference process, and a frequency modulation parameter predictor is applied to predict different scale factors adapting to different input images (section III-D).

B. DC coefficient feature extraction and generation

We denote the origin image as x_0, the reconstructed image as $\hat{x}$, and $\tilde{x}$ presents the image without DC coefficients after the receiver performs IDCT.

DC coefficients feature extraction. As illustrated in section I, DC coefficients represent the average of each image block, which means the DC coefficients have a much smaller feature space than the origin image. First, we introduce an image encoder (DC encoder) and an image decoder, denoted as $\mathcal{E}^{DC}$ and $\mathcal{D}$, to compress the image into a smaller latent space, which can present the DC component feature space, and the extracted feature denoted as z_0. To ensure that $\mathcal{E}^{DC}$ pays more attention to extracting the DC component of the image, we introduce another image encoder (AC encoder, $\mathcal{E}^{AC}$), taking $\tilde{x}$

(a) Mask generation (b) Framework of DCDiff (c) Frequency modulation sampling

Fig. 3: Main components of DCDiff. (a) The insight to generate a spatial mask to apply Laplacian property (section III-C). (b) The pipeline of DCDiff to recover the JPEG images at the receiver's end (section III-B). (c) During inference, frequency modulation sampling is used to enhance the low-frequency generation (section III-D).

as input. $\mathcal{E}^{AC}$ can only extract the feature of AC coefficients, as the DC coefficients in $\tilde{x}$ have been set to zero at the sender's end. The image decoder $\mathcal{D}$ receives two parts of information, one of which is the AC features from the AC encoder, and the other is z_0 from the DC encoder. To better reconstruct the image, $\mathcal{D}$ needs both AC features and DC features, which forces the DC encoder to extract the features of DC coefficients from the origin image.

Diffusion generation. The diffusion model [28] is a generative model that can generate images from noise through multi-step denoising. It includes two processes of diffusion and denoising. During the diffusion process, the diffusion model gradually adds Gaussian noise to the image through a T-step Markov process until the image becomes complete Gaussian noise, following a variance schedule denoted by hyperparameter β_t (Eq. 1).

$$q\left(z_t|z_{t-1}\right) = \mathcal{N}\left(z_t; \sqrt{1-\beta_t}z_{t-1}, \beta_t\mathcal{I}\right) \tag{1}$$

The denoising process is the reverse of the diffusion process. Given z_t, a noise prediction network ϵ_θ is used to predict noise added to the image at t-th step to recover z_{t-1} (Eq. 2).

$$z_t = \sqrt{1-\beta_t}z_{t-1} + \beta_t\epsilon_t, \tag{2}$$

where ϵ_t is the noise predicted by the noise prediction network.

In this article, we aim to leverage the powerful generation ability and knowledgeable priors for images of the diffusion model to generate the DC coefficients of the images. Figure 3 (b) shows the framework of DCDiff. We use a noise prediction network to predict the DC features z_0 from Gaussian noise. Although the diffusion model demonstrates superior performance in generation tasks, it lacks the ability to preserve the structure information of the input images. Inspired by [29], we use a control module to extract the structure information from $\tilde{x}$ and inject it into the convolution block of diffusion model to improve structure consistency.

C. Masked Laplacian distribution loss

While the diffusion model with the control module demonstrates superior performance in image generation with given structure information, it lacks the ability to preserve the content consistency. For example, with no constraints, the generated image $\hat{x}$ may show a car that is yellow or blue—both appearing harmonious to the human but differing from x_0, mainly due to no explicit color information in $\tilde{x}$. To solve this problem, we propose the Laplacian distribution loss to constrain the reconstructed image to have content consistency with four corner blocks, whose DC coefficients are retained.

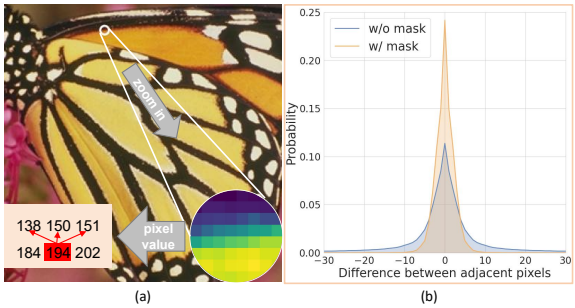


Fig. 4: (a) An example of pixel pairs have an abrupt change and significant differences across all three prediction directions. (b) comparison of the distribution of the difference between adjacent pixels with the high-frequency mask.

We first analyze the characteristics of pixel pairs that deviate from the Laplacian distribution. For example, as shown in Figure 4 (a), there are significant differences in pixel pairs across all three prediction directions. As a result, selecting any direction as the prediction direction will lead to substantial errors. We find that these pixel pairs are usually located in image regions with complex textures and sharp edges, where the pixel values exhibit significant fluctuations. The abrupt changes in pixel values in the spatial domain correspond to the increase in high-frequency components in the frequency domain. As illustrated in Figure 4 (b), we generate a mask to set all high-frequency components in the image to zero and recalculate the pixel value distribution of the low-frequency components in the image. Without the high-frequency components, the difference between two neighboring pixels follows the distribution with a much smaller variance. And the probability of pixel pairs with similar values is much higher than without the mask. Therefore, it is more appropriate to apply the Laplacian property to the low-frequency part of the image to calculate accurate pixel values.

Directly applying a low-pass filter in the frequency domain to filter out high frequencies may lead to changes in pixel values in the spatial domain, thereby affecting the accuracy of the prediction results. So we try to generate a spatial mask. When DC coefficients are zero, after IDCT, the pixel values of $\tilde{x}$ are the weighted sum of AC coefficients. As illustrated in Figure 3 (a), we show the AC coefficients of different parts of the images, the low-frequency part

corresponding to the small pixel values part and the high-frequency part corresponding to the large pixel values part. Thus, the larger the value of $\tilde{x}$, the more high-frequency components correspond at this position. So we follow Equation 3 to generate the mask.

$$\mathcal{M}(i,j) = \begin{cases} 0, \tilde{x}(i,j) > \mathcal{T} \\ 1, \tilde{x}(i,j) \leqslant \mathcal{T} \end{cases} \tag{3}$$

where $\mathcal{T}$ is the threshold used to control the number of high-frequency components to be masked, and we discuss in detail the effect of different $\mathcal{T}$ on the results in section IV-C.

After obtaining the mask, we calculate the Laplacian constraint between pixels in the low-frequency region and define the masked Laplacian distribution (MLD) loss as Equation 4.

$$\mathcal{L}_m = \sum_{i,j} \mathcal{M}_{i,j} \odot ((\Delta_h \hat{x}_{i,j} - \Delta_h \hat{x}_{i,j-1})^2 + (\Delta_w \hat{x}_{i,j} - \Delta_w \hat{x}_{i-1,j})^2) \tag{4}$$

where $\Delta_h \hat{x}_{i,j}$ denotes $\hat{x}_{i,j-1} - \hat{x}_{i,j}$.

D. Frequency modulation sampling strategy

As a generative model, the diffusion model tends to produce high-frequency detail information in images. However, in this paper, we aim to use the diffusion model to generate the DC coefficients, which represent the low-frequency features of the images. Inspired by [30], which investigates that the noise prediction network's skip connections mainly introduce high-frequency features, we try to modulate the frequency to enhance the low-frequency generation. [30] proposes to re-weight the backbone features and skip features during the denoising process using two manual scale factors. However, for image restoration, since the frequency information varies for each image, manually adjusting these two scale factors as hyperparameters is not suitable for every image.

To accommodate the frequency variations of different images, as shown in Figure 3 (c), we use a frequency modulation parameter predictor (FMPP), which relies on the ResNet architecture, to predict the scale parameters s and b. The predictor taking $\tilde{x}$ as input, estimates the scale factors to control the intensity of the enhancement of low-frequency information based on the high-frequency information contained in $\tilde{x}$. To control the magnitude of the enhancement, a sigmoid function is used in the final layer to regulate the range of the scale factor. Based on the experimental results in [30], we constrain the scale factor between 0 and 2. During the denoising process, FMPP initially takes $\tilde{x}$ as input to predict the scale factors and then DDIM is applied to denoise from noise, generating the DC coefficients of the images.

E. Training details

The training is divided into two stages. In the first stage, we train $\mathcal{E}^{DC}$, $\mathcal{E}^{AC}$ and $\mathcal{D}$ together using the loss function as Equation 5.

$$\mathcal{L}_{fir} = \mathcal{L}_{rec} + \mathcal{L}_{per} + \mathcal{L}_{dis}, \tag{5}$$

where $\mathcal{L}_{rec}$ is the $\mathcal{L}_1$ loss between the reconstructed image $\hat{x}$ and the origin image x_0, $\mathcal{L}_{per}$ is the perceptual loss and $\mathcal{L}_{dis}$ is the discriminator loss. In the second stage, we freeze the parameters of $\mathcal{E}^{DC}$, $\mathcal{E}^{AC}$ and $\mathcal{D}$, and train the noise prediction network with the goal of making the DC features $z_0\prime$ generated by the diffusion model as close as possible as z_0. Further, to ensure the generated image satisfies the Laplacian constraint, during each training step, we use the predicted noise ϵ_t to project from z_t to $z_0\prime$ following the Markov process: $z_0\prime = \frac{z_t - \sqrt{1-\bar{\alpha}_t}\epsilon_t}{\sqrt{\bar{\alpha}_t}}$, where $\bar{\alpha}_t = \prod_{i=1}^{t} \sqrt{1-\beta_i}$. Then use the $\mathcal{D}$ to project $z_0\prime$ to the pixel space and calculate the masked Laplacian distribution loss. The loss function used for training the noise prediction network is as Equation 6.

$$\mathcal{L}_{sec} = \mathcal{L}_{ldm} + \sigma \mathcal{L}_m, \tag{6}$$

where $\mathcal{L}_{ldm}$ is the MSE loss to minimize the noise distance between the target and learning noise in latent space, and σ is the weighting parameter. For FMPP, we freeze all other parameters and optimize FMPP using MSE loss, minimizing the distance between x_0 and $\hat{x}$ sampled under the scale factors predicted by FMPP.

IV. Experiment

A. Experiment setup

Dataset. For training data, we randomly select 300K images from OpenImages [31] and randomly crop the image to a resolution of 256 × 256 pixels. For testing data, we use 5 general CV datasets and one dedicated remote sensing dataset [32].

Metrics. We follow [33] to use 4 metrics for quantitative measures. We use the Peak Signal-to-Noise Ratio (PSNR) and Structural Similarity Index Measure (SSIM) to validate the pixel fidelity and the structure similarity. What's more, we use another two perceptual metrics, Multi-Scale Structural Similarity Index Measure (MS-SSIM) and Learned Perceptual Image Patch Similarity (LPIPS) to evaluate the quality of reconstructed images for human perception.

Implementation details. For the first training stage, we train the DC encoder $\mathcal{E}^{DC}$, the AC encoder $\mathcal{E}^{AC}$ and the decoder $\mathcal{D}$ together using the loss function in Equation 5 for 5 epochs with a batchsize of 16 and a learning rate of $1e-4$. For the second training stage, we use the pre-trained stable diffusion [23] model as noise prediction network and finetune it using $\mathcal{L}_{ldm}$ for 5 epochs with a learning rate of $1e-4$ to learn how to retain structural information in $\tilde{x}$ first. And then we add $\mathcal{L}_m$ to loss function, and finetune the model for 10 epochs with a learning rate of $1e-5$ and $\sigma = 2e-4$ to ensure generated images satisfy Laplacian constraint. All training experiments are performed on a server with 8× Nvidia H800 GPUs using the Adam optimizer. During inference, we utilize the DDIM sampling [34] with 50 steps. For baseline comparison, we consider three baselines for DC estimation, including methods based on mathematical calculations [18], [20] and based on neural networks [19].

B. Evaluation results

Qualitative comparisons. Table I shows the comparison results with baselines on six datasets. We compress the RGB images in each dataset with the standard Q_{50} quantization table following the previous works. Compared to compressing grayscale images, during JPEG compression, the discarded DC coefficients of the U and V channels retrain the chrominance information of the image. The error propagation caused by incorrect DC coefficients for U and V channels may greatly affect the color of the final reconstructed image, resulting in lower PSNR and SSIM for SmartCom 2019 [18] and ICIP 2022 [20]. Note that due to AC coefficients retaining high-frequency details from the origin image, the detailed information of the image is not lost during the discarding of DC coefficients, resulting in a relatively low LPIPS. Therefore, compared to directly using a low-quality Q quantization table to reduce the amount of transmission data, discarding the DC coefficients can better preserve image detail without affecting human perception. IEEE TII 2021 [19] tries to use a residual neural network to correct error propagation. However, optimizing solely for mean square error (MSE) can lead to excessive image smoothing, corrupting the detail of high-frequency information in the image, resulting in visual artifacts. As shown in Table I, the LPIPS of IEEE TII 2021 is much higher than others. In contrast,

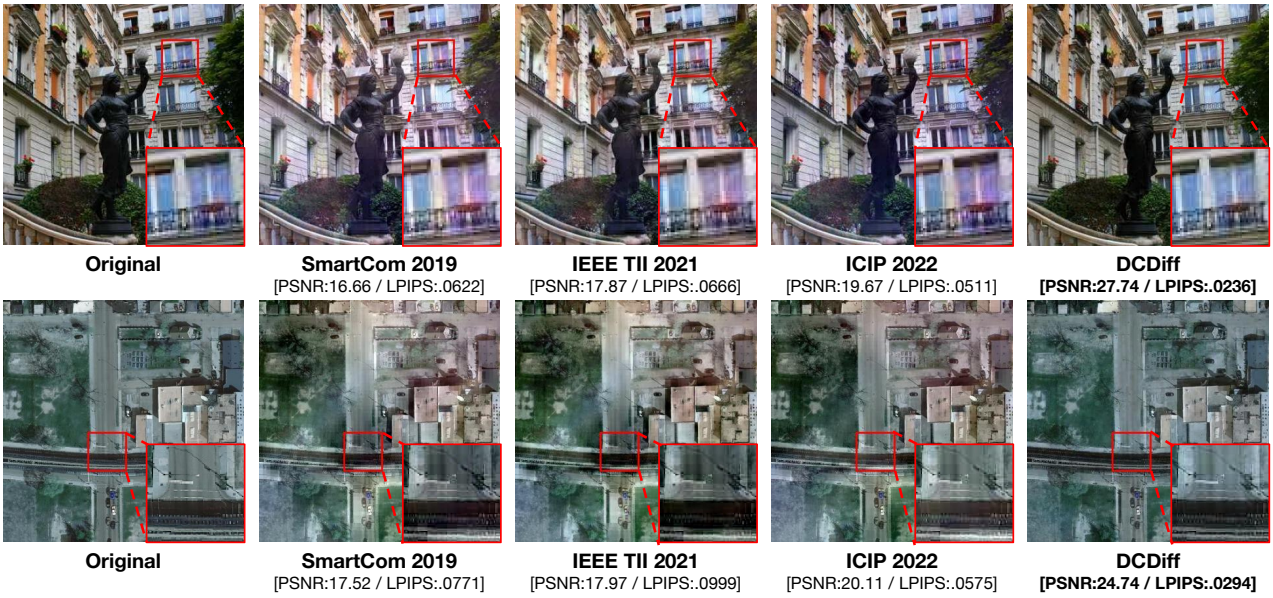

Fig. 5: The reconstructed image after post-processing.

DCDiff is not a block-based iterative method, which avoids error propagation. Additionally, it constrains the generated images using a mask Laplacian distribution loss, preventing excessive smoothing. The results demonstrate that DCDiff can achieve SOTA performance across all metrics on all datasets, increasing PSNR by $3 \sim 6.7dB$.

Visual results. Figure 5 shows the reconstructed images after post processing of DCDiff. We selected a street-view image and an aerial image for visualization comparison. As analyzed above, error propagation in U and V channels may lead to unnatural colors, such as the purple windows in the first row of Figure 5. Furthermore, the baseline's optimization objective is to enforce Laplacian constraints as closely as possible between any two adjacent blocks, which leads to color bleeding in areas with abrupt pixel value changes. For example, at the intersection in the image of the second row, the vertical road is dyed black. Since we use a mask to filter out high-frequency parts of the image and do not rely on block-based iteration, there is no color bleeding or unnatural colors due to error propagation, achieving SOTA reconstruction results.

Compression Ratio. At the sender's end, we follow the setting in [19] to set all DC coefficients to zero except 4 corner blocks, and calculate the compression ratio compared with standard JPEG using standard JPEG coding. As shown in Table II, we first use the same Q-table (i.e. Q_{50} quantization table) for standard JPEG and DCDiff. On all datasets, just by dropping DC coefficients, DCDiff can compress 25% more than JPEG on average. Besides, we also compare DCDiff with more compression of standard JPEG when using a more aggressive Q-table. We tune the Q-table of JPEG until the reconstructed images achieve a similar image quality (i.e. LPIPS) after DCDiff post-processing. While maintaining the same image quality reconstructed at the receiver's end, DCDiff can still compress 10-14% more than tuning Q-table in default JPEG.

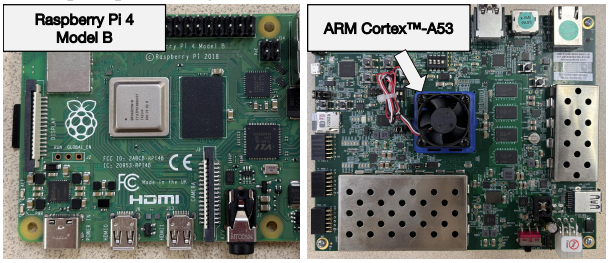

Fig. 6: Two low-cost testbeds for evaluating DCDiff.

C. Ablation study

W/o MLD loss. The masked Laplacian distribution loss can better guide the image reconstruction based on DC coefficients of four corner blocks and AC coefficients. We remove the MLD loss and train the noise prediction network until converges. As shown in Table III, the results show that without MLD loss, the model cannot capture the relation between four corner blocks and the other part of the images, leading to noticeable color distortion in reconstructed images.

W/o FMPP. To show that the frequency modulation can enhance the low-frequency information, we remove the frequency modulation

TABLE II: Compression ratios of JPEG with zero DC coefficients except for 4 corner blocks.

parameter predictor during sampling. The scale factors s and b are equal to 1, which is the same as regular DDIM sampling. The results in Table III show that frequency modulation can help to enhance the backbone features and improve the quality of reconstructed images.

Influence of mask threshold. We further investigate the impact of the threshold used to generate the mask $\mathcal{M}$ on the reconstructed image quality as shown in Table III. A smaller threshold results in most of the image content being masked, leaving only a small portion of the image associated with the information from the four corner blocks, which causes the model to rely on diffusion to generate most of the unconstrained content. A larger threshold causes some high-frequency information in the image, such as object edges, to be included to calculate the loss, which results in blurred edges around objects in the image, creating visual artifacts. Based on the results in Table III, we select $\mathcal{T} = 10$ as the threshold to generate the mask, which can capture most of the image information while filtering out high-frequency content such as object edges.

D. Use case analysis in IoT systems

We deploy DCDiff on 2 widely-used low-power processors: ARM Cortex™-A53[1] and Raspberry Pi 4 Model B[2] (as shown in Fig. 6) for evaluation. On these 2 processors, we compress and transmit captured images using standard JPEG and DCDiff and calculate the throughput. The results in Table IV show that compared to standard JPEG, DCDiff does not add extra computational overhead, which proves that DCDiff can be easily adapted to low-cost front-end cameras with JPEG support.

E. Influence on downstream tasks

Images reconstructed at the receivers' ends are usually used for further processing. To confirm that DCDiff has a tiny influence on the downstream tasks, we choose a remote-sensing image classification task [35] as an example. For all baselines, we use the same setting to drop DC coefficients at the sender's end and input the reconstructed images after post-processing to the image classification model at the receiver's end. As shown in Table V, DCDiff outperforms all baselines with a tiny impact on model accuracy (drop 0.49%).

V. Discussion and Future Work

JPEG v.s. Learned image compression. Transformation-based image compression method mainly applies a spatial-to-frequency transformation (e.g. DCT, DWT) to get the frequency coefficients and then uses a tunable quantization step to compress them. Today, they are outperformed by novel learned compression methods [8], [36]–[38] in various scenarios. Those learned compression methods generally replace the transformation-based compressor with a DNN-based encoder to extract image features and use a decoder to reconstruct images. Since DNNs can be trained to fit data in a similar distribution, learned image compression methods can outperform static ones (e.g. JPEG/JPEG2000) with sufficient data to train powerful encoders [39], [40]. However, there are still a large number of cameras that do not have enough resources to support a DNN-based encoder. On the contrary, JPEG, as the most widely-used image compression method, is well implemented on all existing cameras such that enhanced JPEG methods like DCDiff can also be easily adopted in real-world scenarios to improve image compression.

More improvements in future. First, in this paper, we use the default coding technique of JPEG for evaluating DCDiff. We are aware that, as a step after transformation and quantization, better coding techniques [41], [42] may get better results. Thus, it is important to emphasize that DCDiff studies how to reduce the number of DCT coefficients which is orthogonal to coding techniques. Second, DCDiff uses the diffusion model to reconstruct the images but it can be replaced as any other generative models as long as they can be trained to get rid of deviation-induced errors.

VI. Conclusion

We present DCDiff, an end-to-end DC estimation method for enhanced JPEG compression based on generative models. We propose the MLD loss to suppress error propagation while improving the content consistency of reconstructed images and a frequency modulation sampling strategy to enhance DC coefficient generation. Extensive results indicate that DCDiff can achieve SOTA performance to recover high-quality images and is compatible with various IoT devices to save transmission bandwidth while maintaining high throughput.

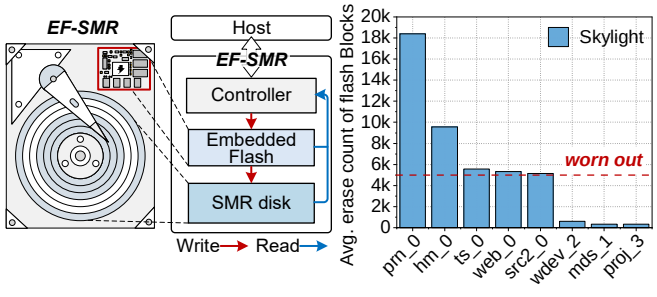
***Abstract*—As the huge discrepancy between traffic and capacity persists, the lifetime of flash in EF-SMR systems faces a grave issue. EF-SMR systems combine NAND flash with Shingled Magnetic Recording (SMR) disks to achieve both low cost and high performance. However, previous research has primarily focused on issues such as *write amplification* and *tail-latency* in EF-SMR disks, overlooking the critical issue of flash lifetime. Studying the durability of EF-SMR systems is essential for developing future high-performance, low-cost storage solutions.**

This paper presents *MiniWear*, a hybrid persistent cache (PC) design aimed at extending the lifetime of EF-SMR systems. MiniWear adopts a hybrid medium persistent cache and proposes a customized scheduling strategy to reduce flash wear without impacting the EF-SMR system performance. At the hardware level, the hybrid PC of EF-SMR, composed of flash and SMR disk, is organized into Flash-PC and SMR-PC. At the software level, a fine-grained scheduling strategy is proposed to better manage PC resources. Additionally, we introduce a proactive balancing strategy to address PC resource idleness. Experimental results show that, compared to existing methods, MiniWear can reduce flash wear by up to 66.67%.

***Index Terms*—Lifetime, Embedded Flash, Shingled Magnetic Recording, Cache Management.**



I. Introduction

Shingled Magnetic Recording (SMR) is a promising technique to promote disk density to more than 10 Tbits/in^2 by overlapping tracks one on another like shingling on a roof [1], [2]. As a side effect of the high density, SMR disks have inherent *write amplification* and *tail-latency* issues caused by Read-Modify-Write (RMW) operations. RMW operations can accommodate random writes but also drive the read/write head to move back and forth frequently, which significantly degrade the system's performance [3], [4]. Embedded Flash with SMR disk (EF-SMR) [5] integrates high-performance NAND flash memory, where random write data is first buffered in the flash before being written to the disk through RMW operations. However, the flash memory in EF-SMR systems faces significant write pressure, as shown in Fig. 1(a), and once the flash is occupied, it needs to be erased by a blocking background garbage collection (GC) process. The frequent GC processes lead to repeated wear of flash blocks, thereby introducing the system's ***lifetime*** issue.

We have conducted a preliminary experiment to demonstrate flash memory wear in the EF-SMR system. As Fig. 1(b) shows, the average erase count commonly exceeded 5k, reaching the upper limits for Multi-Level Cell (MLC) flash memory [6]. Considering the limited durability of NAND flash in erase cycles and the terabyte-scale write traffic in EF-SMR systems, our findings indicate that the *lifetime* of EF-SMR disks faces significant challenges.

Most previous works aim to resolve *write amplification* and *tail-latency* issues [7]–[15]. For example, PORE [12] implements a Partial Open-zone Eviction Strategy to mitigate SMR's write amplification by better balancing cache access frequencies. ROCO [13] uses a solid state drive (SSD) cache that absorbs random writes to reduce the write amplification of the Host-Aware SMR disk. HS-BAS [16] also utilizes SSD caching to diminish the collection costs associated with SMR's internal persistent cache. MAID-Q [14] targets to minimize tail latency by adopting a lightweight reinforcement learning model. MCM [15] reduces flash erasures by partitioning data into cold and hot segments. Unlike previous works, this paper proposes a *hybrid persistent cache* architecture designed to extend the *lifetime* of the EF-SMR system.

This paper introduces ***MiniWear***, a design for the EF-SMR system. Our main objective is to minimize flash wear via hybrid persistent cache, thereby extending the overall lifetime of the EF-SMR system. MiniWear incorporates hardware design and software optimization. The hardware design adopts a new persistent cache architecture with a hybrid medium, defining specific track zones of the SMR disk as SMR-PC. It also establishes a hybrid persistent cache mapping to distribute write stress to SMR-PC, effectively reducing the writing pressure faced by the flash. Based on the hardware design, the software optimization performs a fine-grained scheduling strategy of the persistent cache (PC), achieving efficient allocation of persistent cache resources. This ensures MiniWear can extend the lifetime of the EF-SMR system without degrading performance. In terms of system lifetime, MiniWear is compared with representative benchmark methods, showing a maximum lifetime extension of 66.67%.

(a) EF-SMR system. (b) Average erase count.

Fig. 1: Illustration of EF-SMR system.

The major contributions include:

- *Hybrid Persistent Cache Architecture:* A hybrid persistent cache designed for the EF-SMR system, along with a customized mapping that reduces the write traffic flowing through the flash memory.
- *Scheduling Strategy:* A scheduling strategy is proposed, which enables a fine-grained allocation of PC resources to extend the lifetime of the EF-SMR system further.
- *Experiments:* Comprehensive method validation through a comparative analysis with representative solutions.

The rest of this paper is organized as follows: Section II provides background and discusses the motivation of this paper. Section III presents our proposed MiniWear in detail. Section IV presents experimental results. Finally, Section V concludes this paper and discusses future work.

II. Background and Motivation

A. Shingled Magnetic Recording Disk

In the era of big data, there is an exponential growth in data generation [17], [18]. The emergence of the Internet of Things (IoT), Artificial Intelligence (AI), and other data-intensive technologies has accelerated this trend, leading to a continuous increase in the demand for storage space. Traditional storage solutions, such as Conventional Magnetic Recording (CMR) disks, as shown in Fig. 2(a), struggle to meet the increasing demands due to their limited storage density. This challenge has led to a need for more advanced storage solutions. Shingled Magnetic Recording (SMR) drives are one such solution, offering higher storage density by overlaying magnetic tracks on top of each other in a "shingled" manner, as illustrated in Fig. 2(b). In essence, while CMR maintains gaps between tracks to avoid interference, SMR maximizes space utilization by overlapping magnetic tracks to address the extensive storage demands [19].

B. Embedded Flash with SMR Disk

SMR overlaps track on previous tracks, like shingling the roofs to break through the areal density limitation of conventional hard disk drives (HDDs) [20]–[24]. However, this shingled-like structure incurs an accidental data loss on the tracks due to the write head is wider than the track width. Writing to a specific track can destroy the valid data stored on the adjacent tracks. To avoid accidental data loss, SMR requires an approach named Read-Modify-Write (RMW) operation to address random writes. The RMW operation will first read all valid data on the Band, and after modifying with the randomly written data, the modified data will be written back to the Band sequentially.

Since every RMW operation needs to overwrite the large-size SMR Band, it can lead to the write amplification issue and degrade the system performance. To achieve satisfactory run-time performance, several prior works [5], [12], [13], [25] integrate a NAND flash as a first-level persistent cache (PC) to form a faster EF-SMR disk. All random written data will be provisionally cached into the flash for high performance. When the flash is full, the valid data cached in the flash will be migrated to corresponding SMR Bands through a decent number of RMW operations. However, the capacity of the embedded flash is only about 1% of the total capacity of the EF-SMR disk [5]. Therefore, this indiscriminate data storing into flash puts severe wear pressure on the embedded flash, making it quickly worn out and unusable [26].

C. Motivation

To maintain low costs, the capacity of embedded flash memory in EF-SMR system is limited to 1% of the total capacity [5]. The existing EF-SMR system caches all random write requests to the flash, leading to durability issues, as shown in Fig. 3(a). Specifically, the limited flash capacity handles a large volume of write traffic, causing frequent programming and erasure of flash blocks to continuously satisfy write requests, thereby resulting in significant wear pressure. On the other hand, as each cell can store more bits by the multi-level cell technology, the durability of flash memory cells deteriorates [27]–[30]. For instance, the maximum P/E cycles of single-level cell (SLC) are about 10k, while those of triple-level cell (TLC) are decreased to 3k [6].

The limited flash capacity is the fundamental reason affecting the lifetime of the EF-SMR system, but increasing the flash capacity would raise costs. Therefore, there is an urgent need for a hybrid medium persistent cache in the EF-SMR system, as illustrated in Fig. 3(b). EF-SMR blurs the boundaries between flash and SMR disk by offering low latency and large capacity. Thus, the challenge of adding a hybrid medium persistent cache lies in how to extend the lifetime of the EF-SMR system as much as possible without sacrificing read/write performance. To address the challenge, this paper proposes MiniWear, which achieves this goal by designing a hybrid persistent cache and resource scheduling strategy.

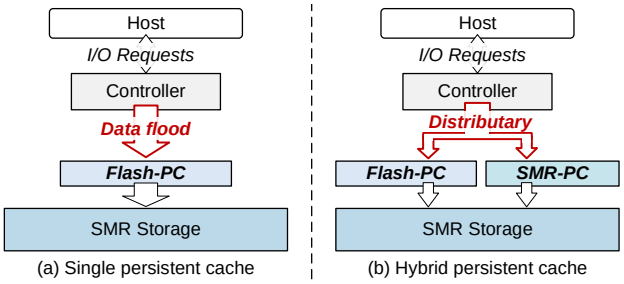

Fig. 3: Single PC utilizes only flash medium, while a hybrid PC incorporates both flash and SMR disk medium.

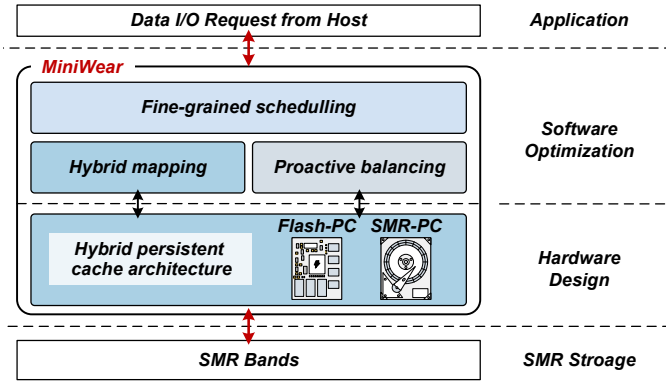

Fig. 4: The system overview of MiniWear.

III. MiniWear: A Hybrid Persistent Cache Design for Embedded Flash with SMR Disk

A. Overview of MiniWear

MiniWear adopts a hardware/software co-design, operating between applications and SMR storage devices to provide data scheduling, as shown in Fig. 4. The system comprises three main components: hybrid persistent cache architecture, fine-grained scheduling, and proactive balancing. The hybrid persistent cache provides hardware support. This foundation allows for a fine-grained scheduling strategy to ensure rational resource allocation. If PC resources are improperly allocated, a proactive balancing strategy adjusts and enhances the system. The hybrid address mapping and scheduling strategies are implemented through the PC manager. These three components are interconnected, forming the core of MiniWear. The hybrid persistent cache consists of Flash-PC and SMR-PC. Introducing SMR-PC helps reduce writing pressure on flash. The fine-grained scheduling strategy manages persistent cache allocation and reclamation, optimizing resource use and minimizing flash wear. The proactive balancing strategy recycles underutilized Flash-PC resources, improving utilization and preventing the cycle of frequent garbage collection due to shortages. The detailed designs of these components are as follows.

B. Hybrid Persistent Cache Architecture

In MiniWear, the hybrid persistent cache architecture consists of two parts: high-performance NAND flash (Flash-PC) and a few designated outer tracks on SMR disk platters (SMR-PC). In the following, we describe Flash-PC, SMR-PC, and the mapping strategy.

Flash-PC: Flash-PC consists of NAND flash memory, with the capacity of 1% of the EF-SMR system, which uses "Block" as the basic unit for scheduling, as shown in Fig. 5(a). MiniWear also adopts this approach, defining a flash block as the unit for Flash-PC scheduling, where one flash block represents one Flash-PC resource. However, the scheduling strategy for flash blocks in MiniWear differs from that of other works.

SMR-PC: We have innovatively integrated SMR-PC into EF-SMR, using a hardware-software co-design approach to extend the system's lifetime without compromising performance. SMR-PC consists of 1% of the outer tracks of the SMR disk, which supports random writes and offers better performance compared to the SMR Bands. As shown in Fig. 5(b). In MiniWear, SMR-PC is divided into equal-sized sectors, with each sector serving as a unit for SMR-PC scheduling. We designed a principle for SMR-PC that caches data using an append-write approach. The mapping relationships are recorded in a mapping table. For repeatedly written data, the append-write approach is used, and the mapping relationships are updated, with the original data automatically becoming invalid. This provides a high-performance caching mechanism to deal with random writes on the SMR disk. This design eliminates the write amplification, ensuring the superior performance of the EF-SMR system.

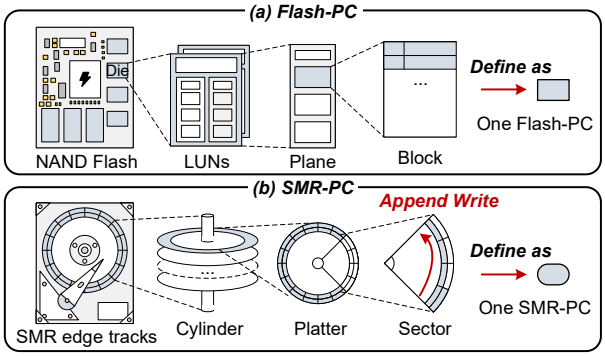

Fig. 5: Hardware design of hybrid persistent cache.

Hybrid Mapping: To effectively utilize the hybrid persistent cache, MiniWear introduces a hybrid mapping from the logic address to the address of PC or SMR. A page-level mapping table is used to record the mapping relationship. A logical page address may be mapped to SMR, Flash-PC or SMR-PC. MiniWear records whether the logical page address is mapped to the PC through the entry in the mapping table. When mapped to SMR, the physical address is the same as the logical address. Otherwise, the corresponding PC type and physical page address are recorded in the entry. Besides a page-level mapping table, there are two priority queues and bifurcated linked lists to handle mapping relationships efficiently. Priority queues record the starting addresses of available resources in Flash-PC and SMR-PC for quick lookup. A bifurcated linked

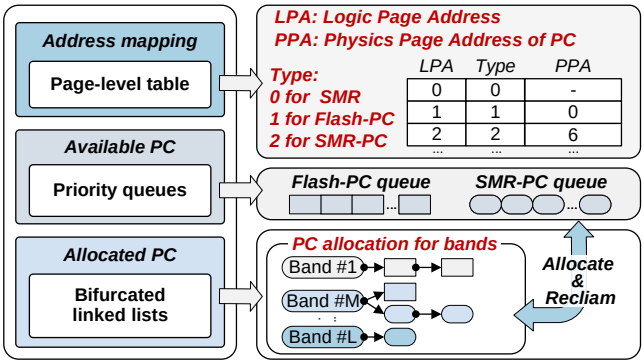

Fig. 6: Hybrid mapping.

list for each Band records the ownership status of both Flash-PC and SMR-PC resources. With the support of these data structures, MiniWear can efficiently traverse available PC and PC used by a specific Band when scheduling. The memory overhead caused by the mapping tables, priority queues, and linked lists will be analyzed in subsection III-E (Memory Overhead).

C. Fine-Grained Scheduling

The fine-grained scheduling strategy is designed for the hybrid persistent cache we defined. This strategy is executed by the PC controller, operating within the translation layer of the EF-SMR system. It controls the *allocation* and *reclamation* of PC to minimize wear on Flash-PC as much as possible, as shown in Algorithm 1.

Allocation: PC is allocated exclusively at the Band level, meaning that once PC is allocated to a Band, it is dedicated to that Band until reclaimed. To ensure the optimal performance of the EF-SMR system, the PC manager prioritizes the allocation of Flash-PC resources, as shown in Fig. 7(a). When Flash-PC resources are insufficient, SMR-PC resources are prioritized, as illustrated in Fig. 7(b). Resource allocation failure can occur in two scenarios: (1) when both Flash-PC and SMR-PC resources are exhausted, and (2) when the SMR Band reaches the maximum limit of SMR-PC resources. Since SMR-PC is less efficient than Flash-PC, its usage should be appropriately restricted. When allocation fails, the system performs garbage collection and reallocates resources after the collection process is complete.

Reclamation: Garbage collection tasks are also controlled by the PC manager, and we categorize garbage collection into three levels: obsolete flash block reclamation, Band-level partial reclamation, and Band-level full reclamation.

Obsolete flash block reclamation: Obsolete blocks refer to allocated flash blocks whose data has become entirely invalidated. Reclaiming obsolete flash blocks can rapidly complete the garbage collection process because it does not require data migration from persistent cache to SMR storage. This maximizes the performance of the EF-SMR system. During this operation, the manager only needs to locate an obsolete block and erase it to complete the current GC process, as shown in Fig. 7(c). *Band-level partial reclamation:* This operation reclaims all SMR-PCs owned by the Band and a portion of flash blocks (whose invalidation rate exceeds a specific threshold, which can be adjusted as needed; for example, set at 25%). The manager sequentially checks whether the Band currently being written to and the Band with the most flash resources meet the criteria for partial reclamation, and reclaims resources from the first Band to meet these criteria, as shown in Fig. 7(e) and (f). *Band-level full reclamation:* If none of the above conditions are met, the SMR Band with the most Flash-PC resources is chosen as the victim, and all its associated PC resources are completely reclaimed, as shown in Fig. 7(d).

Fine granularity is reflected in the individual and partial reclamation of flash blocks. Compared to complete reclamation, these two methods allow for more detailed consideration of the system's state, facilitating more nuanced GC processes. Obsolete blocks contain no valid data, and their reclamation does not involve data write-back operations, maintaining optimal system performance. Reclaiming a single invalid block significantly reduces the number of flash erasures compared to complete reclamation; partial reclamation aims to minimize the number of flash blocks erased during each GC process as much as possible.

D. Proactive Balancing

This strategy alleviates the issue of resource scarcity by proactively reclaiming underutilized flash resources, executed by the PC manager. In the EF-SMR system, there are underutilized flash blocks, also known as "zombie blocks", which are allocated on-demand to SMR Bands but are subsequently seldom used. This directly reduces the total amount of available Flash-PC, forcing more frequent garbage collection processes and indirectly impairing the system's lifetime.

$$T_i = \frac{Access_i}{NumFpc_i} \tag{1}$$

The strategy is implemented as follows: it is executed when the number of passive GC processes reaches a preset threshold (an adjustable empirical value). To identify the victim Band for proactive reclamation, we propose a metric T to estimate the hotness of Bands. This metric is determined by the relationship between the number of accesses to the Band during the interval between two proactive reclamations and the number of Flash-PC resources owned by the Band. Defined in Equation 1, T_i

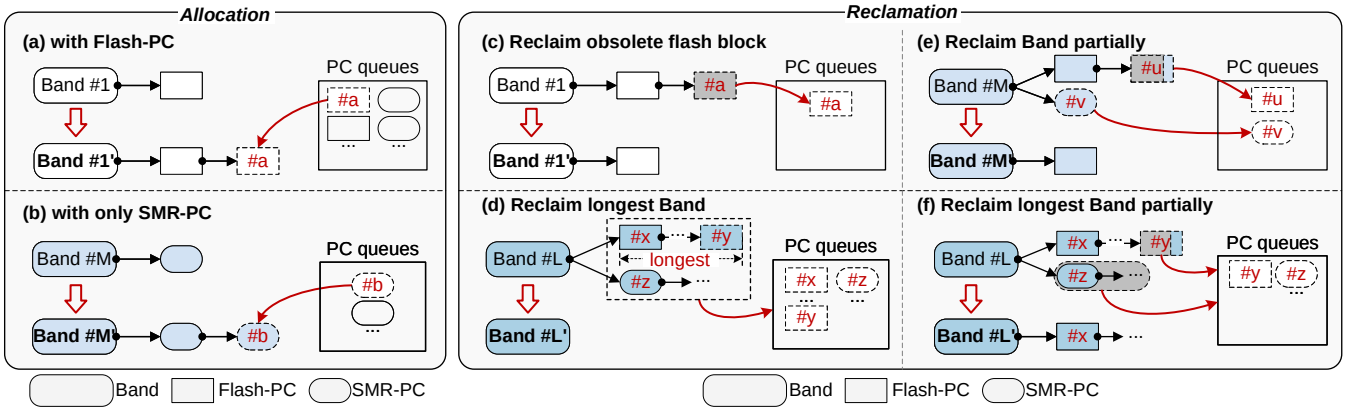

Fig. 7: Fine-grained scheduling.

represents the hotness of $Band_i$, $Access_i$ denotes the number of data accesses for $Band_i$, during the interval between two proactive reclamations, $NumFpc_i$ is the total number of Flash-PC resources owned by $Band_i$ (excluding Bands that do not have Flash-PC). Ultimately, the manager is responsible for reclaiming all PC from the Band with the lowest hotness.

E. Overhead Analysis

Memory Overhead: Flash-PC and SMR-PC each account for 1% of the total SMR Band capacity, resulting in a total persistent cache capacity of 40.96 GiB for a 2 TB SMR device. Specifically, the page-level mapping table requires 40.96 MiB (assuming a 4 KiB page size and 4 B page address), while the priority queue and linked list for Flash-PC consume 640 KiB and 1.28 MiB, respectively (with each linked list node occupying 8 B). The overhead for SMR-PC is similar to that of Flash-PC, and the total memory consumption remains acceptable for EF-SMR systems.

Computational Overhead: For fine-grained scheduling and proactive balancing strategies, we propose several algorithms. The time complexity of these algorithms is $\mathcal{O}(n)$, which does not impose an excessive burden on computational resources, making it acceptable for the system.

IV. Evaluation

A. Experimental Setup

Baseline. We compare MiniWear with Skylight [5], PORE [12], MCM [15] and Duchy [25]. Skylight uses static address mapping to integrate flash memory into SMR disks. PORE reduces I/O latency by limiting the reclamation scope and aggressively using flash resources. MCM differentiates between sequential hot/cold writes and random writes to improve latency and lifetime. Duchy proposes a write filtering scheme to enhance SSD endurance.

Performance Metrics. we compare MiniWear to Skylight [5], PORE [12], MCM [15] and Duchy [25] with the following performance metrics: (1) flash-based PC wear; (2) response time; (3) write amplification;

Parameter Setting. The specific configurations of the EF-SMR are set according to the observation from the realistic SMR disk [5] and Samsung NAND flash chip [31], which are depicted as follows: (1) The capacity of the persistent cache is 2% of the SMR disk capacity, with Flash-PC and SMR-PC each accounting for 1%. (2) The rotation speed of the disk is set as 7200 rpm, and the data transfer time is 0.03 ms; (3) The width of the write head is three times that of the read head (i.e., K=3); (4) The Band/Zone size is set as 40 MiB, totaling 256 in number; (5) The flash operation latencies for one page read, one page write and one block erase are 0.2 ms, 1.3 ms, and 1.5 ms, respectively. (6) The outermost circular tracks used as SMR-PC resources are logically divided into 128 sectors of equal capacity;

Datasets. We employed eight publicly accessible datasets characterized by varying sizes and access patterns, as elucidated in Table I. These datasets have been widely utilized for benchmarking the EF-SMR, as referenced in prior works [32].

B. Result and Discussion

Flash-based PC wear: As shown in Fig. 8(a), we evaluated the average wear count of the flash memory across different datasets and normalized the results. It can be observed that, on average, MiniWear reduces the flash-based PC wear count by 20.08%, 34.82%, 33.76%, and 32.93%, with maximum reductions of 30.67% (i.e., proj_4), 66.67% (i.e., web_2), 58.79% (i.e., web_2), and 62.52% (i.e., web_2), compared to Duchy, MCM, PORE, and Skylight, respectively. The reason for the optimization of flash memory lifetime is the introduction of the new medium (SMR-PC), which alleviates the write pressure on the flash and reduces its erasures. To further investigate the performance under more limited flash, we evaluated the average wear count of the flash memory with different flash capacities and normalized the results. As shown in Fig. 8(b), it can be observed that as the flash capacity decreases, the wear count increases for all methods. However, MiniWear shows a slower rate of increase, indicating that it has the capability to cope with extreme flash wear.

Response time: The average response time is a key indicator of system performance. We collected average response time data for quantitative analysis and normalized the data. As shown in Fig. 9(a), it can be observed that MiniWear reduces

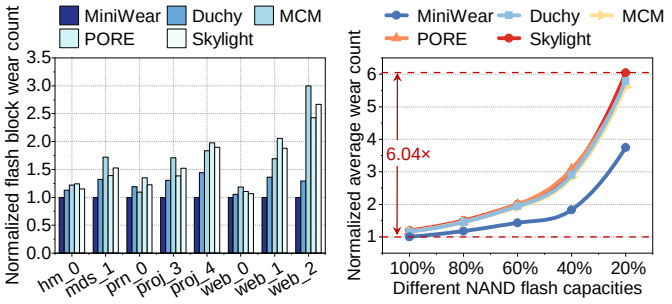

TABLE I: The characteristics of the traces.

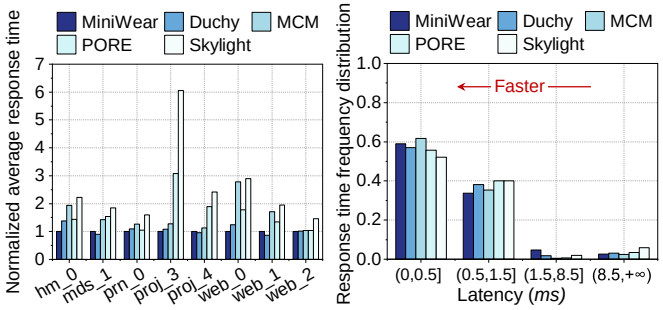
Traces	Data Written (GB)	Data Read (GB)	Write Ratio	Update Ratio
hm_0	9.83	5.41	64.50%	97.72%
mds_1	0.45	5.80	7.12%	79.99%
prn_0	19.01	2.30	89.21%	94.52%
proj_3	0.44	8.12	5.18%	65.61%
proj_4	0.37	24.30	1.48%	88.17%
web_0	5.43	2.31	70.12%	99.21%
web_1	0.28	0.33	45.89%	91.69%
web_2	0.15	19.59	0.75%	52.49%

the average response time by 4.14%, 30.21%, 32.33%, and 53.21%, respectively, compared to Duchy, MCM, PORE, and Skylight. The maximum reduction rates reach 27.59% (hm_0), 64.08% (web_0), 67.55% (proj_3), and 83.48% (proj_3). This improvement is attributed to the fine-grained scheduling strategy, which leverages the architectural advantages of the hybrid persistent cache. Additionally, we analyzed the frequency distribution of response times for each request, as shown in Fig. 9(b), where the x-axis represents increasing response times. MiniWear exhibits the lowest frequency of high response times, indicating greater stability. This stability results from the ability of MiniWear to minimize unnecessary RMW operations during garbage collection.



Observant readers may notice that in Fig. 9(a), for read-intensive workloads (e.g., mds_1), the average response time of MiniWear is slightly higher than that of Duchy. This phenomenon is attributed to the proactive balancing strategy, which involves reclaiming additional flash blocks. This approach can cause fluctuations in I/O latency for read-intensive workloads.

Write amplification: Write amplification is defined as the ratio of the actual amount of data written to the original input data volume. The optimization goal is to minimize this ratio to ensure system performance. We collected write amplification data from Duchy, MCM, PORE, and Skylight and normalized it to our proposed MiniWear. As shown in Fig. 10(a), MiniWear significantly reduces write amplification across all write-intensive and medium write volume traces compared to the baseline schemes. When handling read-intensive traces (e.g., proj_3), MiniWear exhibits slightly higher write amplification than Duchy. This is due to the proactive reclamation process involving RMW operations, which tend to increase write amplification. Additionally, we analyzed the actual data written for the same set of requests, with results summarized in

(a) Normalized flash block wear count. (b) Trends under different capacities.

Fig. 8: Flash-based PC wear.

(a) Normalized average response time. (b) I/O latency during runtime.

Fig. 9: Response time.

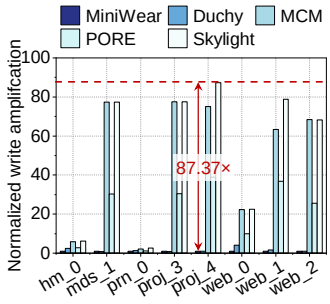


Table II. The data indicate that MiniWear effectively reduces the actual amount of data written, highlighting its capability to minimize unnecessary writes.

V. Conclusion

In this paper, we explore the issue of minimizing wear on NAND flash within EF-SMR disk storage systems. We introduce MiniWear, a novel hybrid persistent cache intermediate layer for the EF-SMR system. By introducing SMR-PC and optimizing address mapping and resource scheduling strategies, MiniWear can effectively reduce the number of flash erasures and extend the system's lifetime. Experimental results demonstrate its superior performance. In the future, we plan to optimize the Wear-leveling module to address "zombie blocks" with finer granularity. We also plan to investigate alternative approaches to partitioning SMR-PC so that MiniWear can perform better under various workloads.

***Abstract*—Numeric optimization methods are widely utilized to tackle complex analog circuit sizing problems, where the challenges include expensive simulations, non-linearity, and high parameter dimensionality. However, the diverse characteristics exhibited by different circuits result in varied optimization landscapes, making it difficult to identify a single algorithm that consistently outperforms others across all problems. In this paper, we introduce a multi-algorithm interworking optimization framework, which achieves optimization superadditivity based on a pool of member algorithms and a powerful algorithm-interworking protocol. We propose a computing resource reallocation method, which employs multi-task Gaussian process regression and portfolio optimization techniques, leading to flexible and prudent online adaption of member algorithms. To efficiently utilize the computing resources for local exploitation, an evaluation data broadcast strategy enables cooperativeness across member algorithms. Besides, algorithms with different modeling overheads are integrated time-adaptively via an asynchronous parallelization mechanism. Comparative experiments against state-of-the-art algorithm-combining tools and optimization algorithms demonstrate the superiority of the proposed optimization framework.**

***Index Terms*—Analog circuit sizing, optimization framework, superadditivity, black-box optimization algorithm, algorithm-combining tool.**

I. Introduction

Analog integrated circuit automation remains in high demand to expedite the time-to-market delivery of industrial products, and the sizing stage is a bottleneck for human practitioners since both subtle expert experience and labor-intensive repetitive work are required. Therefore, various optimization algorithms [1]–[10] have been proposed to automate the analog circuit sizing, dealing with the challenges of **expensive simulations**, **non-linearity**, and **high parameter dimensionality**. However, while the diverse characteristics of analog circuits, including **topologies**, **specifications**, and **technologies**, result in varied optimization landscapes, existing works merely propose algorithms based on a limited number of case-study analog circuit instances, incurring poor optimization generalizability.

In this work, we recognize that it is difficult to identify or design a single algorithm that consistently outperforms others across diverse analog circuits. This difficulty is fatally incurred by the famous No Free Lunch (NFL) theorem [11], which indicates that the superiority of an optimization algorithm on several problems is always accompanied by inferiority on several other problems. Thus, given a pool of candidate algorithms, it is imperative to develop a universal optimization framework for sizing diverse analog circuits.

We introduce a critical concept of **superaddivity** as the destination of optimization frameworks, inspired by the active research in academic fields and landmark success in modern technologies, e.g. Gestalt psychology [12], coalition games [13], compute unified device architecture (CUDA) [14] and large language models (LLMs) [15]. Superadditivity means that the performance of a whole system should be qualitatively better than the sum of the performance of all parts, e.g. CUDA and LLMs respectively organize graphics processing kernels and self-attention modules as their parts, and then emerge with fundamentally superior computing capacity as systems. In the proposed optimization framework, we take member algorithms as parts and pursue the optimization superadditivity, which depends on two prerequisites as follows.

① Construct a heterogeneous pool of optimization algorithms.
② Develop an efficient and effective algorithm-interworking protocol.

For prerequisite ①, we extensively analyze and collect different algorithms, focusing on the optimization characteristics in terms of **sampling efficiency**, **convergency**, and **scalarbility**. Additionally, incorporating expensive simulations in the optimization loop, the ability of **batch sampling** is important for a candidate algorithm to speed up the optimization progression. In our framework, we integrate evolutionary algorithms (**EAs**), Bayesian optimization (**BO**), and mathematical derivative-free optimization (**DFO**), of which the complementary strengths and shortages are summarized in Table I.

TABLE I
The Strengths and Shortages of Different Algorithms

Algorithm	Sampling Efficiency	Convergency	Scalarbility
EAs [1]–[3], [16]	Low	Low	High
BO [7]–[10], [17]	High	Medium	Low
DFO [18], [19]	Medium	High	Medium

EAs, such as differential evolution (DE) [1], genetic algorithm (GA) [2], and particle swarm optimization (PSO) [3], are compatible with batch sampling and scalable for high-dimensional problems, since these algorithms evolve an elite population of visited design points for candidate suggestions, and the related heuristical operators are computing-inexpensive. However, EAs lack strategies to capture fine-grained features of the optimization landscapes and hence have weaknesses in local exploitation. **BO** balance the tradeoff between exploration and exploitation by optimizing acquisition functions in advance of candidate suggestions and thus achieving high sampling efficiency. The formulation of acquisition functions are based on online regression models. However, given high-dimensional design variables, online regression modeling is prone to underfit, incurring over-exploration in BO. Therefore, state-of-the-art BO algorithms, e.g. TuRBO [8], cVTS [9] utilize localization techniques to improve the scalability. As for **DFO**, Nelder-Simplex [18] and BOBYQA [19] are influential, and the latter is popular nowadays due to good sampling efficiency. BOBYQA also employs online models but differs from BO due to the focus on local convergence rather than global search, thereby suggesting candidate points by solving mathematical subproblems rather than optimizing acquisition functions. Since DFO is generally local and serial-limited, we can run several optimization procedures in parallel with different starting points to enable global exploration and batch sampling. This multi-starting point (MSP) strategy is widely adopted [20], although it is still limited by the random selection of starting points, which is inefficient for global exploration in heavily multi-modal optimization landscapes.

For prerequisite ②, algorithm-combining protocols, including passive algorithm selection, active algorithm selection, chaining, and splitting, have been actively studied by recent works. **Passive algorithm selection** [21], [22] picks one algorithm from a pre-built decision tree at the beginning of the optimization run, according to the given dimensionality of parameters, budget of evaluations, amount of computing resources, etc. **Active algorithm selection** [23]–[25] means starting multiple optimization algorithms in parallel and selecting one of them to continue with a decision-maker after a certain number of evaluations. The decision-maker can be realized either with heuristical strategies or pre-trained neural networks. **Chaining** [26] involves running several algorithms sequentially, with the following ones initialized using the evaluation information from previous ones. **Splitting** [27] partitions the design variables, and then each group of them is optimized by its own optimizer. Further, active algorithm selection, chaining, and splitting can be integrated into **hybrid passive algorithm selection**, It has been implemented by Nevergrad [27], making the related ABBO [28] and Shiwa [29] the state-of-the-art algorithm-combining tools.

The main drawback of existing algorithm-combining protocols is the reliance on massive prior experimental experience, which is a burden for the developers and the combined optimization performance is prone to deteriorate in tackling previously unseen problems. Therefore, considering extensibility and generalizability, active algorithm selection with a heuristical decision-maker is more **flexible**. Nevertheless, current heuristical active decision-makers e.g. choosing one algorithm once based on the best observation [23], take speculative risks to produce satisfactory optimization results. Targeting a more **prudent** algorithm selection framework, it is necessary to refine the switching process across member algorithms and employ online modeling techniques to make the adaption of algorithms more comprehensive. In addition, it is also crucial to make the member algorithms **cooperative**, which means enabling heterogeneous algorithms to utilize the evaluation data from each other, hence efficient strategies for evaluation information extraction and transfer are dispensable. Besides, for analog circuits with simulation time limited to several seconds, BO and DFO algorithms suffer from non-neglectable modeling overheads and get distinctly slower than evolutionary algorithms. Therefore, a powerful algorithm-interworking protocol should be **time-adaptive** across different algorithms.

To address the aforementioned challenges of flexibility, prudence, cooperativeness, and time-adaptivity for achieving optimization superadditivity, we propose an innovative multi-algorithm interworking optimization framework MARIO. Overall, we extensively collect a pool of heterogeneous optimization algorithms, run them in parallel, and develop a powerful algorithm-interworking protocol for joint optimization. Our main contributions are summarized as follows.

1) We propose an active computing resource reallocation method, achieving **flexible** and **prudent** online adaption of member algorithms. We employ a customized multi-task Gaussian process to model the optimization potential of member algorithms and utilize portfolio optimization to reallocate the computing resources, improving the optimization desirability periodically.
2) We propose an efficient evaluation data broadcast strategy, making the member algorithms **cooperative** for joint optimization. With the accumulation of evaluated design points, we incrementally partition the design space into Voronoi nests and filter out informative data to broadcast. This strategy is especially beneficial to local algorithms since they can be effectively reinitialized to exploit promising design regions.
3) We propose a practical asynchronous parallelization mechanism, leading to **time-adaptive** algorithm integration in MARIO. If some algorithms exhibit non-negligible modeling overheads, this mechanism adapts faster algorithms to evaluate more design points and get more competitive to gain computing resources, thus assuring reasonable optimization performance.

With fair utilization of computing resources, MARIO achieves more than $3.83\times$ optimization speedup on a test-function benchmark suite and more than $2.59\times$ optimization speedup on an analog-circuit benchmark suite against state-of-the-art black-box optimization algorithms and algorithm-combining tools, based on the overall optimization performance measured by data profiles (see Sect. II-B). Python implementation and experimental results of MARIO can be found at https://github.com/RogerLee0038/MARIO.

II. BACKGROUND

A. Problem Formulation

The automatic sizing for a given analog circuit can be formulated as an optimization problem p as 1.

$$\begin{aligned} p: \quad & \arg\min_{\boldsymbol{x}\in\mathbb{R}^{d_p}} f_p(\boldsymbol{x}) \\ s.t. \quad & \boldsymbol{l}_p \leq \boldsymbol{x} \leq \boldsymbol{u}_p, \end{aligned} \tag{1}$$

where $\boldsymbol{x} \in \mathbb{R}^{d_p}$ represents the d_p-dimensional vector of design variables, f_p represents the objective function, and $\boldsymbol{l}_p \sim \boldsymbol{u}_p$ represent the box constraints of the design space, which are defined by the experience of circuit designers and the rules of process design kits.

Considering constraints on circuit specifications, the objective function is formulated as a weighted sum as $f_p(\boldsymbol{x}) = s_{p,0}(\boldsymbol{x}) + \lambda_{p,1}c_{p,1}(\boldsymbol{x}) + \cdots + \lambda_{p,n_s}c_{p,n_s}(\boldsymbol{x})$, where $s_{p,0}$ is the target specification to be minimized, $c_{p,1:n_s} = max(0, s_{p,1:n_s})$ are constraint violation of other specifications, and $\lambda_{p,1:n_s}$ are weight multipliers.

B. Performance Measurement

Given a set $\mathcal{P}$ of diverse analog circuit sizing problems and a set $\mathcal{M}$ of optimizers, we measure the overall performance of each optimizer $m \in \mathcal{M}$ by the data profile [30] as 2.

$$D_m(a) = \frac{1}{|\mathcal{P}|}\sum_{p\in\mathcal{P}} T_{p,m}(a), \tag{2}$$

where the input variable a represents the number of objective evaluations or the optimization time. $T_{p,m}(a)$ measures the optimization performance of m on a single problem p as 3.

$$T_{p,m}(a) = \frac{f_p(\boldsymbol{x}_0^m) - f_p(\boldsymbol{x}_a^m)}{f_p(\boldsymbol{x}_0^m) - f_p^L}, \tag{3}$$

where $\boldsymbol{x}_0^m$ is the optimization starting point of m, $\boldsymbol{x}_a^m$ is the a-th point suggested by m, and f_p^L is the smallest objective value obtained by any $m \in \mathcal{M}$ within a given optimization budget $\hat{a_p}$. This formulation of $T_{p,m}(a)$ measures whether the problem p can be well optimized by m, based on the objective value reduction $f_p(\boldsymbol{x}_0) - f_p(\boldsymbol{x}_a)$ relative to the best possible reduction $f_p(\boldsymbol{x}_0) - f_p^L$.

In addition, considering different problem dimensionality d_p, the optimization budget $\hat{\alpha_p}$ is usually normalized as $\hat{\kappa}\cdot(d_p+1)$, where $\hat{\kappa}$ represents a budget factor that is common for all $p \in \mathcal{P}$. Then, $D_m(a)$ can be normalized as $D_m(\kappa)$, with $\kappa = \alpha/(d_p+1) \in [0, \hat{\kappa}]$.

C. Portfolio Optimization

For prudent reallocation of computing resources across member algorithms in MARIO, we treat the parallel workers for circuit simulations as funds and different optimization algorithms as investments, then utilize portfolio optimization [31] to periodically make

reallocation decisions. Specifically, given a collection of possible investments with a vector $\boldsymbol{r}$ of expected returns and a matrix $\boldsymbol{G}$ of covariances, an investor can construct a portfolio by putting a fraction $\boldsymbol{\omega}_i$ of the available funds into investment i. Then, the desirability of the portfolio is measured and optimized as 4.

$$\begin{aligned} &\arg\max_{\boldsymbol{\omega}} \ \boldsymbol{\omega}^T \boldsymbol{r} - \eta \boldsymbol{\omega}^T \boldsymbol{G} \boldsymbol{\omega} \\ &s.t. \ \Sigma_{i=1} \boldsymbol{\omega}_i = 1, \ \boldsymbol{\omega} \geq \boldsymbol{0}, \end{aligned} \tag{4}$$

where η is a risk aversion parameter that can be small for conservative investors and large for more daring investors.

D. Multi-Task Gaussian Process

The return vector $\boldsymbol{r}$ and covariance matrix $\boldsymbol{G}$ in portfolio optimization are constructed as introduced in Sect. III-A, with the aid of a multi-task Gaussian process (MTGP) [32]. Given a d-dimensional input space $\mathbb{R}^d$ and M tasks, an MTGP builds a regression model based on an observation dataset $\mathcal{D} = \{(\boldsymbol{\kappa}_i, \boldsymbol{y}_i)\}_{i=1}^N$, where $\boldsymbol{\kappa}_{1:N} \in \mathbb{R}^d$ are training features and $\boldsymbol{y}_{1:N} \in \mathbb{R}^M$ are response labels. We adopt $\boldsymbol{\kappa}$ instead of $\boldsymbol{x}$ here because the MTGP in MARIO will take the normalized number of evaluations rather than the design variables of analog circuits as the training features. Specifically, an MTGP models the covariances over input features and the similarities over tasks with a kernel function $k^{\kappa}(\boldsymbol{\kappa}_i, \boldsymbol{\kappa}_j)$ and a positive semi-definite matrix $\boldsymbol{K}^{tas}$, respectively. After training, the MTGP predicts an arbitrary unobserved response at the input location $\boldsymbol{\kappa}^*$ of the task l with the posterior mean and variance as 5.

$$\mu_l(\boldsymbol{\kappa}^*) = (\boldsymbol{k}^{\kappa}(\boldsymbol{\kappa}^*) \otimes \boldsymbol{K}_l^{tas})^T (\boldsymbol{K}^{\kappa} \otimes \boldsymbol{K}^{tas} + \boldsymbol{I}_N \otimes \boldsymbol{\Lambda})^{-1} \boldsymbol{y} \tag{5a}$$

$$\begin{aligned} \sigma_l^2(\boldsymbol{\kappa}^*) =& k^{\kappa}(\boldsymbol{\kappa}^*, \boldsymbol{\kappa}^*) \cdot \boldsymbol{K}_{l,l}^{tas} - (\boldsymbol{k}^{\kappa}(\boldsymbol{\kappa}^*) \otimes \boldsymbol{K}_l^{tas})^T \cdot \\ & (\boldsymbol{K}^{\kappa} \otimes \boldsymbol{K}^{tas} + \boldsymbol{I}_N \otimes \boldsymbol{\Lambda})^{-1} (\boldsymbol{k}^{\kappa}(\boldsymbol{\kappa}^*) \otimes \boldsymbol{K}_l^{tas}), \end{aligned} \tag{5b}$$

where $\boldsymbol{y}$ is a vector containing the MN response values in the dataset ordered as $(\boldsymbol{y}_{11}, \cdots, \boldsymbol{y}_{1M}, \cdots, \boldsymbol{y}_{N1}, \cdots, \boldsymbol{y}_{NM})$, $\otimes$ denotes the Kronecker product, $\boldsymbol{K}_l^{tas}$ and $\boldsymbol{K}_{l,l}^{tas}$ select the l-th row and the (l,l) element from $\boldsymbol{K}^{tas}$ respectively, $\boldsymbol{K}^{\kappa}$ represents the matrix of covariances between all pairs of $\boldsymbol{\kappa}_{1:N}$, $\boldsymbol{k}^{\kappa}(\boldsymbol{\kappa}^*)$ is a vector of covariances between $\boldsymbol{\kappa}^*$ and $\boldsymbol{\kappa}_{1:N}$, and $\boldsymbol{\Lambda}$ is an $M \times M$ matrix with the (l,l) element as σ_l^2, i.e. the noise variance for the l-th task.

The hyperparameters in a MTGP include the parameters $\boldsymbol{\theta}_{\kappa}$ in the kernel function k^{κ}, the entries of matrix $\boldsymbol{K}^{tas}$ and the noise variances $\sigma_{1:M}^2$ in $\boldsymbol{\Lambda}$. They can be trained by maximizing the marginal likelihood according to the distribution $\boldsymbol{y}|\boldsymbol{\kappa}_{1:N} \sim \mathcal{N}(\boldsymbol{0}, (\boldsymbol{K}^{\kappa} \otimes \boldsymbol{K}^{tas} + \boldsymbol{I}_N \otimes \boldsymbol{\Lambda}))$, which is updated along with the dataset $\mathcal{D}$.

III. PROPOSED METHODS

In this section, we introduce the key techniques of MARIO in detail, including active computing resource reallocation, evaluation data broadcast, and asynchronous parallelization mechanism. The overall workflow of MARIO is depicted in Fig. 1

A. Active Computing Resource Reallocation

Since the circuit simulations are expensive, we measure the computing resources involved in MARIO by the number of parallel simulation workers. These workers parallelize the simulations of the candidate design points, which are suggested batch by batch from member algorithms. Then, the active computing resource reallocation is implemented via a customized MTGP and portfolio optimization.

We employ an MTGP enhanced by exponentially decaying kernels to periodically extrapolate the optimization curves and quantify the optimization potential of member algorithms. Specifically, the current-best-curve progression of member algorithms is regarded as

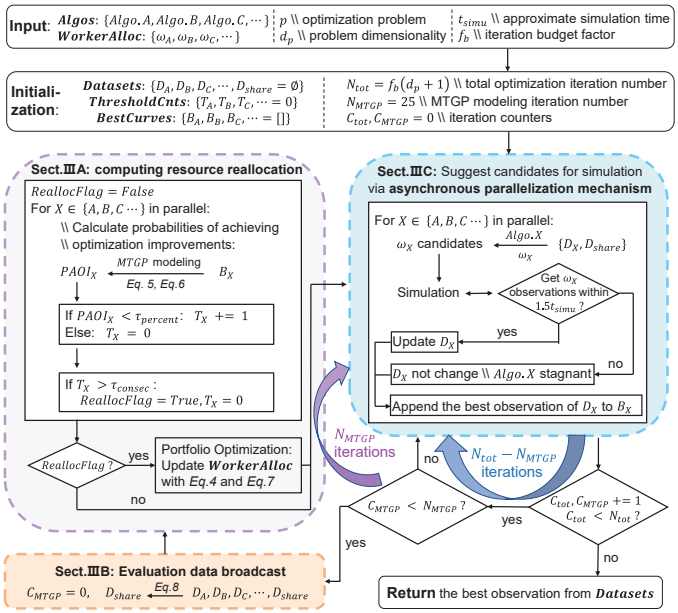

Fig. 1. The overall workflow of MARIO. Given a pool of $\boldsymbol{Algos}$, MARIO runs them in parallel for N_{tot} iterations, while the evaluation data broadcast and the computing resource reallocation are conducted in N_{MTGP} iterations. For broadcast, MARIO maintains a dataset D_{share}, which contributes to the candidate suggestions of all member algorithms. For reallocation, the probability of achieving optimization improvements (PAOI) is calculated for member algorithms by modeling the $\boldsymbol{BestCurves}$. If an algorithm exhibits a poor (less than $\tau_{percent}$) PAOI for a consecutive number τ_{consec} of modeling rounds, the $\boldsymbol{WorkerAlloc}$ is updated by portfolio optimization.

different modeling tasks, with the normalized number of evaluations as the common input variable and the objective values as the responses. After modeling, the MTGP will predict the extrapolated objective values of different member algorithms through a posterior normal distribution. Based on the posterior mean μ and variance σ, the probability of achieving optimization improvement (PAOI) of each member algorithm is calculated as $\mathrm{PAOI}(\kappa^*; \mathcal{D}) = \Phi\left(\frac{v - \mu(\kappa^*; \mathcal{D})}{\sigma(\kappa^*; \mathcal{D})}\right)$, where v represents the current-best observed objective value, κ^* is a prediction point and Φ is the standard normal cumulative distribution. Note that in addition to μ and σ, we also obtain a matrix $\boldsymbol{C}$ of extrapolated objective covariances across member algorithms, which will be used later in 7 for portfolio optimization.

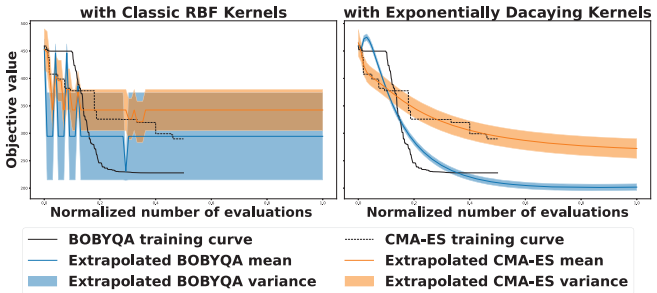

Fig. 2. Extrapolation performance with two different kernels for two different algorithms while optimizing a 10D Ackley test function.

The ability to extrapolate optimization curves is achieved with exponentially decaying kernels [33] as 6.

$$k(\kappa, \kappa') = \int_0^{\infty} e^{-\xi(\kappa+\kappa')} \frac{\beta^{\alpha}}{\Gamma(\alpha)} \xi^{\alpha-1} e^{-\xi\beta} d\xi = \frac{\beta^{\alpha}}{(\kappa + \kappa' + \beta)^{\alpha}}, \tag{6}$$

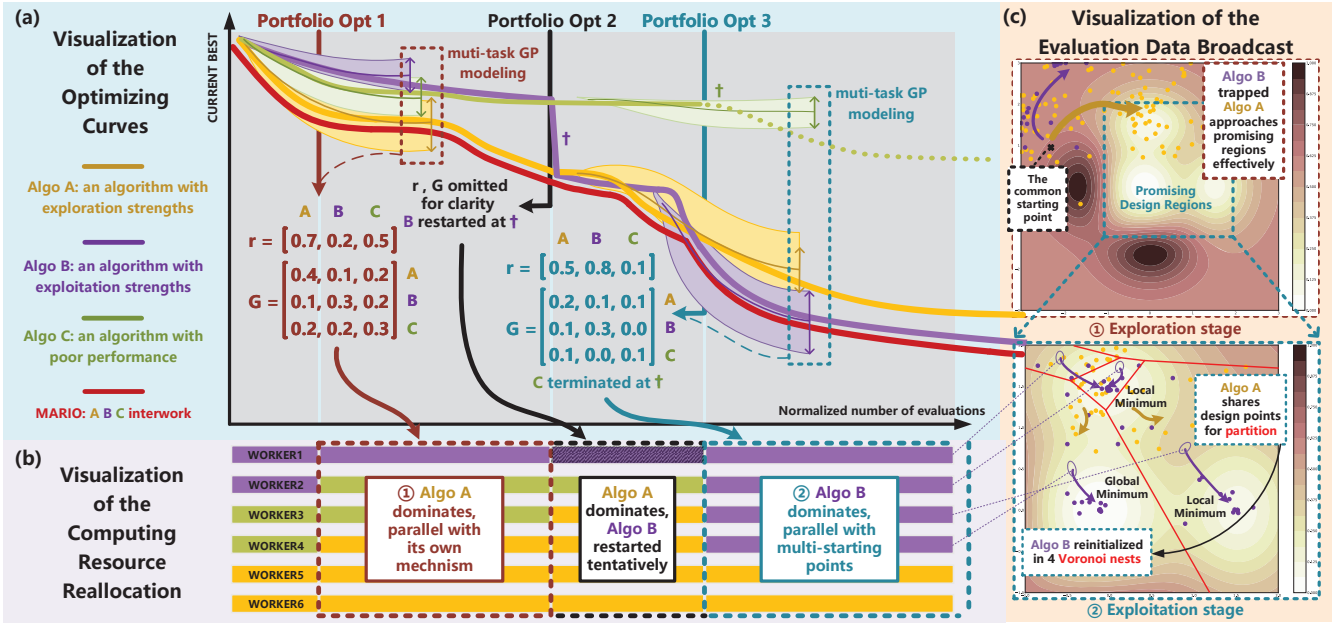

Fig. 3. An illustration of the optimization progression of MARIO. **(a)** A visualization of three optimizing curves and three periods of computing resource reallocation. The red curve results from combining the three heterogeneous member algorithms A, B, and C within MARIO. The $\boldsymbol{r}$ and $\boldsymbol{G}$ are modeled by the multi-task Gaussian process and the parallel workers are reallocated by portfolio optimization. **(b)** A visualization of the evolution of parallel computing resources, where algorithm A dominates optimization after the first two periods of portfolio optimization, and algorithm B dominates in turn after the third period of portfolio optimization. **(c)** A visualization of the evaluation data broadcast strategy. In the early exploration stage, algorithm B is trapped in a local minimum, while algorithm A can approach the promising design regions. In the later exploitation stage, the design space is partitioned into Voronoi nests based on the shared evaluated design points. Then algorithm B is enabled to reinitialize its optimization procedures, exploiting 4 promising regions in parallel.

which is constructed by integrating an infinite set of exponentially decaying functions of the form $f(\kappa,\xi)=e^{-\xi\kappa}$, with κ representing the 1-dimensional input variable. $\frac{\beta^{\alpha}}{\Gamma(\alpha)}\xi^{\alpha-1}e^{-\xi\beta}$ is a non-negative mixing measure weighting the integration range with parameters $\alpha,\beta>0$, and $\Gamma(\cdot)$ is the gamma function. As shown in Fig. 2, exponentially decaying kernels produce more informative and smoother extrapolation performance than classic RBF kernels. Additionally, since the MTGP is based on the 1-dimensional input variable and is efficiently accelerated in MARIO through black-box matrix-matrix multiplication techniques [34], its computational cost is neglectable in comparison to the overhead of circuit simulations.

If a member algorithm exhibits a poor POAI for a certain consecutive number of MTGP-modeling periods, the computing resource reallocation is activated, based on the portfolio optimization as formulated in 4, where the $\boldsymbol{r}$ and $\boldsymbol{G}$ are constructed as 7.

$$\boldsymbol{r} = max(\boldsymbol{0}, \boldsymbol{\mu} - v) \circ \boldsymbol{\omega}_{cur}^{\circ(-1)} \tag{7a}$$

$$\boldsymbol{G} = \boldsymbol{C} \circ (\boldsymbol{\omega}_{cur}^{T}\boldsymbol{\omega}_{cur})^{\circ(-\frac{1}{2})}, \tag{7b}$$

where $\boldsymbol{\mu}$ represents the vector of extrapolated objective means, $\boldsymbol{C}$ represents the matrix of extrapolated objective covariances, $\boldsymbol{\omega}_{cur}$ represents the current allocation of computing resources, $\circ$ represents the Hadamard product and $^{\circ()}$ represents the element-wise power.

We additionally introduce two constraints for portfolio optimization. The first constraint is $\sum_i |\boldsymbol{\omega}_i - \boldsymbol{\omega}_{cur}| \leq \Omega$, which restricts the total turnover Ω of computing resources, considering that the optimization potential of member algorithms is approximately in proportion to the computing resources within a relative-small linearized range. The second constraint is $\boldsymbol{\omega}_i \leq \omega_{max}$ for local algorithms, which avoids the waste of computing resources due to meaningless local exploitation. ω_{max} represents the number of promising design regions, which is derived systematically later in Sect.III-B,

Besides, we adopt a dynamic risk aversion parameter η for portfolio optimization in 4 to make the computing resource reallocation more comprehensive. In the early optimization stages, η is relatively large to encourage member algorithms with high optimization variance. It is reasonable since these algorithms generally serve for global exploration and need to gobble up computing resources to reach promising design regions quickly. Then η gets smaller during the optimization progression, gradually preferring local algorithms that can steadily exploit the promising design regions.

A visualization of three periods of computing resource reallocation among three member algorithms is presented in Fig. 3(a) and 3(b).

B. Evaluation Data Broadcast

To empower optimization superadditivity in MARIO, it is critical to make the member algorithms cooperate with each other. Therefore, we maintain a parallel broadcast process to periodically collect the evaluated design points from different member algorithms and extract informative evaluation data to transfer.

To assure the efficiency of evaluation data broadcast, it is necessary to prune uncompetitive observations because these redundant data heavily retard and even mislead the progression of optimization. Hence, with the accumulation of evaluated design points, We incrementally partition the design space into Voronoi nests and filter out information of promising design regions to broadcast.

The Voronoi nests are constructed by clustering the design points, and the clustering is based on the objective-weighted distance as 8.

$$dist(\boldsymbol{x_i}, \boldsymbol{x_j}) = w\sqrt{\frac{d_s^2}{d_p}} + (1-w)\sqrt{d_o^2}, \tag{8}$$

where $d_s = ||\boldsymbol{x}_i - \boldsymbol{x}_j||$ is the spatial distance, $d_o = \sqrt{(f_i - f_j)^2}$ is the objective distance, d_p is the dimensionality of the design

variables, and w is a weight parameter. Consequently, the design points that are spatially close and qualitatively similar will be clustered into the same Voronoi nest. Note that the total number of Voronoi nests can be controlled by limiting the maximum number of design points inside a nest [9]. After partition, we score each Voronoi nest according to the best-achieved objective value, and the involved design point that achieves this value is regarded as the representative design point of the nest. Based on the scores, we filter out competitive Voronoi nests, which exactly represent the promising design regions.

While global algorithms mainly utilize representative design points to promote exploration, local algorithms can further make use of the information of promising design regions to reinitialize themselves, which leads to adaptive and effective local exploitation, significantly contributing to the superadditivity of MARIO. The reinitialization requires no extra sampling overheads since the broadcasted design observations can be directly reused. Moreover, considering that the serial-limited local algorithms are parallelized in MARIO through the MSP strategy, the computing resource allocation for these algorithms can be restricted according to the number of promising design regions, which accounts for ω_{max} in Sect.III-A.

Fig. 3(c) presents a visualization of the evaluation data broadcast.

C. Asynchronous Parallelization Mechanism

Heterogeneous algorithms naturally exhibit different computational overhead for the candidate-point suggestions, and thus there will be optimization blocks in MARIO if the evaluated design points are synchronously collected. To make MARIO time-adaptive, we design an asynchronous parallelization mechanism, which is important in practice, especially for sizing the module-level analog circuits with simulation time limited to several seconds.

The proposed mechanism employs a timeout parameter t_{out} for the poll of parallelly evaluated design points across member algorithms. If no points are provided by a slow algorithm within t_{out}, this algorithm will be considered stagnant and other faster algorithms will become relatively more competitive in gaining computing resources. In MARIO, we set $t_{out} = 1.5t_{simu}$, where t_{simu} is the allowed simulation time for a given target circuit. This setting indicates that the collection of evaluated design points from a member algorithm will be postponed once this algorithm exhibits a modeling overhead 1.5 times more than the simulation overhead.

IV. Experimental Results

In this section, we show the superiority of MARIO against existing optimizers. The baseline optimizers include state-of-the-art BO algorithms for analog circuit sizing (**TuRBO** [8] and **cVTS** [9]), widely-used evolutionary and DFO algorithms (**CMA-ES** [16], **DE** [27], **TBPSA** [35] and **BOBYQA** [36]), and state-of-the-art algorithm-combining tools (**ABBO** [28] and **Shiwa** [29]).

For MARIO, we realize an instance as **MARIO-1**, combining TuRBO, cVTS, CMA-ES, DE, and BOBYQA w.l.o.g. In MARIO-1, TuRBO, CMA-ES, and DE are expected to act as global algorithms, while cVTS and BOBYQA are expected to act as local algorithms. Note that we remove the original global exploration strategy in cVTS because the evaluation data broadcast strategy in MARIO is a more informative alternative and the main advantage of VTS lies in the boundary-restricted local exploitation. In addition, we realize a counterpart of MARIO-1 as **MARIO-1se**, where the computing resource reallocation is disabled for ablation studies.

For fair utilization of computing resources, the number of parallel workers for all optimizers is 20. Specifically, all optimizers suggest 20 design points for parallel simulations in each iteration, either based on the MSP strategy (for serial-limited optimizers such as cVTS and BOBYQA) or batch sampling (for parallel-enabled optimizers). Besides, we unify the constraint handling for all optimizers via the weighted-sum objective function as introduced in Sect.II-A.

We conduct optimization experiments on two benchmark suites and run all optimizations 10 times to measure the variances of random fluctuations. The random seeds are provided in our code repository for reproducibility. All experiments are conducted on a Linux server with Intel Xeon 6230 CPUs and 128GB RAM.

A. Test-Function Experiments

The test-function benchmark suite includes 17 widely-used functions i.e. Ackley, CosineMixture, Exponential, Griewank, Levy-Montalvo1, LevyMontalvo2, Neumaier3, Paviani, Rastrigin, Rosenbrock, Salomon, Schwefel, Sinusoidal, Michalewicz, SineEnvelope, EggHolder, and Rana. All these functions have scalable dimensions, and we choose the dimensionality of $\{20, 40\}$ for demonstration.

Fig. 4 presents the data-profile accumulating curves of different optimizers on the test-function benchmark suite, with the x-axis representing the normalized number of evaluations. This normalization indicates that given a test function with dimensionality d_p, the maximum number of evaluations is limited to $20 \cdot 50 \cdot d_p$, where 20 is the number of parallel workers and 50 is a fixed budget factor. MARIO-1 and MARIO-1se significantly outperform other baseline optimizers, while MARIO-1 is steadily better than MARIO-1se. In comparison with the best baseline optimizer TuRBO, MARIO-1 achieves 3.83× speedup for the normalized number of evaluations.

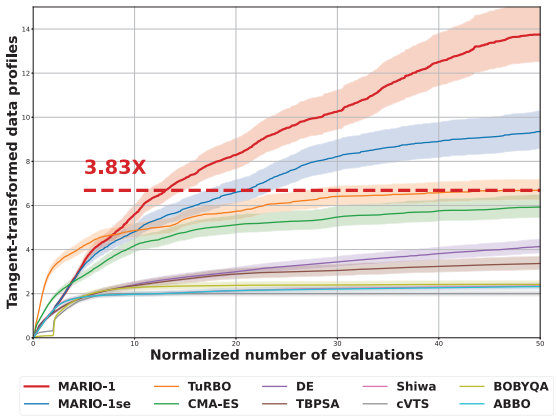

Fig. 4. The data-profile accumulating curves of different optimizers on the test-function benchmark suite. The translucent area shows a variance of 0.1σ.

A breakdown of the best-achieved data profiles of different optimizers on the test-function benchmark suite is shown in Fig. 5(a), MARIO-1 achieves competitive optimization performance across all test functions, leading to the highest data profile of 0.954, which is 5.41%∼35.32% better than the data profiles of baseline optimizers.

B. Analog-Circuit Experiments

Table II summarizes the experiment setup for 15 analog circuits, with a part of them open-sourced [37] and available in our repository. The evaluation-number budget and optimization-time budget for analog circuits are $20{\cdot}20{\cdot}(d_p{+}1)$ and $t_{simu}{\cdot}20{\cdot}(d_p{+}1)$ respectively, with the use of 20 parallel workers and a budget factor of 20.

Fig. 6 presents the data-profile accumulating curves of different optimizers on the analog-circuit benchmark suite, MARIO-1 and TuRBO significantly outperform other optimizers, while MARIO-1 achieves 2.59× and 1.91× speedup compared to TuRBO for the normalized number of evaluations and optimization time, respectively.

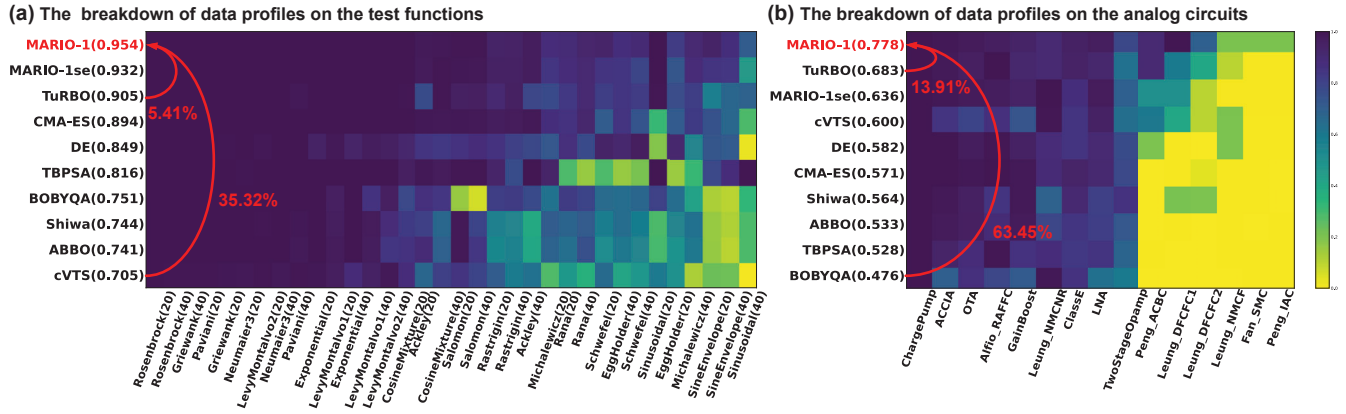

Fig. 5. The breakdown of the best-achieved data profiles for different optimizers on the test-function and analog-circuit benchmark suites. The x-axes represent different optimization problems p, the y-axis represents different optimizers m, and the grids visualize the values of $T_{p.m}$, with the darker color indicating better optimization performance. The row-wise average of $T_{p,m}$ is the data profiles, which are presented following each optimizer on two benchmark suites.

TABLE II
THE EXPERIMENT SETUP FOR ANALOG CIRCUITS

Name	d_p, t_{simu}	Specification Description	Evaluation Budget	Time Budget
Charge Pump	36, 10s	current deviation in 27 PVT corners	14800	2.06h
ACCIA	38, 10s	input referred noise, power, gbw, etc.	15600	2.17h
OTA	59, 5s	gain, ugf, etc.	24000	1.67h
ClassE	13, 10s	out power, dc power	5600	0.78h
LNA	19, 60s	NF, IIP3, etc.	8000	6.67h
GainBoost	20, 10s	gain, slew rate, etc.	8400	1.17h
TwoStageOpamp	10, 10s	loop gain, pm, etc.	4400	0.61h
8 circuits from AnalogGym [37]	23∼33, 20s	10 specs, leading to FOM_{AMP}	9600∼ 13600	2.67h∼ 3.78h

In Fig. 6, no optimizer distinctly outperforms others in early exploration stages, thus the superiority of MARIO-1 mainly results from efficient local exploitation later. Evolutionary algorithms CMA-ES, DE, and TBPSA can not exploit promising design regions effectively, and neither can ABBO and Shiwa, since these algorithm-combining tools also select evolution algorithms in most cases. On the other hand, BOBYQA is talented in local exploitation but fails to reach promising design regions from the beginning. Besides, cVTS and BOBYQA are uncompetitive in our experiments because these two algorithms are serial-limited and merely utilize parallel computing resources with the MSP strategy, which is inefficient for exploring the heavily multi-modal optimization landscapes of analog circuits. The challenge of multi-modality also accounts for the poor performance of MARIO-1se, since it can't reallocate more computing resources for parallel local exploitation. Additionally, the modeling overheads of TuRBO and cVTS are non-neglectable, which is inferred by comparing the optimization performance along with time and the performance along with evaluations. The optimization efficiency of TuRBO is also limited by its restart strategy, which constructs new trust regions from scratch once the old ones are converged.

A breakdown of the best-achieved data profiles of different optimizers on the analog-circuit benchmark suite is shown in Fig. 5(b). The optimization superadditivity of MARIO-1 is remarkable, especially for difficult cases in the right part. The data profile of MARIO-1 is 13.91%∼63.45% better than those of baseline optimizers.

V. CONCLUSIONS

In this work, we propose a superadditive multi-algorithm interworking optimization framework MARIO for analog circuit sizing.

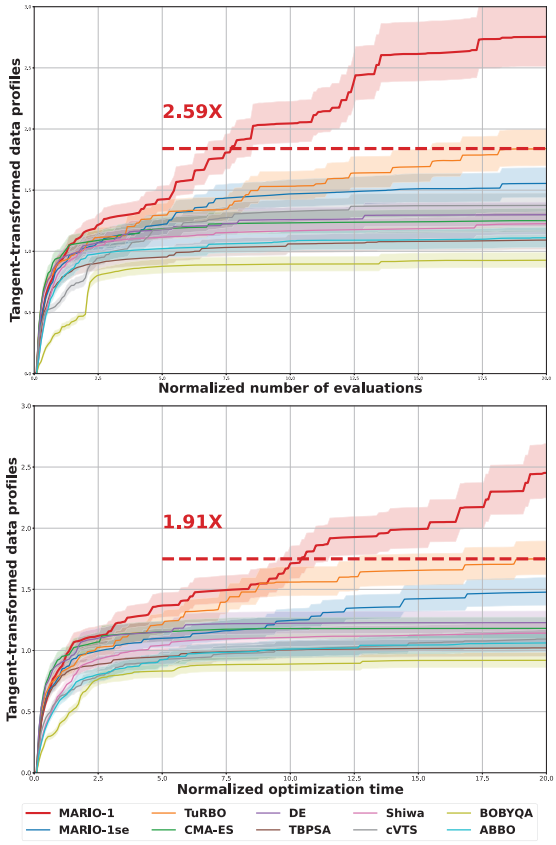

Fig. 6. The data-profile accumulating curves of different optimizers on the analog-circuit benchmark suite. The translucent area shows a variance of 0.1σ.

To demonstrate the superiority of MORIO, we implement MARIO-1, which combines 5 heterogeneous optimization algorithms. In comparison with the baseline optimizers for sizing 15 diverse analog circuits, MARIO-1 achieves more than $2.59\times$ evaluation-number speedup, and more than $1.91\times$ optimization-time speedup.

For future research, the application scenarios of MARIO are not necessarily limited to analog circuit sizing or single objective optimization, and we can further unleash the capacity of MARIO with multi-machine parallelism. Moreover, MARIO is extending-friendly for any new algorithms, with promising optimization superadditivity.
